THE HARVEIAN ORATION.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS, WEDNESDAY, JUNE 27.

By EDWARD H. SIEVEKING, M.D., F.R.C.P.,
Physician-Extraordinary to the Queen; Physician-in-Ordinary to the Prince of Wales; Physician to St. Mary's and the Lock Hospitals; etc.

Veritatis invicta vis est. Adrasteæ legem nemo potest facile effugere, si credendum veteribus et Galeno nostro, qui ipse suo exemplo hoc demonstravit. Sicut vero in multis aliis hoc patuit, ita nescio an unquam clarius quam in novâ doctrinâ de motu sanguinis.—Pauli Marquarti Slegelii, "De Motu Sanguinis Commentatio." Hamburgi: 1650.

Mr. President and Fellows of the Royal College of Physicians.—Gentlemen,—The fog that prevailed in the realms of science before the publication of Harvey's great work, compared to the ever-brightening light that has been shed over them since he taught the doctrine that has been all but universally associated with his name since 1628, necessarily renders us, as it did his contemporaries of this ancient College, anxious to see that his fame suffers no diminution through our neglect.

It might seem impossible for anyone who has carefully studied the literature of the subject, to entertain a doubt as to Harvey's claim to be regarded as the regenerator of human and animal physiology. The feeble opposition of the ungenerous Riolan,(a) who taught a modified Galenic doctrine of the functions of the heart and vessels, was triumphantly met by the clear and practical exposition of Professor Schlegel, of Hamburg. Other men, no less distinguished in their age and country, appear to have established Harvey as the real founder of the doctrine of the circulation, to which we ascribe the origin of modern scientific medicine. Professor Walæus(b) in Leyden, in 1840, Joannes Trullius(c) in Rome, in 1651, supported the new doctrine. Plempius in Louvain, in 1652, voluntarily and publicly professed himself an adherent of Harvey. Previous to the appearance of Schlegel's admirable work in 1650, his friend and compatriot Werner Rolfink,(d) reputed one of the best German anatomists of the time, had, in 1630, given his adhesion to Harvey's views. Nor is it without significance that Descartes,(e) in his "Discours de la Méthode pour bien conduire sa Raison et chercher la Vérité dans les Sciences," in 1637, spoke of the English physician as the man to whom the world owed the knowledge of a continuous circulation of the blood. Although here and there writers, jealous of Harvey's fame, brought forward Servetus, Sarpa, Cæsalpinus, and others still less worthy of being named, as possessing prior claims to the position assigned to Harvey, the great body of scientific men of that and all future days have subscribed to the opinion that we owe the modern doctrine of the circulation of the blood and of the moving power of the heart to him.

After the many disquisitions on the priority of Harvey's claims that have been offered to the Fellows of this College, from the oration of Friend to that of the exhaustive address by the learned Linacre Professor Dr. Rolleston, four years ago, it would scarcely have been befitting in me to bring up this *crambe iterum repetita* on the present occasion, had not a recent event appeared to make it a matter of duty to inquire again into the claims of one of the three names just mentioned.

English physicians were startled last year(f) by the announcement that on October 30 a monument of Andrea Cesalpino was unveiled at Rome, on the ground of his being the first discoverer of the circulation of the blood. Dr. Giulio Ceradini, Professor of Physiology at Genoa, appears to have been the chief orator on the occasion, and to have asserted, after stating that Cesalpino produced experimental proof of the circulation in 1593, that Harvey could in 1628 adduce nothing more than a fresh proof of the circulation in the venous valves, discovered by Fabricius at Aquapendente as early as 1574, by demonstrating that the said valves must oppose the centrifugal movement of the blood in the veins. Ceradini maintained that Harvey's merit really consists in having sustained and won a battle against ignorance and prejudice by divulging the discovery of Cesalpino.

Although the claims of Andrea Cesalpino, of Arezzo, have been put forward and amply discussed—by none, perhaps, more fully and justly than by Dr. Willis in his admirable "Life of Harvey" (g)—it has appeared to be, under the circumstances, a duty of the Harveian Orator of the present year to search the original works of Cesalpino, and to ascertain whether contemporary and later history have erred in awarding to our countryman the palm which really belongs to a greater predecessor of his. One thing appears indisputable: that, whatever Cesalpino has written, his views on the circulation were not considered of much consequence, and certainly not subversive of the old Galenic doctrines, at the time that Harvey resided in Padua, and subsequently Schlegel in Venice and other parts of Italy. The former, whom his greatest detractors(h) have never accused of want of uprightness and honesty, does not allude to the discoveries of Cesalpino; and the latter(i) distinctly says that, having been in familiar intercourse with the most distinguished anatomists in Padua, Venice, and throughout Italy, for some years, he had found "the movement of the blood almost entirely unknown, or that it certainly was regarded as incredible."(k) Schlegel manifestly speaks of the movement of the blood as taught by Harvey, because earlier writers had discussed the question of the circulation, as Harvey himself admits,(l) but, "like persons purblind or groping about in the dark," had failed to recognise the intimate connexion and beautiful harmony of the different parts involved in the process.

The entire tenor of Harvey's life and work forbids the view that he was a plagiarist, and that, as Cesalpino's panegyrist has recently asserted, he arrogated to himself a discovery which belongs to the latter. Contemporary writers failed to recognise in Harvey's doctrine a reproduction of the teachings of Cesalpino; and, though his great adversary, Riolan, was satisfied that Harvey had been anticipated by Aristotle and Cesalpino, we can scarcely doubt that Schlegel correctly describes the state of medical science and the effect produced by the great work published in 1628. He says of Harvey's doctrine(m)—"*Inaudita, communibusque et per multa sæcula inveteratis opinionibus adversissima sententia, omnes commovit.*"

But let us do justice to Cesalpino; for, though it is clear to my mind that he failed to appreciate the truth as it was made plain by Harvey, he approached nearer to him than any of the physiologists of earlier days. Anyone who was satisfied with the evidence afforded by solitary passages in his writings might fairly assert that Cesalpino had taught the true doctrine of the circulation; but, when we search further, and find that he still regards the flow of the blood comparable to the flood and ebb tides of the Euripus; that the arteries, according to him, convey the spirit to which their pulse is due; and that he utterly failed to recognise in the heart the central moving power of the circulation,—we cannot but

(g) Prefixed to the Sydenham Society's edition of the "Works of William Harvey," 1847, p. 60.

(h) Among these we are pained to mention William Hunter, who, in his two introductory lectures to his last course of "Anatomical Lectures," 1734, p. 43 *et seq.*, speaks of Harvey in a manner that is a blot upon the lecturer's name, and shows that he had not investigated the question by a reference to the original works of the men whom he compares with Harvey.

(i) Pauli Marquarti Slegelii, M.D. Hamburg. "De Sanguinis Motu Commentatio," Hamburgi, 1650, p. 7. Schlegel (Latinised, Slegelius), the son of a merchant, was born at Hamburg in 1605, and studied medicine at Altorf, Wittenberg, and Jena. In 1631, in company with Rolfink, he undertook a long scientific tour. He visited Holland and England, then went to Paris, where he remained two years; subsequently spent several years in Italy; and, after taking a degree at Padua in 1636, returned to Germany in 1638. He was at once appointed Professor of Anatomy, Surgery, and Botany at Jena. In 1642 Schlegel was invited to accept the office of "sub-physicus," or assistant officer of health, in Hamburg, where he founded an anatomical theatre. He died in 1653. For further details see "Mittheilungen aus der alteren Medicinal Geschichte Hamburgs," von Physicus Dr. Gernet, Hamburg, 1869; and also "Lexicon der Hamburgischen Schriftsteller bis zur Gegenwart," von Dr. H. Schroeder, now publishing. In the last, a list of twenty-four works by Schlegel is given, which illustrates both the variety and the depth of his studies.

(k) The original Latin is—Quin imo doctrinam illo tempore de motu sanguinis apud omnes fere incompertam aut certe pro incredibile habitam fuisse, neque obtineri potuisse rationibus ab iis ut assentirentur.

(l) Sydenham Society's edition of "Harvey's Works," p. 33.

arrive at the conclusion that his doctrine, by itself, would never have formed the basis of modern physiology.

Cesalpino, whose work was published at Venice in 1593,(n) in the fifth book of his "Peripatetic Questions,"(o) describes the circulation in the following words:—"As rivulets draw water from a spring, the veins and arteries take their origin from the heart. It is further necessary that they should all be continuous with the heart, that the blood contained in them may be preserved by its heat, for it congeals under the influence of cold, as appears whenever it is removed from the veins. Dissection shows that all veins are continuous with the heart alone, for those which pass from the heart to the lungs are continuous with no other viscus; they terminate in the ventricles of the heart, and pass no further. The vena cava and the aorta, having reached the other viscera with the exception of the heart, pass beyond them; or, if they come to an end, they do not pour their blood into a general receptacle (*non in ventrum aliquem transfundunt sanguinem*), but are broken up into hair tubes (*capilla menta*), for nowhere excepting in the heart is the blood contained in a receptacle out of the veins."

Although in this passage Cesalpino speaks of a continuity of the bloodvessels, he still adheres, as shown in another passage,(p) to the view that the venous system depends less upon the heart than upon the liver, which organ possesses a special nutritive power (*vim altricem*), and is the real source of the veins: "non igitur cor sed hepar est principium venarum." Again, elsewhere(q) Cæsalpinus gives his adhesion to the ancient fallacy that the blood passes not only to the lungs from the right ventricle, but also through the septum into the left side of the heart: "partim per medium septum, partim per medios pulmones (sanguis) refrigirationis gratia ex dextro in sinistrum transmittitur."

Even Harvey himself, conclusive as are his proofs of a continuity of the current both in the lesser and greater circulation from the heart as a starting-point back again to the central organ, nowhere gets beyond the prevailing view of an anastomosis between the arteries and the veins. It would be as reasonable to infer that Cesalpino had, without a microscope, anticipated the great discovery of the capillaries by Malpighi, because he accidentally uses the term "capillamenta" to designate the minute divisions of the vena cava and the aorta, as it is to regard him as the true discoverer of the circulation of the blood. Everybody, as Cesalpino says, knew in his day that the arteries took their origin from the heart, in order that they might distribute the vital spirit throughout the body; and, again, he maintains that a continuous movement is propagated throughout the different parts of the body, because there is a continuous generation of spirit, which, by its increase (*amplificatione*), is fitted very rapidly to be diffused everywhere.

Cesalpino argues that the heart is manifestly the chief organ of sensation (*primum sensorium*), because it is associated with every sense of joy or sadness, which are first perceived to exist in the heart. The heart, therefore, is the origin of the nerves. And what, he asks, could such a struggle about the heart effect, unless there were a continuous passage from the heart to the instruments of movement, by which a large amount of spirit (*spiritus multus*) could be conveyed? There is not much in the forgoing passage that we can utilise; but in the following there is a mixture of truth and error which is more suggestive, although it will not bear comparison with the clear and practical deductions, based upon observation in the dead and living body, which Harvey has laid before us in language as free from hypothetical jargon as anything known in science. In discussing the question of suffocation, Cesalpino(r) says: "It appears worthy of inquiry why veins swell on the distal side of a ligature, and not on the opposite side, which those know from experience who open a vein, for they apply the ligature above the point of section, and not below, because the veins swell below, and not above the ligature. But the opposite result ought to happen if the movement of the blood and spirit passed from the bowels to the body at large; for, if the passage be intercepted, no further progress is possible: therefore the swelling of the veins ought to have been above the ligature."

After inquiring into Aristotle's view on the subject, Cesalpino goes on to say: "The passages of the heart have been so prepared by Nature that the vena cava opens into the right ventricle of the heart, from which a passage opens into the lung; from the lung there is another passage into the left ventricle of the heart; from which, finally, an outlet opens into the aorta, certain membranes being placed at the mouths of the vessels to prevent a return: for there is a certain continuous movement from the vena cava through the heart and lungs into the aorta. But as, during wakefulness, the movement of native heat takes place outwards, namely, to the sensorial parts; but during sleep inwards, namely, to the heart,—it appears that during wakefulness much spirit and blood are carried to the arteries, for there is a passage from them to the nerves. But in sleep the same heat returns through the veins to the heart, and not through the arteries; for the natural entrance is through the vena cava into the heart, and not through the arteries. The proof of this is to be found in the pulses, which are large, powerful, quick, and frequent in those waking up, occurring with a certain vibration; during sleep, they are small, languid, slow, and scanty. For during sleep the native heat tends less into the arteries, but rushes more violently into them as the individual wakes up. The veins behave in a different manner, for during sleep they tumefy, but shrink in the waking state, as anyone may see who looks at the veins of the hand. For during sleep the natural heat passes from the arteries to the veins by inosculations which are called anastomoses, and thence to the heart; but, as the tidal movement of the blood (*exundatio*) to the upper parts, and its ebb (*retrocessus*) to the lower parts, like Euripus, is manifest in sleeping and waking, so this kind of movement is not obscure wherever a ligature is applied to a part of the body, or the veins are closed in some other way."

I trust I shall be pardoned if I do not go more fully into this question of priority, but refer those in whose minds any doubt may remain to the original works of Cesalpino, where they will find much to interest them. Even the brief quotations that I have laid before you appear to justify to a certain extent the claims that have been raised for higher distinction among the physiologists of the past for Cesalpino than may have hitherto been awarded him, but at the same time I venture to think that they are conclusive as to the view that Cesalpino cannot be declared worthy to occupy the place so long and universally assigned to our illustrious countryman. Certainly Cesalpino himself was not conscious of having made an important, if any, discovery; for he introduces the subject of the circulation incidentally in a chapter headed "*Cor non solum arteriarum sed et venarum et nervorum principium*," and nowhere lays stress upon what is now claimed as his prerogative. Even among the list of subjects contained in his *Index eorum quæ notatu digna visa sunt* the circulation is not inserted. Lest, as Englishmen, we may be tempted to take a one-sided view of the question, permit me to adduce a few words from the work of one of the most eminent modern French physiologists, Flourens,(s) who, in his "Histoire de la Circulation du Sang," gives evidence of a minute study of the authors who preceded Harvey, says: "Lorsque Harvey parut, tout, relativement à la circulation, avait été indiqué ou soupçonné, rien n'était établi. Rien n'était établi, et cela est si vrai que Fabrice d'Acquapendente, qui vient après Césalpin et qui découvre les valvules des veines, ne connait pas la circulation." And it may be added that he quite misinterpreted the functions of the valves.

A careful study of the entire subject appears fully to justify the opinion expressed by Dr. Willis,(t) that "Cesalpino, tried by a moderately searching criticism, presents himself to us as but very little further advanced than the ancients in his ideas on the motion of the blood"; and, again, that "the world saw nothing of the circulation of the blood in Servetus, Columbus, Cæsalpinus, or Shakespeare, until after William Harvey had taught and written."

We all know that Harvey did not evolve his doctrine out of his inner consciousness, but that, by intense application and the study of vital phenomena, he arrived at the conclusions set forth in 1628, having undertaken a task which at the outset he regarded "as so full of difficulties that he was almost tempted to think with Frascatorius that the motion of the heart was only to be comprehended by God." It will be

(s) "Histoire de la Circulation du Sang," par P. Flourens, Professeur au Muséum d'Histoire Naturelle de Paris, 1854, p. 28. An excellent summary of the history of the circulation is given in Mr. Lewes's "Physiology of Common Life" (vol. i., p. 259, 1859), in which the claims of Harvey and of his predecessors are fairly and succinctly set forth.

(t) "The Life of Harvey"; introduction to Sydenham Society's edition of Harvey's works, p. 63.

interesting to the Fellows of this College, no less than to the world of science at large, to know that we now have it in our power to estimate more accurately the gradual advances by which Harvey eventually arrived at his goal, inasmuch as the original notes of the first lectures which he delivered in this College in 1616 and in subsequent years, as Lumleian Lecturer on Anatomy and Physiology, have been recently rediscovered in the British Museum. Harvey tells us in the introductory letter to his "very dear friend Dr. Argent," the excellent and accomplished President of the College of Physicians, prefixed to his work "De Motu Sanguinis," published in 1628, that he had "for nine years and more confirmed his views by multiplied demonstrations." Hence the first date of the new doctrine is ordinarily fixed in 1619; but the manuscript lectures show that Harvey delivered his first lectures in 1616, and was then already on the threshold of the complete discovery. These lectures formed a part of the library of Sir Hans Sloane, which was purchased by Government in 1754, and, though entered in the Catalogue of the Museum, they have disappeared for above a hundred years. A few months ago, in going over the duplicate books which had been set aside, this manuscript was found, probably in all the better preservation from having been so long buried. Allusion is made to these lectures by several writers. Dr. Rolleston, in his Harveian Oration (page 70), gives all the details that he was able to collect regarding them, and recounts with what diligence they had been searched for. They were also evidently seen by the writer of Harvey's life prefixed to the edition of his works published by the College of Physicians in 1766, but have been mislaid since then. The notes are written in Latin, but the abbreviations and the handwriting are so quaint that no one but a gentleman in the habit of studying manuscripts of the period can decipher them.(u) Mr. Bond, the Chief of the Manuscript Department of the British Museum, has kindly produced a readable transcript of that portion of the lectures which commands our special attention. Possibly this College may consider it a duty that it owes to itself no less than to the memory of the illustrious author to publish these notes, entire or in part, so as to complete as far as possible the history of the subject to which our attention is specially directed. Coupled with Schlegel's admirable "Commentatio de Motu Sanguinis," which has received too little attention in this country, the two would form a not inappropriate memorial of the natal year of William Harvey, of which we celebrate the three hundredth anniversary in 1878.

Every detail concerning Harvey's early studies appears to command our interest; I, therefore, make no apology for presenting you with a few details concerning his first lectures. The volume, which is carefully bound in leather, with some pretensions to elegance, contains about ninety-nine pages of foolscap paper, reduced to a size of six inches by eight. The binding was evidently an after-thought, and the loose pages may have been used for one or more years before they were put into their present form, because they bear the marks of having been folded lengthways twice over, so as then to occupy a very small space of about eight inches by two. There is also evidence that Harvey used the book in its present form for his lectures; for he had attached, by sealing wax, threads of twine along the inner side of the cover, under which he could slip any further notes for future lectures. The writing throughout appears to have suffered little or nothing in distinctness, except that of the title-page; but in evidence of the style and the difficulty of putting it into a modern form, I venture to send round an autotype copy of one of the most legible passages, which happens to be the *résumé* of what Harvey taught in his early lectures regarding the heart and circulation.

The title-page, which is in red ink, is very nearly illegible. It is to the following effect: "Prælectiones anatomiæ universalis, per me Guglielmum Harveium Londinensem, anatom. et chirurg. Professorem. Anno Dom. 1616. Anno ætatis 37. Prælect. April 1st, 1617." Underneath are the numbers 16, 17, 18, which probably imply that these particular notes were used for the lectures of 1616, 1617, and 1618.

The manuscript evidently consists of mere memoranda; jottings of the subject, upon which the speaker could dilate as he chose. Each full page contains about thirty lines, and but few of the words are written out in full. The abbreviations, which sometimes assume an almost hieroglyphic form, are very numerous; and as the terminations of the words are commonly mere up and down strokes, a considerable latitude must necessarily be allowed to the transcriber. Under these circumstances, and from the impossibility of interpreting or verifying some of the allusions and references, the transcript and translation of the portion that particularly concerns us, relating to the heart and circulation, inevitably leaves much to be desired.(v) I may say that this section occupies a little more than fifteen pages of the volume, comprising altogether 441 lines.

The notes are put together in an aphoristic manner, and are occasionally interpolated with English words, for which the writer, at the moment of composition, was unable at once to supply the corresponding Latin term. There are frequent references to other authors—Hippocrates, Galen, Columbus, Vesallius (*sic*), Colsius, Aquapendens, and one, though this is doubtful, to Cæsalpinus. Every now and then we meet with initials W. H., appended, probably, for the purpose of distinguishing the passage as one that the speaker wished to mark as belonging especially to himself. The notes show that Harvey had, at that time, already studied the subject by vivisection, and that he had employed a variety of animals for his inquiry. But one feels throughout that he is still somewhat influenced by the prevailing views, and that he is only laboriously attaining that clear insight which his work, published in 1628, so plainly shows.

Harvey commences the section on the heart and circulation with an etymological assertion, for which, I fear, it would be difficult to find sufficient justification:—"*Cor a currendo, quia semper movetur.*" His first anatomical statement is to this effect(x):—"This (the heart) is the chiefest of all parts of the body, not by any inherent quality, for its flesh is more fibrous, and harder, and colder than the liver, but by the quantity of blood and spirits contained in the ventricles." You see he still clung to the view that the heart contained something besides blood. The heart, he says, cannot bear any serious lesion without death ensuing; still, he adds, showing that he had already devoted attention to pathological anatomy, "*vix ullis vitium cadaveribus vidi, nec consumitur ptysi (phthisi) secundum spem Galeni.*" An amusing instance of a jumble of Latin and English occurs in this section: "*Exempto corde frogg scipp, eel crawle, dogg ambulat*"; in which the English (not one word of which would pass muster at a spelling-bee) is as interesting a feature as the physiological fact embodied in the sentence.

The next section is devoted to an examination of the structure of the heart and its contents. Harvey's initials are attached to such sentences as—"*Hinc cur potius arteria oriri a corde quam vena, non video*"; as—"*Quære de principio venarum, puto a corde.*" He commences the consideration of the use of the heart with the statement—"*Hæ duo lacunæ (the two ventricles) cysternæ sanguinis et spiritus*"; the latter, he subsequently says—"*in totum corpus hinc distribuitur.*" Much comparative anatomy is introduced, and we meet—probably, for the first time in English medical literature, the designation of "bishop's miter" as applied to the left auriculo-ventricular valve. Harvey heads the next division of his subject "*Historia, Transitus Sanguinis et quomodo spiritus fiat.*" In this he discusses the question of the transmission of the blood through the foramen ovale, which he regards as a fœtal arrangement, describing at the same time the changes occurring in the ductus Botalli. The substance, colour, and temperature of the heart are considered; and here, as elsewhere, there are suggestions manifestly derived from clinical practice. Under the heading "*Motus*," Harvey dwells upon difficulties, which he subsequently surmounted, in understanding the movements of

(u) In his own day, Harvey's writing was evidently a puzzle to his readers, for Dr. Ent, in his epistle dedicatory to the work on "Generation," which he edited, says: "As our author writes a hand which no one without practice can easily read (a thing that is common among our men of letters), I have taken some pains to prevent the printer committing any very grave blunders through this." Many of my readers may already be familiar with Harvey's handwriting through the *fac-simile* of a letter of his, prefixed to Dr. Aveling's "Memorials of Harvey" (London, 1875), which fully confirms Dr. Ent's statement, as its authenticity is in its turn corroborated by MS. lectures.

(v) The attempt I have made in translating it has not yielded satisfactory results; and after submitting it to more competent Latin scholars than I profess to be, I fear others would not be much more successful. It would probably be wisest to publish the notes in autotype, with an accompanying transcript, and allow each reader to be his own interpreter.

(x) Principalissima omnium pars, non propria ratione, carne fibrosior enim et durior et frigi*dior* hepate, sed copiæ sanguinis et spirituum in ventri*culis*. Harvey enlarges upon this paragraph under three heads:—1. Unde fons totius caloris; 2. Unde auricula dextra pro aposte*mate* cernetur morte; 3. Unde piscis quasi lacuna san*guinis*, et eo major quo sanguis spirituosior, calidior; puto quo distenti*us* et non concre*tum* possibi*le* ad vitam, unde auriculæ pulsant post emo*tum* cor san*guinis* multitudi*ne*. (The italicised letters are the terminations suggested by Mr. Bond.)

the organ, and especially in determining which was systole and which diastole.(y) He evidently took his audience into his counsel and displayed before them the living heart, for he says:(z) "I have watched the process for entire hours, and was unable to determine the question for myself, either by sight or by touch; therefore, I shall ask you to look for yourselves, and give me your opinion." However, he arrives at this conclusion: that, whether the erection of the heart is to be regarded as the act of systole or diastole, the heart, by its erection, projects the blood and causes the pulse.(a)

One more extract, and I will detain you no longer with the notes, hoping, however, that I have not taken up your time unprofitably with a subject that appears to me to justify our liveliest interest, and to merit a more complete and permanent record than my present opportunity permits.

The passage that I am about to quote forms the peroration to the first Lumleian Lectures on the heart, and comprises a summary of the doctrines on the movement of the heart and the circulation as taught by Harvey at the beginning of his career. I shall give the passage *verbatim*, prefacing it only with the remark that it is initialed W. H.:—

"*Constat per fabricam cordis, sanguinem per pulmonis in aortam perpetuo transferri; as by 2 clacks of a water-bellow to rayse water.*

"*Constat per ligaturam transitus sanguinis ab arteriis ad venas.*

"*Unde* △ (*demonstratur*) *perpetuum sanguinis motum peri pulsu cordis.*

"*An* (*?*) *hoc gratiæ nutritionis, an magis conservationis sanguinis et membrorum per infusionem calidam, vicissimque sanguis calefaciens membra, frigifactus, a corde calefit.*"

Most of this is taught more explicitly in Harvey's work of 1628; but he then, as shown in his letter to Riolan, abandoned the theory that the heart was the source of heat.

I owe you, Sir, and Fellows of the College, an apology for having occupied so much of the brief time at my disposal by the inquiry into the merits of Cesalpino;(b) but it appears to me one of the duties of the Harveian Orator not to allow (as far as in him lies) an aspersion to rest on a name that has been justly called "immortal." Our departed friend Edmund Alexander Parkes, in fervent language, vindicated Harvey's claim to that title, in the posthumous Oration which Sir William Jenner read from this chair last year. He spoke of Harvey's discovery as one "that is not only one of those cardinal discoveries which lie at the very foundation of physiology and medicine, but is one that from its very nature forms one of those great landmarks which must remain in the sight of all." Upon that topic it is unnecessary for me to dilate before an audience in whose ears the words of Parkes still ring. But it may not be unfitting to inquire whether we, the spiritual descendants of Harvey, are carrying on the great tradition which we have received from him in a manner that he would approve of—by a steady pursuit of truth for its own sake, by that rigid sobriety of judgment which everywhere characterised his researches, by that "marvellous industry" and "insatiable curiosity" with which he prosecuted his researches to the day of his death.

Our Hunters, our Marshall Halls, our Bells, our Brodies, all trod in Harvey's paths, and have largely aided in the onward movement of medical science in this country; but I think I do not indulge in a vain "Eidolon" if I look upon the present period of British medicine as one to which pre-eminently the term of the Harveian age of medicine may be justly applied. The future only can determine the meed of praise to be awarded to an individual, and will not fail to correct any exaggerated estimate which a contemporary may form. But as it is one of the functions of the Harveian Orator to speak "in commemoration of those who have added aught to the sum of medical science in the course of the bygone year," I believe myself to be only fulfilling the trust confided in me if I dwell upon the earnest work which we see on all sides, and which, in spite of malevolence and misconstruction, is leading us on step by step to more perfect knowledge, and enabling us more and more to benefit our fellow-men.

Two of our distinguished contemporaries of this College I have already named—one, alas! no more—whose names will shed lustre upon the present time. But there are many both in and out of this College whom this country may be proud of, and whom we cannot but think that Harvey would gladly have extended the right hand of fellowship to, and have recognised as fellow-labourers. Scientific medicine of the present cannot fail to command the grateful acknowledgments of our descendants with such an array of names as Billing and Watson, Burrows, Williams, Carpenter, Sharpey, Beale, Paget, Bennett, Simon, Radcliffe, West, Sanderson, Johnson, Brown-Séquard, Lockhart Clarke, Murchison, Handfield Jones, Richardson, Garrod, Wilks, Pavy, Dickinson, Harley, Bastian, Hughlings-Jackson, Hutchinson, Ferrier, and many others, whose researches have already secured them a renown that nothing my feeble voice might urge can either abate or increase.

Would not Harvey have rejoiced to learn the revelations of the microscope and of the chemical laboratory, which belong especially to our day? Can we not picture to ourselves the flash of joy that would beam from his black eyes as he traced the intricacies of cardiac action and of respiration with the stethoscope, the sphygmograph, and the cardiograph? Would it not have gladdened his heart to see the admirable reports of the Medical Officer of the Privy Council, spreading light over recondite processes, and illuminating subjects not less interesting to the man of science than fraught with benefits to the human race? Would Harvey not have followed with profound intelligence and animation the discussions in our societies on the causes and pathology of cancer, on the communicability and production of tubercle, and the intricate question of syphilitic infection?

Who can study the researches of Dr. Sanderson into the pathology of infective processes without feeling that he is leading us to a profounder study of the most hidden phenomena of disease than was thought attainable a very short time ago? Mr. Simon,(c) alluding to his work and that of his colleagues, says well that their studies are extremely important, and that ordinary professional practice supplies neither opportunity nor immediate stimulus for them; studies of elaborate and purely scientific research in aid of the development of medical knowledge, studies never immediately convertible to pecuniary profit, but perhaps, on the contrary, involving heavy cost; studies, too, which, from their nature, cannot promise rapid results nor be conducted in fragments of leisure, but require systematic and continuous labour extending over long periods of time.

Dr. Sanderson's researches have especially served to open out a new vista with regard to many inflammatory and febrile

(y) Videtur quod arduum et difficile discernere aut visu aut tactu, dilatari et constringi, et qualis sit systole qualis diastole.

(z) Ego per integras horas animadvertendo non facile potui discernere neque visu neque tactu, quare vobis cernendum et indicandùm proponam.

(a) Erectione protendit sanguinem et facit pulsus, pro eresi (an heretical notion) et contra Galenum—"as in a glove," he adds in English; and concludes: Hinc pulsus arteriarum, non ex innata facultate sed protendente corde.

(b) Cesalpino's inquiries into demonology have no bearing upon the subject-matter of the Oration; but I venture to direct the reader's attention to them, as they are often extremely amusing, and may assist in forming some opinion of the writer's character and frame of mind. As a whet to their appetites, I extract the following illustration from the "Dæmonun Investigatio" (chap ix., page 154), of the views that prevailed even among the educated classes in the sixteenth century as to the influence exerted by evil spirits upon man. Cesalpino relates that "A ship having put into Salamis, in the island of Cyprus, for the purpose of purchasing provisions, a young man left the vessel and bought some eggs of a certain woman. He ate them on the shore, and, after the lapse of an hour, lost his voice and became half stupefied. When he essayed to go on board, he was driven back by his associates, who did not recognise him, but regarded him as an ass. As the wretched man was unable to express himself in words, the ship quitted the harbour without him; and he, anxious and having nobody to advise him, returned to the woman by whose influence he suspected that he was detained. He obtained no help from her; and, therefore, waiting his opportunity, remained three years in the country, occasionally carrying burdens according to the custom of asses. At night he stayed with the woman; but, continuing dumb, was unable to give evidence against the poisoner. However, having been accidentally led to the town, and passing a church, the ass was seen by certain Genoese merchants, at the elevation of the host, which happened at the moment to be raised, to bend his hind legs, and to raise his forepaws in adoration. The merchants, seeing this miracle, inferred that the woman who was leading the ass was a witch (for this species of transformation was common in Asia). They brought the affair to the notice of the mayor of the town, who ordered the woman to be seized. She confessed her crime, and, in the hope of pardon, restored the young man to his former condition, and he returned home. She, however, suffered condign punishment." Cesalpino adopts this tale as a fact, and infers that such occurrences prove that the accounts given by poets of the metamorphoses of the companions of Ulysses into animals by Circe were not mere fables. It is not difficult to conceive how the sober mind of Harvey would treat these lucubrations of Cesalpino if he were acquainted with them; but they scarcely impress us with the conviction that the latter was a man capable of effecting a great revolution in science. It may be interesting to modern demonologists to know that a picture by Gius. Sabatelli—painted in the present century—is to be found in a chapel of Santa Croce, in Florence, in which a mule is represented as kneeling before the host which is being conveyed to a sick person (see "Museo di Pittura e Scultura," Firenze, 1842; Tavola, 1182).

(c) "Report of Medical Officer of Privy Council, 1874."

processes; and, although they are not to be regarded as concluded, they have already shed much light, particularly on the origin and course of infective processes. We owe to his earlier experiments the discovery of the fact, "that when in the lower animals local inflammations are produced, either in the skin or peritoneum, by the introduction of irritant substances, two distinct sets of consequences manifest themselves —viz., a chronic disease exhibiting in all respects the anatomical characters of tuberculosis, and consisting essentially in the overgrowth of certain tissues, designated as lymphatic or adenoid, and shown to be in close relation with the lymphatic system; and (2) an acute disease presenting the leading features of pyæmia, attended with the formation of metastatic abscesses, and, as a rule, terminating fatally and very rapidly by the formation of infective abscesses and nodules, associated with inflammation, not only of the peritoneum, but of other serous cavities.

It is no small matter to have learnt from Dr. Sanderson's inquiries into the pathology of diphtheria, that microzymes and micrococci exist which possess the power of colonising in living tissues, and "thereby inducing a variety of inflammation which is distinguished from others by its tendency to result in disintegration, and that this faculty of disintegrative inflammation is possessed by them independently, and can be exercised without the concurrence of any previously existing morbid process." The micrococci found by Sanderson, by Keber, Cohn, and others, in small-pox, the rod-like bodies, distinct from bacteria, belonging to splenic fever, the wavy spirilla discovered by Obermeier in the blood of persons suffering from relapsing fever, and not seen in other acute and infective diseases,—all point to the necessity of remodelling many of our views regarding the essence of disease; while a more intimate knowledge of its pathology cannot fail to give greater precision to our methods of combating morbid processes.

We cannot hope to apply a more scientific treatment to disease than we do now, until we thoroughly understand the origin and course of the disease, and the changes that occur. Although it is manifest that morbid poisons do not all act equally upon man and animals, still, it is also clear that we must be content to study the synthesis of disease, with very rare exceptions, in the brute creation only. Would that it were possible to popularise such researches as those initiated by the Medical Officer of the Privy Council, in order to convince a sentimental public that they open a prospect of hopeful harvest in the field of preventive and curative medicine. Surely it is as much in accordance with the dictates of the most refined humanity to utilise animals for the extension of knowledge that shall afford relief or immunity from disease, as to employ them for the sustentation of life as food and raiment. As some of the agitators against scientific advancement are proof against facts and evidence brought forward in the vernacular tongue,(d) we may hope that they may more readily accept arguments when expressed in the language of Virgil. We would recommend them to read the "Carmen Elegiacum" of Dr. Bridges,(e) in which the poet offers an elegant protest against the imputation that heartlessness and cruelty direct experiments made upon animals. After referring to the good work done by our distinguished fellow Dr. Brunton, whom he describes as

> "Promptus aberrantes vivisecare canes,"

and after alluding to the popular errors prevailing on the subject, he exclaims—

> "Hoc crudele aliquid nobilitatis habet,
> Hic simul humanis prodesse inventa videntur;
> Quoque loco cecedit rana, resurgit homo."

Assuming that we have acquired a power to recognise the germs giving rise to febrile and infective processes, or of the *causa proxima* (to use an antiquated term) of other morbid conditions, we could not hope to determine satisfactorily by chemical reagents in the test-tube the antidote that would neutralise them. This would merely be an ancillary method, guiding to further researches; the real value of the antidote could not be established in any other way than by experiment upon a living body into which the germs had been introduced. Valuable as are the reports of Dr. Baxter,(f) as to the relative disinfecting power of chlorine, permanganate of potash, sulphurous acid, and heat, they deal only with contagia outside the body. We have probably all of us in practice hoped that, by introducing these and similar agents into the diseased body, we might influence beneficially the processes manifestly depending upon such contagia. I fear that as yet no results have been achieved that would in any way justify a belief that the antidote has been discovered, that will neutralise or arrest an infective process in the body, as we have succeeded in doing external to it. Our treatment in these cases, as yet, consists in dealing with the product of the morbific germ, and in assisting nature to bear its assaults with more or less impunity. The goal that we or our successors must aim at is to discover a germicide agent, whether to be introduced by the mouth or by injection directly into the blood; so that, to use Mr. Simon's words,(g) "the bedside practitioner shall be able to apply his counteragents with the precision of one who conducts a mere physical experiment."

But if we are still far from a perfect knowledge of the intimate cause of morbid processes, promising as the investigations are to which allusion has just been made, we have greater reason to congratulate ourselves on our recent advances in the determination of the various phases exhibited during the progress of disease. Few appliances, during the most recent period of medicine, have contributed more to this advance than the thermometer, the universal adoption of which might well be adduced in evidence of that Harveian spirit which I venture to claim as a characteristic and prevailing feature in the medical profession of the present day. Remembering the early days of the stethoscope, and the comparative slowness with which it forced itself into universal recognition, the manner in which the thermometric test of morbid processes has been received in all ranks of the profession, from the time its value was first shown by Wunderlich and Traube, seems to justify a high estimate of the advance made by the students of medicine during the present generation. The thermometer does not give us the reason of the change of temperature in the individual case; but it enables us to form a correct estimate of many processes, the nature of which previously could only be determined in the post-mortem room; and increased diligence in its employment is likely to render more clear the diagnosis of various obscure changes, as, for instance, Bastian(h) and others have already indicated in the department of cerebral pathology. The thermometer tells us a fact, which the most educated tactile sensibility is inadequate to determine with precision; and both in the outset, course, and convalescence of acute disease, it is an invaluable help to judge of the requirements of our patients. Whether more care in observation, or more refined instruments, will materially increase the value of thermometry, remains to be seen; but what we specially require is a means of determining the commencement of the incubative stage of febrile disease, so that we might be enabled to apply our remedies before the zymotic process has actually poisoned the entire system. The interval that elapses between the absorption of a germ and the actual manifestation of the complicated processes to which it gives rise, is the period during which an antidotal or germicide agent would be most certain to effect the desired end. It suggests itself whether we are not likely to find, in a combination of the galvanometer and thermometer, the means of a further advance in this direction; and it seems to me that we must look to the galvanic test also for a solution of the problem, which is so often presented to the practitioner: how pain, which at present is only a subjective sign, can be rendered more objective; how we may estimate and measure this important symptom; how we can secure an instrument which, by anticipation, may be termed on odynometer.

The "*tactus eruditus*," upon which our predecessors justly laid stress, and which cannot now be dispensed with, is rendered more intelligible and receives a scientific basis in the explanations of the varying conditions of arterial tension afforded by the sphygmograph. It is one of those inventions and applications of the modern physiologist which we conceive that Harvey would have especially delighted in, as giving confirmation to many views which he held, and explaining much that necessarily was beyond even his powers of solution. The sphygmograph affords us the *rationale* of those differences of the pulse which the practised physician has long recognised; and though not suited, at least in its present form, for ordinary bedside practice, has already, in the hands of experienced

(d) See especially the Report of the Royal Commission on the practice of subjecting animals to experiments for scientific purposes; 1876; Bluebook.

observers, thrown much light on the changes which the heart and vessels are subjected to in the varying phases of disease. As it has already given precision to our physiological doctrines on the action of the heart, the condition of the arteries, and the balance of the circulation, we may hope that it will aid us still further in determining the action of many substances which affect the circulatory apparatus and the blood, concerning which the medical mind is still in a painful state of dubiety.

In connexion with this subject, I am confident that I re-echo the feelings of every member of this ancient corporation if I dwell upon the loss which the College has sustained, since the last Harveian Oration was delivered, by the decease of a man whom we may justly designate as a genuine follower of our great medical prototype, and who showed by his work that he also "avowed himself the partisan of truth alone," questioning Nature with all the perseverance of the earnest student, and not content with anything but the most rigid examination of the replies she vouchsafed to his inquiries. Among the numerous works of Harvey, tho loss of which we have to deplore,(i) "by certain rapacious bands, which, not only with the permission but by the command of Parliament, stripped his house of all its furniture, but abstracted the fruits of many years of toil," we have to reckon a "Medical Anatomy."(k) One of the various works by which our friend Dr. Sibson has established a name, which will endure while this College lasts, is a "Medical Anatomy," in which he gives evidence of many of the admirable qualities which characterised Harvey. Like Harvey, too, he did not hurry into a publication of his researches, but thoroughly matured his work before bringing his fruit into the great market of literature. To both we may suitably apply the praise bestowed upon Goldsmith, in a somewhat different sense, in the well-known words: "Nihil tetigit quod non ornavit."(l) Sibson's work in connexion with respiration, with the nomenclature of disease, with aneurism, and with sanitary science, deserves a grateful record on our part. There appears a special fitness in the fact, that the last time Sibson appeared before the medical public, he delivered two Harveian lectures "On Bright's Disease and its Treatment," in which we find all those qualities of the scientific physician which have left so deep an impression upon the generation in which he lived. They do not, of course, convey to the reader the many estimable qualities of head and heart, the warmth and heartiness of his friendship, the poetic love of nature and of art, which endeared him to all who had the privilege of intimate intercourse with him, and which we rarely see so harmoniously blended as they were in our departed friend. These, indeed, are enshrined in our affectionate memories; but his chief claim to be mentioned in this place, and on this occasion, lies in the fact that those who knew him best may claim for him, in an especial manner, that he was a representative of the Harveian spirit of honest and truthful research into the mysteries of God's work in nature.

In no department of medical science has careful study offered to the inquirer of late years more promise of reward than in the domain of the nervous system. We have, indeed, been told but recently, in this hall, by one of its most successful cultivators, how much of uncertainty yet surrounds our knowledge of disease of the brain; and yet, whether we dwell upon the physiology of the cerebro-spinal system, the chemical changes which it controls, the localisation of function, the relation of nutrition and nerve-force, or the minute pathology of the brain and spinal cord, it is impossible not to be struck by the progress made by labourers of the present and most recent periods. In this field alone, of all the wide regions of medical science, we find no evidence that our Harvey instituted any special inquiries and observations. In his manuscript lectures on anatomy, the brain and spinal cord are treated in the most summary manner; and although his works afford proofs of his pathological knowledge,(m) of his acquirements and practice in surgery,(n) and of his acquaintance with, and performance of, operations in obstetrics,(o) we search in vain for a sign that he even appreciated the importance of the nervous system. The significance of this part of our fabric has, indeed, been scarcely recognised until the present century; and even now, great as have been the achievements of illustrious students, many of whom we claim as associates of this College, we only appear to see the dawn of the full effulgence of knowledge. Truly, whether we look to the results already secured, or to the promise they offer of greater light, we cannot refuse the claim of tho labourers in this department of medical science to be considered as genuine fellow-labourers of Harvey; conscientiousness, perseverance, concentration and clearness of thought, are the characteristics of many of our contemporaries, whom, in an assembly like the present, it would be unnecessary to recall by name. But they, like the collaborators in other realms of medicine, have materially contributed towards rendering this present time deserving of the title of the Harveian era.

Few things are more encouraging to the medical man, who reads the works of Harvey with attention, than to find that his faith in the value of treatment was in nowise impaired by his studies;(p) on the contrary, he frequently illustrates the value of his physiological discoveries by showing the direct application to be made of them to the arrest and control of disease. The more we study the works that have survived him, the more intense becomes the admiration for the great mind that achieved them; and the greater our regret that barbarous hands destroyed other products of his labour, which we are justified in inferring to have been of the greatest value. As the reputation he enjoyed among his contemporaries has been confirmed by the continuous applause of his successors, we cannot doubt that his powers, brought to bear upon the investigation of disease and its treatment, the results of which were embodied in his (lost) "Medical Annotations," would also have largely advanced the healing art. With his help, it is not unlikely that our control of morbid processes might be greater than it is at present; and that we might already claim a greater precision in this department of our calling than our advances in diagnosis, in the chemistry of the body, and in the knowledge of drugs, can yet justify. Earnest as the work is that is being done in this field of science, it is scarcely commensurate with the results gained in other sections of the domain; though here, too, the Harveian spirit is abroad, and humanity is already reaping benefits which even Harvey could not have dreamt of.

But if we may not justly assert that we have as yet acquired the precision in our control over morbid processes that the general advance of medical knowledge would appear to demand, we may claim for our knowledge of what is summed up under the modern term of State medicine a high position among the sciences that are directly conducive to the welfare of mankind.

In the application of medicine and the allied sciences to the prevention of disease, the present century may claim precedence of rank before any earlier periods in human civilisation. During the last forty years each decennium has been characterised by an ever-growing appreciation of the great truths of sanitary science. From the days of the Health of Towns Reports by Edwin Chadwick to the later days of Parkes and Simon, medical men have continuously and unselfishly waged war against the vested interests of filth and zymosis. Nor have their efforts been futile, if increased salubrity and a higher average duration of life may be regarded as tests of success. Nowhere have these tests yielded more satisfactory results than in our naval and military forces; and seeing how much has been achieved, it does not appear out of place to express a hope that our Governments may always take the precautions that are necessary to insure to medical men, in their official capacities, such power and position that their representations may receive due support. I have already had occasion to dwell upon the Reports of the (late) Medical Officer of the Privy Council. The work of which he has been the ruling spirit constitutes a memorial, which will remain an honour to himself and his colleagues, as it is to the time and

(i) "The Works of Harvey," Sydenham Society's edition, p. 481.
(k) *Ibid*, p. 89.
(l) We hope to be pardoned for taking a slight liberty with Johnston's epitaph on Goldsmith, the commencement of which runs thus: "Olivarii Goldsmith, poetæ, physici, historici, qui nullum feri scribendi genus non tetigit, nullum quod tetigit non ornavit, sive risus essent movendi, sive lachrymæ, affectuum potius et lenis dominator et cet."
(m) "The Works of Harvey," Sydenham Society's edition, pp. 90-197, *et passim*.
(n) *Ibid.*, p. 254. Harvey here speaks of his surgical operations as a common thing; and it is particularly interesting to note that in an age when the "ferrum candens" was still in vogue for the arrest of hæmorrhage, he says:—"I have occasionally, and against all expectation, completely cured enormous sarcoceles by the simple means of dividing or tying the little artery that supplied them, and so preventing all access of nourishment to the part affected.
(o) Harvey's essay on "Parturition" affords satisfactory evidence that he was not a mere theorist, but that he personally engaged in the practice of midwifery. He appears to have paid attention to the process of parturition of animals as well as of the human female (Sydenham Society's edition, pp. 521, *et seq.*; see also p. 534).
(p) See especially Sydenham Society's edition, p. 129.

people for which he laboured. It was with grief that the medical profession heard of Mr. Simon's resignation, and the pain was intensified by the report that his office was to be abolished. In the "Supplementary Reports," which Mr. Simon has brought out since quitting his post, we are promised that some of the investigations, commenced under his supervision, shall be continued; may we hope with the same zeal, earnestness, and success as before. It would be difficult to express adequately the sense the profession entertain of the value and significance of all that has been achieved by the Medical Department of the Privy Council; but I am sure that we all endorse the sentiments that are so well conveyed in the following passage, which I take from Mr. Simon's last Report:(q) —"As for the general value and promise of that kind of work in its bearing on the progress of medicine, I entertain the strongest conviction that, in regard of all antagonism to disease, whether with preventive or curative measures, and whether by official or private hands, medicine's best prospects of increase and success are inseparable from such studies of exact science; and that, in proportion as the pathological insight becomes more clear, the growth of practical power will surely follow."

It would be tedious to dwell here upon details with which my audience is as well, or better, acquainted than I am; the more so, as the time is too short even remotely to do justice to the memory of past or to the labours of present workers. But it is well to bear in mind that, in this field also, we may quote Harvey as an authority for the due appreciation of those elements of health, which it is the object of State medicine to foster and to secure, and which he feelingly dwells upon in his account of Parr, whose body he examined after death by command of his Majesty. Here, as elsewhere in his writings, Harvey indicates much that he doubtless enlarged upon more fully in those works which, unfortunately for medical science, were destroyed in the revolutionary war.

No one can say how much more rapidly medicine would have advanced had not ruthless hands been laid upon those works of Harvey, of which only the titles have been brought down to us. But anyone who has learnt to revere Harvey in what we possess of him, and has become familiar with his marvellous industry, his logical mind, and his powers of observation, cannot but feel that everything that he committed to paper was worth preserving, and was certain to impart knowledge of great value to those not possessed of the same qualities.

In the brief remarks that I have ventured to offer to you, I have dwelt upon the modern manifestations of the Harveian spirit in scientific research. But Harvey has left us other features in his character worthy of imitation. Time does not serve to speak of more than the one that especially recommends itself to the Fellows and Members of this College, for it was the *liberality* of Harvey by which the resources of the College have so largely benefited. His munificence provided the former library and museum; he endowed the College with his patrimonial estate of Burmarsh; and left to it his "bookes, household stuffe, pictures, and apparell"; his "best Persia long carpet"; his "blue embroyedyed cushion, one pair of brass and irons, with fire-shovell and tongues of brasse, for the ornament of the meeting-room."(r) This example has not been left without imitators in the present Fellows of the College, who, in their self-denial and generosity, have of late years repeatedly shown themselves to be not unworthy recipients of Harvey's gifts. It affords me particular pleasure to announce publicly, for the first time, the special act of liberality of a recent distinguished Harveian Orator—Dr. Arthur Farre, who in his oration so eloquently and appropriately analysed Harvey's merits in connexion with the subject of Generation. Dr. Farre has within a few days presented to the College, with his portrait, a most valuable library of ancient and modern works, which you may observe, conspicuous by their elegant binding, on the shelves above. It is the most important donation of the kind that our Corporation has received since that of the Marquis of Dorchester, a former Fellow, in 1680; and one that doubtless affords peculiar gratification to our distinguished Harveian librarian, Dr. Monk, in whose name, as in that of the well-wishers of this ancient body, I am sure I may challenge all associates to give or bequeath to it similar "*pignora amoris*," that each donor may deserve, in the vernacular, the record bestowed upon Harvey in the minutes of the extraordinary comitia of July 28, 1666:—"*Fastis nostris honorifice semper commemorandus.*" The grateful thanks of the College are certainly due to Dr. Farre for his gift; and it affords me particular pleasure to take the opportunity of tendering him from this place our acknowledgments, and our heartfelt wishes for his health and happiness.

In bringing my address to a conclusion, I beg to offer to you, Mr. President, and the Assembly, many apologies for the very imperfect manner in which I have dealt with the topics which I have ventured to touch upon. No one can be more sensible of my inadequacy to fulfil the task which you, sir, with too indulgent trust, have imposed upon me. But though I crave your merciful consideration for my effort, I cannot but admit that I owe you, sir, a debt of gratitude for having imposed upon me what has indeed been a labour of love—that of poring over Harvey's works and studying those of his contemporaries. Every page that I have read has only served to convince me, more and more, of the magnitude of the obligations that this College and all generations of medical men who have lived, or will live, after Harvey, are under to him. Would that I could hope to have added the smallest tribute worthy of so great and good a man to the many offerings that his grateful successors have paid to his memory. But, while conscious of my own unworthiness to dilate on so great a theme, I have no fear that, for want of better advocacy, the power of the Harveian spirit will cease to prevail in English medicine, while so many illustrious workers as grace the present roll of the Royal College of Physicians are evidences of its continued influence.

Though I may not have proved what none but future physicians may fitly endorse, I cling to the belief that in no period of the past has this College been so fully imbued with a consciousness of its high calling, and a desire adequately to fulfil its important duties, as in the present; and that the many labourers in the fields that Harvey cultivated justify a humble admirer of the many distinguished contemporaries with which it is my honour to be acquainted, in designating the present age as especially deserving of the title of the Harveian era of medicine.

It is for the younger generation of the present, and for those who are to follow, to see that the Harveian spirit suffers no abatement. Let them walk in Harvey's footsteps, and they will certainly receive their reward in the acquisition of profounder knowledge; in the freer recognition of the value and aims of medical science by their fellow-men; and, above all, by the assurance of greater power and control over the dark influences that still chequer life and hamper man's onward march to a more elevated and spiritual existence.

(r) Quoted from Harvey's Will; see Dr. Monk's "Roll of the Royal College of Physicians," vol. i., p. 132.

Applications in Syphilitic Ozæna.—Dr. Mauriac recommends the following:—Sugar or powdered talc, 10 parts; subnitrate of bismuth, 5 parts; and calomel, half a part; some of this to be sniffed up several times a day. Or the following powder may be employed:—Alum and tannin, of each 1 part; powdered talc, 10 parts; and subnitrate of bismuth, 5 parts. If there are fungosities or ulcerations, they may be touched with a pencil of nitrate of silver, or with a solution of the strength of a fifth or tenth. Or the following ointment may be applied:—Nitrate of silver, half or a whole part dissolved in a sufficient quantity of distilled water; and cold cream, 20 parts.—*Union Méd.*, June 28.

An Agricultural Colony.—Under this somewhat indefinite name the Council of the Department of the Seine has just opened an establishment for the instruction of idiotic and backward children in such agricultural pursuits as they may be found capable of. This agricultural colony of Vaucluse, as it is called, is situated, though unconnected with the asylum of that name, at Epinay-sur-Orge, in the Department of Seine-et-Oise. A farm with ten hectares of land has been annexed to the colony, whereat all children showing any disposition thereto will be taught various modes of culture. A devoted and intelligent teacher who has taught for thirty-five years at Bicêtre has also been appointed. A chaplain, a professor of gymnastics, and a music master have also been appointed; and any child showing aptitude will be taught a trade in the workshops. The medical management of the establishment is under the charge of a physician and his assistant, with an interne. The Council has established a regular tariff of charges to be made for the children sent by the department, as well as for those sent by their families.—*Union Méd.*, June 26.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

Lecture I.

ON REFRACTION.

Mr. President,—The fact that certain defects of vision can be corrected by optical appliances is one which has been known to the human race from very remote antiquity. In England, spectacles did not come into common use until the reign of Richard II.; but in China, and probably in other Oriental countries, they have been employed from time immemorial. The limits within which these lectures are confined afford me no opportunity of entering into historical questions; but this is scarcely to be regretted, inasmuch as spectacles appear to have been used empirically, and with very little knowledge either of their precise mode of operation or of the conditions which called for them, until the invention of the ophthalmoscope furnished the starting-point for researches in physiological optics which have richly rewarded many of those who have taken part in them. Prior to the time mentioned there had, indeed, been illustrious Englishmen, notably Porterfield and Thomas Young, who had devoted much attention to similar problems. Unfortunately, however, even Young, who alone among these inquirers must be credited with the possession of the necessary combination of physical, physiological, and geometrical knowledge, scarcely appears to have occupied himself with the clinical requirements of mankind; or to have had any extensive or accurate acquaintance with the actual optical wants of the many sufferers from defective vision. Thus, when he had analysed his own astigmatism, and had discovered the form of the lens by which it could be corrected, it does not seem to have occurred to him that the defect was a common one, by which many persons were practically debarred from the full use of their eyes; and neither he, nor in more recent time Airy, made any attempt to arrive at formulæ for dealing with astigmatism which should be of easy and universal application. Many of those who concerned themselves with the phenomena of vision were content to assume the existence of conditions which were optically sufficient to explain the facts; and never troubled themselves to ascertain whether these assumed conditions had any real existence. Thus, in my own youth, there were elementary treatises on optics in the hands of boys; and these treatises, I believe without exception, set forth that short sight was due to unnatural convexity of the cornea, and that presbyopia was due to a progressive flattening of the cornea, which occurred during the decline of life. It is manifest that unnatural convexity of an otherwise symmetrical cornea might produce some of the symptoms of short sight, and also that progressive flattening of the cornea might to some extent imitate presbyopia; but, as a matter of fact, neither of these conditions is met with. The cornea of a myopic eye is, as a rule, somewhat less convex than the normal standard; and there is no flattening of the cornea as life advances. It is hardly necessary to say that, while questions of this kind were disposed of by ingenious guesses, and without appeal to facts, no scientific progress or precision of knowledge could even be expected. Of late years, however, since the investigation of all the optical causes of defective sight has been recognised as forming one of the most important branches of ophthalmic surgery, we have been arriving by degrees at more accurate information; and, although there is still much to be learned, the growth of knowledge within a comparatively short period of time has been sufficient to afford much ground for congratulation, and also sufficient to relieve a very large amount of discomfort or even suffering. It may now be laid down, as a general principle, that almost every eye which has good vision under any limitations of time or distance can be so assisted as to be made independent of these limitations, and able to accomplish its full share of work in the world; while some eyes, which when unaided have not good vision under any circumstances, may have their defects remedied by lenses of various kinds.

The vision of the natural eye ranges from infinity to a so-called near-point, which gradually becomes more remote from the cornea as life advances, but which should not be farther away than eight inches. Such an eye has clear vision of all objects over the specified range of distance, that is, from eight inches to the horizon or the fixed stars; and it can continue the act of seeing, at any point over the whole of this range, for any reasonable time without interruption. The vision of the short-sighted eye is conditioned by space, and so also is that of the presbyopic eye; the former not being able to see clearly any objects which lie beyond a definite distance, and the latter not being able to see clearly any objects which lie within a definite distance. The presbyopic eye has its near-point farther away than eight inches, or than is natural; and the myopic eye has its far-point nearer than infinite distance. In the asthenopic eye, there may be similar limitations of vision within given distances; but the limitation chiefly complained of is one of time. The patient can see, if not perfectly, yet sufficiently well for many purposes, for a given period only; and, when this period is overpast, the sight becomes blurred, or the eyes become painful, and further use of them, in either case, becomes difficult or impossible. In all the foregoing conditions, whenever there is useful sight within any range, however limited, or for any time, however short, we may be satisfied that we have to deal with a defect which can be remedied, always in some degree, and often completely, by optical means, or, in other words, that the fault is in the curvatures of the refracting surfaces of the eye, or in its shape, or in its muscular organs of adjustment or of direction, and neither in the transparency of its media nor in the nervous apparatus of vision, either central or peripheral. The distinction thus made, as we shall see hereafter, is often one of the greatest possible importance to the patient.

There are, indeed, a few cases, chiefly those of high degrees of astigmatism, in which the unaided vision, within all limits of space or time, is always very defective, and in which the defect is nevertheless entirely optical. To these it will be necessary to return hereafter; and they are only mentioned now because they furnish apparent exceptions to the general rule that it is only the eyes which possess good vision under some circumstances to which the surgeon may afford relief by optical means alone.

In order to make clear the nature of limited or conditioned vision, it is necessary to glance at the chief functions upon which vision depends; and in doing this I shall trust to be pardoned if I deal, for a short time, with very elementary matter. There are certain facts so universally known that it would not be proper to dwell upon them at any length; and yet so important, that it would not be proper to omit all mention of them.

The factors of normal vision, then, assuming that the media are transparent, and that the nervous structures are healthy and receptive, are three in number—namely, Refraction, Accommodation, and Convergence. By Refraction, is meant the optical state of the eye when at absolute rest; by Accommodation, the power of adjusting it to see with equal clearness at distances within its far-point; and by Convergence, the power of directing the visual axes of the two eyes to some point nearer than infinity.

Dismissing from consideration, for the sake of simplicity, the actual complexities of its structure, we may regard the eye merely as a *camera obscura*, designed to form inverted images of outward objects upon the percipient layer of the retina. In like manner, we may regard the several refracting surfaces as forming only a single lens of definite focal length; and it is obvious that this focal length may either be equal to, or somewhat different from, the length of the antero-posterior axis of the eyeball. If the length of the antero-posterior axis of the eyeball is precisely equal to the principal focal length of the refracting media, it follows that parallel rays of light, such as proceed from infinitely distant objects, will be united in a focus upon the retina, and the eye is then said to be *in measure*, or *Emmetropic*, as in Fig. 1. If, on the other hand, the eye is longer than the focal length of the media, the focus of parallel rays will be in front of the retina, as in Fig. 2; and, if the eye is shorter than the focal length of the media, the focus of parallel rays would be behind the retina if they could pass through it, as in Fig. 3. These two conditions, in which, taking the focal length of the media as a standard, the eye is

too long and too short respectively, are both expressed by the common term *Ametropia*, the eye being *out of measure;* but it is manifest that the conditions themselves have very little else in common, and that they must require to be separately discussed and differently treated. It is further manifest that a veritably emmetropic eye can only be formed by a correspondence of measurement so exact that it cannot often be expected to occur; and that a certain amount of ametropia, on one side or the other, must be the rule rather than the exception. Unless this ametropia attains a degree capable of easy recognition and measurement, it does not become disturbing to vision, and does not in any way declare its presence; and we therefore call many eyes emmetropic, which, if strictly examined, would be found not to fall within the terms of the definition.

Fig. 1.

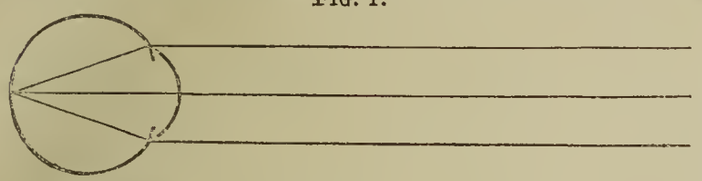

Fig. 2.

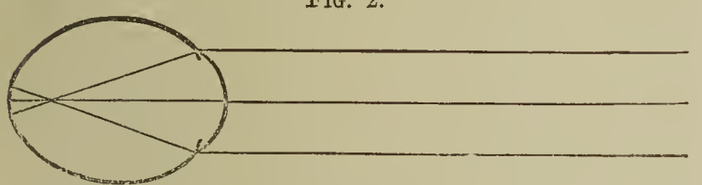

Fig. 3.

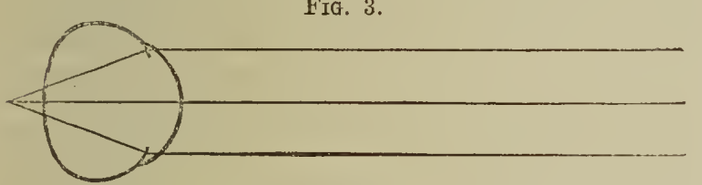
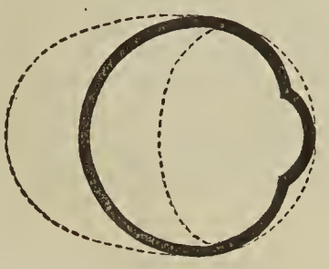


The form of ametropia in which the eyeball is shorter than the focal length of the media was called hypermetropia by Donders, who discovered and first described it; and this word is now universally accepted. It would seem to imply, etymologically, that the focal length is too great; but, as a matter of fact, the focal length is generally much the same as in a normal eye, and the fault is that the axis of the eyeball is too short. The eye is compressed, or flattened from before backwards, as has been shown by innumerable dissections; and as may often be seen in the living subject when the eye is adducted to the full extent. The ordinary length of the emmetropic axis is about 24·5 millimetres; while the shortest axis recorded from actual measurement, in a hypermetropic eye, was only 16 millimetres. In the high degrees of hypermetropia the eye is usually small in all its dimensions, and must then be looked upon as being in a state of imperfect or arrested development. In such cases, the acuteness of vision is often low, seemingly from structural imperfection of the retina; and the orbits sometimes share in the general undergrowth.

The opposite condition, in which the focal length of the media is less than the length of the axis of the eyeball, might properly be called brachymetropia, as suggested by Donders, or hypometropia, as suggested by Scheffler. But it produces short or near sight; and this has long been known as myopia, on account of the tendency of short-sighted persons to diminish the circles of light-diffusion from distant objects by partial closure or nipping together of the lids. This trivial designation has become so firmly rooted in medical literature, and is also so generally understood, that no systematic endeavour has been made to displace it by a more scientific term; and I therefore purpose to use the word myopia, and, so far, to remain in the ancient ways.

In myopia, as in hypermetropia, the departure from correct proportion is on the side of the eyeball itself, and not on that of the refracting media. Every myopic eye is elongated from front to back, so as to be somewhat elliptical in shape, with its major axis in the antero-posterior direction. The longest myopic axis which has been actually measured was no less than thirty-four millimetres; being more than double the length of the shortest hypermetropic axis, and nine and a half millimetres longer than the average of the normal eye. The annexed diagram (Fig. 4) represents the proportions of a normal eye, showing the relation of its anterior portion to a spherical outline; and the interrupted lines within and without the circle represent the proportion, to this normal eye, of the two extreme instances of ametropia which have been mentioned.

Fig. 4.

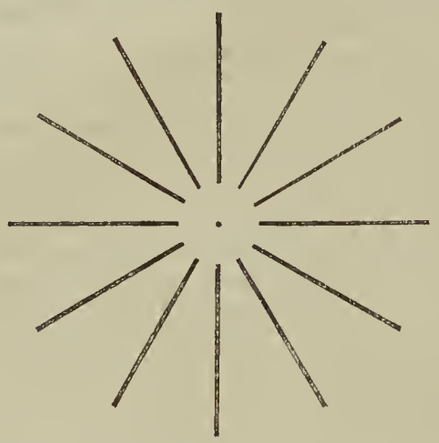


In the majority of instances, the two eyes of the same person will be alike in their refraction, or nearly so, the difference being too small to require to be taken into consideration in practice; but cases arise in which there is a difference of a decided kind. One eye may be emmetropic, and the other ametropic; or one myopic, and the other hypermetropic; or they may both present the same form of ametropia, but in different degrees. As eyes of like refraction might be called isometropic, it was an obvious suggestion that eyes of unlike refraction might be called anisometropic; and this word, and its substantive, anisometropia, were introduced in 1867, by Kaiser, and have ever since been commonly employed in ophthalmic literature. The fact is not important; but I mention it because a recent writer in the *British and Foreign Medico-Chirurgical Review*, in a composition which he would probably call a critical notice of a book of mine, said that the word anisometropia was of my invention, and condemned it in forcible language. It must always be interesting to an author to find that his professed critic is so ignorant of the subject on which he writes, so ignorant even of the headings of the chapters and of the pages of standard books, as to be capable of making such a blunder as this. The word in question is often convenient, as a means of avoiding circumlocution; but last year Dr. Noyes, of New York, proposed to limit its employment to cases in which the refraction of the two eyes is alike in kind, although different in degree, and to use the term *antimetropia* for those in which the refraction in the two eyes is of opposite or dissimilar qualities.

The differences between the two eyes, although often sources of difficulty in practice, are less important than those which may exist between different meridians of the same eye. Young, in 1793, discovered that his vision was not the same for vertical and for horizontal lines; and, having calculated the difference, he caused a glass to be ground for its correction. Professor Airy, the present Astronomer-Royal, repeated Young's discovery in 1827; and he not only calculated the curves of a glass to meet his requirements, but he also communicated his discovery to Whewell, who suggested that, as the eye had no single focus, the condition might be called astigmatism. After this, the matter slumbered until 1862, when Professor Donders, of Utrecht, to whom we are so greatly indebted for his labours in investigating all the anomalies of refraction and of accommodation, announced that astigmatism, so far from being an unusual condition, was almost the normal state of the human eye; and that in about 2 per cent. of all the cases of defective sight it was present in such a degree as to be disturbing to vision. The treatise which he soon after published on the subject left little to be done by subsequent inquirers, except to verify the conclusions at which he had arrived, and, in some small degree, to simplify and improve his first methods of investigation. In this introductory paragraph, it is sufficient to say that the surface of the human cornea, instead of being spherical in its outline, is somewhat differently curved in two opposite directions or meridians, which often correspond with the vertical and horizontal corneal diameters, and are called the two chief meridians, or the meridians of least and of greatest curvature. These chief meridians, even when they are not approximately vertical and horizontal, are always at right angles to each other; and when the difference between them exceeds a certain small degree, there is a conspicuous difference in the distinctness with which lines drawn in different directions are seen from the same point of view and with the same adjustment of the eye. The lines in this star-like figure (Fig. 5), or those in any analogous test-object, are as precisely alike as they can be made; but there are many people who would see them with very different degrees of distinctness; and there are some to whom one particular line would appear confused and blurred, although that at right-angles to the former might be perfectly well defined. I may mention, as a curious illustration of how easy it sometimes is to mistake a surmise for a fact, that a gentleman once consulted me on account of what

he called a "periodical obscuration of vision." I found that he sat in an office which commanded a view of a large clock-dial on the other side of a quadrangle. When the hands of the clock were approximately vertical, he could see them plainly; but when they were approximately horizontal, he could scarcely see them at all. This, which was the fact, he confounded with his own conjecture that he saw differently at different hours of the day; and hence he had been induced to read all he could find about "vital periodicity," and to regard himself as a curious physiological phenomenon. A pair of spectacles, selected in a manner which I must explain hereafter, restored his vision to normal regularity.

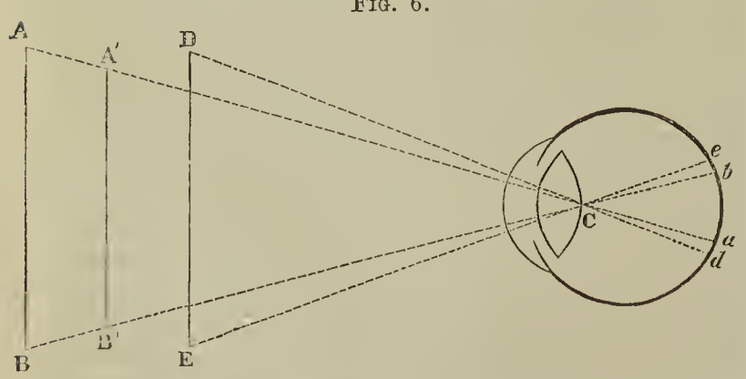
Fig. 5.



The differences between the two meridians in astigmatism may be of every possible kind. An eye may be emmetropic in one meridian and ametropic in the other; or it may be ametropic in both; and in the latter case we may find either different degrees of the same form in the two meridians, or one form in one meridian, and the other form in the other. All these are matters of detail which will have to be considered when the special characteristics of astigmatism are described; and at present it is sufficient to recapitulate that an eye is normal or emmetropic when the length of its axis is the same as its principal focal length; that it is ametropic when this correspondence does not exist; that ametropia occurs in two contrasted forms, according as the axis of the eyeball is too long or too short; that these two forms may be present in the two eyes of the same person, constituting anisometropia or antimetropia; and that they, or different degrees of one of them, may also be present in two meridians of the same eye, constituting astigmatism.

Disregarding, for the present, the effect of accommodation, and thinking of the eye as a passive organ, it may be said that ametropia, in all its forms, occasions a diminution of the natural acuteness of vision, a function which is measurable by means of the visual angle. The magnitude of the visual angle depends upon two factors—the size of the object seen, and its distance. The visual angle is that formed between two lines drawn from the extremities of an object to the nodal point of the eye, that is, to a point lying close behind the crystalline lens. In Fig. 6,

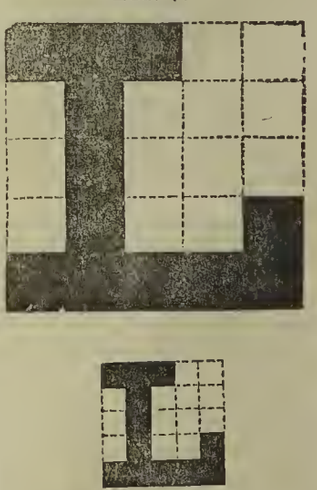
Fig. 6.



C being the nodal point of the eye, and A B an object, A C B is the visual angle of that object, and *a b* is the magnitude of its image on the retina. But the smaller object A′ B′, which is nearer to the eye, is seen under the same visual angle and forms an image of the same magnitude; while the objec D E, which is equal in size to A B, but nearer, is seen unde the larger visual angle D C E, and forms the larger retinal image *d e*. In order that the retinal image may excite visual perception, it must be of a certain size, and therefore the object forming it must be seen under a certain visual angle; and it has been experimentally determined that square letters, which have limbs and subdivisions equal in breadth to one-fifth of the height of the letters, and which are so placed that this height is seen under a visual angle of 5′, are distinctly legible to the normal eye. Dr. Snellen applied this principle to the construction of test-types which give a means of determining the acuteness of vision with exactness. His letters are drawn of the proportions mentioned, and of various magnitudes, each distinguished by a number which indicates the distance, in metres or parts of a metre, at which the height of the letter will be seen under a visual angle of 5′, the breadth of its limbs under an angle of 1′, and at which the letter as a whole should be legible. The acuteness of vision, usually written V in English, or sometimes S (the initial of the German *Sehschärfe*), is expressed by the distance of the test letters from the eye, divided by the number of the smallest letter, which can be recognised with certainty at that distance; the resulting fraction being reduced to its lowest terms. If the distance be six metres, the person who can read letters of the corresponding number at that distance has V equal to 6-6ths, or equal to 1; and this is taken as the normal standard. One who can only read No. 9 has V equal 6-9ths, or 2-3rds of the normal. One who can only read No. 60 has V equal 6-60ths, or 1-10th of the normal, and so on. In order to use this method in practice, a sheet of test-letters of various sizes should be hung up in a good light, care being taken that the number of the smallest size is a little less than the number of metres in the available distance. In my own consulting-room, for example, the letters hang at three metres from the patient's chair, and the sizes range from 2·5 to 60, so that I can recognise variations of acuteness ranging from 6-5ths, or more than the normal, to 3-60ths, or 1-20th of the normal, and the examination is completed in a moment. For my own use, I have a set of test-types which were designed by Dr. John Green, of St. Louis, and which are constructed on the same principle as those of Snellen, but are superior to them in certain points of detail. The letters are so selected as to be of more uniform legibility, and the number of gradations is greater. Green's types, however, are not easily procurable in this country; while those of Snellen, which fulfil every purpose, may be obtained from any bookseller.

Fig. 7 displays two examples of Snellen's letters, which should be legible at twenty-four and at nine metres respectively.

Fig. 7.



In every case of ametropia, of whatever kind, it is manifest that the retina must receive an irregular patch of light, technically called a diffusion circle, from objects which would be represented by a defined image upon the retina of an emmetropic eye. A glance at Figs. 2 and 3 will show that, in the case of myopia, the diffusion circle is formed by rays which have united within the eye and have overcrossed; while in the case of hypermetropia it is formed by rays which have not yet come together; but both these conditions are alike in impairing the distinctness of vision. Now, it is one of the properties of convex lenses that they render convergent the rays of light which pass through them; and it is one of the properties of concave lenses that they render rays of light divergent. It follows, therefore, that if we place a convex lens before a hypermetropic eye, the convergence caused by the lens will enable the eye to bring the rays of light to an earlier focus than by its unaided refraction; and if we put a concave lens before a myopic eye, the concave lens will bring the rays of light to a more distant focus, as shown by the dotted lines in Figs. 8 and 9. In every case of ametropia, therefore, there is a lens which will postpone or promote the union of the rays in the precise degree which is necessary in order to cause them to form their focus upon the retina, instead of either in front of it or behind it; and this lens not only

corrects the ametropia, and restores vision, if not otherwise impaired, to its natural standard, but it also measures the ametropia, which is most conveniently expressed in terms of the lens which will neutralise or rectify it. Hence it is

Fig. 8.

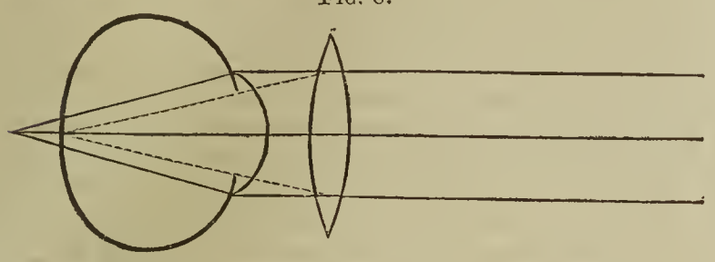


Fig. 9.

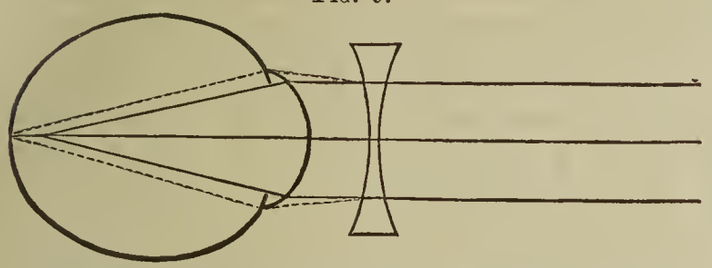

necessary, for the sake of definiteness and clearness of expression, to possess lenses of known and constant value; and this value is expressed by the distance from the optical centre of the lens to the point F, Fig. 10, at which, if convex, it will unite parallel rays in a focus, or, if concave, by the distance of the point F, Fig. 11, from which parallel rays appear to

Fig. 10.

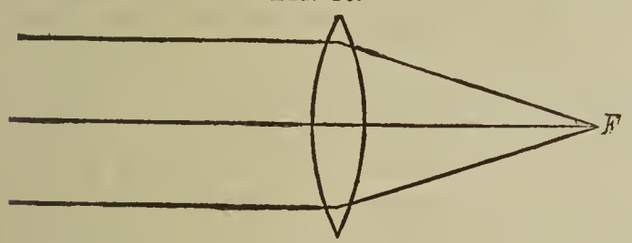

Fig. 11.

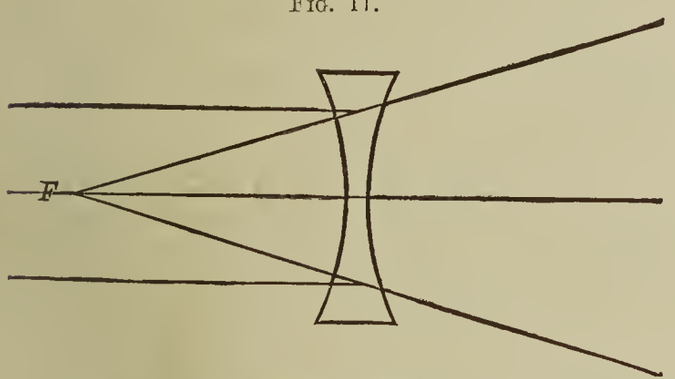

diverge after they have passed through it. This point is called the principal focus of the lens; and its distance is called the principal focal length, or, for the sake of brevity, the focal length only. The more powerful the lens, the greater its action upon the rays of light, the shorter will be its focal length.

(*To be continued.*)

The University of Upsal.—The Swedish University at Upsal is about to celebrate the 400th year of its foundation. One of the richest in Europe, it was first opened September 21, 1477. It consists of the four Faculties of Law, Medicine, Theology, and Philosophy, and has now about 1500 students. It is placed in an old park, and has its library and several remarkable museums.—*Union Méd.*, June 28.

Death from Chloroform.—M. Bachelet, a young student of medicine, a son of the Professor of History at Rouen, having suffered from an intolerable toothache, endeavoured to allay the pain by taking chloroform; but having swallowed too large a quantity, he almost immediately fell down as an inert mass. Notwithstanding every effort, he shortly after died.—*Ibid.*

ORIGINAL COMMUNICATIONS.

A CRITICAL REVIEW OF THE

PREVAILING THEORIES CONCERNING THE PHYSIOLOGY AND THE PATHOLOGY OF THE BRAIN:

LOCALISATION OF FUNCTIONS, AND MODE OF PRODUCTION OF SYMPTOMS.

By EUGÈNE DUPUY, M.D. Paris, of New York;
Corresponding Member of the Paris Société de Biologie; Member of the American Neurological Association, etc.

Part I.

Our knowledge of the functions of the brain, although extensive, is so inaccurate, the attempts made by different authors to elucidate some of the most important problems of cerebral physiology are so one-sided, and the writers for the most part appear to have been so much influenced one by another, on account of the numerous difficulties lying in the way of controlling by experiment the experimental data, added to the natural disinclination of most men to undertake the tedious labour of critical investigations, that both physicians and physiologists have come to accept most eagerly any work written by any author who ignores all doubt as to the absolute truth of his theories, as an inexhaustible mine of arguments and facts for the support of their own speculations, and in this manner they elevate such an author to the position of a universally accepted authority.

Such has already been the fortune of Dr. Ferrier, and it is for that reason that I undertake to write the present review of the whole question of localisation of functions in the brain.

We have in Dr. Ferrier's book(a) all the experimental data discovered both by Fritzsch and Hitzig,(b) and later by Dr. Ferrier. These data have led those physiologists to bring forward this doctrine, which is, however, nowhere expressed in their respective books: that the cortex cerebri is a region which can be excited into activity by electrical stimuli; that each and every convolution of the brain contains one and more *centres*, the anterior and antero-parietal convolutions contain centres which govern motion, and the posterior and postero-parietal convolutions contain centres for common and special sensations. The existence of all these centres can be made apparent by irritating the areas of the cortex with electricity. Dr. Ferrier has even gone further than Hitzig, for besides the sensory centres he describes also centres of inhibition, of visceral sensation, of the senses of thirst, hunger, etc. All those experimental facts, however, were known to the profession before their appearance in book form. Those of Dr. Ferrier have attracted so much attention from the very beginning, that we have since read every day of pathological cases and other facts which are said to find their true interpretation in the theories of that physiologist, at the same time that they are constantly being published with the view of strengthening the deductions arrived at by him.

Dr. Ferrier has made the doctrine of localisation of functions in the brain almost his own. He has so elaborately varied the former experiments of Fritzsch and Hitzig—the experimental starting-point of localisation of functions in the brain,—and so laboriously contrived to support by his discoveries the very original deductions of Dr. Hughlings-Jackson,—all with such partial success,—that I very sincerely believe his book to be a new departure in experimental cerebral physiology. It is therefore not without hesitation that I presume to offer some points of criticism on the deductions contained in Dr. Ferrier's work. I think that the facts which I am enabled to bring forward belong to the *other* side,—Dr. Ferrier having, notwithstanding his high merits, fallen into the common error of being *one*-sided. I desire only to present some facts which cannot be interpreted by the theories of Drs. Ferrier and Hitzig—some deductions which, if they are logically deducted from true premises, as I believe, cannot be explained by the theories of Hughlings-Jackson.

I shall take successively, and in the same order, as far as I can, as they are put forth by him, the points on which I differ from Dr. Ferrier. I have in the beginning to take issue with him on his exposition of the anatomy of the medulla oblongata. This point is not without great importance. The decussation of

(a) David Ferrier, "Functions of the Brain," 1876.
(b) Hitzig, "Untersuchungen ü. das Gehirn," 1874.

the conductors of motor impulses, in the anterior pyramids, goes strongly to support the principal deductions of Dr. Ferrier. But it so happens that in man, as in the other animals, the conductors of the orders of the will to the muscles do not decussate entirely in the anterior pyramids. Few of these conductors decussate there, and superficially too. Before the demonstration of that fact by Sappey and Duval,(c) the experiments of Schiff, Vulpian, and Philippeaux,(d) and a few cases of lesion of one pyramid without loss of motion in man, constituted strong evidence of the fallacy of the accepted teaching. The cases, therefore, which I shall adduce further—of lesions of different parts of one hemisphere causing paralysis of motion on the corresponding side of the body instead of the opposite—will not be disposed of (to suit his theory) by Dr. Ferrier, on the ground that they are exceptional, "just as there are exceptions to the rule that the heart is situated to the left and the liver to the right." And, even were it so, I have collected some cases which I shall also adduce further, and which militate against such an assumption.

The next subject refers to reflex actions. I take notice of the fact, accepted by Dr. Ferrier, that the reflex action which would otherwise result from a stimulus is altogether restrained or inhibited if a sensory nerve in some other part of the body is simultaneously irritated. Also that he attempts to weaken Pflüger's doctrine of psychical or intelligent action on the part of the spinal cord. His arguments are those of Goltz and others. Pflüger's doctrine is the same which was most forcibly advocated, chiefly by Dugès, of Montpellier, and latterly illustrated by some clever experiments of Vulpian. The weight of arguments and facts given by some authors goes to show that in man, if not as clearly substantiated as in other animals, the doctrine is virtually true. The deductions arrived at by Durand de Gros,(e) and latterly by Claude Bernard,(f) are proof of what I advance. The counter-experiments of Goltz are susceptible of another explanation than that given them by him. He did not eliminate this great source of error, which is disposed of by careful differentiation of phenomena due to irritation from those due to loss of function. The inhibitory action of the spinal cord upon itself is not considered; no more is the different influence of each and every part of the cerebrum upon the medulla oblongata, and also the result of ablation of that last organ, considered as a respiratory and circulatory centre, which has strong bearing on the point at issue. For the manifestations of their functions, parts are entirely dependent upon the properties of their tissues, and the properties of the tissues are a mere result of their nutrition. It is out of place to argue at any length on that subject just now; but not so, however, to remember the acceptance by Dr. Ferrier of the theory of "physiological association in the spinal cord between the centres of movements of the same kind in both limbs, due either to their commissural connexions or the organisation of past experience." There are certain experiments of Weir Mitchell,(g) which he quotes for another purpose, but which I think can receive explanation by that theory. Weir Mitchell has seen that on suddenly faradising the brachial plexus in a case of amputation of the shoulder-joint, in which all consciousness of the limb had long since vanished, the patient said at once, "My hand is there again; it is all bent up; it hurts me." Ferrier says that the explanation of these curious phenomena is correctly given by Weir Mitchell, who writes that the excitation of the sensory nerves calls up in idea the correlated movement—*i.e.*, the movement which in the actuality of past experience had coincided with the sensation now revived by the faradic stimulus. I believe that this important fact, together with the theory offered in explanation, comes within the theory of Dugès, of Pflüger, and others. I may be mistaken. I only put in apposition Dugès and Pflüger's experiments with that of Weir Mitchell. It is a landmark of which the utility will be seen when I come to examine Dr. Ferrier's views on the nature of conscious sensation. It seems to me even now, however, that if he considers that experiment of Weir Mitchell together with the explanation offered, he accepts implicitly the doctrine of psychical or intelligent action on the part of the spinal cord. In science we have to take the consequences of our logical deductions; and it is not contrary to sound logic to say that the phenomena of memory and "*partant*" of volition can be explained by the theory of the "*organisation of past experience.*" When an impression is transmitted towards the centre it reaches a group of nerve-cells. These cells only become affected by the impression through a nutritive process. Now, if an impression is frequently sent through one channel, to one centre, it happens that that centre becomes more and more apt to be affected by that impression. We know, on the other hand, that nerve-cells are not permanent structures any more than other structures,—they are potentially permanent. The process of nutrition, *i.e.*, assimilation and disassimilation, make all structures imperceptibly but constantly undergo a process of destruction and reconstruction, so that after the lapse of some period we happen to have a cell materially different from the first one (the materials of which it is made, however, being composed of the same elements), yet endowed with the same function, but better adapted. It is unnecessary for me to dilate on that subject. Let me give an illustration. The respiratory function is carried on through a reflex process. Our voluntary control over the respiratory movements is of a limited extent. If the inspiration is delayed beyond a certain period, the *besoin de respirer* becomes so urgent that voluntary control is no longer capable of restraining the reflex or automatic activity of the respiratory centres. Dr. Ferrier very nicely puts it—"Respiratory movements may continue after all afferent nerves connected with the centre have been divided. In this case there is a true automatic activity conditioned by the state of the blood itself. The diminution of oxygen and accumulation of oxidation products in the blood act as a stimulus to the inspiratory centre, and this again reflexly excites the expiratory movements. When the blood is artificially hyperoxygenated, the movements of respiration come to a complete standstill—a condition termed apnœa. Non-aëration of the blood, resulting from obstruction of the function of respiration, powerfully excites the movements both of inspiration and expiration; and ultimately, if the obstruction is not overcome, causes general convulsions of the whole body, as in asphyxia." Brown-Séquard has the merit of having been the first to establish that theory on experimental data more than twenty years ago. It is clear that the *besoin de respirer*, which is supposed to overcome the force used by the will in order to stop inspiration, is not a force. The will is not overcome by another force. The will, considered physiologically, must have its seat in anatomical structures; and anatomical structures cannot fulfil their functions when their nutrition becomes impaired. Therefore, the force of the will disappears as soon as the conditions of existence of the will are altered, and the automatic activity which governs the respiratory function comes into play. That *automatic activity is organised past experience.* But I do not intend to enlarge on that subject. I am only dealing with it in the physiological point of view; not the metaphysical.

After considering the nature of reflex action, I come to speak of equilibrium. As I differ from Dr. Ferrier on the preceding subject, I am driven to differ from him again when he states that, "without the labyrinthine impressions, optic and tactile impressions are of themselves unable to excite the harmonious activity of the sense of equilibrium." The sense of touch and the sense of sight are made subservient to a sense of equilibrium. Goltz has the credit for the discovery of that new sense. But, is there a *sense* of equilibrium? and is there a centre of equilibrium in the encephalon? It would have been good first to establish in the most irrefutable manner the existence of that sense; but this I consider that the experiments of Goltz and his followers fail to do. They can be interpreted in another and more rational manner: they must, in fact, be interpreted in that other manner. To say nothing of the experiments of Brown-Séquard(h) and the deductions which he has drawn from them, I will only say that Cyon(i) has *proved* beyond dispute that the labyrinth is not a centre of equilibrium. He has at the same time, therefore, given the true explanation of Goltz's experiments. Cyon shows that those disorders of the motor apparatus induced by operations on the semicircular canals do not occur in a uniform manner in different species of animals. In frogs these disorders are almost exclusively limited to the muscles of the trunk; in pigeons, the muscles of the head are those principally involved; in rabbits, those of the eyeballs. Each semicircular canal influences in a special manner the movements of the eyeballs. The excitation of one canal always produces ocular

movements in the two eyes; but in the eyeball on the opposite side to the canal operated upon the movements take place in a contrary way to those on the same side. The pupil contracts on the side of the operation, and remains dilated on the opposite side. The oscillatory movements which follow tetanic contractions of the muscles of the eyeballs after irritation of the canals disappear when the acoustic nerve on the sound side is divided. When a rabbit, having had section of both acoustic nerves performed, is put on a rotating plane describing rotatory movements, the same phenomena are observed which have been described by Purkinje, and which lately have been made the object of interesting researches by Mach. This proves that those phenomena do not arise from the displacement of the endo-lymph of the semicircular canals, as that physicist laboured to show. The phenomena of Purkinje are due to cerebral disorders produced by grave alteration of the circulation which the animals undergo, in the experiment referred to, chiefly in the intracranial vessels farthest from the axis of rotation.(k)

SANTONIN.

By E. MARLETT BODDY, F.R.C.S., etc.

THERE is no doubt that santonin is, for many reasons, by far the most efficient anthelmintic which can possibly be administered to children, and its combination with calomel I have found to be most advantageous in every respect. Santonin, like every other therapeutic agent, requires care in its administration; and if it is allowed to remain in the system it acts deleteriously, like certain cumulative medicines. This pernicious after-action one of course seeks as much as possible to obviate, and the only way to do so as regards santonin is to combine it with some purgative, such as calomel, which carries it off.

According to Falck of Marburg, if santonin is allowed to remain in the system we get a substance called xanthopsin, into which santonin is supposed to be transformed under certain circumstances which at present are not well ascertained. This xanthopsin is excreted by the urine, giving it a remarkable yellow colour, causing a similitude to that secretion passed in jaundice, and its presence there is easily detected by caustic alkalies, which redden the urine. No doubt it is this xanthopsin which gives rise to those dangerous symptoms that have been so largely dilated on of late, and which many attribute to santonin only, forgetting or ignoring the presence of xanthopsin; and this mischievous action I have found from experience to be entirely counteracted, or rather prevented, by administering calomel at the same time.

I generally administer santonin combined, as I have just said, with calomel, or I give it preceded and then followed by that drug; but one plan is as good as the other. The results of so giving this anthelmintic in either of these two modes have been most happy, and I have very seldom found it necessary to repeat the dose, for such treatment is thorough, and consequently precludes the necessity of repetition.

I myself have never had a case where convulsions or retention of urine have originated from santonin; in fact, I have never seen any untoward symptom resulting from it in any way whatever, which I attribute to my combining it with calomel, or preceding and following it up by that purgative.

My experience has convinced me that nothing of a deleterious tendency can possibly accrue from santonin if it is combined with calomel, for by so doing we do not allow sufficient time to elapse for the xanthopsin to act on the system, for when the santonin has done its work the calomel removes it. The latter drug is a more searching purgative than castor oil; being likewise a cholagogue, it causes a greater secretion of bile, which, as my readers know, is the natural purgative. Giving the santonin in one of these two methods aforementioned will entirely prevent all dangerous symptoms arising; there will be no convulsions and no retention of urine, nor will that secretion appear like that found in jaundice, for this one simple reason: the santonin, when it has done its work, is eliminated from the system by the calomel, and consequently the poisonous xanthopsin has not sufficient time to form. Perhaps this substance is the cause of patients seeing objects either yellow or green in colour.

Camberwell-road.

(k) The hypotheses of Goltz, Mach, and Crum-Brown would have much more value than they have if they did not consist, as they do, in a begging of the question; for it is assumed that the liquor of Cotugno does not entirely fill the ampullæ. That *point is not granted*. Therefore, it is not possible to consider their hypotheses any longer; because, if the liquid fills the ampullæ entirely, there can be no notion of direction conveyed.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

ST. MARY'S HOSPITAL.

GLANDERS.

(Under the care of Mr. HAYNES WALTON.)

[Reported by Mr. G. B. COUMBE, House-Surgeon.]

J. E., aged forty-eight, a buyer and seller of horses, of a low class, of very dissolute habits, and a drunkard. Six days before applying to the hospital, and while he was feeling very feeble, bullæ appeared on his face, trunk, and limbs. His symptoms on admission were—bullæ of a size varying in diameter from a quarter to two inches and a half, filled with clear scrum; chemosis of both conjunctivæ; purulent discharge from both nostrils; cough, with thick, stringy expectoration; general prostration.

Mr. Haynes Walton saw the patient at once, and pronounced the case to be one of acute glanders. He said it was the fourth that had come under his care. He ordered iodide of iron, full diet with brandy, and chlorine lotion to be freely used to the mouth and nostrils, and frequent fomentation to the eyes. The bullæ enlarged, the fluid within them became turbid, and they burst at different periods and exposed superficial cutaneous ulceration, from which exuded foul secretion. There were profuse putrid sweats. The purulent ophthalmia increased; the nasal discharge became excessive, bloody, and very offensive. The cough was more severe, and the expectoration was now very fetid, and highly coloured with blood. Fresh but smaller bullæ formed, and followed the course of the larger ones. Prostration was excessive—pulse 136, temperature 103°,—yet the appetite was never lost. Auscultation of the chest gave the physical signs of bronchitis, with consolidation of the lower part of the left lung. The patient was sent to an isolation ward. He required increasing attention, in order to be kept clean. General improvement began with lowering of the temperature and reduction in the pulse, and one by one the symptoms declined. In three weeks from admission the patient returned to the general ward. In a fortnight after, he left the hospital well. The day-nurse who attended him in the isolation ward took the infection, but the symptoms did not go beyond fever and sloughing of tonsils.

In commenting on the case, Mr. Walton made the following clinical remarks:—The patient had, no doubt, been infected from the horse, although he could not remember any details connected with it. Glanders and farcy are identical in their origin, but have different symptoms—the latter showing its acutest local affections chiefly in the lymphatic system. In man, as in the horse, glanders may be acute or chronic. Here was the acute type. There were the bullæ, fever, marked debility, fetid discharge from the nares, with implication of the respiratory mucous membrane, but yet the attack was not of the most severe kind, for gangrene did not succeed to the bullæ; nor were there abscesses in the neighbourhood of the joints, nor ulceration in any of the diseased mucous tracts, nor nephritis, nor death, which is the rule. The treatment was adapted on the principle of supporting the depressed powers. There must necessarily be much depression when the skin and so much of the mucous tract are diverted from their natural functions and suffer such morbid changes. Many attempts have been made to discover a specific for human glanders, without, however, effect.

Note.—In this journal for October 5, 1872, there will be found an exhaustive account, by Dr. Sidney Coupland, of a fatal case of glanders in the human subject. To supplement Mr. Walton's *clinical* remarks, we will only briefly refer to the pathological observations made by Dr. Coupland in the above case. Scattered through the lungs, close under the pleura, were greyish nodules, which were found to consist of nuclear growth round the bloodvessels, and of catarrhal products in the alveoli. In the liver there were also some well-defined nodules, showing nuclear growth round the portal canals, and some increase in the interlobular tissue. In

the spinal cord there were changes very much allied to those which have been described at various times in cases of tetanus, hydrophobia, etc., and to which the provisional name of leucocytal infiltration has been applied. The central canal was blocked by cellular products, and the sheaths of many of the vessels in the grey matter were crowded with leucocytes.

Medical Times and Gazette.

SATURDAY, JULY 7, 1877.

THE ARMY MEDICAL DEPARTMENT.

On the evening of Monday, the 2nd inst., Dr. Lush and Colonel North called the attention of the House of Commons to the state of the Army Medical Department. Dr. Lush stated that certain regulations connected with that branch of the Service prevent the best men in the medical profession from entering it, and he pointed out the well-known disabilities under which the surgeons labour as to leave of absence, as to the right of exchanging, as to allowances for forage, and as to compensation for any grievances of which they deemed themselves entitled to complain—disabilities unknown to other officers of similar rank and pay in the Service. And he declared that the number of medical officers in the army at home, which was 631 in 1869, had been lowered to 531 in 1877. The Department is, he declared, in a most discontented state. Colonel North also spoke strongly of the discontent prevailing in the Department. In his day, the medical officers were the private friends of many of the officers, and the friends of every man in the regiment, and were always treated with respect and attention; while now there "are no medical officers who do not find fault with the treatment of the present Department of the War Office." The Secretary of War, Mr. Hardy, has, as our readers know, the courage of his opinions; and certainly he never showed this more strongly than in his reply to Dr. Lush and Colonel North. He had the courage to declare that every one of the grievances put forward by the medical officers in 1874 had been met; and that the agitation now existing may be traced to one or two individuals, there being, he believed, "a surgeon-major or surgeon in London who had spent his whole time in dissuading young men from joining the Service." The profession must feel flattered by his declaration that they are so easily led. He allowed, indeed, that there had not been so large a number of applications to enter the Service as could have been desired; but he affirmed that there are not so many vacancies as might be supposed. In 1877-78 the Department nominally consisted of 885 medical officers; and its actual effective strength was 842, so that there were only forty-three vacancies. But there are, he said, seventeen candidates at Netley almost ready to join, and then the vacancies would be only twenty-six. There will be an examination in August for these vacancies, and there had been eighty applications for the schedule of instructions, and "these persons *might* enter for competition when the time came." The italics are ours, of course, and we use them to emphasise the character of Mr. Hardy's argument. But to all this very qualified statement it must be replied that at the first *competitive* examination for commissions in her Majesty's Medical Service since the last Army Medical Warrant, only thirty-four candidates competed for fifty vacancies, and at the second and latest only twenty-three presented themselves to compete for the same number of appointments. As to the grievances or disabilities that had been mentioned, Mr. Hardy in reality simply admitted that they exist. The statement that the reason why medical officers obtained no more honours was that they had absorbed them already, that they had obtained a larger proportion of them than they were strictly entitled to, is no answer. The grievance is that the "proportion" allowed is not larger. Similarly, with respect to leave, the grievance is not removed by the statement, "arrangements cannot be made for granting medical officers leave in the same way as other officers without an enormous addition to our expenditure"; nor the forage grievance, by the observation that "the War Office does not wish to encourage a system of perquisites," unless an increase of pay is given instead of the old system of a forage allowance. Nor is it enough to know only that the Secretary for War "has done his best to obtain new quarters for medical officers," or that "he does not see how it is possible to meet the demand for exchanges under the unification system." It is satisfactory to hear, no doubt, that the Director-General of the Army Medical Department has assured Mr. Hardy that "we have never gone to war with a medical system organised upon so good a footing as that which now exists," and that "it could be put into the field and brought into operation at a moment's notice"; for we cannot hesitate to believe that he has received such an assurance, and we do not for a moment doubt that the medical officers would do their duty to the uttermost were we to go to war; nor that, did a breakdown occur, the War Office would be ready to throw the whole blame on the Director-General. But, seeing how impossible it has been to get the vacancies in the Service filled up, that the reluctance shown by young surgeons to enter it has been steadily increasing, and that the discontent prevailing in it seems to be almost as universal as it is great it is simply impossible to consider that the state of the Army Medical Department is anything nearly so satisfactory, as Mr. Hardy apparently thinks it is.

VACCINATION BEFORE PARLIAMENT.

The House of Commons has during the past week been a centre of attraction to all who wish well to good government; but to many, perhaps, the debate on vaccination, introduced on the motion of Earl Percy, may have been comparatively uninteresting. This should not be so. It was Lord Percy's desire that a Committee should be appointed to inquire into the working of the Vaccination Laws. His speech was most studiously moderate, and though not exactly accurate with

regard to certain details, such as assigning a position to our contemporary the *Lancet* which we are sure its modesty cannot accept, it was upon the whole a fair representation of popular opinion on the subject of vaccination. Here it might be well to recapitulate our views on the matter.

Our views on the subject of vaccination are these :—We hold staunchly to the principle of saturating the system with cow-pox as a preventive or modifier of the too well known small-pox. But inasmuch as this cow-pox, as transmitted by vaccination from one human being to another, is liable also to be made a vehicle of at least one other poison—that of syphilis—it is better to give those who desire it the option of vaccination direct from the heifer. In the vast majority of cases the risk of such secondary affection is *nil ;* but the risk does exist. And when people by any measure (be it what it may) are rendered liable to fine and imprisonment, they are also entitled to be protected from any abuse caused by the improper working of the measure. The practice of animal vaccination has not succeeded in this country—wholly, we believe, through the difficulty of keeping up the supply of virus. No objection has been raised against it, save that general one which cuts at the root of all laws for sanitary purposes, and all medicine, sanitary or sanatory,—that the will of God is to be done. We do not advocate in any special sense the application of the principle of animal vaccination as opposed to human vaccination, except for the comfort of certain honest, but it may be troublesome, people, who object to the latter. At all events, they should have the option, which now they have not.

Some of the speeches made in Parliament were most mischievous. Nothing could be worse than for men in a responsible position to openly advocate the policy of allowing a certain number of people who have got earnest convictions to publicly break the law, merely because they were probably few in number. The law must be enforced equally all round, but no law should be made which admits of the possibility of infecting innocent people with a pest which taints generation after generation. It is vain for Government officials to repeat time after time the old story,—they learn their lessons from the same permanent officers ; but if well-known facts are opposed to the opinions of these worthy gentlemen, their advice becomes worth something less than nothing at all.

It was to be regretted that two distinct questions were mixed up together in the discussion—the one was a matter of principle ; the other, we make bold to say, one of detail only. To insist on universal vaccination, and to provide the means for insuring the attention of people to it, are mightily different matters. At all events, it would be far safer to provide against any reasonable objections, than to enforce, by whatever means, a measure which has been shown to be founded on imperfect information. We trust, however, these facts will have due weight with a Government pledged to take some steps to remove a spreading dissatisfaction as regards a matter so important as vaccination.

THE VICTORIA DWELLINGS ASSOCIATION.

The opening of the first buildings of the Metropolitan Artisans' and Labourers' Dwellings Association is a fact of too much importance to be allowed to pass without a few words of notice and congratulation from us. The object of the Association is to work in the same direction as the Peabody Trustees, Sir Sydney Waterlow's Association, and some other bodies—that is, to provide healthy and comfortable houses for artisans, but more especially for the class termed labourers, and persons earning small wages ; and on the 23rd ult. the first buildings erected by the Association were formally opened. They are built on a site belonging to the Association immediately adjoining Battersea-park. They are built in flats, as nearly fire-proof as may be, and the blocks are so arranged and isolated by open-air spaces as to reduce to a minimum the danger of the spread of any epidemic disease that may occur in them. The drains are so arranged as to prevent any escape of foul air from the sewers into the dwellings. Each tenement has a constant supply of fresh water, the use of a washhouse, a coal-bunker, and dust-shoot, and regard has been taken to supply all the best known sanitary appliances. The artisans' dwellings are self-contained—that is, within the outer door, which opens on to a general staircase, are all the conveniences required by a family, except the washhouses, which are detached from the building. These tenements contain, in most cases, three good rooms—viz., kitchen, bedroom, and sitting-room, which can be used as a bedroom. The labourers' blocks are so divided that the rooms can be let singly, or in twos, threes, and fours. Tenants will thus be enabled to occupy additional rooms, as their families increase or their circumstances improve. And the rentals for these rooms will be less than those now too often paid for habitations really quite unfit for occupation. The ceremony of opening the buildings was attended by a brilliant and very influential gathering ; and Mr. Walter, M.P., the Chairman of the Executive Committee of the Association, in an able introductory address, pointed out to his audience that though London is the most healthy capital in the world, its average death-rate not exceeding 23 or 24 per 1000 a year, yet the difference in the mortality of different districts is so great, that in some it is no less than from 40 to 60 per 1000 ; that mortality being distinctly attributable "to the filth and foul air which produce disease." He dwelt on a fact which very few, we suspect, ever try to realise—viz., that the metropolis is increasing at the rate of 40,000 a year ; and showed that all that has been done within the last twenty years by the various societies, including the Peabody Association, for providing improved dwellings for the poor, has not yet housed as many as 40,000, one year's increment of population ; while almost every year some encroachments are being made, and made with general sanitary benefit, on the available space for the London poor, by the formation of new streets, the laying down of fresh railways, the erection of new stations, and by other metropolitan improvements. It is a mistake, Mr. Walter observed, to suppose that London is densely populated ; it is the houses, so-called, that are in fault. In the densest part—and it is one of the most unhealthy parts—of the metropolis, in Westminster, there are under 300 persons per acre ; and by the plan of construction adopted by the Peabody, Waterlow, and other Associations, 1600 per acre can be infinitely better accommodated than 300 under the old system. Some poetical and theoretical philanthropists and reformers insist on remedying existing evils by making the working classes live in the suburbs ; but, as Mr. Walter well said, "in spite of all the poetry attaching to suburban homes, and in spite of cheap railway fares, it is an undeniable fact that the great mass of the metropolitan poor, artisans and labourers, must live near their work" ; and therefore, "instead of spreading London out, you must rear it upwards, you must raise it to the clouds."

The voice of the Earl of Beaconsfield has rarely been heard in public since he left the House of Commons for the comparative repose and dignified ease of the House of Lords ; but the Association was fortunate enough to get him to open the buildings, and his speech on the occasion showed all his wonted vigour and felicity of expression. He impressed on his hearers that "the home is the unit of civilisation. From it spring all those influences which give a character to society either for good or for evil—either for a beneficent or a disturbing character. A man who feels that his home is 'Home, sweet home,' is proud of the community in which he dwells : but the man who feels that his home is a den of misery and crime, immediately assails that society of which he believes he is the unjust victim." "The health of a people," he said,

" is really the foundation upon which all their happiness and all their power as a State depend." He did not warn us against over-population, of the danger of which we have heard so much lately, but said, " It is quite possible for a kingdom to be inhabited by an able and active population; you may have successful manufactures, and you may have a productive agriculture; the arts may flourish, architecture may cover your land with temples and palaces; you may have even material power to defend and support all these acquisitions; you may have arms of precision, and fleets of fish torpedoes; but if the population of the country is stationary, or yearly diminishes—if, while it diminishes in numbers, it diminishes also in stature and in strength, that country is doomed." Therefore he recommended that every assistance should be given to assist the movement to ameliorate the condition of the people by improving the dwellings in which they live; and he again declared, " The health of the people is, in my opinion, the first duty of a statesman." We rejoice to hear such statements from the lips of the Prime Minister of England; and we will not now too curiously and ungraciously inquire how Lord Beaconsfield and his Ministry have fulfilled this " first duty." We may not quite ignore the shortcomings of the Local Government Board, and the suppression of the post of Medical Officer to the Privy Council: we may lament the fact that houses are still being built everywhere in the kingdom, without any efficient supervision as to the simplest sanitary requirements, and that still so very much remains to be done for the health of the people; but we acknowledge gratefully the passing of the Artisans' Dwellings Act, the Food and Drugs Act, and the Public Health Act, 1875, and we will hope that Lord Beaconsfield will have the courage to introduce yet more sanitary measures, and to provide a more effective administration of them.

We will only further remark that, like the other associations of similar character, the Association, the first buildings of which were opened the other day, is partly philanthropic and partly commercial in character. It is, as Mr. Walter stated, philanthropic in so far that it intends exclusively to provide buildings for a certain class of the population, " and that the humble class, which have not the means of providing good homes for themselves "; and commercial in so far that it is intended that the undertaking shall yield a fair and proper return to the shareholders. It is hoped that the return will not be less, and it is not desired that it shall be more, than 5 per cent., while an ordinary building investment may be calculated to yield from 6 to 7 per cent. The difference goes to the advantage of those for whom the buildings are erected. Her Majesty the Queen, who takes a deep interest in the movement, commanded Lord Beaconsfield to express her wish that her name should be associated with the institution, and the buildings are in future to be called the " Victoria Dwellings for Artisans and Labourers."

THE WEEK.

TOPICS OF THE DAY.

In reference to the scheme for the drainage of the Lower Thames Valley, it is stated that the Duke of Richmond and Gordon will move to make certain additions to the Bill to be introduced on this subject, to the effect that all contributions which the Sanitary Authority of Surbiton shall be required to make towards the common fund shall be payable out of the improvement rates leviable in that district. Also that the Lower Thames Valley Drainage Board shall have the power of communicating with the sewers of any other main sewerage board in their district on certain terms to be agreed on; any dispute to be settled by the Local Government Board, subject to the proviso contained in the Public Health Act of 1875. Further, in the event of the sewers belonging to the Twickenham Sanitary Authority becoming wholly or in part useless in consequence of the works to be executed, such compensation may be awarded to them as may be deemed just; and the Local Government Board is to direct the mode in which, and the parties by whom, such compensation shall be paid.

Mr. Chance, the magistrate for Lambeth, took occasion last week to mention that he had paid a visit to the St. James's Home for Inebriates at Kennington, and he wished to state publicly the satisfaction he had experienced in inspecting the place. He found many of the offenders who had been brought before him installed there as inmates, and conducting themselves in a creditable manner. There was one woman in the Home who had been more than one hundred times charged at the Lambeth Police-court with drunkenness, and other persons were housed and fed who had been a number of times charged at his court. He considered the institution was performing a great public good, and deserved the support of the benevolent.

The forty-third anniversary meeting of the Statistical Society was held last week at the Society's rooms, the retiring President, Mr. James Heywood, in the chair. The report presented was highly satisfactory, and stated, amongst other items, that the Howard Medal of 1876, with £20 added, had been awarded to Dr. J. C. Steele, Medical Superintendent of Guy's Hospital, for his essay " On the Mortality of Hospitals, General and Special, in the United Kingdom in Times Past and Present." The Howard Medal for the present year will be awarded in November next, the subject being " On the Condition and Management, Past and Present, of the Workhouses and similar Pauper Institutions in England and Wales, and their Effect on the Health, Intelligence, and Morals of the Inmates." The subject of the essay for the Howard Medal of 1878 will be " The Effects of Health and Disease on Military and Naval Operations." It has been decided by the Council to grant a sum of £20 in each case to the writer who gains the medal. The new President is Mr. G. Shaw-Lefevre, M.P.

A very sad boat accident is reported from Portadown, county Armagh. Last week, Dr. Biggar, with his assistant Dr. Stevenson, and a servant-man named Collins, went out in a boat on the river Bann. The boat capsized, and the occupants were thrown into the water. Dr. Stevenson succeeded in swimming near the bank, and was rescued; Dr. Biggar and Collins were drowned. The bodies were recovered, and an inquest was held, but Dr. Stevenson could give no particulars of the accident. A verdict of " Death by drowning " was returned.

Acting on the sound common-sense principle which has begun to be developed in the metropolitan parochial authorities, another open space was last week given to the people. The old burial-grounds of the districts of St. Pancras and St. Giles, covering between eight and nine acres, and situated close to the Midland station, have been converted into a pretty garden, at an expense of £5000. Sir James Hogg, the Chairman of the Metropolitan Board of Works, performed the opening ceremony, and the Baroness Burdett-Coutts laid the foundation-stone of a memorial sun-dial. We hope that before long all the old intramural burial-grounds may be converted from their present state of uselessness into breathing-spaces for the overcrowded population of London.

The Society for Improving the Condition of the Labouring Classes may be congratulated upon having presented a most satisfactory report at their recent annual meeting, which was held at Willis's Rooms, the Earl of Shaftesbury presiding. As a proof that the work of the Society is much appreciated by a large section of the working population, whose sanitary and moral condition it strives to advance, it was stated that its lodging-houses are filled to repletion, whilst its assets amount to more than £12,000. It was observed in the course of the

proceedings that a distinctive feature of the Society's operations is the success with which it has renovated existing houses, thereby rendering unnecessary the purchase of expensive sites for new dwellings, or the removal of the poor to places distant from their employment. Another point deserving of attention is the comparatively low rate of mortality in the Society's dwellings, in none of which was there a single case of small-pox during the past year.

The case against Hezekiah Thornton, medical botanist, for illegally assuming the title of "doctor," was again before the Bradford magistrates last week. The defendant had been previously convicted; he had appealed to the Court of Queen's Bench, and the case had been sent back to be re-heard. The magistrates imposed a fine of £10 and 22s. costs, from which decision the defendant will again appeal.

The outbreak of small-pox at Orsett, Essex, still continues, several fresh cases having occurred, making about forty in all, but, fortunately, several have been of a mild type. One of the nurses at the union hospital has been attacked. Most of the patients, it is ascertained, had not been vaccinated.

A report has just been issued by the Educational Officer of the Society of Arts, which, amongst other matters, gives the result of the recently held examination in domestic economy. The subject was introduced for examination for the first time last year. The examiners appointed for this year were—for "Housekeeping and Thrift," Miss E. Shaw-Lefevre; for "Clothing and its Materials," Miss Mary Willis; for "Health," Dr. Ogle; and for "Cookery," the National Training School. Though the number of candidates was small, it was larger than last year. In "Cookery," all the candidates passed; in "Health," twenty-six failed; and only three passed in the first class. The questions set were of a most practical character, having reference in most cases to knowledge required for every-day use, or (as in "Health") such as may be at any moment needed. A hope is expressed that next year this examination will be more widely known, and that, consequently, there will be a larger number of candidates.

On Monday last a large number of ladies and gentlemen visited the new wing of the Hospital for Sick Children, in Great Ormond-street, on the invitation of the Chairman and the Committee of the Hospital. The new wing contains wards for sixteen children, a bath-room on each floor, a ward kitchen and linen-store on each floor, nurses' rooms, lifts, etc. There are two ventilating towers, and beneath the red tiles of the conical top of another tower a water-cistern is concealed. The wing is a separate building, parted off entirely from the rest of the Hospital, and is to be used for infectious cases. The walls are in Parian cement, coloured with distemper in light sage-green and brown. The top of the building is asphalted for a garden, and half an acre of ground behind is being converted into a playground. The total capacity of the Hospital will now be 104 beds, but the Committee have purchased some old houses in Great Ormond-street, and, as soon as sufficient funds are collected, these are to be cleared away to afford more accommodation. The foundation-stone of the new wing was laid, it will be remembered, five years ago by the Princess of Wales, and the total cost has been £2500.

The fatal cases of small-pox in London, which have steadily, though slowly, declined in the seven preceding weeks from 78 to 44, were in the week ending June 30 again 44 in number. The deaths included 8 of children under five years of age; and 21 of the 44 occurred in private houses. There were only 10 other deaths from small-pox in the twenty towns now included in the Registrar-General's weekly returns—viz., 5 in Liverpool, 3 in Oldham, 1 in Leeds, and 1 in Salford.

At the annual meeting of the Birmingham Medical Benevolent Society, Mr. Alfred Freer, of Stourbridge, was appointed President; Mr. Watkin Williams, President-elect; Mr. Berry and Dr. Wade, Treasurers; Mr. Kimbell-Knowle and Mr. C. J. Bracey, Vice-Presidents; and Mr. T. H. Bartleet, Hon. Secretary for the ensuing year.

THE RECENT HOSPITAL SUNDAY COLLECTION.

Up to the beginning of the present week the sum officially reported to have been received at the Mansion House for the Hospital Sunday Fund amounted to the sum of £23,000. This result would convey the idea that greater promptitude had this year been exhibited in paying over the various sums received; but it is still very problematical whether the total amount subscribed will exceed £30,000. The experience of past years has shown that the great bulk of the contributions is received at the Mansion House within three weeks of the day of collection; after that time the Fund is kept open by the dilatory proceedings of some of the collectors, though why all the money received could not be at once accounted for it is difficult to understand. A moderate promptitude in handing over the various collections would facilitate the duties of the Committee, and enable the distribution to be made before the autumnal recess, when so many of the members have left town. This in itself would be a boon to the recipients, and should be an argument for prompt action on the part of those ministers who kindly undertake to assist the movement. There is not much in the way of novelty to instance in the record of this year's collections. The sums received at most of the well-known places of worship were about up to the average of past years, the largest amount (£425 17s. 5d.) having been received from St. Peter's, Eaton-square, through the Rev. G. H. Wilkinson. We must, however, repeat the observations that we have more than once made in reference to London Hospital Sunday. This year it was announced that about 400 congregations more than last year would be asked to contribute to the Fund; and yet the total amount subscribed does not up to the present time appear to have proportionately benefited. When the enormous size and immense wealth of the metropolis are taken into consideration, the amount annually realised by this Fund does not compare favourably with the sums received in provincial towns on similar occasions, and after five years' experience it still remains an open question whether the principal and recognised London hospitals have benefited by the introduction of the movement. There is but one opinion as to the impartial and laborious manner in which the Committee of Distribution perform their duties; but it is also certain that many charities prefer their claims (to the detriment of the leading institutions) which would not be responded to by the public on personal solicitation. If it could be satisfactorily proved that the introduction of a Hospital Sunday collection in London had resulted in a clear gain of £30,000 to these institutions, we should be among the foremost to advocate its continuance but we greatly fear that the movement has resulted in the gain of some of the less deserving institutions of the metropolis at the expense of some of the largest and most deserving.

CHARING-CROSS HOSPITAL SCHOOL.

The distribution of prizes for the session 1876-77 took place at Charing-cross Hospital on Wednesday afternoon, the 27th inst., the Right Hon. the Earl of Wharncliffe in the chair. After the chairman had briefly opened the proceedings, Mr. Hird (the Dean) read the report of the Medical School Committee, which referred to the recent enlargement of the Hospital and the opening of the new wards by their Royal Highnesses the Prince and Princess of Wales, and the increase in the number of beds, which now amounts to 236. He also spoke of the increase in the number of students during the academical year, the entries being thirty-five for the full and

twenty-four occasional, making a total of fifty-nine new students; and of the extensive alterations recently made in the school premises for their comfort and accommodation. He also referred to a special class that had been instituted for the Primary Fellowship examination under the direction of Dr. Cantlie and Mr. Godlee, and to the many valuable books that had lately been purchased, and to those presented to the library by the staff. The chairman then proceeded to distribute the prizes as follows:—Scholarships: Llewellyn (£25), John Brown; Golding, (£15), H. G. Jacob. Governors' gold clinical medal, John Brown. Pereira Prize (£5) and bronze medal, John Brown. Silver Medals: Medicine, John Brown and A. W. D. Leahy; Physiology, H. G. Jacob; Anatomy, H. G. Jacob; Surgery, R. C. Rowbotham; Chemistry, H. F. Corbould; Botany, Charles Curde; Materia Medica, H. G. Jacob; Midwifery, John Brown; Forensic Medicine, John Brown; Practical Chemistry, S. Nockolds. Bronze Medals: Medicine, T. M. Hughes; Physiology, C. R. Crane; Anatomy, James Turton; Surgery, T. M. Hughes. Certificates of Merit: Senior Physiology, W. H. Day and R. W. Oswald; Junior Physiology, James Turton and J. S. E. Cotman; Senior Anatomy, R. W. Oswald and Charles Curde; Junior Anatomy, J. S. E. Cotman and Martin Henry; Senior Surgery, A. W. D. Leahy and John Brown; Junior Surgery, H. G. Jacob and Charles Curde; Chemistry, C. R. Crane and J. C. Culling; Botany, F. J. Grindon; Materia Medica, T. M. Hughes and F. W. Brookes; Midwifery, Henry Hoole; Practical Chemistry, Charles Curde and W. H. Day; Pathology, John Brown. The chairman, after congratulating the recipients, addressed the students at some length in a very earnest and impressive manner. A vote of thanks to the Earl for his kindness in presiding at the meeting, accompanied by hearty cheering, terminated the proceedings.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

The annual election of Fellows into the Council of the College took place, as usual, in the Library of the institution, on Thursday, the 5th inst. Punctual to the hour advertised (two o'clock), Mr. Prescott Hewett, the President, took the chair, accompanied by the Vice-Presidents, Messrs. Birkett and Simon, and some members of the Council. Having shortly explained the object of the meeting, he called on Mr. Trimmer, the Secretary, to read the circular convening the meeting, and also those portions of the by-laws relating to elections into the Council. This having been done, the President invited the Fellows to proceed at once to the election of three Fellows in the vacancies occasioned by the decease of Sir William Fergusson, Bart., and by the retirement in the prescribed order of Messrs. John Gay and J. E. Erichsen, who offered themselves for re-election, the new candidates being Messrs. William Adams, William S. Savory, and Timothy Holmes. The polling then commenced, and was not brought to a close until 5.30, when the President stated that, as usual, Mr. Stone would take the result as read off from the papers by the Secretary, and that blank forms would be handed to any gentlemen desirous of checking the votes. This having been done, the President announced that the choice of the Fellows had fallen on Messrs. Erichsen, Savory, and Holmes. The numbers polled by each candidate were as follows—viz., for Mr. Erichsen, 189 (including 31 plumpers); Mr. Savory, 149 (including 10 plumpers); Mr. Holmes, 123 (including 11 plumpers); Mr. Gay, 112 (including 7 plumpers); Mr. Adams, 94 (including 6 plumpers).

As showing the great interest taken in the election, it is deserving of mention that many Fellows attended from distant provincial towns, as Messrs. Archer, Birmingham; Ashby, Grantham; Baker, Birmingham; Balding, Royston; Bartleet, Birmingham; Blackmore, Manchester; Bowen, Birkenhead; Campbell, Stourbridge; Cattlin, Brighton; Childs, Bungay; Colgate, Eastbourne; Cooper, Slough; Dobson, Bristol; Foster, Bradford; Franklin, Leicester; Green, Bristol; Harris, Redruth; Holman, Hurstpierpoint; Horsfall, Leeds; Hough, Cambridge; Humphry, Cambridge; Hussey, Oxford; Ingle, Manchester; Jordan, Birmingham; King, Hull; Lancaster, Bristol; Lee, Salisbury; Longmore, Southampton; Lund, Manchester; Monckton, Rugeley; Nicholls, Chelmsford; Parker, Liverpool; Postgate, Birmingham; Prall, West Malling; Rayne, Newcastle-upon-Tyne; Smith, Stevenage; Smith, Warrington; Steele, Bristol; Symonds, Oxford; Symonds, Lincoln; Tait, Birmingham; Taylor, Guildford; Thomas, Birmingham; Thomson, Oldham; Thomson, Ross; Ward, R.N.; Webber, Modbury; West, Birmingham; Wheelhouse, Leeds; Wiblin, Southampton; Wood, Shrewsbury; Bennett, Sydney, New South Wales; and O'Shaughnessy, Calcutta. In the evening the Fellows dined together at the Albion Tavern, under the presidency of Mr. E. Law Hussey, of Oxford.

THE TITLE OF "M.D."

In the Court of Second Exchequer, Ireland, a case important in its results to medical practitioners was tried, on June 18 and 19, before Mr. Baron Deasy and a city common jury. The action was brought by Mr. Baxter, a medical practitioner in Dublin, to recover £62 1s., alleged to be due by the defendant, as executor and sole legatee of his late sister, Miss Anne Maria Kirwan, for attendance and medicine. The defendant pleaded payment into court of £20; that any sum justly due had been paid before the action was brought; and that the plaintiff, as an apothecary, was only entitled to a fee of 5s. a visit, and not 10s. as he had charged. In the course of cross-examination, the counsel for the defendant elicited the fact that the plaintiff, although only a Licentiate of the Apothecaries' Hall, Dublin, used to place the letters "M.D." after his name on his bills. At the conclusion of the arguments, Baron Deasy, in charging the jury, said this claim of the plaintiff was not put forward until the only person who could dispute it had passed away—a claim unsupported by anything save the statement of Mr. Baxter, and contradicted by documents under his own hand, proving what his own fees were. The conduct he had pursued for years in affixing the letters "M.D." to his name, when he had no more right to do so than any other person in the community, was deserving of the strongest disapprobation. It was not only a legal offence, but an offence against morality and integrity, and he was sorry to see a man in Mr. Baxter's position insensible to that fact, and holding himself forth to his customers as a doctor of medicine, when he was no more a doctor of medicine than the patients themselves. He pointed out that it had been proved that when the plaintiff had furnished the bills to Miss Kirwan he had claimed only 5s. a visit. It would be entirely for the jury to say whether they would allow him to double his rate of fees after his patient's death. The jury found for the defendant.

THE ANNUAL REPORT ON THE SEAMEN'S HOSPITAL, GREENWICH.

A general report on the cases under treatment at the Seamen's Hospital, Greenwich, during the year 1876, has just been published by Mr. Johnson Smith, F.R.C.S., the Senior Resident Medical Officer. During the period 2106 patients were admitted. Of these, 972 were passed into the medical, and 1134 into the surgical wards. The increase in the number of admissions that has been noted year by year since the removal of the Hospital from the river on board the *Dreadnought*, may be attributed in part to an increase in the number of sick applicants from the mercantile marine. The supply of patients, however, from this source has not increased to any very considerable extent, for, though more and more seamen have been admitted during the past seven years into the medical wards, there has, during that period,

been a progressive falling-off in the number of those applying for the treatment of venereal disease. In noticing the cases of scurvy treated during the year, the report states that, notwithstanding the recent increase in the number of cases received, and although the views of the medical inspectors differ much as to the etiology of the disease, and the value of such preventive agents as were maintained by the special legislation of 1867, the view expressed by Dr. R. Barnes is, after all, the most correct—viz., that "the abolition of scurvy is entirely a question of diet, and a very simple question of diet. The whole secret consists in adding to the ship dietary a moderate proportion of fresh vegetables, or, in default of this, half an ounce daily of preserved lime-juice." The absence of erysipelas in the return of deaths for 1876, and the fact that in three cases only out of the six fatal cases of pyæmia had the affection been contracted in the Hospital, serve to give an exceptional character to the past year, since in no previous year since 1859 had so small a mortality from the affections in question been noted. In 1876, as in the previous year, the antiseptic method was almost generally practised in the surgical wards.

ST. ANDREWS GRADUATES' ASSOCIATION.

The ninth anniversary session of the Association of the St. Andrews Graduates was held at the Westminster Palace Hotel on Thursday, June 28. Two hours were most interestingly and instructively spent previously in Westminster Abbey under the kind guidance of the Very Rev. the Dean, Lord Rector of St. Andrews. At the dinner, in the evening, Dr. Lush, M.P., was in the chair, and was supported by Lord Gordon, Mr. Knight, M.P., Mr. Ramsay, M.P., Prof. Smyth, M.P., Mr. Walter James, M.P., Mr. Rowley Hill, M.P., Dr. Cameron, M.P., Dr. Mitchell, Dr. Bucknill, Dr. Crichton Browne, Mr. Balfour Browne, Dr. Richardson, F.R.S., Rev. Dr. Rogers, Dr. Paul, Dr. Day (of Stafford), Dr. Cholmeley, Dr. Kesteven, Dr. Weir (of Malvern), Dr. MacEwen (of Chester), Dr. Griffith (of Portmadoc), Dr. Cleveland, Dr. Wiltshire, Dr. Mott, Dr. Sedgwick, and many other London and country graduates. Dr. Lyon Playfair, M.P., was, to his great regret, prevented attending by his Parliamentary duties. Dr. Paul was presented with a handsome claret-jug and goblets for his services as Treasurer since the foundation of the Association. A very cordial vote of thanks to the Dean of Westminster was passed; and the hearty congratulations of the Association were offered to Dr. Richardson, F.R.S., on the recognition of his services to literature and the University by the conferring on him of the degree of LL.D. of St. Andrews. The following were elected as the Executive for the year 1877-78: —*President of Council:* Dr. B.W. Richardson, F.R.S. *Honorary Treasurer:* Dr. Paul. *Honorary Secretary:* Dr. Sedgwick. *Council:* Drs. Cholmeley, Christie, Cleveland, Crosby, Henry Day, Dudfield, Griffith, Griffiths, Holman, Lawrence, Lush, M.P., Macintyre, Mr. Menzies, Professor Pettigrew, Dr. Julius Pollock, Rev. Dr. Rogers, Drs. Joseph Rogers, Lawes Rogers, Cooper Rose, Royston, Scott, Seaton, Whitmore, Willett, Duckworth Williams, Rhys Williams, Wiltshire, George Bird, Falls, Surgeon-Major Franklin, Drs. Mortimer Granville, Kesteven, Charles Mott, Bransby Roberts, Stocker, and Weir.

HEAT-STROKE.

The *Daily Telegraph* one day this week published an article which most forcibly illustrated the old paradox, that a little knowledge is a dangerous thing. It seems the Editor had received a communication from a gentleman calling himself an engineer. The editor did not see fit to reject this manuscript entirely, but instead, he gave the substance of it in a leading article, thus giving the painful absurdity of the would-be health-dealer all the great weight of the editorial "*we*." According to what we could gather from this editorial, the letter-writer had seen what he called sun-stroke in brickfields, and, acting on a simple theory, had been successful in curing many such cases. The theory was this: Frost-bite is cured by the application of ice; why should not heat-stroke be cured by the application of heat? The answer is plain and obvious. Frost-bite is not cured by ice; it is cured by heat; but this heat must be so gradually applied that it is found to be best to generate it by a body such as ice or snow. This is used as a friction-agent. The friction generates the heat; the ice or snow modifies it. But to apply heated bricks to an over-heated body is a different story. What is to be said of an engineer who does not understand the theory of heat?

THE UNIVERSITY OF LONDON AND MEDICAL WOMEN.

We understand that the Senate of the University of London (or, to speak more correctly, a small majority of its members) continues to pursue the course of action, with regard to the admission of women to degrees in medicine, which it commenced in February, and of which Convocation has so distinctly disapproved. At the meeting of the Senate on Wednesday last, general regulations were adopted with respect to the character of the examinations; and, as we warned the graduates several months ago would probably be the case these regulations admit two important modifications in the examination of women for the ordinary degree. First, women who may have already commenced or completed their medical education are to be treated with special consideration; and secondly, foreign certificates will be accepted in lieu of home ones. Meanwhile, the constitutional question of the behaviour of the Senate towards Convocation in this matter, to which we referred last week, is occupying the earnest attention of a large portion of the medical graduates, who are taking active steps to obtain an early opportunity of giving public expression to their opinion.

DR. BROWN-SÉQUARD.

The four lectures given in Liverpool recently by Dr. Brown-Séquard—that on the 27th ult. being on the occasion of the meeting of the Lancashire and Cheshire branch of the British Medical Association—were listened to with much interest by large and appreciative audiences. The most spacious of the theatres of the Royal Infirmary School of Medicine was on each occasion crowded by medical men from the town and neighbourhood. In these, as in his recently published lectures, Dr. Brown-Séquard vigorously opposed what he conceives to be the unfounded theories of Fritsch, Hitzig, Drs. Ferrier and Jackson, and those other physiologists who maintain that there are special psycho-motor centres in the cerebral convolutions for the face, arm, leg, and other parts of the body.

THE CHAIR OF PHYSIOLOGY IN ABERDEEN.

By the resignation of the present incumbent, the chair of Physiology (or, according to Scottish phraseology, of the Institutes of Medicine) in the University of Aberdeen is now vacant. The only candidate of whom we have heard is Dr. Stirling, who now assists Professor Rutherford in Edinburgh. It is not very often one can say that an unopposed election to such a post is good. In this case it would be impossible to do better than to elect Dr. Stirling.

NORTH-EASTERN HOSPITAL FOR CHILDREN.

At the ninth annual meeting of the North-Eastern Hospital for Children, recently held, it was stated that the Committee had for some time felt the necessity of appealing to the public for funds to enable them to carry out certain proposed alterations. For this object at least £5000 would be required, towards which the sum of £1260 had already been been promised. The people among whom the Hospital was placed were poor, living as it were from hand to mouth, and

it was from richer districts that assistance must be solicited. The Secretary read the list of subscriptions towards the building fund, which included £500 from Mr. Joseph Gurney Barclay, the chairman of the meeting, and further donations were announced.

ARMY VETERINARY DEPARTMENT.

THE Secretary of War appears to be even less happy in his management of the Army Veterinary Department than he has hitherto been in that of the Army Medical Department; for in reply to a question, a few nights ago, as to the condition of the former, he stated that it is true that "no candidates had offered themselves for the fifteen vacancies now existing" in the Department. Many schemes had been submitted to the War Office, and were "under consideration," but, till their probable cost and results had been inquired into, he did not consider it advisable to make any proposal on the subject.

MEDICAL PARLIAMENTARY AFFAIRS.

Vaccination.—Mr. Sclater-Booth, replying to Mr. Greene, said he had made inquiries with reference to a man at Liverpool, who refused to let his children be vaccinated; and, as a result, the whole family of eight children had been ill with small-pox. One child had died, and another was dangerously ill. He had been repeatedly fined. Such cases had frequently come under his notice. It was reported that the fines were regularly paid by the Anti-Vaccination Society. Mr. Hopwood also asked a legal question with reference to the case of Joseph Abel, as to whether the magistrate may at his own discretion make an order for vaccination, or not. Mr. Sclater-Booth replied that, in his opinion, a magistrate has no discretion after the case has been clearly proved against the man for neglect of vaccination.

Drainage of Ash.—An inquiry was made respecting the drainage of the town of Ash, which was said to be very defective. The local authorities had been instructed by the Local Government Board to take the necessary steps to ameliorate the sanitary condition of the parish; but they seem, said Mr. Sclater-Booth, to have arrived at the conclusion that no drainage was required. As the case presented certain difficulties, he had not decided what course to adopt.

Militia and Army Surgeons.—Dr. Playfair drew attention to the position of the militia surgeons under the Royal Warrant of 1870, by which much of the work and emoluments appertaining to the duties of militia surgeons was transferred to army surgeons. This was especially hard upon those who had served for many years, as they could not at their advanced age get sufficient private practice. Militia surgeons would now receive, at the most, £45 a year, with considerable deductions. Lord Cardwell and the present Secretary for War had promised to consider their claims for compensation, but hitherto nothing had been done. Dr. Lush said that there was much discontentment in the Medical Department of the Army. The new system of military tactics required that large bodies of troops should be moved with celerity, and it required the anxious supervision of the surgeons to keep the troops on rapid marches in good fighting health. In 1869 there were 631 medical officers of the army at home, but this number has been reduced to 531. Attempts were made three years ago to remedy this grievance, but without any result. Army surgeons suffered from disabilities unknown to officers of similar rank and pay, especially with regard to forage, leave of absence, and the right to exchange. He quoted cases in support of these statements. Colonel North also spoke strongly against the present treatment of the Medical Department by the War Office regulations. Mr. Hardy controverted the statements made, and said that the agitation might be traced to one or two individuals. To his knowledge a surgeon in London had spent his whole time in dissuading young men from joining the Service. He alluded to the three-years system in India, rendered necessary by the exigencies of the climate. In consultation with the Director-General of the Army Medical Department, that day, he had been assured that the Medical Department had never been organised upon so good a footing as at the present, and it could be put into the field and brought into operation without a moment's delay. There are now only forty-three vacancies in the Department, which would be reduced to twenty-six when the seventeen candidates now completing their course at Netley were attached to their regiments. For these vacancies there would be an examination in August. He referred to the question of compensation, and said that while no lump sum had been paid, the effect of the new regulations was to give immediate promotion, with relative increase of pay. On the forage question, the War Office, discouraging a system of perquisites, had arranged to give forage where the medical officer had a horse, but not otherwise. It was obvious that medical officers could not be granted leave of absence in the same way as other officers. He did not see how it was possible to meet the demand for exchanges under the unification system. All must take their share of foreign service. He referred to the greater experience of army surgeons in the examination of recruits for the militia, and to the avoidance of delay between the examination and the preliminary drill when this work was taken out of the hands of the militia surgeons. Here again compensation was made by increasing the pay from 14s. 4d. a day to £1 6s. 6d. As the recruiting was done by piecework—*i.e.*, so much per man examined—the supposed hardship was scarcely perceptible.

Vaccination.—Earl Percy rose to call attention to the manner in which vaccination is practised in this country. He was anxious that those who opposed vaccination should be left without the shadow of an excuse for their conduct. He would not defend the law-breakers, nor, on the other hand, those who, while occupying positions of trust for enforcing the law, neglected to put it in operation. When a law was once established, it was incumbent on all good citizens to respect it. It is very desirable that any doubts as to the purity of the lymph-supply shall be removed, and that the public should have every confidence in the public vaccinators. The weakness of the lymph now in use had been long admitted. No attempt had been made to replace it from a new source, and small-pox is increasing in the country. He said that the opinions of doctors on the subject of the transmission of disease by means of vaccination had considerably changed of late years, although Mr. Simon, in his reports, said that almost all European doctors denied the possibility of transmitting disease when vaccination is properly performed. He candidly confessed that he had no remedy to propose, but he desired to have further inquiry made by the Government, especially with reference to the results of the Belgian system of vaccination from the calf. Dr. Seaton, who had reported unfavourably of this system, made his investigations in 1869, since which time the method of animal vaccination had been greatly improved. He concluded by moving—"That it is expedient that an inquiry should be instituted into the practice of vaccination for the purpose of ascertaining whether it cannot be conducted in a more satisfactory manner than at present." Mr. Sclater-Booth controverted the deductions of Earl Percy with reference to the prevalence of small-pox, and pointed out that this disease is being steadily kept in check wherever vaccination is properly carried out. During the last century one-fifth of our soldiers and militiamen suffered more or less severely from this disease. The National Vaccine Establishment had never neglected an opportunity of introducing a new stock of vaccine matter. It was an error to assume that the whole of the vaccine matter in this country is worn out by lapse of time. He could assure the House that there was no widespread feeling in favour of animal vaccination. There was nothing to show that medical men of eminence considered that the system of vaccination required amelioration. The evidence quoted by Sir Trevor Lawrence in proof of the potency of vaccine lymph in protecting those engaged in nursing small-pox patients from becoming infected with the disease ought to be sufficient to satisfy everybody that vaccine lymph is not becoming effete. The experience of our small-pox hospitals goes to prove that, while the disease has lost none of its virulence and fatal tendency, it is alone kept in check by efficient vaccination. With regard to accumulated penalties for non-compliance with the Act, he thought it very undesirable to prosecute repeatedly for the same offence, but he was not prepared to say that, in districts where the Anti-Vaccination League had interfered unduly, the magistrates were not justified in convicting and in enforcing penalties. He desired to mitigate the severity of the law, but he did not think it possible to carry through Parliament a measure having the effect of breaking down the stringency of the law on the subject. He could not take any steps while an epidemic was raging, but when the epidemic had abated he would consider the scruples of those who objected to vaccination. Lord Percy's motion together with a rider of Mr. Pease condemning accumulated penalties, was lost by a large majority.

FROM ABROAD.

The Sea-Bathing Hospital at Berck.

In 1861 the Paris Assistance Publique, encouraged by the excellent results of the trials that had been made of treating scrofulous affections at the seaside, opened a small Hospital at Berck, near Boulogne-sur-Mer, capable of receiving 100 children. It was constructed of slight and inexpensive materials, and so rapidly as to be completed in eighty-five days. Between 1861 and 1868, 924 children had been treated in the Hospital, with results confirmatory of those obtained during the early trials. The Assistance Publique thereupon resolved to erect a larger establishment; but, instead of remaining faithful to the plan of rapid and economical construction, inspired by the same ideas that have presided over the erection of the new Hôtel-Dieu at Paris, it determined to have a grand edifice. In 1869 it opened its new Hospital, the first establishment of which for 584 beds cost 3,235,130 fr.—each bed costing, therefore, 5539 fr. The site of the new Hospital, too, has been so unfortunately chosen that it has been constantly in danger of being submerged by the sea, so that from 1872 to 1876 defensive works have been required which have cost 221,254 fr. These works are, however, found insufficient, and a new demand of funds for continuing them has been made on the Municipal Council. The Council, finding that from 1869 to 1876 the Hospital has received 6748 scrofulous children, or an annual mean of 800, and being unwilling, as long as a prospect of saving it remained, to abandon an establishment that has cost nearly 4,000,000 fr., has, upon the proposition of Dr. Bourneville, voted the sums asked for. A further sum has also been required for the rectification of the water-supply, which has been as badly organised as the site has been injudiciously chosen. "If," says the *Gazette Médicale* (June 23), "we say so much on the economical question concerning this Hospital at Berck, it is that the question in regard to establishments of this kind is intimately confounded with the medical and philanthropical question. After all the expense of construction, maintenance, and defensive works, each bed has cost at the end of 1876 the sum of 6205 fr.; and the additional defensive works about to be undertaken will raise this sum to a still higher figure. But the more this is raised the fewer of these little sufferers will be admitted to the benefit of seaside treatment. Then, again, the larger a hospital, and the more patients it contains, the less are its sanitary conditions in a satisfactory state. Hygiene, economy, and the interest of numbers, then, agree in commending the adoption in future of small hospitals of slight construction, the number of which may be multiplied according to the necessities for their erection and the funds to be disposed of for that purpose." In the matter of hospitals, whether as regards their erection, their hygienic conditions, or the results obtained within their walls, the hackneyed saying, "They manage these things better in France," certainly will not apply.

Diabetes in Children.

At a meeting of the Société de Biologie (*Gaz. des Hôp.*, No. 44), M. Redon read a communication upon this subject, which, he observes, has been but little investigated. From inquiries he has made among a great number of practitioners, and from his own observations, he has come to the conclusion that the ideas which prevail respecting it are incomplete and erroneous. Basing his observations upon thirty-two cases which he has collected (six of these not yet published), he finds that, while the etiology is very much the same as in the adult, yet the relationship between the diabetes and the various diatheses is brought out more clearly.

Thus, parents the subjects of gout, arthritism, herpetism, scrofula, or certain nervous affections, insanity, convulsions, etc., may either produce children who are all diabetic, or only some diabetic and others exhibiting other forms of vitiated constitution. In more than one-half the cases the disease manifested itself before the ninth and twelfth years. The affection has been so often overlooked that it certainly occurs much more frequently than is suspected, and should be always sought for when a child seems to be suffering from any ill-determined form of disease. It seems to occur pretty equally in children of both sexes. Polyuria is of nearly constant occurrence, the quantity of urine being proportionally greater, as well as the quantity of sugar eliminated. Polyphagia exists in four-fifths of the cases, and wasting is an early and rapid symptom. The pulse is very frequent. The disposition of the child undergoes in the progress of the disease great change; the child from being restless, excitable, and mischievous, becoming dull and taciturn. Complications are of less frequent occurrence than in the adult, probably because of the shorter duration (from some months to two years) of the disease. Dryness of the skin is an extremely frequent characteristic, and this symptom alone may in many cases give rise to a suspicion of this disease. Phthisis, which is usually regarded as a frequent termination of the affection, was only observed in four out of twenty-two deaths, and even in these it was doubtful that it was the cause of death. The children die in a state of marasmus, life being insensibly extinguished, and sometimes there is a state of coma. The prognosis is not so fatal as it has hitherto been considered, for of thirty-two cases at least six were cured—the recovery being always contingent on the prompt recognition and early treatment of the disease. On these conditions a great proportion of cures, which may be rendered permanent by appropriate hygienic measures, may be obtained; while, when the diabetes is overlooked, or only recognised too late, it will always prove fatal. The treatment consists almost entirely in appropriate regimen and hygiene, and should be of the same character as that employed by Prof. Bouchardat for the treatment of the adult.

The Mortality Returns of the German Empire.

With the present year was commenced by the newly established sanitary authority at Berlin an interesting publication. It is entitled *Veröffentlichungen des Kaiserliche Deutchen Gesundheitsamtes*, its chief object being to furnish a weekly account of the mortality which occurs in the towns of the German Empire having 15,000 inhabitants and above; the meteorological conditions which have prevailed during the same periods being also stated. By the last number which has come to hand (that for June 3-9), we find that the 7,026,313 inhabitants of 149 towns (distributed into eight geographical or climatic groups) furnished a mortality of 4183, or 31 deaths per 1000. During the same week there were 5387 births, the natural increase of population being therefore 1204. The deaths which occurred during the first year of life varied in the different groups of towns from 33·9 per cent. to 47·7. In Berlin it was 50·6, and in Munich 46·4. The proportions of deaths above sixty varied in the different groups from 8·6 per cent. to 20 per cent. The "causes of death" are grouped somewhat roughly under four heads: (1) Infectious diseases—viz., 1, small-pox; 2, measles and rotheln; 3, scarlatina; 4, croup and diphtheria; 5, pertussis; 6, abdominal typhus (gastric and nervous fevers); 7, typhus (*Flecktyphus*); 8, cholera; 9, dysentery; 10, puerperal fever; and 11, other infectious (non-specified) diseases. (2.) Other predominant diseases—viz., 1, phthisis; 2, acute inflammatory diseases of the respiratory organs; 3, apoplexy; 4, acute articular rheumatism; 5, diarrhœa; 6, cholera nostras. (3.) All other diseases, none of which are specified. (4.) Violent deaths—viz., 1, from accident and unknown causes; 2, from suicide; 3, from homicide. With each number of the *Veröffentlichungen* is published a chart exhibiting graphically at eight points of observation (Conitz, Breslau, Munich, Heiligenstadt, Berlin, Bremen, Cologne, and Carlsrühe), in the German climatic circles, the daily variations of the barometer and thermometer, the relative amount of humidity and the rainfall, and the direction of the wind, so that an exact statement of these particulars for every day of the year will be on record. Besides these returns relating to the German empire, the mortality returns are also given of thirty-three of the chief cities of Europe and America; and a distinct department of the publication is reserved for foreign sanitary news—for example, the present number contains information concerning the epidemic of small-pox in England, the plague at Bagdad, and a report of Dr. Castaldi's sanitary visit to the shores of the Caspian.

A supplement is also published every week, giving successive detailed accounts of the mortality and sanitary state of the various German towns embraced in the scheme; but the supplement accompanying the present number contains the summary of the first quarter's returns. The general summing up of this first quarter of 1877 (details of which are given for every city) is as follows:—The total population of the 149 towns for the quarter is returned at 6,981,775. There occurred

72,537 living births, or 41·6 per annum for 1000 inhabitants, and 47,236 deaths (exclusive of children born dead), or 27·1 per 1000 inhabitants. Of the deaths, 16,210 occurred during the first year, or 34·3 of the whole mortality; 7186 between 2 and 5 years, or 15·2; 2687 between the 6th and 20th years, or 5·7; 6632 between 21 and 40, or 14·0; 6427 between 41 and 60, or 13·6; and 7663 from 61 to 80 and upwards, or 16·2. Of these deaths, 18 (0·04) took place from variola; 744 (1·6) from measles and rotheln; 1026 (2·2) from scarlatina; 2130 (4·5) from croup and diphtheria; 875 (1·9) from pertussis; 819 (1·7) from abdominal typhus (nervous and gastric fever); 34 (0·07) from typhus (*Flecktyphus*); 24 (0·05) from dysentery; 348 (0·7) from puerperal fever; 261 (0·5) from other and non-specified infectious diseases; 7251 (15·3) from phthisis; 5671 (12·0) from acute inflammations of respiratory organs; 1709 (3·6) from apoplexy; 88 (0·2) from acute articular rheumatism; 1237 (2·6) from diarrhœa; 423 (0·9) from cholera nostras; 23,615 (49·9) from all other unspecified diseases; 586 (1·2) from accidents; 414 (0·9) from suicide; 33 (0·07) from homicide.

The *Veröffentlichungen*, imperfect as they are (seeing that the causes of 23,615 deaths remain unspecified), will prove of great interest, and are to be purchased at a low price (10s. per annum, exclusive of postage). There is a copy in the library of the Royal College of Surgeons.

FOREIGN AND COLONIAL CORRESPONDENCE.

FRANCE.

PARIS.

HOSPITAL HYGIENE: HOSPITAL PRIVIES AND CLOSETS; DEFICIENCY OF BATH ARRANGEMENTS, AND OF THE ORDINARY WASHING APPLIANCES; VENTILATION.

In my last letter I called attention to the almost complete neglect of isolation in the case of erysipelas and the acute specific fevers in the Paris hospitals. I wish, in the present letter, to speak of some other points in connexion with the hygiene of these establishments, which, though of minor importance compared with the one of which I have already treated, yet demand from the authorities more attention than has hitherto been given to them. I cannot pretend to a knowledge of the interior arrangements of, by any means, all the hospitals in Paris, but that abuses such as I shall mention should exist in any of them is indicative of the very partial attention as yet paid to such subjects. There are, I am glad to say, signs that the Administration is gradually waking up, but the progress made is slow—much slower than it should be when the importance of good hygienic conditions in hospitals is considered, and much slower than many of the members of the medical staffs would have it.

I would first speak of the water-closets—or rather privies, for it is the exception, so far as I have seen, to find water laid on. These, for the most part, partake of the general want of attention to the principles of health and comfort which one finds in the closets everywhere throughout France. Until within the last three years there had been provided, for the use of the patients at the Hôtel Dieu, simply round holes in the floor, lined with tin, and a couple of iron bars at the sides for the patients to hold themselves up with; and though this exceedingly primitive state of things has been since that time remedied, yet the closets are still far from what they should be; and both there, and at some other hospitals I could name, the smell from the privies is at times so bad in the wards as to be quite offensive on first going into them. At the Salpétrière, which is one of the largest establishments in Europe, having over 5000 inhabitants, and which, therefore, ought to have its sanitary arrangements well systematised, and brought as nearly as possible to perfection, the privies are of the worst possible description. In one building the accommodation provided consists of six seats, placed close together, and without any divisions between them, from which large brick tubes, as large as the seats themselves, lead downwards and backwards at an angle of 60° to the cesspool, which is in full view of anyone standing in front of the seats; and in other parts of the hospice, where separate closets are provided, so little attention is paid to cleanliness that it is quite disagreeable to go near them. These are only instances of what one finds in most of the older hospitals, and will, I think, show how much room there is for improvement in this respect.

From the closets I will pass to the washing arrangements in the hospitals. There is in these great inequality in different institutions, some hospitals being provided with a system of baths of the latest patterns, others being left in a very deficient state as regards ordinary baths, and almost entirely without medical baths of any kind. Prominent amongst the latter, I must again mention the Salpétrière. In this great establishment, in which are collected large numbers of patients suffering from mental diseases, or from chronic nervous diseases, and a considerable number of children, the deficiency of the ordinary baths for purposes of cleanliness is a matter of common complaint, and medical baths may be said not to exist. I was present lately, on an occasion when a patient had been ordered a douche by her physician. The only available douche was in quite a different part of the building, and was within the jurisdiction of another physician, without whose leave it could not be used. As he had left the hospital, this could not be obtained, and the treatment had accordingly to be postponed. I may add that this solitary douche is an exceedingly inefficient one, and that as the water-supply is by no means constant, its use is in this way much restricted. When we consider how important an adjuvant in the treatment of mental and chronic nervous disorders the proper use of various kinds of baths has become, it will be evident that no time should be lost in remedying the deficiencies at the hospice. At Bicêtre—which is for men what the Salpétrière is for women—there is an equal want of proper arrangements for the carrying out of medical treatment by baths. It is not everywhere, however, that such inefficiency exists, for at some of the hospitals the baths are everything that can be wished. Thus, at St. Louis, the great hospital for diseases of the skin, there is a very perfect system of baths of every kind—a large number of ordinary baths for purposes of cleanliness, of sulphur and mercurial baths, good vapour and fumigation baths, and douches of every description; and all these are available for both out and in-patients. At the Hospice of St. Anne, for the insane, an equally perfect system exists, and both at the Children's Hospital in the Rue de Sèvres, and the Hospice for Foundlings, there is a good supply of baths, those at the Children's Hospital being available for out-patients. This is as it should be; but the sight of these perfect systems serves to bring into more prominent relief the want of them at the many hospitals which are yet without them. We have by no means arrived at perfection in England in this respect, but we will hope that the day is not far distant when both in London and Paris we shall reach the consummation for which the *Progrès Médical* has long been pleading—viz., that each hospital shall have its complete system of baths available for both in- and out-patients.

Apart, however, from the question of the presence or absence of a complete system of baths, there is room for great improvement in the ordinary washing arrangements in the hospitals. In every hospital in England of which I have seen the internal working it has been a rule that every patient should have a bath on admission, unless it were distinctly ordered to the contrary by the medical attendant; and if a patient cannot be actually put into a bath, he is—if there be no reason to the contrary—well washed in bed. Here, however, it is quite the exception for a patient to have a bath on admission, and many of them lie in their accustomed state of dirt for the whole time they are in hospital. In a large hospital several storeys high, moreover, there should be an ordinary washing-bath, if not for each ward, at any rate for each storey, as it is naturally difficult or impossible to carry many of the patients down to the regular bath-house, even where such exists: these, however, are hardly ever to be found. It is rare, also, to find lavatories provided for the patients, and basins even are looked upon as unnecessary luxuries, the patients being generally expected to wash in pails, or, more commonly, simply at a tap. The Salpétrière must be here again brought forward as peculiarly deficient, for in that establishment, the inmates of which, if not actually invalids, consist of women admitted for old age and helplessness, the only arrangements provided for washing are pumps in the different courts of the building, and to these places the poor old inmates have to come, whatever the weather, if they wish to make themselves clean. That such a state of things should exist is almost incredible, and it becomes none the less so when we find that at St. Anne, one of the most recently built of the charitable institutions, the Administration has provided lavatories, which, like the baths at the same institution, are irreproachable.

These are all points of which some of the leaders of

medical opinion in Paris have long complained, and it is due to M. Bourneville, the editor of the *Progrès Médical*, to mention the untiring advocacy he has accorded in his paper to the measures for improvement in these respects, and for repeated efforts he has made to get the Administration to move in the matter.

Before closing my letter I must say a few words upon the ventilation in the hospitals. I am not aware of a single hospital where there is any means, other than the windows, provided for the ingress of air. As these are almost always constructed more or less on the usual French plan, which makes it difficult to open them at all without opening them so much as to produce violent draughts in the wards, it results that in the colder weather the wards are entirely shut for hours at a time, and the air becomes exceedingly heavy and close. One is constantly struck with this on entering the wards for the morning visits, when the patients are still breathing the used-up air of the previous night. This is a defect which becomes much more apparent in some wards than in others, for they vary very greatly in height and in the cubic space accorded to the patients. Even in the same hospital this is the case, the wards on the ground floor being perhaps only ten or twelve feet in height, and the space not unfrequently further restricted by large pillars, whilst those above may be twenty or even twenty-five feet in height. It is, I am afraid, too much to expect that the Administration will spend much money in introducing proper ventilating apparatus into their hospitals, but even with the existing state of things a little careful supervision on the part of the internes would do a great deal towards remedying this defect.

The different points to which I have thus called attention are merely the expression in the hospitals of characteristics in the French nation which have become proverbial. Every Englishman who has been much in France has had reason to complain of the water-closets, and he will no less have remarked the difference between the two countries in the means provided for the toilet, and in the matter of ventilation. Moreover, we find the average Frenchman much less acute than the average Englishman. But it is time that the responsible authorities became thoroughly alive to the fact that what may be done with impunity in households, and in connexion with people in health, cannot be done when we have to deal with large numbers of people collected into one building, —and people not in health, but in every stage of disease. That they are beginning to appreciate the importance of hygiene is evident from the great care which has been taken to provide their more recent establishments—such as the Hospice of St. Anne—with the most recent hygienic arrangements; but that considerable callousness still exists is evident from the way in which at other institutions flagrant defects are allowed to remain unremedied—defects which, in many instances, might be set right at a comparatively small cost.

It has been decided that the ratepayers of Keighley will have to pay the sum of £125 14s. 1d. incurred by the anti-vaccinating Guardians in defending themselves against the Local Government Board.

Students of Berlin University in the Summer Session of 1877.—Of the 2490 students who attended the winter course, 768 have left, and 515 new ones have entered, making the present number 2237, being an increase of 260 as compared with the summer of 1876. Of these 2237 students, 135 are theological, 792 jurists, 297 medical, and 1013 philosophical. The number of medical students has not only increased as compared with the last summer session (when it was 260), but exceeds that of the last winter session (281), leading to the hope that the declining state of the medical school has become arrested. Not only have the civilian medical students thus increased, but the military medical students have risen from the 160 of last winter to 215. Besides the 2237 matriculated students there are those of various public academies, etc., who attend lectures, making up the total number of auditors to 4311. Of the 297 medical students, 216 are Prussians, and 24 natives of other parts of the German Empire. Among the foreigners are 32 Russian and 14 Americans, but no English. Pharmaceutists and dentists are 43 in number, but they are registered in the Philosophy Faculty. With regard to the professorial medical staff, there are 12 ordinary professors, with Professor von Langenbeck as the senior, 17 extraordinary professors, and 45 privat-docenten.—*Berlin. Klin. Woch.*, June 18.

LEGAL INTELLIGENCE.

THE CARMICHAEL MEDICAL PRIZE FUND.

In the Rolls Court, Dublin, judgment was given on June 26, in the case "*In re* the Trusts of Carmichael's Will, *ex parte* the Royal College of Surgeons, Ireland." The late Surgeon Carmichael, of Dublin, by his will of October 11, 1849, left £3000 to the Royal College of Surgeons, Ireland, the interest of which was to be applied in pursuance of elaborate directions set forth in the sequel of his will. Prizes of £200 and £100 respectively were to be given every four years for the two best essays on specified medical subjects. The trust fund produced about £88 a year, or £350 every four years, and out of the balance, after providing for the prizes, the cost of printing 700 copies of the successful essay was to be defrayed. In case no essay of sufficient merit was sent in, the prizes were to be doubled in value at the end of the next four years, and any ultimate surplus of interest was to go to the Royal Medical Benevolent Fund Society of Ireland. In 1869 a scheme was framed in accordance with the founder's intentions, and settled by the late Master of the Rolls, who refused to make any provision for payment of the gentlemen who were to examine the candidates' essays.

Mr. Wm. M. Johnson, Q.C., applied on behalf of the Royal College of Surgeons, that they might be at liberty to apply the sum of £150 out of the trust funds, in paying three of their members £50 each for examining the essays sent in to compete for the prizes payable out of the fund. The petitioners' case, which was supported by the affidavit of Surgeon Colles, was, that the scheme, as settled, had become unworkable from their inability to get competent persons to undertake gratuitously the task of judging the essays, which were generally very numerous and very long. Consequently the College had not for the four-year period ending in the spring of this year issued the necessary advertisements for candidates for the prizes, and they had allowed the first Monday in May—the day fixed for the purpose—to pass without having awarded any prizes.

Mr. F. Walsh, Q.C., for the Royal Medical Benevolent Fund Society, argued that, according to the will of the late Surgeon Carmichael, and to the frame of the scheme as settled by the late Master of the Rolls, that Society was entitled to the accumulation of interest now standing to the credit of the fund.

The Master of the Rolls, in giving judgment, expressed his deep regret that such an application had ever been made. The late Surgeon Carmichael was a man of great eminence in his profession, and one would have imagined that the Council of the Royal College of Surgeons, out of respect to his memory, if not with a desire to advance science or from any other motive, would have taken care that these valuable prizes should not be allowed to lapse. The Council should either have refused the bequest altogether, or, after taking it, if they could not get any of their body to judge the essays gratuitously, they should have provided remuneration for that out of their own funds. With the greatest respect for the Royal College of Surgeons, he was bound to say that they had acted in this case in a manner not creditable to themselves. He felt coerced by every consideration to refuse the prayer of the petition with costs.

Dr. Hetley, of Norbury Lodge, Upper Norwood, has been appointed a Justice of the Peace for the county of Surrey.

Jubilee of Professor Phœbus.—The jubilee of Geheimer Medicinal-Rath und Professor Philip Phœbus was celebrated at Giessen on June 15, on the occasion of his completing the fiftieth year of his doctorate. Appointed Professor of Pharmacology at Giessen in 1845, he has continued to remain at this University notwithstanding offers made him from Dorpat, Agram, and St. Petersburg. He founded the first Pharmacological Institute, and continued its direction until 1867, and became the most able exponent of the branch of medical science to which he had devoted himself. He was also a pathological anatomist of repute, and an able medical observer, as his works on the Pathological Anatomy of Cholera and on Hay-Fever amply testify. On the occasion of the jubilee, warm congratulatory letters were forwarded to him by the Berlin Medical Society and the Hufeland Society.—*Berlin. Klin. Woch.*, June 11 and 18.

NEW INVENTIONS AND IMPROVEMENTS.

HYGIENIC GARTERS.

The employment of the differentiating adjective "hygienic" by inventors and manufacturers is a by no means to be despised practical proof, among other proofs, of the increasing popular appreciation of hygiene and sanitary science; and this is an additional reason why we should notice the "Hygienic Garter" produced by "The Patent Elastic Webb Company (Clapham-road, S.W.). Medical men well know that the ordinary flat, strap-like, circular garters often act injuriously by their interference with the superficial venous circulation; but the peculiar construction of the hygienic garter—viz., a specially-arranged finely-corrugated elastic webbing, enclosed within silk ribbon—seems well calculated to do away with the usual objections. These garters are comfortable, and very well made, and really deserving of commendation. We will, however, give the manufacturers one hint about them. We have shown them to several ladies, each one of whom made the objection that the clasps do not look secure. We suspect that the objection is an "idea" only; but, nevertheless, it may stand in the way of the sale of the garters.

BRAVAIS' DIALYSED IRON.

"Fer Bravais," which is a nearly pure concentrated solution of peroxide of iron in the colloid form, obtained by dialysis from the soluble oxychloride, is a very elegant and valuable preparation. It has no styptic taste, mixes well with water in any proportion, does not stain the teeth, and does not cause constipation. It is provided in a very neat form, in a box which contains a little pipette with an indiarubber cap for the delivery of the drops, and may be taken pure, dropped on a lump of sugar, or stirred in a glass of wine. The English agents for it are Messrs. Burgoyne, of Coleman-street, and Messrs. Roberts, of 76, New Bond-street.

It is fair, however, to add that the preparation is not quite a new one in England. Messrs. Squire, of Oxford-street, also manufacture a similar solution, which they claim to have brought out in 1869.

GRANULAR EFFERVESCING HYPOPHOSPHITES OF SODA AND OF LIME.

We have received from Messrs. Young and Postans, of 35, Baker-street, examples of pleasant and useful preparations of Granular Effervescing Hypophosphites of Soda and of Lime. They are made of such a degree of strength that each contains five grains of the hypophosphite to the teaspoonful. They keep well, and will be found trustworthy and serviceable.

NITRITE OF AMYL CAPSULES.

A safely ready means of administering nitrite of amyl has, from the increasing appreciation of the value of the drug, become a desideratum of no little importance; and this has been well and happily provided by Messrs. Allen and Hanbury, of Plough-court. They have devised a method of sealing-up the remedy in little glass capsules, which can be readily broken, in a handkerchief, when wanted, and each of which contains about four minims of the nitrite. They are sold in handy little boxes, each of which contains six, and should entirely supersede the ordinary rough-and-ready mode of sniffing at a bottle containing the agent, or of "pouring a little of it" on a pocket-handkerchief.

GRANULAR EFFERVESCENT SALICINE; GRANULAR EFFERVESCENT SALICYLATE OF SODA; GRANULAR EFFERVESCENT SALICYLIC ACID.

Messrs. Savory and Moore, New Bond-street, have sent us some admirable preparations of effervescent salicine, effervescent salicylate of soda, and effervescent salicylic acid, which may be confidently recommended as very convenient and palatable preparations of these remedies, now so much employed. The granules are very well formed, and effervesce briskly. The common forms of these remedies are neither elegant nor agreeable to take, and these effervescing ones of Messrs. Savory and Moore's will, we doubt not, be gladly and largely employed. In each preparation a teaspoonful contains a five-grain dose of the respective drug.

MEDICAL NEWS.

University of Dublin.—Summer Commencements, 1877.—At a meeting of the Senate of the University, held on Thursday, June 28, in the Examination Hall of Trinity College, the following degrees and licences in Medicine, Surgery, and Midwifery were conferred by the Right Honourable Judge Longfield, *pro* Vice-Chancellor:—

Licentiati in Medicinâ.—Hall, Jacobus Campbell; Manning, Georgius Henricus.

Licentiatus in Chirurgiâ.—Hall, Jacobus Campbell.

Baccalaurei in Chirurgiâ.—Adams, Johannes Jacobus; Battersby, Henricus Joseph; Booker, Gulielmus Arturus; Byrne, Gulielmus; Conolly, Johannes Vincentius; Crofts, Freeman Wills; Dobbs, Arturus Franciscus; Hamilton, Gulielmus; M'Cartie, Fredericus Fitzgerald; Malet, Henricus (*stip. con.*); O'Dwyer, Malachias; Sheppard, Rev. Henricus Drought; Thompson, Jacobus Eduardus.

Baccalaurei in Medicinâ.—Adams, Johannes Jacobus; Barton, Travers Boyne; Battersby, Henricus Joseph; Booker, Gulielmus Arturus; Byrne, Gulielmus; Cooper, Carolus Alfredus; Crofts, Freeman Wills; Dobbs, Arturus Franciscus; Hamilton, Gulielmus; Malet, Henricus; O'Dwyer, Malachias; Patterson, Johannes; Sheppard, Rev. Henricus Drought; Walsh, Gulielmus Butler; Whittle, Ewing Mould Glynn (*ad eund. Cantab.*).

Magistri in Arte Obstetriciâ.—Sinclair, Eduardus B. (*honoris causâ*); M'Clintock, Alfredus (*honoris causâ*); Macan, Arturus Vernon.

Magistri in Chirurgiâ.—Battersby, Henricus Joseph; Taylor, Sidney Hamilton; M'Dermott, Radolfus.

Doctores in Medicinâ.—Elliott, Thomas; Moran, Jacobus Joseph; Murphy, Jacobus; Popham, Samuel Lane; Porter, Joseph Franciscus; Sheppard, Rev. Henricus Drought; Thompson, Jacobus; West, Arturus Annesley; Wolseley, Cadwallader Brooke; Whittle, Ewing Mould Glynn.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, June 28:—

Gristock, William, 26, Blandford-square.
Johnson, William Henry, Hogsthorpe, Lincolnshire.
Marriott, Frederick Thomas, Western General Dispensary.
Marsh, Frank, Tillington, near Stafford.
Oxley, Alfred James Richard, Conisbro', Yorkshire.

The following gentleman also on the same day passed his primary professional examination:—

Burt, Alfred, Guy's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Greenfield, W. S., M.D., M.R.C.P.—Assistant-Physician to St. Thomas's Hospital, *vice* W. M. Ord, M.B., F.R.C.P.

James, Henry Godfrey, L.R.C.P.E.—Assistant Medical Officer to the East Riding Asylum, Beverley.

Ord, W. M., M.B., F.R.C.P.—Physician to St. Thomas's Hospital.

NAVAL, MILITARY, &c., APPOINTMENTS.

Admiralty.—Staff-Surgeon Samuel Campbell, M.D., has been promoted to the rank of Fleet-Surgeon in her Majesty's Fleet, with seniority of May 29, 1877. Staff-Surgeon William Harris Lloyd, M.D., has been promoted to the rank of Fleet-Surgeon in her Majesty's Fleet, with seniority of May 31.

Bengal Medical Establishment.—To be Surgeons-Major—Surgeons Kenneth M'Leod, M.D., James Cleghorn, M.D., John Bennett, M.D., Edward Barton Gardner, James Kelly, M.D., Lionel Dixon Spencer, M.D.

Madras Medical Establishment.—To be Surgeons-Major—Surgeons Alexander Porter, M.D., Samuel Bradshaw Hunt, William Smyth Fox, and David John McCarthy, M.D.

Indian Military Forces.—The undermentioned officers of her Majesty's Indian Military Forces to be granted a step of honorary rank on retirement:—To be Surgeons-General—Deputy Surgeon-General John Nicholas Tresidder, Bengal Army; Deputy Surgeon-General Charles Manners Smith, Bengal Army. To be Deputy Surgeon-General—Surgeon Major Edward McKellar, Bengal Army.

Militia Medical Department.—The undermentioned Surgeons to be Surgeons-Major, under the provisions of the Royal Warrant of July 12, 1876:—Charles Harwood (1st Derby), Alexander Leslie Gracey (Northumberland Artillery), Lyttleton Frederick Osbaldeston (Hertford), Stephen John Frederick Stafford (Norfolk Artillery).

War Office.—1st Regiment of Life Guards: Surgeon Thomas William Thompson to be Surgeon, *vice* Edgcombe Venning, who resigns his commission. Grenadier Guards: Surgeon George Ballingall Stuart, M.B., to be Surgeon, *vice* Surgeon-Major W. R. Lane, appointed Battalion Surgeon, Scots Guards. Scots Guards: Surgeon-Major Ralph Lane, from the Grenadier Guards, to be Battalion Surgeon, *vice* Surgeon-Major J. W. Trotter, retired on temporary half-pay. Medical Department: Deputy Surgeon-General Stanhope Hunter Fasson, M.D., from half-pay, to be Deputy Surgeon-General, *vice* N. Henry Stewart, M.D., deceased; Surgeon Major Thomas John Tucker retires upon half-pay; Surgeon-Major Curtiss Martin retires upon temporary half-pay; Surgeon-Major Edward Louis M'Sheehy, M.D., retires upon temporary half-pay; Surgeon-Major Reginald Croft Lever, M.B., retires upon temporary half-pay; Surgeon-Major Arthur Rudge retires upon half-pay; Surgeon Nugent Wade retires upon temporary half-pay. The Christian names of Surgeon Jackson, M.B., are "Thomas Wilson," and not

"Thomas" only, as hitherto stated. Surgeon-Major Arthur Rudge, who retires upon half-pay, to have the honorary rank of Deputy Surgeon-General; Surgeon Edward McCarthy, M.D., retired upon half-pay, to have the honorary rank of Surgeon-Major.

BIRTHS.

BARLOW.—On June 30, at Norfolk House, Albion-road, Dalston, the wife of Robert Barlow, M.R.C.S. Eng., of a daughter.

CLOTHIER.—On June 28, at 6, Ridgmount-terrace, Highgate, N., the wife of Henry Clothier, M.D. Lond., of a son.

GRIEVE.—On July 1, at Canje House, Berbice, British Guiana, the wife of Robert Grieve, M.D., of a son.

HAWARD.—On June 29, at 5, Montagu-street, Portman-square, the wife of Warrington Haward, F.R.C.S., of a son, stillborn.

MACSWINEY.—On June 23, at Dover, the wife of Eugene Valentine MacSwiney, M.D., A.M.D., of a son.

PAIRMAN.—On July 1, at 42, Robert-street, Hampstead-road, N.W., the wife of Robert Pairman, M.D., of a daughter.

PRINGLE.—On June 27, at Angelton, Bridgend, the wife of H. T. Pringle, M.D., Medical Superintendent of the Glamorgan County Asylum, of a son.

THOMPSON.—On June 24, at the City and County Lunatic Asylum, Stapleton, Bristol, the wife of George Thompson, L.R.C.P. Lond., M.R.C.S. Eng., Medical Superintendent, of a son.

MARRIAGES.

LEE—HUTCHINSON.—On June 26, at the parish church, Burnham, Henry Lee, F.R.C.S., of 9, Savile-row, W., to Marion, only daughter of William Hutchinson, Esq., of Grove-place, Burnham.

TEMPLETON—CAMPBELL.—On June 28, at Elderslie House, Largs, N.B., John Stewart Templeton, Esq., of Glasgow, to Emily Jane Fraser, third daughter of William Campbell, M.D., of Burnyside and 22, Cromwell-crescent, London, S.W.

THOMPSON—PAGET.—On June 30, at St. George's, Hanover-square, Henry Lewis Thompson, Rector of Iron Acton, Gloucestershire, late Censor of Christ Church, to Catherine, elder daughter of Sir James Paget, Bart.

TURNBULL—ROCHFORT.—On June 28, at St. Barnabas Church, Kensington, George Wardlaw Turnbull, M.D., of Exmouth, to Ellen, youngest daughter of the late Lieutenant Dalway, R.N., and widow of the late Colonel Rochfort.

DEATHS.

GOMPERTZ, W. F. L., F.R.C.S., late Surgeon 6th R.L. Militia, on June 23, aged 55.

HANKS, MARY ANN DINAH, wife of Henry Hanks, L.R.C.P. Edin. M.R.C.S. Eng., at 146, Mile-end-road, on June 26.

TURNBULL, SOPHIA, wife of Matthew James Turnbull, M.D., at Tweed View, Coldstream, on June 28, aged 51.

VACANCIES.

LADIES' CHARITY AND LYING-IN HOSPITAL, LIVERPOOL.—House-Surgeon. Applications, with testimonials, to the Honorary Secretary, at the Hospital, Myrtle-street, Liverpool, on or before July 9.

ROYAL FREE HOSPITAL, GRAY'S-INN-ROAD.—Junior Resident Medical Officer. Candidates must be possessed of a medical or surgical qualification from one of the Examining Boards of the United Kingdom. Applications, with testimonials, to the Secretary, on or before July 11.

SEAMEN'S HOSPITAL, GREENWICH.—House-Surgeon. Candidates must be Fellows or Members of the Royal College of Surgeons of England, unmarried and under the age of thirty years. Applications, with particulars of professional qualifications, and references as to moral character, to the Secretary, on or before July 12.

WEST KENT GENERAL HOSPITAL, MAIDSTONE.—Honorary Physician. Candidates must be Doctors or Bachelors of Medicine of some University of Great Britain or Ireland, or Fellows or Members of the Royal College of Physicians in London. Applications, with legal testimonials and certificates of competency and character, to the Secretary, at 16, Knightrider-street, Maidstone, on or before July 12.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Lexden and Winstree Union.—Mr. C. J. Worts has resigned the Ninth District; area 11,530; population 3208; salary £90 per annum.

APPOINTMENTS.

Alresford Union.—Charles E. Covey, M.R.C.S., L.S.A., to the First District and the Workhouse.

Bolton Union.—George L. Latour, M.D. Ire., M.R.C.S. Eng., as Resident Assistant Medical Officer at the Workhouse.

Isle of Wight Union.—James M. Williamson, M.C. and M.D. Edin., to the Godshill District.

Penistone Union.—Alex. G. Duncan, M.B., C.M., L.R.C.P. Edin., to the Denby District.

COMPARATIVE LONGEVITY.—Official documents establish that, per million inhabitants, there will be found 71,602 who have attained their sixtieth year in Italy, 72,910 in Great Britain, 76,982 in Holland, 78,187 in Sweden, 86,657 in Denmark, 88,432 in Belgium, and 101,495 in France. Of centenarians there are 15 per million in Great Britain, 7·3 in France, 7 in Belgium, 2·6 in Sweden, and 1·3 in Holland. Women furnish most examples of this prolonged longevity.—*Lyon Méd.*, July 1.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Sigma.—According to M. Léon Duprat, beer is a more ancient drink in France than is generally supposed. It was adopted by the ancient Gauls from Germany. St. Louis subjected the brewers, together with the chief corporations then existing, to special statutes and regulations of their own. In the sixteenth century there were two sorts of beer brewed in France—the "*bière des convents*" for nuns, and the "*bière des pères*" for monks. In Louis XIV.'s time there were seventy-eight breweries in Paris. The Exhibition of 1867 gave a great stimulus to the consumption of beer in Paris.

A Fellow by Examination.—Mr. Savory was one of the eight candidates for the four vacant seats in the Council of the College of Surgeons in 1873, when Sir James Paget headed the poll with 200 votes; Mr. Walton, 136; Mr. Southam, 113; and Mr. Marshall, 106,—who were duly elected. Mr. Forster, since elected a member of the Council, was only one below Mr. Marshall, viz., 105; Mr. Savory, 97; Mr. Hird, 62; and Mr. Hussey, 29. At the election in 1871 Mr. Spencer Wells headed the list with 131; Mr. Critchett, 130; Mr. Clark, 127; Mr. Busk, 117; Mr. Holt, 104; and Mr. Cock, 74.

Mr. Mitchell.—The late Mr. Jones, of Jersey, removed the scapula only from his patient, whom he left with a useful arm. The preparation is in the Museum of the College of Surgeons.

An Old Subscriber.—The "Pencillings" in this journal were written by the late Dr. J. R. Lynch, under the *nom de plume of* "Probe."

Associate.—Professor Henry Smith, of King's College, was admitted a Fellow by examination on December 7, 1849. He was asked, but declined to come forward on the present occasion for a seat in the Council.

A Pupil.—"Lessons in Elementary Anatomy," by Mr. S. G. Mivart, will give you the desired information.

Juventus.—The Census of France is taken every five years, and not, like that of the United Kingdom, at decennial periods. But on the last occasion the war and the disturbances which followed it interrupted the ordinary course of these inquiries, and an interval of six years elapsed—*i.e.*, between the Census of 1866 and the Census of 1872.

Vegetarian.—Of esculent plants the watercress is one of the oldest known. It is said to have been eaten by the ancients along with lettuces to "counteract the coldness" of the latter by their stimulating qualities. Nicholas Meissner, of Erfurt, it is stated, made—about the middle of the sixteenth century—the first effort at cultivating cresses artificially, and to this day Erfurt is celebrated for its *Kresse*, supplying most of the Rhine towns with it. In the neighbourhood of London watercress culture was first commenced at Northfleet, near Gravesend.

Dr. Daniell.—The Mr. Robert W. Keate who was appointed the Governor-in-Chief of the West African Settlements was a son of Mr. Robert Keate, of Albemarle-street, Surgeon to St. George's Hospital, and twice President of the Royal College of Surgeons.

A Naval Surgeon.—The egg of the great auk is very scarce; duplicates, belonging to the College of Surgeons, were sold at Stevens's a few years ago for thirty guineas each.

Mr. Williams.—The late Mr. George Cooper, F.R.C.S., was re-elected Master of the Society of Apothecaries in 1868. He died last week in the eighty-fifth year of his age. His son, Mr. Clarence Cooper, of H.M.'s Indian Army, is a Fellow of the College by examination.

Dr. Hamilton.—It was the custom of the ancients to place coins on the eyes of the corpse when buried, called "Charon's penny." The following lines on a notorious quack were written by a well-known satirist:—

> "This quack to Charon would his penny pay;
> The grateful ferryman was heard to say—
> 'Return, my friend, and live for ages more,
> Or I must haul my useless boat ashore.'"

Inspector-General.—You have been correctly informed, that, not having signed the by-laws of the College since your election as a Fellow, you could not vote at the annual election yesterday. Mr. Allingham, the Honorary Secretary, would, however, have admitted you to the Fellows' Festival had you applied to him.

AN ADVERTISEMENT.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—The following advertisement appeared in the *Daily News* of July 2:—

"Town Traveller.—A gentleman, with a first-class business amongst bakers and confectioners in London and suburbs, has time for an additional engagement. The advertiser is thoroughly conversant with the drug trade, and has a connexion.—Address," etc.

I call your attention to it, for these things ought not to be. Your valuable journal can do much by exposing the infamous practices that are going on in the adulteration of our food. We know too well the deleterious compounds that are sold at confectioners' and other shops; but if medical men were to take up the question and sift it to the very core, there is but little doubt that we should be a better and happier people. I trust you will not think the question insignificant, but do something for poor humanity's sake. I am, &c. A FRIEND.

Broadstairs.

Kenneth.—We believe the pauper boarding-out system in Scotland is a conspicuous success.

STREET NOISE IN THE OLDEN TIME.

Taylor, the water poet, when there were only some dozen hackney-coaches and a few private carriages, writes:—"I pray you but ask the streets and the chambers or lodgings in Fleet-street or the Strand how they are pestered with coaches, especially after a masque or play at the Court, where even the very earth shakes and trembles, the casements shatter, tatter, and clatter, and such a confused noise is made, so that a man can neither sleep, speak, hear, write, or eat his dinner or supper quiet for them; besides, their tumbling din—like a counterfeit thunder—doth sour wine, beer, and ale most abominably, to the impairing of their healths that drink it."

THE RAINFALL IN THE BRITISH ISLES IN 1876.

We learn from Mr. Symon's report "On the Distribution of Rain over the British Isles during the Year 1876," that the rainfall was greater by 14 per cent. than the average from 1810 to 1869, or sixty years, and that the excess was largest in England and Wales, while Ireland had only a small excess of rainfall. The special characteristic of 1876 was the absence of heavy individual rains, the heavy falls being rather less than usual, though very near the average. As compared with that of 1875, the rainfall of 1876 was greater in some counties than in others, as is usually the case. The information will no doubt be found interesting to observers.

COMMUNICATIONS have been received from—

Mr. R. BRUDENELL CARTER, London; Mr. JOHN CHATTO, London; Mr. GEORGE BROWN, London; Messrs. FELTOE and SONS, London; Mr. BARTLEET, Birmingham; REGISTRAR OF APOTHECARIES' HALL, London; Messrs. BAILEY and SON, London; Dr. L. SEDGWICK, London; Dr. MADDEN, Dublin; Mr. KEMP, London; Dr. H. THOMPSON, London; Dr. SIEVEKING, London; Dr. DOWSE, London; Dr. CARTER, Liverpool; A FRIEND, Broadstairs; Dr. STIRLING, Edinburgh; Dr. J. W. MOORE, Dublin; Dr. PAVY, London; Mr. J. BOOTH, London; Dr. HETLEY, Norwood; Dr. J. W. WAKLEY, London; LIBRARIAN OF CHARING-CROSS HOSPITAL; Dr. W. S. GREENFIELD, London; Mr. T. M. STONE, London.

BOOKS AND PAMPHLETS RECEIVED—

APPOINTMENTS FOR THE WEEK.

July 7. Saturday (this day).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

9. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

10. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

11. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

12. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

13. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, June 30, 1877.

BIRTHS.

Births of Boys, 1129; Girls, 1162; Total, 2291.
Average of 10 corresponding years 1867-76, 2171·9.

DEATHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·99 in. The lowest reading was 29·82 in. at the beginning of the week, and the highest 30·09 in. on Thursday morning.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

SELECT LECTURES ON MEDICAL JURISPRUDENCE.

By FRANCIS OGSTON, M.D.,
Professor of Medical Logic and Medical Jurisprudence in the University of Aberdeen.

LECTURE XVII.

WOUNDS—*Continued.*

6. "POISONED WOUNDS," *which should come next in order, will be reserved for consideration under* "TOXICOLOGY."

7. *Burns*, to which I have now to call your attention, though, in general, sufficiently characteristic to admit of being classed apart from the injuries previously considered, vary amongst themselves to a considerable extent with the producing cause, whether that cause has been an elevated temperature, either in the form of dry heat, or through the medium of liquids or of incandescent bodies. The varying effects of heat on the body have been differently classified by surgical writers, those effects rising in severity, from the mere reddening of the surface, to the destruction of the deep-seated parts.

I purposely here exclude the injurious effects of certain irritant and escharotic substances, which are capable of giving rise to consequences not unlike the agencies which owe their injurious or destructive properties to the mere elevation of their temperature, but which are not likely to be readily confounded with burns, strictly so called; unless we take in the sequelæ of both the one and the other, when the diagnosis may become impossible from the similarity or identity of their effects.

Injuries of this class are only liable to come within the province of the medical jurist when called on to determine—(1) whether, when death had followed their production, they had in any particular instance been the cause of death; or (2) whether, when found on the dead body, they had been inflicted during life or only after death.

Death following burns may take place in two different ways. Severe and extensive burns, particularly in the young, may destroy life from the depression of the nervous system, owing to the number of cutaneous nerves injuriously affected; or, where the party has escaped this first danger, he may perish, at a later period, from the inflammatory reaction, and its usual consequences—extensive suppuration and hectic fever—even where he has escaped some of the intermediate consequences.

Little difficulty is likely to arise, in the inspection of the dead body, as to the connexion of certain morbid appearances in its interior with injuries of this class, present on its exterior, dating before the extinction of life. It is where the appearances on the dead body, characteristic of burns, are met with on its exterior, that the inquiry may originate—Could these have been produced on it before death? Instances of this sort are referred to by Foderé, Taylor, Christison, and Caspar, where death had been the result of violence, and fire had been subsequently applied to the corpse, to conceal the murderer's deed, and to suggest the idea of accidental *death by fire.*

The data possessed by us for the satisfactory settlement of the point as to whether certain appearances on the surface of the dead body, of a characteristic sort, ought to be regarded as of vital or only of post-mortem origin, are derived from the researches of Christison and Taylor, the results of which, with some minor differences, are substantially in agreement.

According to Sir Robert Christison, "of the effects which follow the application of heat to the living body, the most immediate is (1) a blush of redness around the burnt part, removable by gentle pressure, disappearing in no long time, and not permanent after death. Next to this in order," and following almost simultaneously, is (2) "a narrow line of deep redness, separated from the burnt part by a stripe of dead whiteness (bounded towards the white stripe by an abrupt line of demarcation), passing at its outer edge by insensible degrees into the diffused blush, but not capable of being removed, like it, by moderate pressure." This line of redness may be seen, he states, after the application of the actual cautery. The phenomenon which follows these is (3) the appearance of blisters, which, when the agent is a scalding fluid, generally appear in a very few minutes in the living, or may be delayed for hours when the scalds are extensive, as in young children; while, when the agent is an incandescent body, this appearance is not of such invariable occurrence, though often observed very soon after an ordinary burn from the clothes catching fire.

A line of redness near the burn, not removable by pressure, and blisters filled with serum, Sir Robert Christison considers as "certain signs of a burn inflicted during life." In a series of experiments in bodies dead from ten to thirty minutes, he failed to produce such appearances by boiling water, by a hot poker, or by cauterising irons.—(*Edin. Med. and Surg. Jour.*, vol. xxiv., pages 320-23, *pass.*)

A repetition of the experiments of Christison by Dr. Taylor led him to the same results and the same conclusion, though he warns us that *the absence* of the appearances thus relied on as vital does not point with certainty to the opposite conclusion. Caspar, after repeating and varying Christison's and Taylor's experiments on the dead body, failed to produce redness or serous vesication; and strongly asserts that "it is quite impossible to confound a burn inflicted during life with one inflicted after death."—("For. Med.," vol. i., page 302.)

This last author has met and combated the assertion of Leuret, that in anasarcous subjects vesications filled with serum may be caused by heat in the dead body twenty-four hours after death.—(*Ann. d'Hyg.*, vol. xiv., page 371.)

The only qualifications of the above conclusions of Christison and Taylor I would be disposed to make are (1), that not only must we take into account the occasional *failure* (as admitted by Christison), under certain circumstances, of vesication after vital burns, but also *the non-occurrence*, in some instances, of the redness of the burnt part; and (2), that *vesication without* accompanying *redness*, on a dead body, would not suffice to authorise the conclusion of *a burn during life*, as such blisters are met with after pemphigus in the living, and in the corpse from the progress of putrefaction.

My attention was called to the first of these points by the occurrence in police practice of the following case:—A woman was found at the Links (Aberdeen), in a state of insensibility from cold. Among other means adopted for rousing her, tin flasks filled with boiling water were applied to her feet and sides. On examining her two hours after, the cloths in which the jars were wrapped were found to have slipped aside at the chest, and the cuticle on the insides of both forearms was seen to be shrivelled and loose, but with entire absence of redness and vesication at these parts. She was at the time still insensible, with the pulse at the wrist barely perceptible. It was only next morning, when she had completely recovered from the effects of the cold, that the insides of the forearms were noticed to be largely blistered, and the blisters surrounded with broad patches of redness. It must be seen in this instance, had recovery not taken place, that the appearance of the arms, at the first visit, would have indicated post-mortem, not vital burns.

In connexion with the subject of burns, it may not be out of place here to notice the alleged occurrences of what has been termed *spontaneous human combustion*, and the occasional *preternatural combustibility of the human body.*

The first of these points may now be safely set aside as inadmissible, notwithstanding the high authority of Orfila and Devergie in its favour, and some cases advanced previous to their time, in proof, as it was believed, of such spontaneous combustion.

The second point, the occasional *preternatural combustibility of the body*, is also believed by our best writers on medical jurisprudence to carry with it its own condemnation. The arguments in its favour rest upon the occurrence at times of such cases as the following, which, with a similar one, came under my own notice in 1869:—A woman of sixty-six, of intemperate habits, was left in her house alone at 10 a.m. At eleven (an hour after) her body was found on the third step of the stair

near the kitchen, the step on which the corpse rested and one of the spokes of the wooden hand-rail being charred, as were the seat of a chair and a small portion of the front of a straw mattress on a bed, in the kitchen on the same floor, and adjoining the staircase. Contrasted with this moderate amount of combustion of the surroundings of the woman's body was the extent of its effects on herself. On the front of the head and face the absence of the soft parts left the exposed bones blackened and calcined. On the back of the neck and chest patches of a greasy charcoal were found here and there, and beside them the spinal column and several of the ribs exposed and burned black. The abdominal wall was wanting; the intestines a burned and blackened mass; and the surface of the liver calcined. "The upper limbs" were "distorted, the elbows strongly flexed, and everywhere charred to a great depth, the bones, however, even the fingers, preserving their position. The right thigh had its deeper muscles still uncharred, but presenting the appearance of roast beef, very dry. The skin and superficial muscles were totally burnt away. The right leg, only partially attached to the thigh, was entirely converted into a greasy, black, charred mass, even the bones not escaping." "The right foot, totally detached from the leg, had been changed into a soft, black, greasy, and shapeless cinder. The left thigh, leg, and foot in a condition similar to the right. Not a vestige of clothing remained anywhere." This case was published, from our notes of the judicial inspection, by my then assistant, in the forty-fifth volume of the *British and Foreign Medico-Chirurgical Review* (pages 191-92). An elaborate study of the subject proves, in the opinion of the reporter, the occasional preternatural combustibility of the body, a point in which I am disposed to agree with him, notwithstanding the ingenious attempts to explain any such instances as the above. That the combustion in this case had originated from a few smouldering ashes in the kitchen grate can scarcely be questioned, but appears to me to be insufficient to account for the fact of such extensive destruction of the body from the limited amount of combustible matter *ab extra*, without assuming that the body was in a condition unusually favourable for, and predisposed to, the feeding at its own fire, particularly when we consider the well-known fact of the difficulty experienced in its destruction by combustion.

The question, however, of the occasional preternatural combustibility of the human body, is one which I think should still be considered as *sub judice*.

(8). Of *Dislocations* it would be waste of time to speak, as on this subject I have nothing to add to what is to be found in ordinary surgical treatises.

Lastly. As regards *Fractures*, one or two medico-legal points require to be adverted to, arising out of the mode of their production.

In the first place, then, we are not to set down fractures in every case as *necessarily the result* alone *of external violence*. On the contrary, they have been known, occasionally, to arise from muscular action, either ordinary or violent. Under *Infanticide* I adverted to cases of such injuries occurring spontaneously in *the fœtus in utero*. Nor are such so-called spontaneous fractures unknown *in adults;* either as the result of violent muscular efforts on healthy bones, or of slighter muscular contractions, or insignificant or unknown causes, in rickety subjects.

A case of this last sort occurred to a carter in town, a few years ago. He had extensive comminuted fractures of both femurs from jumping down from the shaft of his cart; and on previous occasions fractured limbs from equally slight causes.

It has been laid down by Caspar that *severe and extensive fractures* met with *in the dead body* afford *a presumption that such fractures took place during life;* and that "an amount of force, which, if applied during life, would indubitably have produced fissures, if not fracture or complete smashing of the skull, leaves the dead skull quite uninjured."—("For. Med.," vol. i., page 245.) This, it may be observed, however, is contrary to what is asserted in surgical works.—("Holmes," vol. ii., page 36.)

As regards *the presence or absence of effused blood in the vicinity of fractures in the dead body*, difficulty will be experienced by the medical jurist in determining, in this way, the date of the injury. The test which alone has to be relied on with undoubting confidence, in proof of the fracture having been caused during life, is the commencement, at the part, of the restorative process. The presence of *coagulated blood* betwixt the interstices of the fractured bones was formerly held to indicate a fracture in *the living* as distinguished from one in *the dead body*, but this sign only proves that the injury took place *recently before* or *recently after death*. Should the evidence establish that the fracture must have been produced *during life*, or *many hours* after death, then the discovery of coagula of blood between the fractured ends of the bone would at once decide the case; for after the cooling of the body, it is altogether improbable that any blood effused should then coagulate, notwithstanding the strange assertion to that effect by Caspar, formerly adverted to. The fact should be borne in mind, however, that, though rarely, *blood has been found effused around fractures in the dead body;* while again, as I had occasion to notice formerly, *fractures followed by instant death* may give rise to little or no effusion of blood.

It occasionally happens that blows or falls of no great severity will cause fractures of a severe or fatal kind, only admitting explanation by attention to circumstances.

In a case examined by me, in 1839, death from diffuse suppuration took place on the seventh day after a blow on the shoulder, producing a comminuted fracture of the head of the humerus, which, at the inspection, proved to be made up of cancelli, covered with a shell almost as thin as paper. In another case, in November, 1840, a fissure, commencing at the temple, branching off in different directions at the base of the skull, and following a large effusion of blood inside the dura mater, led to the death of a man who had in a scuffle either received a slight blow or lost his balance and had fallen on soft ground (it was not certainly known which). The skull in this instance was unusually thin and diaphanous. In a third case, in January, 1857, a man was seen to go into a granary at Ythsie (Aberdeenshire), taking with him a bottle of whisky. An hour after, he was found insensible on the stone floor, and died in a few minutes after. It was conjectured that he had lain down on the drying-floor at one end of the building, six inches above the general level, and, when attempting to leave it by some steps, had fallen forwards on the stone floor. On inspecting the body, along with Dr. Irvine, of Tarves, we detected a comminuted and depressed fracture of the frontal bone; two linear fractures—one running from the left temple across the top of the head, downwards through the right temporal bone, and ending in the foramen lacerum anterius, with branches in different directions; the other from the summit of the head to the base of the skull on the opposite side; a linear rent two inches and a half in length and averaging a quarter of an inch in depth across the upper and fore part of the interior of the left cerebral hemisphere; a transverse fracture of the sternum; and a fracture of one rib. In this instance the man was a thick-set, bulky, and heavy person, which, with probably a considerably added momentum from a run forwards, may explain the extent of the violence from such a short fall. A case almost parallel was examined in 1854, after a fall from the quay of our harbour; but in this instance the fall had been from nine to ten feet. Occurrences like these present but few difficulties to the medical jurist, though, as far as regards the injuries to the cranium, such effects of falls are not uncommon, even where the height had not been great. In October, 1857, I was present at an inspection by my assistant, where a workman had perished, seven hours after a fall down six steps of a stair, from extensive fractures of the base of the skull.

Further, I may remark on this subject, that though it can only be on the rarest possible occasions that we are in a position to determine from the appearance of a fracture of bone, independently of its attendant injuries, the amount of violence it has received, or the character of the instrument by which it has been inflicted, yet such exceptional cases may occasionally be encountered. We have seen, for instance, under gunshot wounds, that a ball discharged at point-blank distance will traverse the cranium, leaving the entrance and exit openings of regularly rounded forms, free from splinters, and the former especially nearly of the size of the projectile which had passed through the cranial vault. What is more to the point to observe here, as being still rarer, is, that the size and shape of a fracture, inflicted by a blunt body with considerable violence, may sometimes correspond to the size and shape of the striking part of the instrument which has been employed. Thus, in the case of murder at Cairnhall in 1864—referred to under "Identity" in connexion with the footprints of the murderer—the fatal blow with the back of an axe had penetrated the skull, leaving the fractured and depressed portions of a four-sided shape, and of the length and breadth of the back of the weapon. Again, in the case of a young man tried for the murder of his mother, in Aberdeen, in June, 1867, the same

correspondence was encountered in two depressed fractures of the left frontal and temporal bones, inflicted with the head of a hammer.

This brings me to the consideration of a subject rising out of these concluded, viz.:—

Blood-stains and their verification—a topic of considerable importance to the medical jurist, and one which has of late attracted the attention of chemists and microscopists to a large extent.

The duty of verifying the character of stains, suspected to have been caused by blood, falls to the medical jurist on different occasions. Thus, where a person has been found dead from wounds inflicted by another, and where an instrument is detected in the possession of, or which had been known to have belonged to, the suspected murderer, *with red stains on it;* or where *such stains* are found *on the clothes or person of the accused*, it may be of importance to the proof of his guilt that these stains are shown to have been actually produced by blood.

The appearance of blood *so recently effused as to be still liquid* is so *characteristic* as to leave but little room for hesitation or doubt as to its nature. But where the homicide has been effected some time prior to the examination; where the blood with which the clothes or the instrument is stained has had time to dry up; or where the instrument has been partially cleaned or the clothes attempted to be washed,—it must often be a matter of doubt, in the mere view of these, whether they are owing to blood or some other red matter.

Before proceeding to the more particular examination of suspected blood-stains, their general appearance should be carefully noted, attention being directed to their position, number, configuration, size, amount, disposition of colour, and other particulars. By this means it may sometimes be ascertained whether the blood has flowed continuously or in jets—*i.e.*, from a vein or an artery; whether it has come directly from a wound, or merely from contact with blood previously effused in another situation. Blood, too, which has escaped from an incision *at or after death* may thus be occasionally distinguishable from the blood which has escaped *earlier from the fatal wound.* Further, it is possible at times to determine in this way the position of the parties—*i.e.*, of the wounded man and his assailant—at the time when the wound was inflicted.

Thus, in an interesting English case reported in the London *Medical Gazette*, vol. lxvii., page 612, a woman was found dead at the foot of a stair, with fractures of the skull and vertebral bones, and a branch of the temporal artery divided. That, in this case, the wound of the artery had not been caused by the fall was clearly brought out by the discovery of jets of blood on the wall at the top of the stair, four or five feet from the floor, such as must have come from an artery during life.

In a case of murder which I investigated at Glenmillan in 1869, the locality of the fatal blow was brought out in the same way. The man's body was found in a field about thirty yards from the nearest house. His skull was beaten in, apparently by some ponderous weapon, such as the back of an axe. But though the quantity of blood at the place showed that he had perished at the spot where his body was discovered, yet the finding of jets of blood on the side posts of the door of the house, and on the plaster of the wall in its vicinity, at the height of four or five feet from the ground, pointed out the house-door as the place where the injury had been inflicted.

In the further case of the death of the woman at Cluny, formerly referred to, from a wound in the temporal artery, by following out this line of observation it came out very clearly that the deceased had been in bed when she received the wound; that after she had bled there for some time she had got up and found her way through a passage to the kitchen; that after groping about for a little she had succeeded in lighting a candle, had gone back to the bedroom, and returned to bed.

Again, in a case of murder at Cults, to which I shall have to recur, two wounds in the genitals were found to have been inflicted after a large proportion of the blood in the body had escaped through a deep incision in the throat. This was ascertained from the observation of the circumstance that the effusion from the genital wounds consisted merely of reddish serum which had gravitated from the wounds directly downwards while she lay on her back, the posture in which the body was found.

(*To be continued.*)

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

LECTURE I.—ON REFRACTION.

(*Concluded from page* 11.)

THE lenses used for spectacles, at the time when the principles which should govern their employment were first investigated with scientific accuracy, were commonly distinguished by arbitrary numbers. A manufacturer made twelve different powers, and he numbered them from 1 to 12 consecutively as a matter of convenience. In optical researches, lenses had long been described by their focal lengths expressed in inches; and Donders, when he first published, adhered to this nomenclature, and employed a scale which had a lens of one inch focal length as its unit. Putting aside a few very rare exceptions, a lens of two inches focal length is the strongest that is ever required in ophthalmic practice, and this is only one-half of the inch unit. Hence, Donders launched us at once upon a system of fractional expression. According to his original nomenclature, a lens of two inches focal length was $\frac{1}{2}$, a lens of twenty-four inches focal length was $\frac{1}{24}$, and so on throughout the whole series, which comprised twenty-five pairs of convex, and the same number of concave lenses, of the powers shown under "focal length" in Table I.

TABLE I.—*Inch Scale of Test-Lenses.*

Focal length in inches.	Intervals.	Focal length in inches.	Intervals.
2		11	
	$\frac{1}{10}$		$\frac{1}{132}$
$2\frac{1}{2}$		12	
			$\frac{1}{84}$
3		14	
		16	
$3\frac{1}{2}$		18	
4			$\frac{1}{180}$
		20	
$4\frac{1}{2}$			$\frac{1}{120}$
	$\frac{1}{45}$	24	
5			$\frac{1}{120}$
	$\frac{1}{30}$	30	
			$\frac{1}{180}$
6		36	
			$\frac{1}{200}$
7		40	
			$\frac{1}{200}$
8		50	
			$\frac{1}{300}$
9		60	
			$\frac{1}{240}$
10		80	

It was found before long that the use of this series was attended by the gravest practical inconveniences. In the first place, it is often necessary, in estimating degrees of astigmatism, or in determining the power which should be given for working at some specified distance, to add or to subtract one lens to or from another. This necessarily involves the addition or subtraction of fractions—an operation which many people cannot perform correctly without (and some not even with) the aid of pencil and paper, and which, in the consulting-room or the out-patient department, is very troublesome and inconvenient, always occupying time which might be better employed. So much was this the case that Dr. Schobbens actually worked out and published in the *Annales d'Oculistiques* for 1867, a table of reciprocals, by which

such calculations were to be faciliated. The second objection was that the steps of the series were irregular, no two of them being separated by the same interval, and many of the intervals being widely different. The right-hand columns of Table I. show some of the optical intervals between lenses which stand next to one another in the series; and you will see, for example, that while the first half-inch interval (that between $\frac{1}{2}$ and $\frac{1}{2\frac{1}{2}}$) is equal to a lens of $\frac{1}{10}$, the last half-inch interval (between $\frac{1}{4\frac{1}{2}}$ and $\frac{1}{5}$) is equal to a lens of $\frac{1}{45}$. The first inch interval (between $\frac{1}{5}$ and $\frac{1}{6}$) is equal to a lens of $\frac{1}{30}$; the last inch interval (between $\frac{1}{11}$ and $\frac{1}{12}$) is equal to a lens of $\frac{1}{132}$. The first two-inch interval (between $\frac{1}{12}$ and $\frac{1}{14}$) is $\frac{1}{84}$; the last (between $\frac{1}{18}$ and $\frac{1}{20}$) is $\frac{1}{180}$. The first four-inch interval (between $\frac{1}{20}$ and $\frac{1}{24}$) is $\frac{1}{120}$; the last (between $\frac{1}{36}$ and $\frac{1}{40}$) is $\frac{1}{260}$. The interval between the two strongest lenses has already been stated to be $\frac{1}{10}$; that between the two weakest is $\frac{1}{240}$. There is no attempt at any kind of optical regularity; and the intervals are nothing but a succession of anomalies. The last, and perhaps the most important, objection rested upon the want of uniformity among the inches themselves. Lenses are made and measured in three countries—England, France, and Germany; and the inches of these three countries are not coincident. The Paris inch exceeds the English by one-sixteenth; and this difference, in some of the higher powers, is too considerable to be disregarded. A lens of four Paris inches is equal to an English four and a quarter, and a lens of eight Paris inches to an English eight and a half. If a surgeon prescribes in Paris inches, and the patient receives a lens measured in English inches, the intentions of the prescriber are not precisely carried out; and the difference, especially with very sensitive eyes, or in the correction of astigmatism, is sometimes highly important. Moved by these considerations, the International Congress of Ophthalmology decided in 1867 to appoint a committee to report upon the question; and, in 1872, having received the report, to adopt a metrical scale; but there were many obstacles to be overcome before this decision could be carried into effect. In the first place, the manufacturers of lenses rebelled against the proposal as a matter of commerce, and objected so strongly to having their inch grinding tools rendered obsolete, that at one time metrical lenses could not be procured. I obtained a set myself, nine years ago, from Paetz and Flohr, of Berlin; but both they and the Paris makers, so lately as in 1874, refused to supply another set, or even to make good some breakages in that which I possessed; and, in consequence of this refusal, I still described inch lenses in the treatise on Diseases of the Eye which I published in the following year. Ever since 1868 I have had the great practical convenience of working with metrical lenses; but I was obliged to translate them into inches in prescribing. A second difficulty arose from the fact that there was not complete agreement as to the nature and the divisions of the metrical scale which would be most convenient in practice; but both these difficulties were at length removed by Professor Donders, who announced, last year, that Dr. Snellen and himself had agreed upon a convenient scale, and that they had persuaded a Paris optician—Roulot, of 3, Rue des Vieilles-Haudriettes—to manufacture and supply the lenses. Professor Donders came to this country and delivered a lecture explanatory of the new system at Moorfields. To this lecture the leading London opticians were invited; and, since it was delivered, the practice of prescribing in the metrical scale has become common.

Table II.—*Metrical Scale of Test-Lenses: Number of Dioptrics.*

20·0	13·0	8·0	4·50	2·50	1·25
18·0	12·0	7·0	4·0	2·25	1·0
16·0	11·0	6·0	3·50	2·0	0·75
15·0	10·0	5·50	3·0	1·75	0·50
14·0	9·0	5·0	2·75	1·50	0·25

In this scale, the lenses of which, thirty in number, are enumerated in the above table, the unit is a lens of one metre focal length; and this unit is called a *Dioptric*. We take as our unit, you will observe, a weak lens instead of a strong one; and the first result of this arrangement is that our other lenses are multiples of the unit instead of being parts of it. The lens of one metre focal length, or the one dioptric, being No. 1 of the series, No. 2 is a lens equal to two of the former—that is, it is of double the power of the dioptric, or of half the focal length. It is two dioptrics, and its focal length is half a metre. No. 3 is equal to three dioptrics—that is, its focal length is one-third of a metre. Throughout the series every whole number expresses the number of dioptrics to which the lens so numbered is equal; and hence, from whole number to whole number, all the intervals are the same. There is a difference of one dioptric between No. 6 and No. 7; and there is equally a difference of one dioptric between No. 1 and No. 2. This difference, however, is sometimes too great for practical purposes; and hence a few quarter and half dioptrics have been added to the lower powers of the scale. These introduce the simple decimal fractions 0·25, 0·50, and 0·75; but these fractions are so easily manipulated that they cause no inconvenience. A quarter dioptric is a lens having a focal length of four metres; a half dioptric has a focal length of two metres; and three-quarters of a dioptric has a focal length of one metre and one-third. A glance at the table will show that the quarter dioptrics of the series go up to No. 3, and the half dioptrics to No. 6. For higher powers, such fine divisions are not needed; but if they were needed, the uniformity of the scale affords a ready means of supplying them. If I want a lens of six and a half dioptrics, or of eight and a half dioptrics, I have only to place 0·50 as an addition to 6 or 8, and my requirement is at once fulfilled. In describing these lenses, as with those of the old scale, it is customary to indicate convexity by the *plus* sign, and concavity by the *minus* sign. Thus, + 2·0 is a convex of two dioptrics; — 3·0 is a concave of three dioptrics.

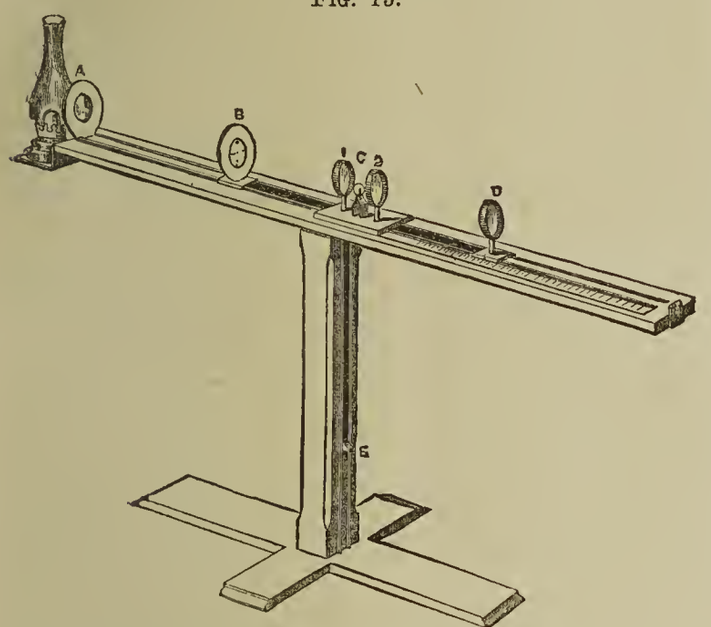
We have been so much accustomed to think of the degrees of ametropia in inches, that a little practice is required before we are quite at home with the new nomenclature; and, in hearing of a myopia of five dioptrics, one is tempted at first to ask how much that means on the old scale. It will greatly facilitate the necessary translation of the thoughts, if we consider that a metre is equal to 39·337 English inches; that is, for all practical purposes, it is equal to forty inches. This means, using English instead of Paris inches, that the dioptric is the old $\frac{1}{40}$; the No. 2 is the old $\frac{1}{20}$; the No. 4 is the old $\frac{1}{10}$. At the extreme end of the scale we have the lens of a quarter dioptric, equal to one of 160 inches, and only half the strength of the weakest of the inch series. Next, we have the half dioptric, equal to a lens of 80 inches. Next, we have the three-quarters of a dioptric, equal to a lens of 53 inches. Coming to the higher powers, we find many coincidences, the chief of which are indicated in Fig. 12, where the line represents a metre. One dioptric coincides with 40 inches; 2 dioptrics coincide with 20 inches; 3 dioptrics coincide, nearly

Fig. 12.

with 13 inches; 4, with 10 inches; 5, with 8 inches; 8, with 5 inches; 10, with 4 inches; and so on throughout. If we wish to translate dioptrics into Paris inches, we must consider the metre equal to 36 inches instead of to 40. The coincidences obtained by either method are important, as showing that the difficulties raised by manufacturers were almost entirely imaginary, because every glass ground on the old tools has its proper value on the dioptric scale, and all that is necessary is to define and register this value. In order to facilitate such determinations, Dr. Snellen has invented a very ingenious instrument, to which he gave the name of "phakometer," or lens-measurer, and which is shown in Fig. 13. It is based upon the principle that, when an object and its image formed by a convex lens are of equal size, object and image are equidistant from the lens, and are both separated from it by an interval equal to twice its focal length. The instrument consists of a foot, supporting an upright pedestal, which carries a horizontal bar eighty-six centimetres in length. At one end of this bar is a small shelf, which supports a lamp; and the flame of this lamp is in the principal focus of a lens (A), which therefore transmits parallel rays. The luminous object is a black metal

screen (B), pierced with several holes, and covered with ground glass. The holes are arranged in the form of a cross, and are illuminated by the parallel rays already mentioned. The screen (D) on which the image is received consists of ground glass, and has on it black dots, which correspond accurately with the little openings on the screen, but are reversed in position. The luminous object and the screen are moved by the same mechanism, so that they can be made to approach or to recede from a lens placed between them, at the centre of the bar, at an equal rate. Each is affixed to one extremity of a thin very flexible steel ribbon, which runs along the track on which object and screen move, and which descends into the upright on which this track is supported. The centre of the ribbon is secured to a movable button (E), so that pushing the button upwards causes the distal extremities of the steel band to pass in opposite directions along the track; while pulling it down brings them nearly together in the centre, followed, of course, by the object and by the screen.

Fig. 13.



The lens to be examined is held in a clip (C), consisting of two metallic rings placed in the centre of the apparatus, midway between the luminous object and the screen. One of these rings has an upright spur, designed to point out the true centre of the lens under examination. Two auxiliary convex lenses, each of 2·75 dioptrics (1 and 2), are placed one on either side of the clip, fifty millimetres apart, in order to shorten the focal distances equally on both sides, and thus to diminish the length of the instrument. The luminous object and the screen can be separated from each other 777·94 millimetres, at which distance a sharp image of the luminous points is formed upon the screen, and the zero point of the scale is situated. This scale is engraved on a strip of metal which runs parallel to the track on which the screen moves; and its divisions correspond with the metric lenses from 0·25 up to 20. A small pointer projects from the screen for the purpose of denoting the division of the scale opposite to which it stops.

The lens which is to be tested is placed in the central clip, and the object and screen are moved from or brought towards each other until a sharp image of the luminous points is formed upon the screen. The division of the scale opposite the point of arrest of the screen shows the value of the lens in dioptrics. If the luminous points do not coincide with the dots on the screen already described, the lens is improperly centred, and must be moved until correspondence is secured. The true centre of the lens is then indicated by the pointer attached to the clip.

The use of this phakometer requires only a few seconds, and it enables the optician to determine the value in dioptrics of every lens in his possession. It is not less valuable to the surgeon, who can accurately test the lenses supplied to his patient, and can discover whether they are properly centred in their settings. It is the custom of manufacturers to assume that all lenses ground upon the same tool are of the same focal length, and to number them accordingly; although it is manifest that differences in the refracting power of different pieces of glass may occasion corresponding differences in the results. It is therefore desirable that every lens should be separately tested before it is taken into stock, as in no other way can occasional errors be prevented. The phakometer is being made by Mr. Browning, of 63, Strand, from whom it will shortly be procurable.

Having thus secured a series of testing lenses arranged upon a sound principle, they are used as measures for the degrees of ametropia. The accommodation being paralysed, if necessary, by atropine, and the patient placed opposite to a scale of test-types, at a convenient distance, we find, if he is ametropic, that his vision is below the normal standard of acuteness, and that it is improved by a lens of some description. Assuming that we are unacquainted with the form of his ametropia, we take a concave and a convex lens, each of one dioptric, and place them alternately before the eye under examination, the other eye being closed or covered. If the concave lens improves vision, there is myopia; if the convex lens improves vision, or does not impair it, there is hypermetropia. The existence and the form of ametropia being thus ascertained, the next point is to arrive, by successive trials, at the lens which gives the best vision, which raises it to the natural standard or nearly so, or, at all events, which does better than any other. This lens at the same time corrects and measures the ocular defect. If it is a convex of five dioptrics, we say that the hypermetropia is equal to five dioptrics, or more shortly, to 5. If it is a concave of three dioptrics, we say that there is a myopia equal to 3. Excepting in moderate degrees of ametropia, we must not expect to obtain, by any lens, vision fully of the normal standard; for in the hypermetropic eye there is something which approaches very nearly to arrest of development, often with corresponding defect of functional activity; and in the myopic eye there are often morbid changes in the deeper tissues of the organ. We may expect, however, to obtain from the patient a decided preference for one glass over all others; and, if we do not find this decided preference—if the patient sees little difference between the effects of two or three adjacent members of the series,—we must suspect the existence of astigmatism. To such matters of detail I must return on a future occasion, my object in this preliminary lecture being to define the general principles by which the varieties and degrees of ametropia are recognised and expressed.

In the foregoing method of examination with lenses and test-types we have to deal only with subjective phenomena; and, except for the check afforded by repeating the examination at a different distance, we are almost entirely dependent upon the statements made to us by the patient. It follows, of course, that we are also dependent upon his good faith and his accuracy of observation; and there are many conditions in which these cannot command our implicit trust. In young children, or in persons of defective intelligence, we may be deceived by the patient without intention; and in other cases, as by soldiers seeking to be discharged, or perhaps sometimes by railway plaintiffs, we may be deceived with full intention. It is therefore important to be able to test ametropia objectively, and independently of the statements which are made to us; and this can to some extent be accomplished by the aid of the ophthalmoscope. The course of the rays which enter an eye, to form or not to form a picture upon the retina, and the course of the rays which leave it, are strictly correlated phenomena; and, when a glass is required to afford the patient a clear view of outward objects, a similar glass is also needed in order to afford a clear view of the retina of such a patient to the surgeon. The glass used with the ophthalmoscope is therefore a measure of ametropia. But a more complete account of this method of examination, and of the limitations of its usefulness, will be most suitably entered upon after accommodation has been described, and when the special varieties of ametropia are themselves under consideration.

Another contrivance which promises to be useful in the measurement of refraction, and which at the same time affords a certain amount of control over the statements of the patient, is an optometer which has recently been suggested by Dr. Hirschberg, of Berlin. This instrument, which is now being made at my request by Mr. Browning, superficially resembles a binocular opera-glass. The distance apart of its two tubes can be regulated to suit different distances between the pupils; and one of the tubes can be closed by a metal cap when only one eye is under examination. Each tube contains two biconvex lenses of rather high power; an ocular of say two and a half, and an object-lens of four centimetres of

focal length. The precise power is not material, but the two must be different. When the patient looks through this optometer at test-types placed at their full legible distance, the object-lens receives rays which are approximately parallel; and when the two lenses are separated precisely by the sum of their focal lengths, the rays which leave the ocular lens are also approximately parallel, so that they afford a perfect image to an emmetropic eye. The image is, of course, inverted; but this disadvantage may be overcome by inverting the test-types to begin with. If the lenses are brought nearer together, the rays which leave the ocular will be divergent, so that they will afford a clear image to a myopic eye; and if the lenses are separated by a longer interval than the sum of their focal lengths, the rays which leave the ocular will be convergent, so that they will afford a clear image to a hypermetropic eye. In either case, the degree of divergence or of convergence of the rays depends upon the amount of approximation or of separation of the lenses; and one of the tubes is marked with two scales, each having its zero at the point where the lenses are separated by the sum of their focal lengths, and where the issuing rays are parallel. One of these scales shows the distance between the object-lens and the ocular in millimetres, the other indicates dioptrics of ametropia for each distance of separation. We have only to desire the patient to look through the instrument, and to adjust it so as to obtain the best view of the distant test-types, in order to read off the degree of his myopia or hypermetropia, as the case may be. In order to test his accuracy, we next reverse the instrument, telling him to look through the object-lenses instead of through the oculars, and to adjust it again. If the scale is at the zero point, no other difference than a diminution of the size of the image will be produced by the reversal; but for any other distance between the lenses a change in the amount of divergence or of convergence will be produced, and a corresponding change of adjustment will be required. This amount of change is a known quantity in each ease, and may be marked upon a third scale, which will then show whether the patient has made the amount of readjustment which his former statement would require. Should he have done so, it may fairly be inferred that he was accurate on both occasions. A full account of Hirschberg's optometer, with the necessary formulæ for calculating the degrees of divergence or convergence of the emerging rays, will be found in tho second part of the inventor's "Beiträge zur Praktischen Augenheilkunde." Of the several uses of this optometer I shall have to speak again in subsequent lectures.

THE HEALTH OF BRADFORD.—In noticing the report on the health of the borough of Bradford for the year 1876, by Mr. Harris Butterfield, the Medical Officer of Health, we find that the vital statistics of the district for that period show a considerable improvement in the health of the locality. The death-rate is lower than in previous years, and does not compare unfavourably with that of other large manufacturing towns. The epidemic of scarlet fever which proved so fatal in 1875 passed away towards the end of that year, but 143 deaths were, nevertheless, attributed to it in 1876. Mr. Butterfield remarks that this is a disease which is very frequently imported, and is consequently difficult to deal with, owing to the natural disinclination of parents to send their children into hospital. Without sending children to the Fever Hospital at the outset of the fever, the spread of infection would be limited if parents would use this institution as a house of recovery, where children could be isolated and cared for during the time that the skin was desquamating. A very large proportion of the fatal cases registered at Bradford were from the effects of cold during convalescence, none of which, however, occurred in the Fever Hospital, from the superior care and nursing which the patients there enjoy. It is also at this period that the danger of infecting others is at its highest, although this consideration is often lost sight of by those in attendance on the case. Only one death from small-pox occurred during the year, and this was in the workhouse, in the person of an unvaccinated child, who acquired the disease while tramping with its mother through Lancashire. Several cases were imported into the borough, but by prompt measures of isolation and disinfection any serious outbreak was averted. Had it not been for the facilities afforded for isolation by the Fever Hospital, Mr. Butterfield thinks it would have been almost impossible to have prevented an epidemic.

ORIGINAL COMMUNICATIONS.

A CRITICAL REVIEW OF THE

PREVAILING THEORIES CONCERNING THE PHYSIOLOGY AND THE PATHOLOGY OF THE BRAIN:

LOCALISATION OF FUNCTIONS, AND MODE OF PRODUCTION OF SYMPTOMS.

By EUGÈNE DUPUY, M.D. Paris, of New York;
Corresponding Member of the Paris Société de Biologie; Member of the American Neurological Association, etc.

PART I.

(*Continued from page* 13.)

I HAVE to examine now the functions of every cerebral organ taken individually. The optic lobes, or corpora quadrigemina, come first. It is unnecessary to draw conclusions based upon facts of comparative anatomy. Dr. Ferrier says "that with the view of breaking up these ganglia in the monkey he passed a wire cautery in a horizontal direction through the anterior occipital fissure, so as to traverse the nates or anterior tubercles of the corpora quadrigemina. The result of the procedure was that the nates were ploughed up and disorganised by the cautery." Dr. Ferrier thinks that the concomitant lesions of the hemisphere had nothing to do with the causation of the following phenomena. The animal was rendered *completely blind.*(a) The tests applied, however, leave room for some doubt in my mind as to the completeness of the loss of sight; for Dr. Ferrier adds, "The pupils were *dilated* and *inactive*, the left somewhat more than the right." I am of opinion that the dilatation of the pupils beyond the normal limit of dilatation is sufficient to prevent the animal from distinguishing objects. I am careful not to say that it *destroys sight.* The sense of sight may be, or may not be, lost in the experiment reported above. All I know is this: that I have seen a person unable to write, to read, to distinguish anything upon a table covered with books and instruments beyond a mass, all because he had taken by mistake a toxic dose of belladonna, and suffered consequently with dilatation of the pupil. Oculists have frequent occasion of treating persons who cannot see, not through loss of the sense of sight, but through paralysis of the ciliary muscle. I have seen also cats, on which I had performed the operation of tying the ends of very fine and long copper-wire conductors of a faradic machine to both first cervical sympathetic ganglia, become unable to distinguish objects, their pupils being excessively dilated by the operation. These cats could not find their way in the room; they struck at every piece of furniture. I do not desire to be understood to say that the optic ganglia and their ganglionic appendages have no relation with the sense of sight; I wish only to show that, at the very least, the inability to see for the animals operated upon by Dr. Ferrier can be explained by another cause than the one he urges; that there was no incapacity through destruction of a *centre*, but through perversion of the external organs of sight. The reasons for this view of mine are obvious. It should have been proved first that the sense of sight is localised in the parts destroyed by the wire cautery, because, as matters stand now, there is begging the question. Nor are other experiments of Dr. Ferrier's more conclusive. When he irritated with electricity the exposed optic thalami and corpora quadrigemina, he observed, besides the dilatation of the pupils, movements also. If this experiment proves anything, it proves that the parts acted upon are centres for general movements of the body, as well as for other functions. We know that the corpora quadrigemina when irritated have a powerful effect on the viscera. Pathological cases up to this time throw a very dim light on the obscurity which still exists concerning the special function or functions of the thalami optici. We know nothing more certain on that subject now than when Vulpian wrote ten years ago that we knew nothing certain concerning them.

I suppose that the functions of the cerebellum are investigated next because of the relation which exists in the mind of Dr. Ferrier between the sensory centres, the optic bodies, and the corpora quadrigemina, and the cerebellum as co-ordinating centre. I shall say little concerning the cerebellum. Experiments very carefully conducted have shown that it can be

(a) The italics throughout are mine, except when otherwise indicated.

removed entirely, and yet the animals *spontaneously execute all the movements of the eyeballs*, which, Dr. Ferrier thinks, are incited from that organ. Ollivier and Leven(b) have shown that pricks in any part of the cerebellum will give rise to a variety of motor symptoms in the eyeballs—a variety of such a kind, that it is impossible to associate any special order of motor phenomena with a particular lesion. Diseases have given us cases of all kinds, but none are more obscure than those of the cerebellum. I have also seen that irritation of the dura mater in the neighbourhood of the pons, in an animal deprived of the greater part of the cerebrum and cerebellum, and which has not lost too much blood, will give rise to motor phenomena of the eyeballs identical with those observed by Dr. Ferrier after irritating the cerebellum. Luys(c) has reported two cases, with autopsy, of deafness of long standing. He saw at the autopsy that the acoustic nerves, in each of the two cases, were destroyed on both sides. He followed the degeneration through the posterior portion of the optic thalami up to the fourth ventricle, and also the cuneiform convolutions of the *occipital lobule*. But he writes, "Sections of the cerebellum and of the protuberance, examined in the same manner [microscopically, for he speaks of the neuroglia being diseased ?], showed no particularity to mention." He believes, therefore, that the centres of these nerves are in the occipital lobules. His testimony, on account of the eminence which he has gained as an advocate of localisation, is of value, but it seems to me to be right against Dr. Ferrier's theories, as will be made still more apparent further on. What I have said above, and the experiments of Cyon, impel me to reject altogether Dr. Ferrier's theory of the functions of the cerebellum. There is another hypothesis in science concerning the cerebellum. Rolando wrote in the beginning of this century that he considered the cerebellum to be an organ of "reinforcement"; that it played the part of an "electro-motor." Luys has propounded the same view; so has Weir Mitchell. I entertained the same notion some years ago; I thought, as my predecessors did, that I had even demonstrated the truth of that theory. I am compelled to change my opinion now. Animals deprived of their cerebellum are not weaker than they ought to be after such a severe traumatism; and if they appear weaker just after the cerebellum is extirpated than after the cerebrum is removed, it is simply because in the first case the blood-supply of the medulla oblongata is more diminished and altered than in the second instance, although the vessels destroyed are smaller. Besides, the cerebellar peduncles have very powerful inhibitory effects on the spinal system. Far from me the idea of being hypercritical. I believe that nothing helps more to lead to discovery than the judicious use of hypotheses. But we must consider an hypothesis to be nothing more. In that disposition, when we come to discover that what we thought true is not true, we have made a great progress already. This is the kind of progress which has been made up to this time; it will no doubt be conducive to progress of a more positive nature. For these considerations I think Dr. Ferrier is again begging the question when he writes "that though the faculty of co-ordinated progression may be retained notwithstanding the destruction of the cerebellum, yet the loss of equilibrium practically renders it impossible; but if the faculty of locomotor co-ordination is destroyed by lesion of the optic lobes and pons, equilibration must necessarily be rendered impossible. The centre may remain intact, but its afferent and efferent factors are either wholly or partially interrupted or annihilated." I say that there is begging the question, because Dr. Ferrier has first laboured to show that the senses of sight and of tact are less essential than the *sense* of equilibrium, of which the organ is in the labyrinth; and this being taken for granted, he shows now that they all have one common superior centre—the cerebellum. By that theory we can understand how lesions of either of the senses of tact and of sight, or of the one which has its seat in the labyrinth, can bring on incoördination; for the connexions between them and the centre (cerebellum) are broken (in cases of destruction of the corpora quadrigemina or optic lobes, for instance), which is practically equivalent to destruction of the centre. as he very clearly puts it in the quotation given above. But before testing the value of that ingenious and captivating theory—so simple, too,—may I not ask what are the proofs given that the cerebellum is the centre of co-ordination; and what are the proofs that the connexions of the senses of sight and tact, and of the sense (so called) of equilibrium, which has its seat in the labyrinth, with the cerebellum—if they happen to have any—by means of direct fibres, are for the purpose of co-ordination? It will be seen that as soon as the first postulate is not taken for granted on sheer assertion, the whole fabric falls to the ground. I will not refer to the phrenological hypothesis concerning the cerebellum, because it is absurd. My object is only to show that Dr. Ferrier's theory must be considered to be only identical in value with those which were propounded by his predecessors.

By far the most important of the subjects treated by Dr. Ferrier are those which comprise the functions of the cerebrum. I read here a well-deserved homage paid by Dr. Ferrier to Fritzsch and Hitzig for having been the first to demonstrate experimentally the fact of "definite localisation"; and at the same time the statement that vital differences exist between him and Hitzig "in regard to the extent of the localisation, and with respect to the true character and significance of the phenomena." These discrepancies do not arise from the methods of exploring the brain used by the authors named. Hitzig has used the faradic current quite as extensively as Dr. Ferrier, besides the galvanic current. There is a difference between the effects of the two currents; but practically, and in the point under consideration, there is not: both have the same results. Hitzig and Ferrier maintain that they have, each by his special method of exploring, proved that the *cortex cerebri is excitable*, and that the contractions in various groups of muscles which they have observed on irritating the *cortex cerebri* are the results of *excitation of the grey matter* of the hemispheres.

I, for one, take exception here. I do not believe that the movements which are observed to follow electrical irritation of the cortex cerebri are due to discharge of the cells then irritated. When Dr. Ferrier published his first researches, three years and a half ago, I wrote a little pamphlet in which I examined the validity of the theories advanced by Hitzig and by himself, and also by Dr. Hughlings-Jackson. I tried at the time to control by experiment the experimental data of Hitzig and Ferrier. I urged several objections against those new theories. Of all the objections, pathological and experimental, which I brought forward, Dr. Ferrier has only recalled one; and that one, although not without importance, is not the most important. By placing the sciatic nerve of the frog, prepared after the manner of Matteucci, on the posterior part of the hemispheres, I found that active contractions of the gastrocnemius muscle of the frog resulted when I irritated the anterior convolutions of the brain, thus showing that the current had passed along the whole extent of the hemisphere. That fact is undoubted. It has been ascertained by several other experimenters by different methods. I said that the fact permitted us to think that the electricity was conducted to the basal ganglia, and there excited *these ganglia and the nerves which spring from them.*(d) Ferrier does not accept this view. He writes—"The effects of irritation of the basal ganglia are capable of exact estimation. Irritation of the corpus striatum is followed by general contraction of the muscles of the opposite side of the body; and it is impossible, by applying the electrodes directly to the surface of this ganglion, to produce localised contraction in any one muscle or group of muscles."

In the winter of 1874 I showed to several distinguished physiologists in London that the impossibility to which Dr. Ferrier refers is no impossibility. Professor J. Burdon-Sanderson, in a paper published in the *Proceedings of the Royal Society*,(e) says, "Dr. Dupuy found that after ablation of those parts of the hemispheres which contain the supposed centres, movements, similar to those described by Dr. Ferrier, can still be produced by electrical excitation of the cut surface." Dr. Burdon-Sanderson, in order to settle the difference between Dr. Ferrier and myself as to the identity of the phenomena observed by us both individually, repeated the original experiments of Dr. Ferrier, and my own also. He investigated the most characteristic of the combined movements so accurately described by Dr. Ferrier, as produced by excitation of particular spots on the anterior part of either hemisphere, by comparing them with those produced by excitation of deeper parts, as I had done. The results of his experiments are exactly what I had myself seen. He exposed the anterior portion of the hemispheres, which comprises the several spots by the excitation of which

(e) *Proceedings of the Royal Society of London.* June, 1874. No. IV.

the following characteristic movements could be produced:—1. Retraction of the left forepaw, with flexion of the carpus, accompanied by similar movements of the hind leg. 2. Closure of the left eye, and elevation of the upper lip. 3. Retraction of the left ear. 4. Rotation of the head to the left side. The active spots for these several movements are as follows:—For (1), a point immediately behind the outer end of the crucial sulcus; for (2), the surface about the outer end of a sulcus which lies immediately behind (1); for (3), the surface behind the sulcus last mentioned; for (4), a spot a centimetre further back on the same convolution. These active spots are well defined; their limits and relations are in exact accordance with the statements of Dr. Ferrier. Now (as I had done), Dr. Sanderson severed from the deeper parts (by a nearly horizontal incision, made with a thin-bladed knife, and the instrument withdrawn without dislocation of the severed parts), the area of the surface of the right hemisphere which comprises the active spots above mentioned; and the excitation of the active spots thereupon repeated, the result is the same as when the surface of the uninjured organ is acted upon. Moreover, if a similar incision is made in a parallel plane, but at a lower level, this is not the case;(f) but on removing the flap, and applying the electrodes to the cut surface, it is found that there are on it active spots which, as regards the effect of excitation, have the same topographical relation to each other as the former. If, further, a surface of brain is cut away, so as to expose the outer and upper part of the corpus striatum, and the electrodes are applied to this surface, the movements (1), (2), (3) are produced in the same way as before, but more distinctly; the active spots are quite as strictly localised, and their relations to each other are the same as at the natural surface.

Professor Burdon-Sanderson, from these facts, believes that it is not in the convolutions, but (according to the old doctrine) in the floor and outer walls of each lateral ventricle, that the centres for such movements are to be found.

For aught I know, the old doctrine is as good as the new one. Both are substantiated by the same series of experimental data. The experiments related above, therefore, do not seem to me to warrant this conclusion drawn by Dr. Ferrier, that his "positive results (like which Dr. Burdon-Sanderson's and mine are as positive, being identical), determined by exact experiment, effectually dispose of vague statements respecting the supposed influence of currents conducted to the basal ganglia."

The counter-experimental results just adduced above, therefore, still leave open the question of knowing (1) whether the cortex cerebri *is* or is *not* excitable by electricity;(g) and (2) whether certain convolutions contain organs which are essential to the production of the muscular movements of the character described by Hitzig and Ferrier.

Let us see how Dr. Ferrier has disposed of the arguments which are so contrary to the doctrine of localisation. He says that as the cortical centres act downward on the muscles, necessarily through the basal ganglia and motor tracts, the application of electrodes to the medullary fibres (which connect each centre with the corpus striatum) is essentially equivalent to the stimulus caused by the functional activity of the centre itself. There is here a *petition de prineipe*. It is known that fibres will convey impressions when irritated; but that fact does not disclose the functions of the parts with which the fibres are connected. For instance, tickling the sole of the foot induces laughter; this does not imply (at least, I never heard) that the centre for the innervation of the muscles which are concerned in the act of laughing is in the sole of the foot. If I argued like Dr. Ferrier, however, I think I ought to believe that the sole of the foot contains centres which innervate the muscles concerned in the act of laughing! His postulate and mine are identical.

But he writes very excellently, "The mere fact of motion following stimulation of a given area does not necessarily signify a motor origin. The movements may be the result of conscious modification, incapable of being expressed in physiological terms, or they may be reflex, or they may be truly motor in the sense of being caused by excitation of a region in direct connexion with the motor parts of the crus cerebri. The method of stimulation by itself is incompetent to decide these questions, and requires to be supplemented by localised destruction of those areas, stimulation of which is followed by definite motor manifestations."

There are experimental facts of that order which have been adduced by Hitzig, Gudden, Carville and Duret, together with similar ones found by himself, which Dr. Ferrier brings forward to prove his postulate.

Localised destructions of those areas, in the hands of all those who have performed that experiment, have resulted in slight paralysis (*paresis*), which some have called "paralysis of muscular sense" (Carville and Duret, Gudden, Brown-Séquard; Schiff called it "paralysis of tactile sensation," Hitzig, "paralysis of muscle-consciousness"). I have found in 1873(h) that destruction (scrubbing) of the whole surface of one cerebral hemisphere does not prevent the animal from using his legs. The paresis which results from removal of the centres is not *permanent*. After a few days the animal uses his leg as well as before. He can, in some instances, use it in a normal manner a few hours after he has recovered from the effects of the ether administered, and before inflammation has set in; as in the case of the dog of which I have just spoken. It is good to take notice, also, that although *all the centres* of one hemisphere are destroyed, the anterior leg only shows signs of paresis, and only in the carpal articulation. Goltz(i) has since shown that by washing away the cortex cerebri of a dog, that kind of paresis ensued (as described under different names as above), which disappeared to such a degree that the dog—which had been taught to give the paw on command before the operation, and who could not give the right paw now (the cortex of the left hemisphere being washed away)—after the lapse of some eight days began to give that right paw when asked, and in about four weeks he could do it as well and as readily as before the operation.

This would be the place to examine the question of supplementation of one centre by another—but I shall do it further on.

(To be continued.)

(f) Putnam, of Boston, has found the same thing. He has concluded that the movements produced in the first case really came from the cortex, as he thought that his negative results proved. What follows disposes of his theory.

(g) I do not speak of other modes of irritating the cortex; for mechanical, chemical, and physical (except electricity) have never given results. There is one exception, however. Nothnägel has defined a spot in the cortex of the brain of rabbits, which, on being pricked with a needle, drives the animals into a variety of movements. He calls that *centre*—"*nodus cursorius*." Unless the rabbits used by that experimenter differ from those usually found in the markets of France, England, and America, I cannot account for the results he has obtained. It is more than likely that he has pricked also the underlying ganglia.

IS LEPROSY CONTAGIOUS?

By GAVIN MILROY, M.D., F.R.C.P.

No. VI.

Since the publication of my last paper in this journal for July 22, 1876, some very instructive fresh information on this question has been made known to the profession from various trustworthy official sources, and specially (1) from the "Reports on Leprosy (second series), comprising Notices of the Disease as it now exists in North Italy, the Greek Archipelago, Palestine, and parts of the Bombay Presidency," by Dr. V. Carter, published under the sanction of Her Majesty's Secretary of State for India; (2) from the "Report on Leprosy in the North-Western Provinces of India," by Mr. Planck, the Sanitary Commissioner of those provinces, dated October 19, 1876; and (3) from the Report, by Dr. Lewis and Dr. Cunningham, on Leprosy in India, forming Appendix (B) in the Twelfth Annual Report of the Sanitary Commissioner with the Government of India.

Recent medical experience in those places in North Italy which were visited by Dr. Carter leads to some valuable suggestions respecting the natural history of the disease in that portion of Europe. The most important of these is that which shows that, while the malady has not yet entirely disappeared from the region, it has undoubtedly within the last thirty years very sensibly diminished, and is still manifestly on the decline in point of frequency among the indigenous poor population. This gratifying change appears to have occurred *sponte sud*, or, at least, quite independently of any attempt being made anywhere to arrest or control the continuance of the malady by compulsory isolation, or any coercive restraint of the sufferers. Professor Bo, of Genoa, one of the most enlightened of Italian sanitarians, and who has for many years been well acquainted with the state of the leprous poor in the Western Riviera,

considers that "segregation of lepers, with separation of the sexes, is the only rational means of checking the spread of the disease"; and in respect of treatment, that "hygienic measures are most useful." Dr. Carter says that the Professor "speaks doubtfully of contagion." At Varazze, where, in 1841, Dr. Boeck met with fifteen cases, "leprosy has now almost, if not quite, ceased in this locality. There is no accommodation for any lepers now." Dr. Rambaldi, the physician in charge of the Leper Hospital near to San Remo, informed Dr. Carter that of late years patients afflicted with other diseases besides leprosy, such as cancer and other chronic maladies, have been admitted into the institution, and without any ill effects to any of the inmates. Dr. Rambaldi does not regard leprosy to be communicable by contact with the sick.

There is no record, as far as I know, of the present state of Central or of Southern Italy in respect of the existence, or otherwise, of leprous disease among any portion of the inhabitants. Dr. Carter did not visit that part of the peninsula. From the mere want of exact information on the question, it would be, it may be reasonably feared, a too hopeful and encouraging conclusion to infer an entire absence of the malady in a population whose health condition is well known to be, in many districts of the country, far from being what is desirable in respect alike of food and of general sanitation. Happily, from a recent communication in Virchow and Hirsch's journal, we obtain some valuable matter on the subject of our inquiry in regard of Sicily, furnished by the researches of Dr. Profeta in the island. The following summary of his paper is derived from the Report on Leprosy in India by Drs. Lewis and Cunningham:—

"Since the year 1867, the author has collected information regarding 114 cases of leprosy in Sicily—eighty men and thirty-four women. In three-fourths of the cases he was able to trace the disease to inheritance; in a few instances he had to trace the malady in relatives four times removed. In no instance was there any evidence of contagion, although twenty-two of the lepers had lived with their families for many years.

"Children, who had been suckled by leprous women, had not apparently been infected thereby, nor had revaccination with lymph obtained from leprous persons been shown to transmit the disease. (It is not mentioned how long a period has since elapsed.) The inference that leprosy may be dependent in some way on a fish diet is not supported by experience in Sicily, seeing that the disease prevails among the inland population to a greater extent than along the coast; nor do poverty, want, or filth seem to exercise important influence as factors, for the disease is even more prevalent among the well-to-do classes; and least of all could the disease be attributed to malarial influences. So that the author has come to the conclusion that heredity is the only ascertained etiological agent in its propagation.

"Of the 114 persons, 9 were affected at ages ranging from seven to ten years; 26 at from eleven to twenty years; 30 at from twenty-one to thirty years; 22 at from thirty-one to forty years; 11 at from forty-one to fifty years; and in 7 cases the disease was not manifested until the persons had reached ages ranging from fifty-one to sixty-five years.

"The duration of the disease, taking the average of all the cases, was thirteen years, the minimum being three years, and the maximum forty.

"Both the tuberculated and anæsthetic forms of leprosy occur in Sicily, the latter form being somewhat more common than the former."(a)

From Sicily we may now proceed eastward to Crete, which continues to afford many instructive and trustworthy data respecting the natural history of leprosy among a poverty-stricken population under Mohammedan rule. Dr. V. Carter visited the island in November, 1874. The Report of the College of Physicians contains some interesting matter derived from the writings of a resident physician, Dr. Brunelli, who, it is pleasing to find, communicated to Dr. Carter the results of his subsequent experience, which has served to confirm his former conclusion. "He is of opinion that, as a rule, the disease is certainly not contagious, although individual instances that it may exceptionally be so are not unknown." He is also of opinion that "the disease can be eradicated only by advancing civilisation. . . . Civilisation alone will be the efficient means of eradicating the evil, for it tends to remove those occasional causes which operate in eliciting the malady in subjects predisposed to it; and if these be removed, the predisposition will wear out, and with it all traces of the disease."

In the large leper village of Candia—with a population of about 1000 inhabitants, of whom ninety are afflicted with the malady, and who freely mix with the rest without restraint—"many intelligent lepers assured us (Dr. Carter and Dr. Ittar, a resident physician) that not one instance is known here of leprosy being propagated to a healthy person from a diseased."

From Crete we pass on northwards to Scio, one of the islands in the Ægean Archipelago, situated nearly opposite to Smyrna. Dr. Carter found here an asylum which then contained twenty-three leprous patients, but formerly used to have many more.(b) There is a chapel attached to it, and a resident priest of the Greek Church. "The crowding and mingling with the sick, however patriarchal, time-honoured, or profitable to the establishment, seems to be objectionable; but no one appears to demur to the practice." The lepers are allowed to beg in the town every Saturday.

Before proceeding to Palestine, I may remind the reader of the experience of Dr. Wortabet of recent years in Syria, quoted in my paper (No. 4) in the *Medical Times and Gazette* for January, 1876. On the authority of the Rev. Mr. Tappe, the manager of the Home for Lepers in Jerusalam, Dr. Carter states that "there is now no fear of catching the disease: and for the last seven years there has not been an instance of any communication of leprosy to a sound person connected with the establishment." And the instructive fact is added by Dr. Carter:—"Great difficulty was experienced at Jerusalem in procuring suitable attendants for the sick; the natives of the country refused to wash soiled linen and superintend the necessary baths ordered for lepers. Happily, this difficulty was removed by the spontaneous devotion of a German missionary and his wife, who have for some years conducted the Leper Home in an admirable manner, only to be looked for amongst earnest people. This example is not without its interest for India, where supervision by trustworthy agents is equally desirable as in Syria." Dr. Chaplin, the physician to the Home, stated his opinion that "the disease may undoubtedly be derived *de novo;* possibly it may be transmitted, but it is not contagious."

Since the publication of the evidence by the Civil Surgeon at Umballa, cited in my paper (No. 4) in the *Medical Times and Gazette* for January 29, 1876, I am not aware of any further trustworthy information on the subject from Bengal, until the appearance of the official report by Mr. Planck, the Sanitary Commissioner of the North-West Provinces, from which the following instructive extract will be read with interest:—

"Altogether, I think the conclusion probably well founded that at least the majority of those cases in which both husband and wife suffered were cases of intermarriages between members of leprous families, the hereditary taint existing both in husband and wife. But granting that this conclusion may not be warrantable, still the fact remains that in 855 cases of cohabitation, only eleven, or 1·3 per cent., are discoverable in which suspicion of the communication of the disease from the husband to the wife, or from the wife to the husband, arises. Gauged by this test, the probability of any contagious origin of leprosy, arising out of the ordinary intercourse of lepers with the general public, becomes infinitesimal—a view further strengthened by the fact that, in some of the 885 cases above mentioned, it is recorded that a leprous husband had married two or three wives, who cohabited with him without in any such instance any wife being affected with leprosy."

Mr. Planck cautiously adds this remark:—

"Yet, although infinitesimal, it cannot be declared non-existent, as viewed by the light thrown on this point in the histories under consideration. For, in addition to the perhaps doubtful cases recorded above, one leper at Cawnpore attributed the disease to contagion, in that he lived next door to a shopkeeper who was a leper. And, most important of all, Dr. Fitzgerald records the case of a colonel in the Indian service, who some years ago became a leper, and could account for his misfortune only by the fact that he had continued to cohabit

(a) *Jahresbericht über die gesammten Medicin.*, X. Jahrgang, Band i., Abth. 2, S. 431. Berlin, 1876.

(b) Howard, in his account of Lazaretto, page 65, says:—"The only hospital I have seen for lepers is in the island of Scio, near the city bearing that name. It contained about 120 lepers, consisting of men and women, lodged in separate apartments, in a long range of rooms elevated above the ground. The situation is airy and pleasant, and most of the lepers are accommodated with little gardens, which supply them with almonds, pot-herbs, and delicious figs and grapes. Water has lately been conducted within from the mountains in streams, one supplying those in health, and the other the lepers."

with a native woman after she had been attacked with leprosy."

The Report by Drs. Lewis and Cunningham is the first instalment of the results of the investigation recently undertaken by the Government into the whole subject of leprosy as it exists in our Indian Empire, and which promises to be of the utmost value to science and to humanity. The present Report is confined mainly to the examination of the patients in the Asylum at Almorah in Kumaun, founded by General Sir Henry Ramsay more than thirty years ago, and supported by his generosity.

"The history of the Asylum gives no support to the doctrine that leprosy is a contagious disease, but strong evidence to the contrary. The reverse has been stated with regard to the history of the Asylum, but it will be seen, from the information elicited, that not the slightest foundation existed for such a statement.

"The theory that leprosy is a contagious disease has in recent years been revived in some quarters, and a careful inquiry was therefore made for any evidence bearing on the point. The means which most naturally suggested itself for doing so was an examination of the history of all the married lepers; for were the result of this to show that the wives or husbands (as the case might be) of lepers suffer frequently from the disease, this would be some evidence in favour of contagion, except in cases in which the marriage was demonstrated to be one contracted between lepers, or in which there was a family history of leprosy for both the contracting parties. Even with these limitations, evidence of this nature, collected in a district in which leprosy is endemic, would be by no means conclusive, as the possibility of remote hereditary taint, or even of *de novo* development of the disease, would remain. In the present instance, as will be seen, we are fortunately not obliged to enter into such considerations." . . . "Of the fifty-two lepers married, eighteen had leprous wives or husbands, but as seventeen of these marriages were contracted between lepers in the Asylum, there remains only one case in which the possibility of contagion is to be considered; and certainly this isolated instance cannot be regarded as affording any trustworthy evidence, as in an endemic area the possibility of the occasional occurrence of marriages between predisposed parties must always exist. The history of the Asylum furnishes no other evidence in favour of contagion; there is no evidence of attendants or others employed about the institution, or of those in any way connected with it, having suffered from the discharge of their duties in any way."(c)

OBSERVATIONS ON SCARLET FEVER,

TOO OFTEN DANGEROUSLY CALLED "SCARLATINA."

By ARTHUR E. T. LONGHURST, M.D., etc.

Small-pox excepted, there is perhaps no single disease that the physician is called to encounter, which, from its subtleness, the intensity of the poison, and the frequently very high death-rate, causes him more anxiety, or the public greater perplexity, than scarlet fever. Here and there mild sporadic cases occur, but more frequently the affection is epidemic in this or that locality, in families, schools, barracks, board ship, or elsewhere, to the alarm and consternation of all.

"The Cyclopædia of the Practice of Medicine for 1875," vol. ii., gives a very interesting review of the disease; and though, as there stated, it is now two centuries since Sydenham succeeded in laying the foundation of our present more exact knowledge of the disease, even yet, on many points, opinions are diverse, and its very nomenclature cannot be considered universal, either by the profession or by the general public.

For some years past my attention has been directed to the disease. But without entering at length into its history, etiology, pathology, or treatment, my observations will be especially directed towards establishing greater uniformity of professional opinion on the following points:—

1. The proper nomenclature.
2. The period of the disease in which infection is most active.
3. The main channels through which it is propagated.
4. The proper preventive measures to be adopted on the appearance of the affection.
5. The time at which all danger of infection from the sufferer may be considered at an end.
6. The same as to the sick-chamber, and house, school, or other locality in which the affection first appeared.

Referring to the nomenclature of the disease, though designated "scarlet fever" in the recognised classification of diseases (its synonym being scarlatina), it is curious that, not only in the treatise alluded to, but also in many medical works, it is styled "scarlatina," and is too often so designated both by medical men and the general public. The term "scarlatina" is, I think, open to very serious objection, both in the profession and out of it, for its use frequently occasions much misunderstanding between doctor and patient, or family. Very often we hear it said, in reference to this or that case, "Oh! it is only scarlatina, and such and such precautions are not at all necessary"; whilst the neglect of them is followed by the occurrence of fresh cases, and the extension of the disease far and wide. It is, then, evident that the use of the word "scarlatina" is liable to much misapprehension, and even danger; and I feel sure that it should be discontinued. Whilst the general establishment of such belief, and its uniform observance, will be the first and a very important step towards preventing the disease from assuming an epidemic form.

Intimately associated with the nomenclature is a proper understanding and use of the words "contagion" and "infection." And I think it most desirable that here also there should be uniformity of practice; for the use of both terms occasions much confusion, particularly amongst the uneducated, who think that if not in actual contact with the sufferer they need not fear infection, and will say, though they have imprudently entered the house, or even the chamber of the sick person, "Oh! there is no fear, for I never even touched him." There can be little doubt that the word "infection" is best, as conveying the impression that the fever-poison may be absorbed from the atmosphere or surroundings of the patient without actual contact with his person; and in dealing with the general public we should always strive to impress the real meaning of the words used, and their seriousness, in order that immediately on the appearance of the disease the necessary precautions to prevent its extension may be at once enforced.

Now, as regards the exact stage in which infection is most active, uniformity of professional opinion is very necessary; but without occupying space by reference to the many views on this particular point, and to which I am anxious that the observation of the profession should be directed, I will merely say that my own observation forces me to the conviction that the early period of the disease is that in which infection is most active, and in support thereof I will enumerate the following reasons:—

1. That the early intensity of the symptoms on all parts and tissues favours belief of the special communicability of the early stage of the disease, and also that though the first case may prove fatal in a few days, or even hours, before desquamation has been reached, it is often followed by others.
2. That in instances of extension of the disease I have observed more fresh cases prior to desquamation of the first than after it.
3. That, as instanced in my own person during an epidemic a few years ago, the infection is frequently conveyed from cases not having a rash or desquamation at all.
4. That attempts at inoculation of the disease, by introducing scales of the epidermis under the skin of healthy persons, have failed.
5. There is no evidence to prove that the infection is contained in the scales of the epidermis separated during desquamation; nor do I believe, viewing them as effete dead particles of the skin, that they can be infection-carriers.

Other reasons might be adduced, but they are unnecessary. And without confining myself to the limit of this or that so-called stage of the disease, careful observation forces me to the conclusion that within an hour, possibly even less, of having imbibed the poison, a person may communicate it; and that the period in which the infection is most active is the

(c) "Among the cases reported to the College of Physicians in support of the contagious nature of the disease, there is one quoted on the authority of a native sub-assistant-surgeon, in which it is stated that two men, who acted as gatekeepers at the Almorah Asylum, were attacked with leprosy whilst so employed. ('Report on Leprosy,' London, 1867, page 141.) On referring to the Superintendent of the institution, the Rev. Mr. Budden, for information on the point, we have been informed that the sub-assistant-surgeon in question 'knew nothing about the Asylum; and the statement has no foundation whatever. Nothing of the kind has ever occurred in the Asylum since I took charge of it in 1851."

stage of inflammatory fever up to the full development of the eruption, that the intensity subsides with the subsidence of the fever, and that it is not during the desquamation stage.

Referring to the main channels through which the disease is propagated, a concurrence of professional opinion is also very desirable, and would set aside many needless and irksome restrictions in the management of a case, and tend to limit the disease. Doubtless the channels or media of communication are numerous; amongst them are the exhalations from the mucous membrane of the throat and tonsils, the bodily excretions, urine, etc., but I feel satisfied that the chief sources of infection are the breath, the vaporous exhalations from the skin during the inflammatory stage, and the clothes, which contaminate the atmosphere of the building and its locality, and thus spread the disease by direct absorption of the poison through the lungs into the blood during respiration. Instances of contamination through a morbid atmosphere alone are very numerous; and the shortest contact therewith—a few minutes, if not seconds,—is sufficient to originate the disease in an unaffected person. That, as in cholera, so in scarlet fever, the clothes worn by a patient prior to the appearance of the disease in his person possess the same activity for the spread of the infection is proved by the frequent instances of a reappearance of the disease after weeks, or even months, in persons who have accidentally come into contact with the overcoat or other article of wearing apparel or bedding which had not been thoroughly disinfected. In the same way, a person sleeping in a room long vacated, but not thoroughly disinfected and cleaned, absorbs the subtle poison from the walls during respiration, as he might do arsenic from a green paper. The conveyance of infection through a letter by post is, I think, very doubtful, and I incline to the belief that in the instances so recorded, the postman rather than the letter, has been the means of communication.

If, then, we accept the proposals that the period of greatest activity of the infection is the inflammatory stage, and that the vaporous exhalations of the skin and breath and the clothes themselves are the main channels through which the disease is communicated, we shall be in a better position to consider the preventive and other measures which should be adopted on the first appearance of the disease, during its progress, and on the recovery or death of the sufferer.

Accepting the fact that the disease cannot be cut short, and that it naturally tends to recovery, what are the effective prophylactic measures to be at once put into operation on being called to a case of scarlet fever with a view to prevent its extension? Undoubtedly our first objects must be to trace if possible the source of the infection, to establish as far as practicable a temporary quarantine about the building and locality until certain sanitary measures have been enforced, to isolate the sufferer, and completely to disinfect or to destroy at once all articles of clothing recently worn or in use by the patient; avoiding at the same time all needless expense and perplexity in the family or community attacked.

For isolation, the first point will be, wherever practicable, to set apart two rooms (at the top of the house, if possible), one for the patient, the other for the nurses or those in immediate attendance on the sick; to empty both rooms of all needless furniture, curtains, carpets, etc.; then put the bedstead of the patient in the middle of the room, hang up an old blanket or sheet (wet with a solution of carbolic acid and water, strength two ounces to one gallon, with which the sheet should be kept sprinkled) in the doorway of the room, and perhaps before that of the attendant's also, during the inflammatory stage of the disease. Select, if possible, some person who has already had the fever to take up all articles of food or nursing required, to put them on a table outside the sick-room, and to bring away all articles requiring removal. To open at once all doors and windows of the house or dwelling, that, by a thorough ventilation for an hour or so, all infection may as far as possible be removed; and then, having shut them, further to disinfect the house by burning off some sulphur on an open tin or dish, by placing chloride of lime in open plates or dishes about the halls or passages, and then adding a little water to liberate the chlorine, or by sprinkling a solution of carbolic acid and water (half an ounce to a pint) about the floors, the doors and windows being again thrown open. The constant ventilation of the sick-chamber must be insured by an inch or so of the top sash of the window being frequently, if not constantly, open both by day and night, according to the state of the weather, with a fire in the grate, if necessary, to regulate the temperature at about 60°, or higher if the sufferer complains of chilliness, or if there be any lung complication. A basin of carbolic acid and water (strength as above) should be in the room, into which the pocket-handkerchiefs, or, better still, the old rags used by the patient should be instantly plunged; and a tub containing a like solution should be outside the bedroom door for the reception of all soiled articles of clothing or bedding. The spitting-cups, chambers, or other vessels used by the patient should also contain some of the disinfecting liquid, and their contents should be instantly removed. The attendants should wash their hands frequently in water containing a little carbolic acid; their clothes should be of some washing material, and be frequently changed. The glass, china, etc., in use by the patient and attendants should, if possible, be kept upstairs ready for use, and in order to lessen so far as possible the communication with other inmates of the house. The clothes, bedding, etc., having been subjected to the precautions named, to be marked "infected," and sent in separate bundles to be washed. And though some have doubted the efficacy of vaporous fumigation of the sick-chamber to such an extent as would leave the air still respirable, experience satisfies me of its utility, and I am sure that it should be done at intervals during the disease.

In the event of fatal cases, it is hardly necessary to add that the burial should take place as early as possible, and that all needless display at the funeral should be avoided; the bedding, etc., should be burned, and the thorough disinfection and cleansing of the sick-room must be carried out as will be detailed below. By an efficient carrying out of the measures above advocated we may, I feel sure, very often prevent an extension of the disease, and save needless expense and perplexity, in families, schools, and other communities. And I may here state that the practice of breaking up families and schools on the appearance of the disease has always appeared to me very questionable, both as regards the trouble and expense which such a measure involves, and on account of the fresh probability that the disease is thereby very seriously extended.

With regard to the medicinal treatment, there is no specific which will cut short the affection, and, as stated, I shall not enter at length into that question or occupy space in support of this or that remedy. Doubtless the treatment best calculated to lead to favourable results will be that which has regard to local conditions and peculiarities, climate, season of the year, the special features, if any, of the outbreak itself, the age, temperament, habits, and constitutional peculiarity of those attacked. Should there be any doubt as to the nature of the affection at first, the thermometer, or a hot bath, temperature 100° to 104°, will decide the question.

We have now to consider the time or stage of the disease when all danger of infection from the person of the sufferer may safely be considered at an end. The present conflicting views or opinions of the profession as to the stage in which infection is most active, will not, I fear, allow of a positive decision on this point. For myself, believing that the intensity of the infecting power of the disease is comprised within the time before specified, and disbelieving in the supposed infective power of the separated and effete cuticle, I think that our decision must be determined by other conditions than those which attend desquamation. My impression is that we cannot fix any exact date, but I incline to the belief that, when the pulse and temperature have resumed their healthy standard and the symptoms of general health are re-established, allowing the sufferer to be up and about, we may consider all danger of infection from his person has passed, even though the process of desquamation may not be entirely completed. Allowing, then, a fulfilment of the above conditions, that the sufferer had taken a bath in another room, and then had dressed himself in a completely new set of clothing, I think that he might safely mix with his family. I feel, however, that further evidence on this point is desirable, and I am anxious that the observation of the profession be directed to it.

With regard to the time at which the sick-chamber, house, schoolroom, or other dwelling, may be considered safe for re-occupation, we cannot fix any exact period, for all will depend on the efficiency of the protective measures adopted. So soon as the chamber is vacated the floor should be sprinkled with disinfectants, Condy's fluid or permanganate of potass liquor, and then, the doors, windows, and fire-grates being closed, it should be subjected for twelve hours to a most complete vaporous fumigation by some of the substances named. The bedding should be destroyed; but if for pecuniary or other reasons this is not thought desirable, it may be exposed to a

very high temperature in an oven, or should be spread about the room, and after twelve hours' fumigation the mattresses should be opened, and the contents, together with the blankets, etc., be soaked for two or three days in a solution of Condy's fluid and water (two ounces to one gallon), then washed in cold water, and allowed to dry in the open air. The complete vaporous disinfection of the room will diminish very much the liability of infection for those who are to be employed in carrying out the necessary cleaning and repairs. After thorough disinfection the room should be left open day and night for forty-eight hours, a fire being kept up in the daytime; then the walls should be rubbed over with a damp cloth, the paint and floors scrubbed, left to dry, and then the room may be safely given over for whitewashing and other repairs of re-papering, painting, etc. So soon as these precautions have been effectively carried out, the room may safely be re-occupied, without reference to the time which may have elapsed since the patient left it. The house itself will, of course, in the meanwhile have participated in the thorough ventilation and general precautionary measures, particularly with regard to all clothing or woollen material that could possibly have become infected prior to the disease having shown itself.

The preventive measures advocated against a spread of the disease in a house or given family will apply equally to a school or other similar institution, and by attention to them, if my views as to the infecting period of the disease be at all correct, I think many needless restrictions as to family and patient may be set aside. It may not be thought necessary on the appearance of the disease to break up at once a home or a school, and the members of a family need not be entirely shut up from their friends and the outside world, but be allowed to meet them in open-air exercise and occupations. Such freedom cannot, however, be safely enjoyed without the strictest observance of the sanitary measures detailed; and should the disease, notwithstanding such precautions, become epidemic, then schools, etc., must be broken up, and a more rigid quarantine insisted on.

Wilton-street, S.W.

Slow Pulse.—M. Rendu brought a labouring man, aged thirty-eight, before the Lyons Medical Society, as exhibiting a remarkably slow pulse—viz., 41 to 42 per minute, no difference being, however, notable whether he was in the erect, recumbent, or sitting posture. The man, who was robust and in perfect health, had applied for some trifling ailment. Not only is the case interesting on account of the slow pulse, but because it proves an exception to the rule laid down by Graves, that whenever there is no appreciable difference in the pulse in the different positions of the body, there is always hypertrophy of the heart accompanied by dilatation. Graves only met with six cases in which the difference was not observable, and in all these this lesion was present. However, in the present case there is no sign whatever of disease of the heart.—*Lyon Méd.*, July 1.

Composition and Quality of the Metropolitan Waters in June.—The following are the returns (by Dr. Meymott Tidy) of the Society of Medical Officers of Health:—

Names of Water Companies.	Total Solid Matter per Gallon.	Oxygen required by Organic Matter, etc.	Nitrogen: As Nitrates, etc.	Ammonia.		Hardness. (Clarke's Scale).	
				Saline.	Organic.	Before Boiling.	After Boiling.
Thames Water Companies.	Grs.	Grs.	Grs.	Grs.	Grs.	Degs.	Degs.
Grand Junction .	18·40	0·050	0·129	0·001	0·008	11·0	4·2
West Middlesex .	17·70	0·054	0·129	0·000	0·007	12·6	3·3
Southwark and Vauxhall . .	18·90	0·064	0·108	0·001	0·009	12·6	3·0
Chelsea . .	18·80	0·076	0·090	0·002	0·009	13·2	3·3
Lambeth . .	19·90	0·074	0·150	0·000	0·008	13·2	3·7
Other Companies.							
Kent . . .	28·70	0·003	0·450	0·000	0·002	19·4	7·0
New River . .	18·20	0·033	0·150	0·000	0·006	12·6	3·3
East London .	17·80	0·047	0·090	0·000	0·007	12·0	3·0

Note.—The amount of oxygen required to oxidise the organic matter, nitrites, etc., is determined by a standard solution of permanganate of potash acting for three hours; and in the case of the metropolitan waters the quantity of organic matter is about eight times the amount of oxygen required by it.

The water was found to be clear and nearly colourless in all cases but the following, when it was slightly turbid—namely, in that of the Grand Junction, Southwark and Vauxhall, and the Lambeth Companies.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

LEEDS GENERAL INFIRMARY.

CASES OF PARALYSIS TREATED BY ELECTRICITY.

(Under the care of Dr. HEATON.)

[Reported by Dr. E. H. Jacob, Resident Physician.]

Case 1.—Hemiplegia—Rapid Recovery under Faradism.

P. S., aged fifty-two, was admitted into the Infirmary on March 13, 1877, under the care of Dr. Heaton. He was of intemperate habits, but had never been laid up before, except once—viz., with abscess in the axilla. Four days before admission, one evening, while taking food, he was seized with pain in his left foot, extending up the leg. He then found himself unable to move it, and in a few minutes his arm also became affected. There was no paralysis of face or loss of speech, and he did not lose consciousness.

On Admission.—There is complete loss of power over the left leg, and partial paralysis of the arm; none of the face. Sensibility intact. The patient seems rather dull, and talks a good deal at night. Heart-sounds are loud; no murmur. Arteries rather hard, but the radial pulse small; lungs healthy; appetite good; bowels regular; urine 1020, no albumen.

March 19.—Feels pretty well. Cannot move leg at all, but can hold pretty well with the hand.

April 12.—The patient has now been in hospital a month, taking a grain of quinine three times a day. His arm has gained considerable power, but he can barely move his leg. Faradism ordered to be applied daily.

17th.—He can move his leg much better, and bear some little weight upon it.

19th.—He can walk with the help of a stick.

20th.—The patient can now walk without a stick, but drags his leg somewhat. Discharged; to attend to be faradised three times a week.

Case 2.—Multiple Paralysis.—Treatment by Iodide of Potassium and the Constant Current.

J. T., aged thirty-four, a collier, was admitted on January 16, 1877, under the care of Dr. Heaton. His family history was good. He was a moderate drinker, had worked hard and in very damp places for the last six years, being generally in a stooping position. He had had gonorrhœa, but no chancre or other signs of syphilis. In May, 1876, while at his work, he had a sudden attack of vertigo. This continued, but was not severe until the end of a week, when it suddenly became worse in the middle of the night. The giddiness continued, and in about two months the right side of his face became paralysed. This lasted a week, and then suddenly disappeared. He still went on working, although suffering slightly from vertigo, till the latter part of December, when he began to suffer from diplopia, and the vertigo increased. He then gave up work. He observed then some numbness in the third, fourth, and fifth fingers of his right hand, and in the front of his left foot and leg. He was also rather deaf in the right ear. He never had any pain in his head.

State on Admission.—He is a tall thin man; feels very weak, and fell down this morning on getting out of bed; face anæmic. There is slight ptosis of the left eye and external strabismus; the left pupil is rather larger and less sensible to light. He can fix either eye and see well with it, but sees multiple images with both together. Tongue is protruded slightly to the left. He has constant vertigo while walking, but none if he lies still. There is slight cloudiness of the edges of the optic disc on the right. The right hand is much weaker than the left, and the extensor muscles especially are wasted. There is wasting also of the extensors and peronei on the left leg, which feels cold and numb. He hears a watch at one inch on left side, close to ear on right. Tuning-fork is heard on the left side of forehead, not on the right; with ears closed it is heard with both, more with the left. Tested with the dynamometer, he can grasp twenty-seven pounds with his right hand, thirty-eight with his left. He has to strain to pass urine, and his bowels are confined. Appetite good; tongue clean; urine 1015, no albumen. He was ordered pot. iod. gr. v., liq. strychniæ ℥ iv., ter die.

January 23.—Dose of iodide of potassium raised to ten grains.

24th.—Ptosis of left eye increased.

30th.—Ptosis of left eye complete. Patient says his right hand is getting stronger and warmer.

February 5.—He still complains of vertigo, and coldness of left leg. Constant current applied from sacrum to foot.

9th.—Left leg warmer and stronger (under constant current). Ptosis continues, and the movements of the left eye are sluggish. There is tenderness over the right ulnar nerve as it passes the condyle of the humerus, and numbness along its course and distribution. This was much relieved by application of galvanism.

March 2.—The extensors of right arm and left leg answer to twenty cells of battery, slowly interrupted, but not to faradism. The muscles were separately worked every day with a slowly interrupted galvanic current. The limbs always feel warmer after the galvanism. Iodide of potassium increased to twenty grains thrice daily; and on February 13 to thirty grains thrice daily.

3rd.—Extensor muscles act more strongly to galvanism, and faradism now produces slight contraction. The arm and leg were now treated daily with both faradic and interrupted galvanic current. Galvanism was also applied daily to the left eye.

15th.—He passed nearly two pints of dark blood from rectum. The ptosis is much improved.

16th.—Medicine omitted on account of sickness, and some stomachic mixture ordered.

18th.—Has had much difficulty in passing water since leaving off the medicine. He was ordered liq. strychniæ ℳv. ter die. Galvanism continued.

April 4.—He now walks pretty well. The extensors of the left leg and right hand are rather weak, but answer to faradism. The ptosis has entirely disappeared, but there is still some external strabismus. He feels in good health. The diplopia was corrected by prismatic spectacles.

Discharged on April 7.

Case 3.—Spinal Meningitis—Treatment by Constant Current.

D. M., aged fifty-seven, a labourer, was admitted on February 6, 1877, under the care of Dr. Heaton. For the last twelve months he has suffered severe pain in his legs, with great loss of power. His legs used to give way under him as he walked, and he suffered much from pain in the head, and general tremor of limbs. The patient was fairly nourished, of fresh complexion, and intemperate habits.

State on Admission.—He can stand for a few minutes, and walks with difficulty, dragging his legs. His feet feel very numb, and he can barely stand with closed eyes. There is occasionally slight tremor of the hands in repose, but on the slightest movement of his limbs or body he is seized with violent sharp pain in his limbs and general tremors. He has pain of the same character at uncertain intervals, even without moving. His legs are not wasted; sensibility in them not materially affected, though he says they frequently feel cold and numb. He can flex and extend them with difficulty. Reflex motion normal. The tongue is protruded straight, but not very far. The left pupil is rather larger than the right. There is occasional slight difficulty in swallowing. Speech is rather thick, and has been so since June last. He speaks slowly; occasionally sees double. He hears a watch against ears equally on both sides; hears tuning-fork best on his right temple. He sleeps badly. Appetite fair; bowels constipated. Urine, specific gravity 1010; no albumen; he has some difficulty of micturition. Slight cough with scanty mucous expectoration. Heart healthy.

He was kept in bed with no medical treatment till February 12, when galvanism was ordered—a continuous current of fifteen Muirhead cells from the nape of neck to the feet being applied; the current was strong enough to cause a tingling, but no pain. The positive pole with a large flat sponge was applied to the neck; the feet placed in salt and water connected with the negative pole. The current was allowed to run for about ten minutes.

February 15.—Has been galvanised for three days. He expresses himself as much more comfortable, the pains being lighter in severity and less frequent.

21st.—He still has occasional pains, especially pain of an aching character from the right leg up to the right side of the head, which becomes sharp if he moves. The trembling is very rare now. He has occasional vertigo, but much less than before. His legs feel stronger. The galvanism was continued, the period of application being somewhat longer.

March 10.—Improving. Had one sharp pain in the last twenty-four hours.

27th.—He can now walk a considerable distance. Very rarely has any pain, and only occasionally slight vertigo. Discharged March 28.

Remarks by Dr. Jacob.—The above cases illustrate the principal uses of the various kinds of electric current at the disposal of the therapeutist. In the first case, muscles healthy in themselves, but paralysed by a central lesion, were roused into increased activity by a faradic current. In the second the lesions appeared peripheral, the muscles gave the "reaction of degeneration," and answered only to the slowly interrupted battery current, though after this had been employed for some time faradic irritability returned. In the third case the constant battery current was used to relieve a subacute inflammatory attack in the central nervous organs. In this case, no doubt, rest in bed was of some service in the treatment, but during the week subsequent to admission, when no treatment but a placebo was adopted, there appeared to be no material improvement.

MIDDLESEX HOSPITAL.

HÆMATOCELE—TUNICA VAGINALIS LAID OPEN, AND BLOOD-CLOTS TURNED OUT—RECOVERY.

(Under the care of Mr. LAWSON.)

George F., aged sixty-two, was admitted into Forbes ward February 8, 1877, under Mr. Lawson, suffering from great distension and discoloration of the left side of the scrotum.

He stated that seven weeks previously he had accidentally squeezed his testicles between his thighs. This produced great pain, and was followed immediately by swelling and discoloration of the skin. On the following day the swelling had increased, and the scrotum and penis had a dark, bruised appearance.

On his admission, a tumour the size of a large cocoanut occupied the left side of the scrotum; it was very tense, with a distinct sense of fluctuation. The skin was very dark coloured. It was clearly a case of hæmatocele. There was no pain in the tumour, and it only occasioned inconvenience from its size and weight. A lotion of ammon. hydrochlorat. ʒij., sp. vini. rectificat. ʒiv., aquæ ℥xij., was ordered to be constantly applied.

Under this treatment the size of the tumour and its tension diminished. But as after the first fortnight no further progress towards recovery took place, Mr. Lawson decided to open the tunica vaginalis and turn out the blood-clots, and secure any bleeding vessels he might find.

On February 28, the patient having been put under ether, Mr. Lawson made a long incision through the scrotum, which completely laid open the tunica vaginalis. A large quantity of blood-clot and fluid blood was removed, and all bleeding vessels tied. A fold of lint soaked in carbolised oil was placed in the wound and covered with wet dressing.

From this time the patient progressed very favourably; the wound granulated from the bottom, and in a month's time he left the hospital quite well.

A Shameless Hoaxer.—Some of our contemporaries have announced the receipt by some of the metropolitan hospitals of very handsome donations from a Major Moriarty; and it is true that a cheque for £500 on the Provincial Bank of Ireland (Parsonstown Branch), and signed Denis Moriarty, was sent, with a letter from "Major Moriarty," to the Great Northern Hospital; and one for £1000, similarly signed, to the University College Hospital. Two or three other medical charities also participated to a smaller degree in "Major Moriarty's" benevolence, so far as the receipt of cheques goes. But we regret to add that the cheques sent to the Great Northern and the University College Hospitals were returned from Ireland endorsed, "No account at Parsonstown Branch"; and the letters of acknowledgment from the secretaries of the hospitals to Major Moriarty came again to them through the Dead-Letter Office. We fear the other charities honoured by the Major's approbation have also found his cheques equally worthless.

SATURDAY, JULY 14, 1877.

THE FUTURE OF SANITARY SCIENCE.

At the commencement of the able address which Dr. Richardson delivered, on the 5th inst., to the members of the "Sanitary Institute of Great Britain," he lamented that the occasion did not seem a fitting one for the production of "one of those essays which appeal to the imagination, while they prepare the mind for the reception of sanitary principles and practice." We venture to think that his labour and time were more usefully employed in dwelling, as he did, on the directions in which the Institute should work, the aids they may have to call on, and the powers they may have to consult and to propitiate. Dr. Richardson has on former occasions indulged his fertile powers of imagination in picturing for us a "City of Health," and in constructing ideally perfect dwelling-houses; but if the Sanitary Institute is to be of use, its members must have more immediately practicable objects set before them. The "whole natural scope" of the Institute is, Dr. Richardson says, "to sow the seed of sanitation; to think out plans of projects for working methods; to lend its many minds, as if they made up the minds of one man, for devising from the past the best for the present; and respectfully to declare their conclusions." This is surely work enough; and the best help, perhaps, that could have been given to its members on the present occasion was to point out "the lines on which they would have to move—viz., the political, the medical, and the social,"—and to indicate "certain points in which they are most likely to come in contact with these powers, and the changes they may expect to work in and through them."

Dr. Richardson declared that our legislators have, by a long precedence, taken the lead in sanitary affairs over those of other nations; and that by comparison with all other nations in the world we have obtained legislative measures which are splendidly comprehensive. He considers that no other country in the world can present an approach to the Public Health Act of 1875. "Its constitution of sanitary authorities throughout the kingdom; the power it vests in those authorities to appoint learned medical officers of health; the provisions it makes for securing to each locality better sewerage, freedom from nuisances, improved water-supply, regulation of cellar dwellings, governance over offensive trades, and removal of unsound foods; the provisions for prevention of spread of infection, and for the erection of hospitals and mortuaries; and the provisions for the regulation of streets and highways, lighting of streets, establishment of pleasure-grounds, and regulation of slaughter-houses; these, as well as the general provisions for the carrying out of the Act, are most commendable as practical plans, by the working of which the nation may be tempered into sanitary mould of thought and character." Dr. Richardson did not point out the very imperfect and blundering manner in which the Act has so far been administered; but he may be said, perhaps, to have implied this, when he observed that much of it is, "by the necessities of the constitution of our country," of a permissive nature; and that sanitary science is still far in advance of sanitary legislation; and when he urged the necessity for a State Department of Health, presided over by a Health Minister. To this we must undoubtedly come sooner or later, and the Health Department must be freed entirely from the administration of the Poor-law, and many other matters which, as well as that of sanitation, are at present administered by the Local Government Board. And Dr. Richardson was in the right, we think, in asserting that Vaccination Acts and all measures concerning the national health would be much more effectively and easily administered by a Health Department than by a Local Government Board, or by any central authority, the title of which fails to convey the meaning of its functions. The people would probably then much more fully and generally recognise such Acts as general health measures, and be by so much the less inclined to look on any of them as legal tyrannies and restraints, or as productions of party politics. And had we a State Department exclusively devoted to the health of the people, "men, whose lives have been devoted to the study of life and health, would be prepared," he said, and we may hope, "by their devotion for the accepted service of their country in public form, and the Houses of Parliament would become, at last, congenial spheres for their labours. The Houses would be strengthened by such adhesions; the men would be more honoured and useful."

To insist upon, and work for the establishment of, a State department exclusively devoted to the health of the people, should be one of the first, if not the first, of the objects of the new Institute. Another great and crying need of the day, Dr. Richardson pointed out, is a digest of all our practical sanitary laws, so prepared that every person of intelligence can read and understand what may be legally enforced for the maintenance of health. And even of greater importance than this is the "systematic enumeration, week by week, of the diseases of the kingdom through the length and breadth of the kingdom." We have no need to enlarge to our readers on the value of this. If the Sanitary Institute will constantly persist in demanding from the Government the systematic registration of disease, and devote itself to the consideration of "the best means of collecting the facts on which the weekly reports of disease will have to be based," it may, in that direction alone even, do a work that will more than justify its existence. Then Dr. Richardson dwelt forcibly on the need that the politician should come forward, more determinedly than he has yet done, in order to secure for those he governs three great requisites—pure water, pure food, pure air. He, in common with large and increasingly great numbers, holds that it is hopeless to trust to companies in a matter of such vital moment as the supply of water, and equally hopeless to trust to the undirected action of local authorities. Government must do one of two things in this political part

of sanitation—"It must either produce a process or processes for pure water supply, and insist on every local authority carrying out the proper method; or it must—and this would be far better—take the whole matter in its own hands, so that under its supreme direction every living centre should, without fail, receive the first necessity of healthy life in the condition fitted for the necessities of all who live." Dr. Richardson insisted, at some length, on the want of legislation for supplying pure air, and on the vital necessity of this; and he insisted also on the need of political aid in "quenching the drunkenness of our land." It may almost be said that at present he is nothing if not teetotal; but we, in common with the medical profession at large, are so fully and deeply conscious of the frightful evils caused by intemperance, that we do not care, now at any rate, to criticise his insistance on "abstaining temperance," but will only say that we quite agree with him in regarding the battle against intemperance as a great sanitary question. We do not believe that legislation can directly make people temperate, but indirectly, by providing pure water, pure food, pure air, and healthy homes, legislation can bring invaluable help to the cause of national temperance.

Passing on from the political to the medical aspect of his subject, Dr. Richardson gave great praise to the medical profession for the part they have taken in urging—as may be thought, against their own interests—that prevention must take the place of cure. Of the great future of preventive medicine he spoke at considerable length, and with much enthusiasm, and concluded this part of his subject with a few words deprecating the fear of over-population. "It is felt by some," he observed, "that the medical sanitarian of the future will have his best efforts thwarted by the forcible excess of life beyond the means that can be found for the support of life, as if life were a mere secondary principle in the universal order. I see no such cause for fear. That in the progress of life on the earth the day will ever come when the earth will not supply food for its people, is, to my mind, pessimism carried to an insane vulgarity. It is clear that man can always reduce to his wants the lives of all animals except man. The question rests therefore on the abnormal increase of man alone. Nature knows that, and rules accordingly. . . . I think it my duty to deal plainly with a question which affects so closely the future of sanitation, and to express, from an experience which is confirmed, as I know, by some of the highest ornaments of my learned profession, that nothing is wanted to correct the danger of over-population but improvement of mental process; nearer communion with the Eternal Mind in His works; purer artistic education, healthier homes, more rational amusements, and the ennobling influence of a holier life amongst those who assume to be the cynosures of the nation." Then treating, finally, of the future of sanitary science in relation to social life generally, Dr. Richardson dwelt on the importance of teaching sanitary science "so as to carry the sympathies of the learner and his more refined tastes along with his reason, so as to attract and charm his senses as well as his intellect." He declared his desire strongly to enforce that "it is the section of the nation which Dr. Farr classes as the domestic, the six million of women of the nation, on whom full sanitary light requires first to fall." Health in the home, he said, is health everywhere. Elsewhere it has no abiding-place; and the woman is the presiding genius of the home. "The men of the house come and go; know little of the ins-and-outs of anything domestic; are guided by what they are told, and are practically of no assistance whatever. The women are conversant with every nook of the dwelling, from basement to roof, and on their knowledge, wisdom, patience, and skill, the physician rests his hopes. How important, then, how vital that they shall learn as a part of the earliest duties, the choicest sanitary code." And the address closed with an eloquent expression of the surpassing value of the help sanitarians will obtain if they can win the matchless generosity of women, and "their overpowering love for every device tending to promote the happiness of all things of life," to the cause of sanitary science.

THE NEW ARMY MEDICAL ORGANISATION.

Few but those behind the scenes would believe that until a month or two ago a great country like our own had no regular organisation for the management of the sick and wounded in war. Certain old traditions, it is true, existed, but even the experience of a campaign like that of the Crimea, which exposed our shortcomings in this respect, had failed to impress upon the authorities the necessity for instituting and publishing an improved system for the treatment of the wounded soldier. The Franco-Prussian War of 1870, with its terrible list of casualties, first called attention to our own want of organisation, and in 1872 a committee was appointed to report upon a system of Field Hospital Equipment. The present complications abroad, however, may be considered responsible for the definite and complete arrangements which have been formulated. In the new organisation the first help is intended to be given to the wounded soldier by the surgeon attached to his regiment, who will be accompanied in the field by an orderly, carrying slung over his shoulder a Medical Field Companion, which contains all that is necessary for the first dressing of wounds. The surgeon with a regiment, however, is not to remain behind, but to keep moving on with his corps, and each company is to have a stretcher carried on its company cart, two men per company being trained and told off as stretcher-bearers; when the battalion comes into action these bearers will leave their rifles and knapsacks in the cart, take out the stretcher, and pass at once under the orders of the surgeon. The second step in the assistance of the wounded is the establishment of "bearer companies," which are a combination of the old ambulance and sanitary detachments. For an army corps there will be four "bearer companies," each containing within itself the means of giving first help on the field, of removing the wounded from the field, of establishing dressing stations, and of transporting the wounded to the field hospitals, which will be established in the rear. Each bearer company, including its officers in charge of the bearers, its transport officers and men, is to be placed under the direct command of the senior medical officer. A bearer company will consist of eight surgeons (one of whom is to be in charge of the whole); a captain and two lieutenants of orderlies, a sergeant-major, ten sergeants, ten corporals, 110 privates as bearers and eleven privates as *bâtmen* (servants and grooms) for the officers; a transport officer, with eight non-commissioned officers and artificers, a *bâtman*, and forty-seven drivers. There will be fifteen riding-horses, and ninety-four draught-horses. The carriages (which are all two-horsed) are divided into a first and second line. In the first line are two surgery-waggons containing two operating-tents, and the equipment for the establishment of two dressing-stations, each waggon being complete in itself for setting up a dressing-station. Two other waggons carry blankets, kettles, cooking-pots, etc.; there are two water-carts, one cart with the current day's rations, and ten ambulance-waggons for the carriage of wounded men, each carrying several spare stretchers. In this first line of seventeen carriages is everything necessary for the establishment of two dressing-stations, and it is capable of division into two sections, each complete in itself. The second line consists of two general service waggons, carrying the tents and blankets of officers and men, and twenty-three ambulance-waggons for the carriage of the wounded. One bearer company is to be attached to each of the three divisions of an

army corps—half a bearer company to the cavalry brigade, and half to the corps of artillery. The bearer column with its first line of carriages is to march in the rear of the division; in action, the surgeon-major in charge selects the best positions, establishes dressing-stations, pitches the operating-tents, and sends forward bearers with stretchers to bring in the wounded.

The next arrangement is the field hospitals, and these are in the proportion of twenty-five per corps, each field hospital being arranged for 200 men. But only twelve of them are with the corps, the remainder being at the base of operations, or distributed along the line of communications. The detail of the *personnel* of a field hospital has not been changed; but the new field hospital—divisible into two half-hospitals, each complete in itself—is far more complete than of old. In the old one there was absolutely no provision made for carriage of tents, blankets, officers' baggage, or water. In the present plan there are two water-carts, and four waggons for tents, baggage, etc.; besides four hospital waggons carrying ward equipments and cooking utensils, and two pharmacy waggons of a pattern recently approved, containing medicines, splints, and every convenience for dispensing; and these latter are perhaps the most complete that can be found in any service in the world. The control of the twelve field hospitals with an army corps will be delegated to the principal medical officer of the corps, while the other thirteen will be under the officer in charge of the communications of the corps, who will have a medical officer of rank upon his staff to supervise their conduct, while another medical officer of high rank will superintend the despatch of stores, and the removal of wounded at the base of operations itself. Under the old arrangements it was contemplated that a single army corps would require 418 carriages for the medical department alone, of which 268 were to be ambulance-waggons. Under the new organisation the total number of carriages is reduced to 313, including all the additional carriages given to field hospitals; and of these 313 it is contemplated that 140 may be raised from local transports. The number of ambulance-waggons, including those to be locally obtained when required, is reduced from 268 to 132. The number to be provided from home, and to be permanently present with an army corps, is reduced from 268 to 40.

The space at our command is not sufficient to admit of our giving several of the minor details of the new organisation, but from the foregoing sketch it will be seen that for the first time in the history of this country the authorities have carefully considered and laid down a plain for the treatment of the wounded; and in the unfortunate event of active operations, we may fairly hope to escape the confusion in our medical arrangements which has characterised some of our former campaigns. Further, we believe that the new scheme does not exist only on paper, but that all the different departments are really at work, busily completing all the medical arrangements for at least one army corps of 30,000 men.

THE MADRAS FAMINE.

We are glad to be able to report that the Madras Government have put an end to Sir Richard Temple's policy of reducing the wages of famine labourers to a bare subsistence allowance, or an allowance which, as we have shown, was, on Dr. Cornish's authority, practically a starvation allowance. Our contemporary, the *Madras Weekly Mail*, of May 26, also says that "the Madras Government have received from the Secretary of State a telegram authorising them to depart from the Temple wage of 1 lb. of grain, *plus* 6 pies, and to pay adult male labourers 2 annas per head, and women and children in proportion." It was, indeed, high time to acknowledge that the "experiment" must be given up. The *Times'* correspondent in Southern India, from whose letters on this subject we have quoted before, says, in writing under date of May 26—"The reports from famine relief officers in all parts of the country during the last few weeks have been so unanimous in regard to the rapid deterioration of health and physique of the labourers on relief works, that the Madras Government have accepted the overwhelming evidence against the reduced wages, and have ordered that no more experiments 'on the limits of human endurance' shall be made—at least, in connexion with famine relief. Sir Richard Temple has always denied that there was any connexion between his reduced wages and the number of starving and starved people flocking into the feeding houses, but the famine official, only last week, in taking the statistics of one of those camps in which the people are gratuitously fed, found that upwards of 50 per cent. of the adults had been employed for various periods on relief works until their strength failed and they were driven to apply for food without work. This process, in fact, has been going on all over the country, and the gratuitous relief now includes nearly 400,000 persons, and before another month is over we shall, probably, have half a million on our hands who are so reduced as to be wholly unable to earn a livelihood." He draws attention to the very grave difficulties that the Madras Government will have to encounter in dealing with those "who have been so weakened by long-continued privation as to be unable to maintain themselves," and gives a terrible account of the state of things in some of the relief camps which he had himself visited. In the town of Madras also, he says, the mortality bills, "calculated on the population returns of the last census, showed something like 150 deaths per 1000 for the month of March, and for April and May there has been a slight decrease, but the rate is still over 130 per 1000. As I have said before, the population is abnormally large, owing to the influx of emigrants, so that these proportions are not so high as the figures would indicate, but there can be no doubt that the mortality is most distressingly high among the poorer residents, and especially so among the starved emigrants from other districts. Every hospital in the town and every relief camp is full to overflowing of sickly and diseased creatures who have been laid low by sheer want of the necessaries of life; and while this steady set of sickly and diseased objects towards Madras continues, your Registrar-General must not be surprised to find the mortality of Madras topping that of all other 'foreign cities' included in his weekly bills of health." But, he adds, the European troops, the prisoners in goal, and the European and native public who can afford to live in comfort, are not unhealthy. Nor is there any undue sickness and mortality among these classes in other localities where famine prevails. The *Times'* telegram from Calcutta, dated July 8, states that Dr. Cunningham, the Assistant Sanitary Commissioner, who was deputed to investigate the peculiar forms of disease among the famine-stricken people, says that "he was unable to discover any form of fever that could in any way be ascribed to the influence of want. In spite of the high degree of mortality among people in the relief camps, he found that fevers of any kind practically did not exist, death being almost entirely due to diarrhœa and dysentery. On the other hand, the general results of his researches confirm the belief that morbid conditions exist which may with propriety be termed famine diarrhœa, and famine dysentery." And he describes pathological changes which account "for the failure of curative measures in these diseases, as no diet can avail when the means are destroyed by which alone it can be appropriated to the necessities of the body." These are precisely the pathological changes and the diseases which we spoke of in our notice of Sir Richard Temple's "experiments" on May 19, as the results of a starvation allowance of food; and we pointed out that Dr. Cornish, in his second memorandum, dated April 6, had warned the authorities that

these diseases would appear, and that he showed they had been already described by medical officers as then causing the mortality in the relief camps; but the Supreme Government in India then refused to believe it. Our contemporary the *Times* says, "The evils of a famine are great, but the more permanent evils of an artifically induced pauperism may, to the eye of a statesman, be even greater and even more necessary to be guarded against. The question, after all, is one of fact." These are mere truisms which no one wishes to dispute, but we must regret that the facts were not recognised sooner. The *Times* asserts that "Sir Richard Temple's theory is the correct one," but it admits, happily, at last, that "there seems reason to suppose that it has been a little too austerely worked," and that "it may be well that the sternness of the Central Government has been somewhat tempered for the unfortunate Madras natives." Much credit is due to the Duke of Buckingham's Government for having at last insisted on such a tempering of the sternness of the Supreme Government; but we trust that no such sternness, no such "experiments," will ever again be allowed for even a much shorter period.

We are happy to add that rains have already fallen in some districts of the Madras Presidency, and that there is some reason to hope that the suffering will be rapidly reduced.

THE UNIVERSITY OF LONDON AND THE ADMISSION OF WOMEN TO DEGREES IN MEDICINE.

A SLIGHT change has taken place in the position of affairs at the University of London. The Senate at its last meeting accepted the report of its committee on the admission of women to degrees in medicine, which suggests, as we have before pointed out, some important modifications in the regulations as they are to apply to women. In the meantime the right of the Senate to act as they have done is being actively canvassed. At the suggestion of Mr. Goldsmid, the legal bearing of the question is being referred to the Law Officers of the Crown, and until their decision is given the matter is at a standstill. The Senate are, however, pressing for an early opinion, in order, it is pretty generally understood, that they may push on to a hasty conclusion this matter, which seems to us to have been hurriedly and unadvisedly taken in hand. There is from their point of view all the more reason for this, as the moral bearings of their recent action are to be brought before an extraordinary meeting of Convocation, if the chairman sees fit to call one in accordance with two influentially signed requisitions. One of these emanates from the Annual Committee, who decided upon this course, by a majority of fifteen to seven, at an extraordinary meeting held last week; the other comes from a number of independent graduates. The question for the lawyers to decide is twofold. Russell Gurney's Act empowers qualifying bodies to grant their qualifications to women: the qualifying body in question is the University of London. They must tell us what the University of London actually is—that is, whether it consists of the Senate alone, or whether it is not the Senate and Convocation as well. And then they must tell us whether or not the Senate, as the sole *executive* body in the University—which it undoubtedly is—has the legal right, by accepting a permissive Act of Parliament, to make such an alteration in the regulations and constitution of the University as it could not otherwise have done without obtaining a new charter, for which the consent of Convocation is necessary. We have little doubt that the second question must be answered in favour of the legality of the Senate's proceedings; but the first point appears to us to be more open to question. Neither of these lines of argument, however, touches the undoubted fact that, by adopting the course the Senate have thought advisable, they have gone directly in opposition to the spirit of the existing charter, which intends the decision of such questions to be one of the most important functions and prerogatives of Convocation. We cannot but hope that the majority in the Senate will be wise in time, and will seriously consider the opinion of the graduates. The subject involves matters much deeper than the mere admission of women to degrees; it touches the interests of all the Faculties in the University, and may possibly shake that harmony between the Senate and Convocation on which the satisfactory conduct of the University so largely depends.

THE WEEK.

TOPICS OF THE DAY.

IT is satisfactory to find that the Metropolitan Board of Works is beginning to take steps for enforcing the Infant Life Protection Act. A woman residing in Draper's-place, Burton-crescent, was last week summoned at the Clerkenwell Police-court, for retaining and receiving for hire more than one infant, for the purpose of nursing and maintaining them apart from their parents, she not being licensed so to do. Mr. Napier, who supported the summons, said that he had seen the house occupied by the defendant, and even if she had applied for a licence it would not have been granted, owing to the wretched condition of the place. Inspector Whiting deposed that on June 14 last he visited the house, and found two children under the age of one year; he visited the house again on the 18th ult., and saw the same two children. The kitchen was used as a nursery, and was wholly unfitted for the purpose. The defendant admitted to him that one of the children had been under her care from the age of three weeks, and the other child for the past three months; she received five shillings a week for each. The house was not registered under the Act. Mr. Sidney L. Smith, Medical Officer of St. Pancras, said that one of the children was brought to him on the 14th ult., and on a subsequent occasion; it had evidently been much neglected and imperfectly nourished. The magistrate, after looking at the Act, said that he had power to imprison the defendant for six months with or without hard labour; he had also power to inflict a fine not exceeding £5. Mr. Napier said that this was only the second case under the Act, and he did not press for a severe penalty. The defendant was then fined 40s. and 23s. costs.

The Waterworks Committee of the Manchester Corporation have just laid before the Council a scheme for the purchase of Thirlmere, one of the umberland lakes, and for the conveyance of water from it to the city by an aqueduct 100 miles long. The works are to occupy seven years in execution, and will cost £1,100,000, for which sum means will be provided for impounding 50,000,000 gallons of water per day. The water is stated to be even superior to that of Loch Katrine. It is proposed to raise the level of the lake so as to give it an area of 700 acres, and the reservoir will contain 800,000,000 cubic feet. A draining ground of about 11,000 acres is also to be purchased, and the Committee were advised that the water could be supplied by gravitation. The Council gave power to the Committee to carry out the scheme.

A case of the most perfect indifference for the healing art and its professors was recently exhibited at Bristol. Henry Griffin, a stoker, was committed to take his trial at the Assizes for a revolting outrage on a pensioner named Thomas Bowman. The parties lived at a common lodging-house, and the prisoner on coming home put his arm round Bowman's neck, saying he would kiss him, and bit a piece out of his lip. Prosecutor had not had the wound dressed, as he said that having gone through the Crimean war he had many wounds about his body, and he supposed the present one would heal like all the rest.

The Stafford House Committee has put forward another urgent appeal for further subscriptions to aid the Turkish sick and wounded. At the meeting of the Committee, held at the end of last week, four surgeons (Mr. T. L. Attwood, Mr. Hume, Mr. Sandwith, and Mr. Edmunds) were appointed to proceed at once to the seat of war, and it was arranged that they should start immediately.

The Hospital for Diseases of the Chest, City-road, which has recently been entirely renovated, refurnished, and virtually remodelled, was reopened last week. About £2700 has been expended in new buildings, and fourteen beds have been added by the charitable munificence of one lady; while another £1000 has been expended in the improvement of the old buildings. After a short religious ceremony, Lord Charles Bruce, who takes an active interest in the welfare of the charity, declared the buildings open, and in thanking the public for the assistance which had been rendered, expressed his hope that increased assistance would be forthcoming to aid in maintaining the usefulness of the institution.

In commenting on the recent outbreak of cholera at Bombay, the *Times of India* of June 15 observes—"We regret to say that cholera is still very prevalent in some parts of the native town, and also at Mazajou and Colaba. At both the latter places the Goanese Christians have held special services in their churches, while a body of natives, more or less disorderly, have paraded the streets to conciliate the cholera-god. The following return shows the number of cases, both in town and harbour, from the 8th to the 11th inst. inclusive:—June 8, 38 cases, 21 deaths; June 9, 36 cases, 21 deaths; June 10, 49 cases, 26 deaths; June 11, 52 cases, 26 deaths. The cholera is of a mild type, for the ordinary ratio of deaths to attacks is about 70 per cent. Neither has it any appearance of an epidemic, for the cases occur simply at scattered intervals, and have found no regular and infected centres. Perhaps the most reassuring fact to Bombay citizens is that the disease is almost entirely confined to strangers who have come into the town within the last few months, and whose wretched condition, and the inferior food on which they have to subsist, predisposes them to attack. For instance, out of the twenty-six deaths on the 11th inst., all but three occurred among the immigrants. Still this attack is another reason why we should desire an early and heavy monsoon, which will happily wash the last traces of the disease away. In the meantime the health officer and his assistants are doing all that lies in their power, by constant inspection and the free use of disinfectants. Cholera has unfortunately appeared amongst the shipping in the harbour. During the last three or four days a number of cases have occurred, some terminating fatally. We hear that on board one steamer there were no less than nine seizures, four of which proved fatal."

At a recent meeting of the Carlisle Urban Sanitary Authority, the Medical Officer of Health, Dr. Elliot, presented his annual report for the year 1876. This contained a comparison of the state of the public health during the years 1874, 1875, and 1876, and especially as regarded the prevalence of zymotic or preventable diseases. In 1874 the deaths from typhus and scarlatina were 275,—very nearly two-thirds of the deaths from zymotic diseases, and nearly one-fourth of the deaths from all causes in that really unfortunate year. In 1875 there were, from scarlet fever, 26 deaths, of which 18 were in the first quarter; and in 1876 the deaths from scarlatina were 2. Typhus numbered 97 in 1874, 29 in 1875, and 6 last year. The mortality from all causes has also largely diminished during the year 1876. The number of deaths from all causes was 1055 in 1874, 934 in 1875, and 800 in 1876—showing a diminution from each year to the next of more than 100 deaths; and this is most evident when referring to zymotic diseases, the numbers in each year respectively being 399, 222, and 131. The periodical improvement per quarter in the rates per 1000 is equally gratifying, the rates during the last three periods of 1876 being 19·6, 21, and 20, which is considerably better than the national average, and which must be considered especially good in an urban population.

Latest advices from Teheran state that a very general exodus is proceeding from Resht, in consequence of the prevalence of plague at that place. No official statistics have been issued, but the number of cases is believed to be from twenty to thirty daily. Some fears have been expressed that if this disease occurs in a bad form the large bodies of troops acting on the borders of Persia will not only become sufferers from it to a large extent, but may also be the means of conveying it to other and distant districts.

A rather important case was tried in the Crown Court at Newcastle last week. The master of a vessel that arrived in the Tyne from Carthagena was summoned by the chief officer of Customs at Shields, under the old Quarantine Act, for refusing to answer, or for answering falsely, certain routine questions put by the Customs authorities as to the health of those on board. The officer in this case, being satisfied at the time with the replies given, permitted the vessel to haul into dock, and the crew were discharged. The next morning, however, one of them was found in a lodging-house, suffering from a malignant form of small-pox, from which he died. It appeared in evidence that the man was observed to have "a rash" on him during the passage, but was, nevertheless, put into the same cabin with three other men. The jury found that the captain intentionally concealed the fact that the man was labouring under some eruptive disorder, that he had noticed it three days before, and that therefore the fact ought to have been reported. The defendant was thereupon fined £200 and costs. This conviction, as showing that the courts will not deal lightly with those who knowingly import epidemic diseases into this country, will be of the greatest importance. Too often the formal sanitary questions asked by the Customs authorities are evaded, or not correctly answered; and as the officers of the port sanitary authority have no power to stop a ship, except in cases of cholera, these latter officials are in a great measure dependent on the reports, true or false, communicated to them by the Customs officers.

The evils of what is known as the "sweating system" were brought prominently to light in a case which was heard on Monday last at the Marlborough-street Police-court. A journeyman tailor was summoned by his employer, under the provisions of the Employers and Workmen Act of 1875, for not completing some work, and was adjudged by the magistrate to pay a fine or be committed to prison in default. Mr. Lewis asked that the case, which had been heard behind the back of the defendant, might be reheard, as there was a question of vital importance to the public health involved. The defendant was summoned for not making a coat for which he had received payment in advance; and the answer was that at the time the coat was sent to him to be made up in a room occupied by himself and family, in the upper part of a house in Green's-court, he had two children lying dangerously ill with an infectious disease, one of whom had since died, while the other was still ill. Mr. Newton said the application came too late, and he could not rehear the case; it was true the case had been heard in the absence of the defendant, but that was because the defendant had failed to attend on the hearing of the summons. The "sweating system" undoubtedly requires a thorough supervision in the interests of sanitary reform.

The fatal cases of small-pox in London fell last week to 23, a lower number than in any week since the beginning of November last. The 23 cases included 14 recorded in the Metropolitan Asylum Hospitals, 1 in the St. Pancras Small-

pox Hospital, and 8 in private dwellings. The death from small-pox of the third unvaccinated child in a family living in Burdett-road, Mile-end, was registered. In the nineteen other English towns now included in the Registrar-General's weekly returns, only 6 deaths occurred from small-pox—viz., 5 in Liverpool, and 1 in Salford.

THE MEDICAL DEFENCE ASSOCIATION.

The first annual general meeting of this Association was held at the rooms of the Medical Society of London, on Friday, the 29th ult. Dr. B. W. Richardson, F.R.S., President of the Association, was in the chair, and there was a numerous attendance of members. The Honorary Secretary, Mr. George Brown, read the report of the Council, which, after giving a sketch of the origin and progress of the Association, proceeded to narrate the work which had been done since the foundation of the Association in 1875. It appeared that the Association had made satisfactory progress, and had been the means of performing much useful work. The following provincial branches have been formed, viz. :—The East Anglian Branch, of which Dr. Copeman, of Norwich, is President; the North of England Branch, Dr. Dennis Embleton, Newcastle-on-Tyne, President; the Sunderland Branch, Mr. J. Davis, President; the Nottingham Branch, Mr. Stanger, F.R.C.S., President; the Shropshire and Mid-Wales Branch; the West Cornwall, the Accrington, and the Forest of Dean Branches. These branches, together with the Central Association, contain nearly 400 members. Seven prosecutions have been conducted by the London organisation, all of which have been successful; many unqualified persons have been compelled to cease practising through the action of the Association; and in consequence of representations made to the district coroners by members of the Association, several inquests have been held on the bodies of persons who have died after having been attended by unqualified men. The provincial branches have also done some good work, having prosecuted successfully in several cases of unqualified practice, and other cases are now pending. The report also referred to the action which has been taken by the Chemists' Trade Association in support of the claim, which the chemists have now distinctly made, to the right to practise medicine, and expressed the belief that the Council would be successful in resisting these pretensions. The operations of the Council, however, have not been confined to the endeavour to check unqualified practice. Efforts have been made, both by memorial and personal interview with the President and members of the General Medical Council, to get this body to take immediate steps to effect a reform in the Medical Act of 1858. The report concluded by thanking the editors of the medical journals for their notices of the proceedings of the Association, and by recommending the organisation to the continued support of the profession. The report of the Treasurer, Mr. W. Spencer Watson, showed that the finances of the Association were in a satisfactory condition. The whole work of the Association had been done for less than £70, and at the end of the year there was a balance in hand of £22. Mr. J. Wallis Mason and Mr. W. B. Hemming having made a few remarks on the satisfactory position of the Council, and its claims to professional support, the President moved that the report and balance-sheet be adopted and printed for circulation among the members. In doing so, he remarked that he had never seen voluntary work done more earnestly or at such small expense as the work of this Council and Association. In selecting cases for prosecution, the Council had been obliged to exercise much care and discrimination; and as a result of this care, the Association was now able to say that it had done nothing which had not a successful issue; and as the report stated, the cases prosecuted did not by any means represent all that had been achieved. With respect to the General Medical Council, which had been referred to by Mr. Mason and Mr. Hemming, the President gave it as his opinion that the profession should have direct representation on that body. The report of the Medical Acts Amendment Committee was then read and adopted; and it was resolved on the motion of Dr. G. Danford Thomas, seconded by Dr. W. Beech Johnston—"That the President of the Medical Defence Association be requested to communicate with the President of the General Medical Council, with the view of bringing before him the various claims of the Medical Act as amended by the Council of the Medical Defence Association, and adopted at the annual meeting." A vote of thanks to the Council, the Hon. Treasurer, and Hon. Secretary was proposed by Mr. W. B. Hemming, seconded by Mr. H. W. Williams, and carried unanimously, after which the following officers were elected for the ensuing year, viz. :—*President :* Dr. B. W. Richardson, F.R.S. *Vice-Presidents :* Drs. Alfred Carpenter, Edward Copeman, Dennis Embleton, Andrew Clark, Messrs. W. Bowman, James Lane, Spencer Watson, Drs. Alfred Meadows, J. Hayball Paul, A. Ernest Sansom, and C. J. White. *Honorary Treasurer :* Mr. W. Spencer Watson. *Honorary Secretaries :* Messrs. George Brown and W. Douglas Hemming. *Council :* H. Adcock, L.R.C.P. Edin.; F. H. Alderson, M.R.C.S.; J. E. Brooks, L.R.C.P. Edin.; G. H. Blackmore, L.R.C.P. Lond.; H. Cuolahan, M.D.; T. Cooke, F.R.C.S.; W. H. Drew, M.R.C.P. Edin.; S. Gardner, M.R.C.S.; W. B. Hemming, M.R.C.S.; W. Beech Johnston, M.D.; C. Royston, M.D.; C. P. Langford, M.R.C.S.; N. C. Maclean, M.D.; J. W. Mason, M.R.C.S.; M. Reid, L.R.C.P. Edin.; W. S. Riding, M.D.; Walter Smith, L.R.C.P. Edin.; J. Stevenson, M.D.; G. Danford Thomas, M.D.; and H. W. Williams, M.D. A vote of thanks to the President having been carried by acclamation, the meeting terminated.

A ROYAL VISIT.

His Royal Highness the Prince of Wales again visited the Museum of the Royal College of Surgeons on Saturday last, and on this occasion was accompanied by her Royal Highness the Princess of Wales, and her brother the Prince Waldemar of Denmark and suite. The Royal party was received by Mr. Prescott Hewett, the President of the College, Serjeant-Surgeon Extraordinary to her Majesty; Professor Flower, F.R.S., Conservator of the Museum; and Mr. Trimmer, the Secretary,—by whom they were conducted over the institution, when the many interesting objects contained in the Museum were explained. The Princess appeared much pleased with the fine skeleton of the first tiger shot by the Prince in his recent tour in India, when his Royal Highness pointed out the fatal bullet preserved *in situ*. After prolonging their visit for nearly two hours, their Royal Highnesses on leaving expressed to Mr. Hewett the great pleasure they had derived in viewing the fine and admirably preserved collection, her Royal Highness saying she would pay another visit. A little incident, honourable alike to all parties, is worth recording, as showing the marked kindness of the excellent President of the College towards a deserving officer of the institution. When introducing Mr. Stone to their Royal Highnesses, he alluded to his "life-long devotion to the best interests of the College," adding that he had just entered on his forty-sixth year of faithful services to the College.

SOLDIERS' RATIONS IN MODERN TIMES.

Our contemporary *Nature* had last week an article on soldiers' rations which is of more than common interest. The army rations of several European countries are compared, not only as to the kind and weight of food supplied, but also as to their elementary components and actual nutritive worth. In this country a soldier's ration is three-quarters of a pound of meat, and one pound of bread, which in war time is supplemented by a quarter of a pound of cheese, together with cocoa, tea,

sugar, etc. The dietary of our troops in the Crimea yielded altogether 23·52 ounces of nutritive principle to each man per day. But according to our contemporary the fare of the German soldier yields a total nutriment of very nearly thirty-three ounces, even when the recently introduced pea-sausage is not the staple supply. Even the Turks, it is said, probably receive as much real nutriment as the British soldier—that is to say, on paper. The Turkish soldier, it is stated, rarely tastes meat, but will fight for any time upon rations of meal and bruised Indian corn. The nutritive value of Russian and Turkish rations seems to be about on a par, though the writer expresses some doubt as to what the Russian really does eat. The latter receives two pounds of black bread, and a quarter of a pound of fresh meat or bacon, with garlic, salt, and tea. It must, however, be remembered that these statistics are compiled from documents or published "regulations," and that the shortcomings on the score of rations, which more than once cropped up in relation to the Crimean war in our own service, have a wonderful knack of coming to the fore wherever active operations are in force; on such occasions the soldiers of nearly every country have in many instances to "take the will for the deed."

THE DERBYSHIRE COUNTY LUNATIC ASYLUM.

In presenting the twenty-fifth annual report on the Derbyshire County Lunatic Asylum for the year 1876, Dr. J. Murray Lindsay, the Superintendent Physician, states that of the 419 patients remaining in the Asylum on December 31st last, not more than 39 (19 males and 20 females), or 9·30 per cent., are deemed curable. The admissions of the past year, he states, have been of a more unfavourable class than usual, both as regards their physical condition, mental state, and duration of insanity; as many as 119, or about two-thirds of the entire number, had been insane upwards of three months before admission. For this reason Dr. Lindsay thinks it necessary again to call attention to the evil which results from delay in sending cases into the Asylum in the early stages of their malady. This delay, he adds, is mistaken kindness on the part of relatives and friends, and by no means wise economy on the part of parochial authorities, as it is unfavourable to recovery. Instead of the Asylum being looked upon as a hospital to which patients labouring under mental aberration should be sent in the earliest stages of the disease, there appears to be an increasing tendency to detain them at home, and to delay their despatch to the Asylum until every resource has failed. The aged, feeble, or paralysed may linger on a short time, whilst the maniacal and melancholic are frequently sent after the malady has lasted a considerable period, valuable time having been lost, and the patients are so prostrate and exhausted, from long-continued previous excitement and abstinence from food, that it is impossible to rally them. Of this latter class Dr. Lindsay complains that the Derby Asylum has received too many examples during the past year.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

On Monday, July 9, the Fellows of the College proceeded to vote for three members of Council to fill the vacancies caused by the recent deaths of Mr. Henry Wilson and Dr. John Cronyn, and by the resignation of Dr. Archibald Jacob. The voting was remarkably close, and resulted in the election of Dr. Anthony H. Corley, Surgeon to the Richmond Hospital; Dr. William Stokes, Junior Surgeon to the Richmond Hospital; and Mr. Benjamin F. McDowell, Surgeon to Mercer's Hospital. Dr. Jacob resigned his seat on the Council in order to qualify himself for the competition for the chair of Ophthalmic Surgery, vacant through tho death of Mr. Wilson. Among the other candidates for this chair are Mr. H. Rosborough Swanzy, Surgeon to the National Eye and Ear Infirmary; Mr. Loftie Stoney, Ophthalmic Surgeon to the City of Dublin Hospital; and Dr. R. Rainsford, Surgeon to St. Mark's Ophthalmic Hospital. The Professorship of Midwifery, rendered vacant by the death of Dr. Cronyn, will be filled up early in August. Several candidates have entered the field, among whom, we believe, are Dr. Rutherford Kirkpatrick, Dr. Arthur V. Macan, Dr. Roe, etc.

MEDICAL PARLIAMENTARY AFFAIRS.

Imbeciles in Ireland.—Lord O'Hagan moved the second reading of a Bill having the effect of providing means for the education and moral improvement of lunatics and imbeciles in Ireland. Admirable institutions of the kind had been established in England, but, with the single exception of Dr. Stewart's asylum, no attempt had been made to provide for this unfortunate class in Ireland. The blind, the deaf, and the lame are carefully provided for by the guardians of the poor, but the imbeciles are entirely neglected. The Act for ameliorating the condition of this class of society in England was passed in 1862. The Lunacy Commissioners, in their Report for 1868, strongly objected to the association of imbecile with lunatic children. Many of these children, as proved from statistics, could be carefully trained in industrial and other pursuits, and at the same time have their intellectual and moral culture attended to. He alluded to the beneficial results to imbecile children of such institutions as the Royal Albert Asylum. The Duke of Richmond, in his reply, reminded the noble lord that a committee is now sitting and taking evidence on the general question of the operation of the lunacy laws. The Government were prepared to take such steps as should secure a full inquiry into this important question. The Bill was thereupon withdrawn.

Public Health.—Directions for a memorandum have been prepared, showing the clauses to be taken from the Acts now in force in the metropolis for the public health, distinguishing between those which are from Acts not in force and those which are new. Mr. Sclater-Booth further explained that the Bill does not propose to transfer any power from the Secretary of State or Privy Council to himself, because all the powers under the consolidated Acts were so transferred by the Local Government Board Act, 1871. In January last, in the exercise of these powers, a circular letter was addressed to the district boards of the metropolis on the subject of providing hospital accommodation under one of the Acts now proposed to be consolidated, and no exception was taken by them in their replies to the Local Government Board. The only new powers proposed to be conferred on the Local Government Board are with respect to the provision of mortuaries and the approval of voluntary arrangements between two or more Authorities for providing joint hospital accommodation. Mr. Sclater-Booth added that some fresh powers are given to district boards. It was hoped the memorandum would be in the hands of members on July 7.

Broadmoor Lunatic Asylum.—In reply to the charge of mismanagement of this Asylum, Mr. Cross explained that the working of the institution had been carefully scrutinised by a committee of gentlemen, and their report was laid on the table. He agreed that the expense was at present enormous. He hoped before another year to be able to report that some satisfactory arrangement had been made. He had come to the conclusion that it was wrong to mix criminal and non-criminal lunatics together, so that ever since he had been in office he had ordered that no person convicted of crime should be sent to Broadmoor, notwithstanding his subsequent lunacy; but this rule only applied to men, because there was no other place for female lunatic convicts to be incarcerated. The lunatic criminals already sent would remain, but no more could be sent. It was fallacious to compare with other asylums the relative proportion of attendants, on account of the dangerous character of the lunatics at Broadmoor. It was difficult to discharge lunatics when they had no friends or relatives to whose care they could be committed.

The Nightingale Fund.—The annual report for the past year of the Nightingale Fund shows that there were at the commencement of the present year twenty-nine probationer nurses in the school at St. Thomas's Hospital. Thirty-six were admitted during the year. Of the total number (sixty-five), twenty-five had completed the course of training and received appointments, three had resigned, and six were discharged as not suitable for the work.

ANNUAL FESTIVAL OF THE ROYAL COLLEGE OF SURGEONS.

After the annual election of Fellows into the Council of this institution, a notice of which appeared in the *Medical Times and Gazette* last week, a large party of the Fellows dined together at the Albion Tavern, under the presidency of Mr. E. L. Hussey, the Senior Surgeon to the Radcliffe Infirmary, Oxford. In giving the toast of "Her Majesty the Queen," the chairman reminded the Fellows that it was by the power of the present sovereign that they received the charter under which they met year after year on such occasions as the Fellows' Dinner. And when proposing "The Health of the Prince of Wales and the rest of the Royal Family," he said that the present heir-apparent was for some time a resident in the city in which he himself practised; and, if it was not indecorous to refer to the personal life of a member of the Royal family, he would add that he had sufficient opportunity of witnessing the perfect correctness of his Royal Highness's conduct as a prince and a gentleman.

"The Army, Navy, and the Auxiliary Forces" was ably proposed by Mr. Timothy Holmes, and responded to by Sir Joseph Fayrer and Dr. Shepherd (of Middleton-square).

The toast of "The Medical Corporations" was proposed by Dr. Monckton, of Rugeley, who, in reference to the Apothecaries' Company, said he had not forgotten the time when his tremblings as a student were exchanged for the pride of licentiateship; and as a provincial medical practitioner he had not failed to observe that it was to the Hall that the thanks of the country and the profession were due for the improved education, character, and position of the general practitioner at a period when the two other Corporations took less interest in that personage than they now happily do. For the Royal College of Surgeons he professed the strongest personal attachment, remembering the days of old when within its portals he had worked, though in a humble capacity, with Owen and Quekett, under the eyes of a Grainger, a Green, an Arnott, and a South. And again, on a recent occasion, he seemed to think the glory of the College had culminated as he listened to the eloquent and stirring oration of Paget in the presence of the future sovereign of these realms. Dr. Monckton then spoke of the high degree of culture and dignity to which the College of Physicians had attained, and the noble hospitality dispensed within its walls; and, in leaving the toast of the three Corporations in the hands of the company, he would only further express his hopes that, in combining to promote the success of the Conjoint Scheme, time would show that they had worked together for the substantial good and well-being of the profession at large.

Dr. Bennett, the President, returned thanks for the Royal College of Physicians.

Mr. Luther Holden, in speaking for the Royal College of Surgeons, said that he could assure the Fellows and Members that the College was never more prosperous, and never stood higher in public estimation than at present. This was proved by the continually increasing number of students who sought its diploma, by a glance at the constantly increasing and most valuable additions to its Museum, which was the most complete of its kind in Europe, and by its financial position. Whatever changes might be produced in the profession by the probable "Conjoint Scheme" of examinations, Mr. Holden assured the Fellows and Members that the Council would leave no stone untouched to transmit to their successors the precious charge which had been entrusted to them, with its dignity, its prosperity, and its hold upon the profession unimpaired.

Mr. Bradford responded for the Society of Apothecaries.

Mr. Wood, in proposing "Health and Prosperity to the Provincial Schools of England," remarked that nothing showed more decidedly the tendency to decentralisation inherent in the Anglo-Saxon race, than the multiplicity of the centres of education, and markedly of medical education, which developed themselves all over the kingdom. Like the petty universities of Germany, the medical schools of England were both numerous and powerful in their struggle for existence. And although the tendency of this metropolis, as of all other chief cities, was to attract and absorb the conspicuous talent and enterprise of the country, in the medical profession it had by no means left the provinces denuded. The names of provincial surgeons and teachers eminent in the past would occur to everybody's recollection. Hey and Teale, of Leeds; Jordan, Hodgson, and Frere, of Birmingham; Heath, of Newcastle, etc., of a former era, are worthily represented by Bickersteth, Humphry, Cadge, and many others, among the living representatives of the provincial schools of surgery. It was on occasions like the present that the metropolitan teachers came more closely in contact with their provincial brethren. In the examination-room the power and results of the provincial teaching were best estimated, and none could better judge of the value of the provincial schools than the examiners of the College of Surgeons. But he must say that it was pleasanter to meet the representatives of the provincial schools at the festive board than at the examination board. He hoped that the provincial schools would long continue to help to redress the balance of metropolitan surgical opinion, when wavering to a decision, by their practical common sense and intelligence.

"The Metropolitan Schools" was ably and eloquently proposed by Mr. E. Lund, of Manchester, and responded to by Mr. Timothy Holmes, of St. George's Hospital.

Mr. Holden proposed "The Health of the Chairman.' He said: It is exceedingly grateful to me to be commissioned by our master of the ceremonies to lead you all into the sweetness of good-fellowship by proposing the health of our chairman. This pleasing duty has been assigned to me by reason of our long and intimate friendship. Dating from student's days at St. Bartholomew's, I never knew a more painstaking or truthful student. Such as he was as a student, so he is now—an honest, earnest worker, very little altered by time. I could say much about him, if he would leave the chair, which I hardly like to say to his face. You too might think that I was using the too flattering expressions so often used on these occasions. Long may we have the pleasure of seeing his features, so pregnant with intellect and decision of character, at our annual Fellows' Dinner.

The Chairman, in reply, said: It is, I believe, the established custom of the Festival that the chairman's chief duty shall be to propose what may be called the introductory toasts, and to return thanks for his own health, if you should pay him the compliment of receiving such a toast. The first part of this duty I have discharged; the other part remains, and it is by no means an easy one. It is a task requiring some skill, and more than an average amount of practice, to acknowledge in fit terms such a compliment as you have paid me, and paid too with a grace more due, I suspect, to the favourable opinion of my friend Mr. Holden, than to any merit of which I am conscious as arising from any services I have rendered to you or to the profession. I trust you will accept these few words as the expression of my grateful sense of the honour you have done me, and the kindness with which you have received my name. I hope I shall not start a subject of discussion. I wish to make a suggestion for the future occupation of this chair. You can see that there are around me many men, my seniors in professional standing, to say nothing of their right of precedence from reputation. I cannot help thinking that we might go on as smoothly hand-in-hand through the Register of Fellows, if we took the chairman of the Annual Festival from among the country Fellows every third year, instead of every other as we do now. There are, I believe, now on the Register, between the chairman of last year and myself, not less than twenty Fellows resident in London, who have claims which ought not, I think, to be lightly regarded, or set aside without sufficient reason in favour of a junior from the country. I merely throw out the suggestion for the consideration of future stewards. If the question has been considered, and the present *rota* established on principles which past stewards have thought best, I do not suggest that it should be reopened. And for the future, in this chair I hope you may long continue to have, after me, a succession of men as well able to fill the chair and do honour to the occasion as the many well-graced actors who have left the stage before me, and whose well-known voices have fallen in sweeter accents on your ears. The chairman of this year's Festival soon passes from your presence; but as he fades from your memory, believe me,—

> "He ne'er will forget the short vision that threw
> An enchantment around him while lingering with you."

After several other toasts,

The Chairman rose to propose the last toast, and said: As the last act of the chairman's life I have to give you a toast; it is, "The Health of our Hon. Secretary, Mr. Allingham."

He is the Executive Officer of the Committee of Stewards, without whom (I hope I may say it without offence, especially as they have all left the room) they could not be brought together, to act and to plan what is before us. I am one of those who remember all the enthusiasm and high feeling with which this Festival was established. Is it not due to the Secretary that it is not likely to drop? I don't wish to keep you long, but we ought not to part without this acknowledgment, and making the small return which our thanks can give for all the work he has so kindly done for us—an amount of labour which, to my knowledge, has extended each year over weeks, and even months. He has done his work so well, and he has held his office so long, that I am sure you will join with me when I add that I grieve to think it is Mr. Allingham's last year of office.

FROM ABROAD.

On Constipation.

Dr. William Thompson, Professor of Therapeutics in the University of the City of New York, publishes in the *New York Medical Record*, May 5, an interesting clinical lecture on constipation, of which the following is an abstract:—

The form of constipation treated of is perhaps met with in males as commonly as among females, and may be due either to deficient action of the small intestine, or to deficient action of some part of the large intestine. 1. *Deficient action of the small intestine* may be due either to deficient secretion or to a want of innervation and muscular action; but although these two causes are distinct, in many cases they are both in operation. *Deficient secretion* may be due to disturbance of the action of the liver, and therefore may date back to some prior disease disturbing the action of that organ. Thus, constipation from this cause is common in the Southern States as a sequel to diarrhœa, and is often met with in the Northern States as the result of malarial poisoning. There is in these cases no extraordinary accumulation and impaction, but a sluggish action of the bowels, medicine being required to produce stools in four or five days, which are even then moderate in amount and quite dry. In most cases there is present a dull pain, or rather an incomfortable sensation, at the back of the head, which is best relieved by a free discharge of bile. The tongue is not large and flabby, but usually small, with a little redness at the tip and along the edges. The secretions of the mouth are viscid, indicating the condition of defective secretion that prevails all along the canal. Mild cathartics in these cases are injurious, and active purgatives still more so. What is wanted is the presence in the intestine of a small increase of lubricating liquid, and this is obtained by causing the patient to take a great deal more water than customary—drinking on rising, for example, two tumblers full of water; and as a rule those who drink a considerable quantity of water are not constipated. Its laxative action may be insured by the addition of some saline, as carbonate of soda or salt—the water to which this is added not passing so readily through the mucous membrane into the general system, and thus more readily exciting peristaltic action. A half-drachm of sulphate magnesia dissolved in a pint of water will for this reason act sufficiently as a cathartic. A curious fact is that the addition of small doses of quinine to salines increases their power of acting on the intestinal canal. Thus, mag. sulph. ʒj., quin. sulph. gr.j., taken in a tumbler full of water every morning, rarely fails to produce all the laxative effect required in every form of deficient secretion—as, for instance, in constipation following fever—where we wish to obtain free evacuations. Patients should be told not to expect much effect for a week or two; but, if they can be induced to persist in the daily use of large quantities of water, great benefit will almost always follow. The popular belief in the laxative effect of fruit has some truth in it—as, for example, oranges; but to overcome constipation by these, many have to be eaten, and in warm climates they prove quite effectual. Figs are also useful, providing large quantities of water are taken with them—water, in fact, being one of the most important agents in this form of constipation. If there is flatulence, four grains of assafœtida may be given with nine grains of soap as a pill, while nux vomica may be added when there is *defective innervation*, which is usually the case when the constipation occurs in persons of sedentary habits and occupations. In such there is a tendency to headache, with deficiency in excretion of the colouring matters of the bile. They are usually of dull, sallow colour, with a tendency to greasy matters on the surface, the entire movements being sluggish, and the pulse usually slow. These persons, contrary to those mentioned above, do not bear much water, which weakens their digestive powers, and does not induce much peristaltic action. If such patients can be sent away from their occupations, the waters of a mineral spring may benefit them much; and where they cannot, water used externally in the form of a nightly very cold sitz-bath, followed by good reaction, is often of the greatest benefit. In other cases, the spine and abdomen may be sponged on rising every morning with cold salt water, rendered as irritant as possible; or cold water may be dashed on the abdomen while the patient is in the standing posture. In this class of cases nux vomica is a very efficient remedy, given in combination with any other suitable drug. It will increase the efficacy of small doses of the resinous cathartics, which are irritant and stimulant. Small doses of rhubarb, with nux vomica and soap, in a pill, may be given much more beneficially than when given alone. Faradisation—one pole being placed over the spine, and the other passed up and down over the abdominal walls—will in many cases be found beneficial.

2. *Deficient Action of the Large Intestine.*—This also may depend upon deficient secretion, or defective innervation; but far more frequently on the latter. One of the worst forms of this is when the constipation depends upon deficient nerve-power in the rectum alone, and which, if overlooked, may give rise to rectal abscess. The patients have little knowledge that they should have a movement, and when the sensation does occur they have little or no power of expelling the fæcal accumulation. One of the most common causes of this condition is chronic inflammation set up about hæmorrhoids. The relaxed condition which follows the defective innervation renders prolapsus of the rectum very probable. These patients are remarkable for being generally low-spirited, so that even insanity may be induced by such a state of the rectum, disappearing when this has been relieved. In treating these cases the first indication is to keep the rectum empty; and when accumulations do take place they are best removed by enemata. These, however, should never be prescribed as a regular treatment, for if the habit is acquired of emptying the bowels daily by their aid they can never be dispensed with. When the accumulation which has caused the enema to be employed has been thoroughly removed, other means should be resorted to for restoring the innervation of the bowel; and in these cases the injection of strychnia into the submucous tissue is an exceedingly valuable specific. If necessary, a fold of the mucous membrane may be drawn down, and the injection inserted. It will frequently cure the worst forms of prolapsus of the rectum, as well as that condition in which there is simple debility with hypertrophy of the mucous membrane. "I have relied upon this agent almost exclusively in this class of cases of constipation, whether the real cause was hypertrophy of the mucous membrane from long-standing hæmorrhoids, or there was simple deficiency of power in the rectum to expel its contents." In cases of cystitis dependent upon large prostate there is always accumulation in the rectum from deficient innervation; and whenever a patient complains of incomplete emptying the bowel, this should be thoroughly cleared out by an enema, and strychnia injected—often with material relief to both diseased conditions. In other forms of constipation there are accumulations of scybalous matters in the upper part of the rectum and in the transverse colon. When these last are dislodged they come down into the sigmoid flexure; and mineral waters, such as the Kissengen, are very useful in effecting such dislodgment, loosening the scybalæ without depressing the patient. The water may be taken in the morning; a suppository of stramonium or belladonna (sufficient to cause a little dryness of the throat and slight dilatation of the pupil) may be introduced in the evening. Constipation may be met with during the recovery from pneumonia and other febrile affections, arising from accumulations at various parts of the canal. Compound jalap powder is a very effective means for preventing such accumulations.

Specialising Midwifery in the Paris Hospitals.

A movement has been set on foot to bring about in Paris a practice which has long since prevailed in London. The faulty organisation of the Paris hospitals, it is observed in a recent number of the *Gazette Médicale*, consigns the midwifery

department of these to the physicians or surgeons of the hospitals, without their being possessed of any special competency. In order that a remedy may be provided for so abnormal a state of things, the following petition, signed by Dr. Bourneville, editor of the *Progrès Médical*, and fifteen of the rising young doctors of Paris, has been transmitted to the Municipal Council:—"The undersigned, considering that the practice of midwifery and the treatment of the accidents that often accompany it, which necessitate operations that are in general difficult and laborious, exact knowledge that is truly special; and considering that, in the present state of the organisation of the hospitals, the wards occupied by pregnant women, lying-in women, and nurses, form part of the ordinary medical services devoted to acute diseases, which take up nearly all the time of the visits of the physicians: we pray that the Assistance Publique do institute wards exclusively destined for pregnant and lying-in women and nurses, that these services may be exclusively confided to *médecins-accoucheurs*, just as the medical services are confided to physicians, and the surgical services to surgeons, and that the nomination of these *médecins-accoucheurs* be effected by canvass." The *Gazette Médicale* observes that, following the spirit dictating the above petition, the midwifery wards of the hospitals, or, what would be better, maternities substituted for them, should be exclusively reserved for women, who for some reason cannot avail themselves of assistance rendered *à domicile*.

REVIEWS.

A Systematic Handbook of Volumetric Analysis; or, the Quantitative Estimation of Chemical Substances by Measure applied to Liquids, Solids, and Gases. By Francis Sutton, F.C.S., Public Analyst for the County of Norfolk, etc. Third Edition. London: J. and A. Churchill. Pp. 430.

When a book like this reaches a third edition, not much requires to be said on its behalf. Since the book first appeared many improvements have been made in the art of volumetric analysis,—many new processes have been invented, many old ones perfected: with all of these the book keeps on its way, constantly up to the mark of the day. We should not have thought it necessary to say even this much for it were it not for one particular reason. We are often asked as to the best book on water analysis, and we can always reply with confidence that there is nothing better to be had than the section on the subject in this work. Smaller treatises are to be found, but perhaps the fairest is that now before us.

The Microscopist: a Manual of Microscopy and Compendium of the Microscopic Sciences. Third Edition, rewritten and greatly enlarged, with 205 illustrations. By J. H. Wythe, A.M., M.D., Professor of Microscopy and Biology in the Medical College of the Pacific, San Francisco. London: J. and A. Churchill. Pp. 259.

Though it cannot be said that we are at the present time greatly in want of books on the microscope, constructed on the plan of the present work, nevertheless many will be glad to receive it, for various reasons. It is, to begin with, a kind of encyclopædia of microscopic science, and though of by no means equal merit, gives a fair view of most of the departments of knowledge on which it treats. Where it seems to us most defective is when it deals with human physiology and pathology, but perhaps this is of the less importance, as the work, from its scope and purport, is suited rather to the amateur than to the practical student of medicine. It is illustrated by many beautiful plates and drawings, the former for the most part tinted and well executed. Coming as it does to us from the shores of the Pacific, from a city which, within easy recollection, could hardly be said to exist, it impresses us with a great idea of the energy and success of our Transatlantic brethren.

A Manual of Dental Anatomy, Human and Comparative. By Charles S. Tomes, M.A. London: J. and A. Churchill. Pp. 406.

We have carefully read and studied this little work, and we may at once say, have been highly gratified with its character and contents. There was no really good book on dental anatomy such as the medical or dental student requires. Such as existed were either far too strictly scientific or too flimsy. Students, working as medical and dental students have to work—that is to say, in a certain definite and prescribed course—require works specially constructed for their use, and in this way Mr. C. S. Tomes' book is likely to be most valuable. We would here refer more particularly to the earlier portion of the book, where the anatomy and physiology of the human teeth are considered. This we can safely say is a most useful and succinct account of all that relates to the structure and development of these important organs. The work is brought down to the latest date, and is in every way thoroughly reliable.

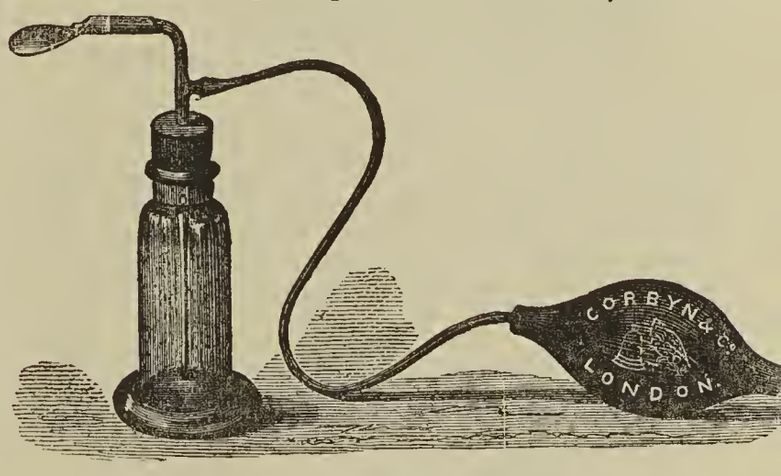
Elementary Text-Book of Physics. By J. D. Everett, M.A., D.C.L., F.R.S.E., Professor of Natural Philosophy in the Queen's College, Belfast. London: Blackie and Son. Pp. 314.

This seems to us to be an exceedingly useful and admirable little treatise, especially adapted for upper forms at schools; and we may be sure that in the hands of the accomplished translator of Deschanel's Physics the work will be well done. One useful feature is that it contains a number of examples for the pupil's working out.

NEW INVENTIONS AND IMPROVEMENTS.

"THE THROAT-SPRAY."

Messrs. Corbyn, Stacey, and Co., of 300, High Holborn, have introduced a neat and handy instrument for the application of remedies in the form of fine spray, especially to the throat and mouth. It is as simple as possible in construction, and not



likely to get out of order; and a small vulcanite *tongue depressor* is ingeniously adapted to it, which serves to keep down the tongue gently, and so to leave the way clear to the back of the throat, while at the same time it catches any condensed spray, and prevents its running over the tongue. The box for the apparatus contains also a measure-glass.

"LAXORA" LOZENGES.

The "Laxora Lozenges," introduced by P. Guyot, of 82, Southwark-street, may be commended as a mild and useful aperient. They consist of a core, or centre-part, composed of manna, cassia-pulp, and other like laxatives, we believe, enclosed in a crystalline chocolate crust; are not at all unpleasant to the taste, and will, we doubt not, be readily taken by children as well as by adults. The lozenges are a successful example of the many efforts that are being made in these days to disguise medicines and make them pleasant. They will be very acceptable in the nursery.

"SOLUTIO OPII PURIF."

From Messrs. C. J. Hewlett and Son, of Gracechurch-street, we have received a new form of opiate, to which they give the name "Solutio Opii Purif." It is meant, we suppose, to compete in public favour with our old and tried friend, Battley's "Liquor Opii Sedativus," and it is "guaranteed perfectly free from resinous matter and other impurities." We do not think that it is quite free from resinous matter, as in drying it leaves behind a gummy residue, so that if a bottle of it is left undisturbed for some time after use, the stopper becomes

very firmly fixed—gummed-up, in fact; but it is, we believe, a pure solution of opium, and is free from some of the objections that attend the use of the tincture. The dose of it is from five to forty minims.

MEDICAL NEWS.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen passed their primary examinations in Anatomy and Physiology at a meeting of the Board of Examiners on the 10th inst., and when eligible will be admitted to the pass examination, viz. :—

Bates, William R., student of the Liverpool School.
Benthall, Winford, B.A. Cantab., of the Cambridge School.
Beverley, Albert, of the Leeds School.
Brooke, Henry G., of the Manchester School.
Dale, Benjamin H., of the Bristol School.
Dennis, Frederic S., of the New York School.
Dixon, Harry A., of the Manchester School.
Harrison, Arthur, of the Sheffield School.
King, Henry W., of the Edinburgh School.
Kirker, Gilbert, of the Belfast School.
Luckman, Edward L., of the Manchester School.
Manners, Arthur, of the Liverpool School.
Milne, James K., of the Manchester School.
Oglesby, Henry N., of the Leeds School.
Rendall, Stanley M., of the Edinburgh School.
Robins, John J., of the Newcastle School.
Russell, James W. L., of the Sheffield School.

The following gentlemen passed on the 11th inst., viz. :—

Baker, William J., student of St. Bartholomew's Hospital.
Dester, William P., of the Bristol School.
Freeman, Edward J., of the Dublin School.
Gibbon, William, of the Manchester School.
Hamilton, Seton G., of St. George's Hospital.
Hayward, John D., of the Liverpool School.
Pickworth, Alfred J., of the Liverpool School.
Sankey, William A. C. O., of University College Hospital.
Taylor, William M., of the Newcastle School.
Todd, Octavius, of the Aberdeen School.

Twenty candidates having failed to acquit themselves to the satisfaction of the Board, were referred to their anatomical and physiological studies for three months. The Board adjourned to this day (Friday), when the examinations will be resumed, and not be brought to a conclusion until next week. At a meeting of the Council on Thursday, the recently elected members—Messrs. Erichsen, F.R.S., Savory, F.R.S., and Holmes—took their seats.

The following were the questions on Anatomy and Physiology submitted to the 137 candidates at the written portion of this examination on Saturday last, when they were required to answer at least four, including one of the first two out of the six questions, viz :—1. Describe the structure and function of a lymphatic gland. 2. Explain why a distant and a near object, lying before the eye, cannot be, at the same time, distinctly seen. What is the mechanism by which a sharply defined image of each in turn is formed on the retina? —3. What are the distinctive characters of the male and female pelvis? 4. Describe in order the parts brought into view in the back of the forearm by the removal of the superficial layer of muscles. 5. Describe the dissection required to expose the profunda femoris artery; and give its branches, their distribution and anastomoses. 6. Describe the course, relations, connexions, and distribution of the glosso-pharyngeal nerve.

APOTHECARIES' HALL.—The following gentleman passed his examination in the Science and Practice of Medicine, and received a certificate to practise, on Thursday, July 5 :—

Blomfield, Arthur George, Barton-le-Clay, Bedfordshire.

The following gentlemen also on the same day passed their primary professional examination :—

Butterworth, John Tyngle, Birmingham General Hospital.
Bennington, Robert Crewdson, St. Thomas's Hospital.
Campbell, William Frederick, St. Mary's Hospital.
Clowes, Joseph Smith, Guy's Hospital.
Green, Thomas Beaufoy, University College.
Leatham, Henry Blackburn, St. Thomas's Hospital.
Lloyd, John Jenkin, University College.
Powell, John James, St. Thomas's Hospital.
Temple, Thomas Cameron, Middlesex Hospital.
Weekes, Francis Henry, St. Thomas's Hospital.

APPOINTMENTS.

COLE, EDWARD F. J., M.R.C.S. Eng.—Colonial Surgeon to the Island of St. Helena.

SMITH, W. H., M.R.C.S., L.S.A.—House-Surgeon to the Beckett Hospital and Dispensary, Barnsley.

NAVAL, MILITARY, &c., APPOINTMENTS.

ADMIRALTY.—Staff Surgeon Duncan Hilston, M.D., has been promoted to the rank of Fleet Surgeon in her Majesty's Fleet, with seniority of May 3, 1877, and will stand on the list as senior to William George Ridings. Deputy Inspector-General of Hospitals and Fleets William Loney has been placed on the Retired List from the 3rd inst., with permission to assume the rank and title of Inspector-General of Hospitals and Fleets on the Retired List from the same date.

WAR OFFICE.—Surgeon-Major Alexander Peile Cahill, M.D., retires upon half-pay, with the honorary rank of Deputy Surgeon-General; Surgeon-Major Francis Henry Macfadin retires upon temporary half-pay; Surgeon-Major William Robert Burkitt retires upon half-pay. Assistant-Surgeon Richard John Magee (Kilkenny) to be Surgeon of Militia under the provisions of the Royal Warrant of July 12, 1876.

YEOMANRY CAVALRY.—Cheshire: William Charles Watson, gentleman, to be Surgeon. North Somerset: John James Saville, gentleman, to be Surgeon.

BIRTHS.

BADCOCK.—On July 5, at 58, Buckingham-place, Brighton, the wife of Lewis Carter Badcock, M.D., of a daughter.

CONRY.—On July 5, the wife of John Conry, L.K.Q.C.P. Ire., Surg. R.M.A., of a daughter.

CRAN.—On July 6, at Blackrie House, Aberdeenshire, the wife of John Cran, M.D., Canonbury, of a son.

DAY.—On June 25, at Clayton House. Chapel-street, Pentonville, N., th wife of W. H. Day, L.R.C.P., M.R.C.S., of a daughter.

EASBY.—On July 4, at March, Cambridgeshire, the wife of W. Easby, M.D., of a daughter.

GILCHRIST.—On June 28, at Edinburgh, the wife of James Gilchrist, M.D., Dumfries, of a son.

MAY.—On July 8, at Clinton House, Twickenham, the wife of Percy May, M.R.C.S., of a daughter.

NIX.—On July 7, at Upper Marylebone-street, W., the wife of Edward J. Nix, M.D., L.R.C.S. Edin., of a son.

SHAROOD.—On July 6, at 7, Headland-park, Plymouth, the wife of Edward Julian Sharood, M.D., Staff-Surgeon H.M.S. *Cambridge*, of a daughter.

SIMS.—On July 4, at 25, Halfmoon-street, W., the wife of F. Manley Sims, F.R.C.S., of a daughter.

MARRIAGES.

BLAKISTON—HARPER.—On July 10, at St. Stephen's, Lewisham, Arthur Alexander Blakiston, M.R.C.S., L.S.A., of Benenden, Kent, youngest son of the late Rev. Robert Blakiston, Rector of Ashington, Sussex, to Emiline Cotton, third daughter of E. Norton Harper, Esq., of Lee, Kent.

MACRAE—LAING.—On July 5, at St. Paul's, Knightsbridge, Charles Colin, barrister-at-law, only son of A. C. Macrae, M.D., of Westbourne-terrace, to Cecilia Mary Bruce, daughter of Samuel Laing, Esq., M.P., of 36, Wilton-crescent.

MCVAIL—ROWAT.—On July 7, at Clapton-park Congregational Chapel, John C. McVail, M.D., of Kilmarnock, to Jessie, eldest daughter of the late John Rowat, of Kilmarnock, N.B.

POWELL—CUMMINS.—On July 2, at the Church of the Holy Trinity, the Rev. Dacre Hamilton Powell, M.A., Curate of Holy Trinity Parish, to Edith Louisa, second daughter of W. Jackson Cummins, M.D., of Charlotte-quay, Cork.

ROBERTS—LINDFIELD.—On July 7, at Christ Church, Albany-street, Regent's-park, H. W. Roberts, M.R.C.S.E., L.S.A. Lond., of Lewisham High-road, to Eliza, daughter of the late Thomas Lindfield, Esq.

STACY—WEBBER.—On July 5, at St. Mary's, Abbey-road, Fitz Roy, son of J. E. Stacy, F.R.C.S., to Lizzie, daughter of the late Thomas Webber, Esq., of Edgware-road.

WATNEY—HALL.—On July 3, at St. George's, Hanover-square, Alfred Raby Watney, to Annie Elizabeth, youngest daughter of Alfred Hall, F.R.C.P., of Brighton.

DEATHS.

HEBERDEN, THOMAS, M.D., at 98, Park-street, Grosvenor-square, on July 8, aged 75.

KIDD, LEONARD ALEXANDER, second surviving son of Surgeon-Major Kidd, M.B., A.M.D., at Marley Villa, Simla, Punjaub, on June 10, aged 3 years and 6 months.

NICHOLAS, MARTHA, wife of George Edward Nicholas, M.D., of Wandsworth, at Wandsworth, Surrey, on July 6, aged 48.

STACPOOLE, ARTHUR PEMBERTON, second son of G. C. Stacpoole, M.D., in Philadelphia, U.S., on June 8, aged 27.

SCOTT, CHARLES, M.D., C.B., Inspector-General of Hospitals, Honorary Surgeon to her Majesty, late of the 32nd Light Infantry, at St. Edmund's Villa, South Lambeth-road, London, on July 9, aged 74.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

WEST LONDON HOSPITAL, HAMMERSMITH-ROAD, W.—House-Surgeon. Candidates are requested to attend the meeting of the House Committee with testimonials, on July 16, at 10 a.m.

WILTS COUNTY LUNATIC ASYLUM.—Assistant Medical Officer. Candidates must be duly qualified and registered medical practitioners. Applications, stating age, and accompanied by not more than six recent testimonials, to the Clerk to the Committee of Visitors, marked on the outside "Applications," on or before July 18.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

VACANCIES.

Bolton Union.—The Harwood District is vacant; area 4738; population 10,118; salary £50 per annum.

Faringdon Union.—Mr. Caleb Barrett has resigned the Shrivenham District; area 14,714; population 2721; salary £70 per annum.

Isle of Wight Union.—Mr. J. E. Beckingsale has resigned the Workhouse; salary £90 per annum.

Southmolton Union.—Mr. Richard Ley, jun., has resigned the Ninth District; area 11,650; population 1937; salary £33 10s. per annum.

APPOINTMENTS.

Alresford Union.—George R. Lawrence, M.R.C.S Eng., L.S.A., to the Second District.

Abingdon Union.—George Gossett, M.R.C.S. Eng., M.B. Camb., to the First District.

Blackburn Union.—Wm. Crawford, M.B. and C.M. Glasg., to the Witton District.

Greenwich Union.—Henry W. Roberts, M.R.C.S. Eng., L.S.A., to the South Deptford District.

Macclesfield.—Charles Estcourt, F.C.S., as Analyst for the Borough.

North Bierley Union.—Robert T. Bryden, L.R.C.P. Edin., L.R.C.S. Edin., to the Thirteenth District.

St. Thomas Union.—Thos. Markby, M.R.C.S. Eng., L.S.A., to the Woodbury District.

PRINCE MILAN has conferred the Gold Cross of the Takova Order upon Mr. William Collingridge, in acknowledgment of services rendered during the Turco-Servian war. Mr. Collingridge is said to have been the first English surgeon upon the Servian field.

MR. G. A. WRIGHT, B.A. Oxon., M.R.C.S. Eng., has just been appointed Anatomical Assistant in the Museum of the Royal College of Surgeons, in the vacancy occasioned by the removal of Mr. Doran, F.R.C.S., to the office formerly occupied by Dr. Goodhart.

NAVAL MEDICAL SUPPLEMENTAL FUND.—At the quarterly meeting of the directors of the Naval Medical Compassionate Fund, held on the 10th inst., Dr. J. W. Johnston in the chair, the sum of £85 was distributed among the various claimants.

NEW FUNCTION OF THE LIVER.—Under this title we recently (*Medical Times and Gazette*, June 9, page 621) gave a translation of Prof. Schiff's paper, published in the *Archives de Physique* of Geneva. In the *Philadelphia Medical Times* of May 26 will be found an elaborate account by Dr. Lautenbach of the results derivable from 283 experiments performed by him in Prof. Schiff's laboratory, and leading to these conclusions:—1. The liver has for one of its functions the office of destroying certain of the organic poisons. 2. A poison is being constantly formed in the system of every animal, which it is the office of the liver to destroy.

PHOSPHATE OF LIME IN RELATION TO FRACTURES.—In a recent thesis, M. Midrin, in reference to the question whether the administration of phosphate of lime hastens the consolidation of fractures, comes to the following conclusions:—1. Phosphate of lime cannot be relied upon for this purpose. 2. Introduced directly into the economy, it is not absorbed when it is insoluble. 3. When given in a soluble form, it is eliminated in the urine. 4. It is furnished in sufficient quantity by milk, bread, cereals, seeds, etc., and is assimilable only in this manner. 5. Its immediate action is only antacid and absorbent.—*Jour. de Thérap.*, June 10.

HARVEY TERCENTENARY MEMORIAL FUND.—A meeting of the subscribers to this Fund will, by the permission of the President of the Royal College of Physicians, be held at the College, Pall-mall East, on Wednesday next, July 18, at 5 p.m. The business of the meeting will be the following:—1. To elect Honorary Treasurers to the Fund; Sir G. Burrows, Bart., M.D., and Prescott Hewett, Esq., will be proposed for this office. 2. To receive the Honorary Secretaries' report of the progress of the Fund and a statement of accounts. 3. To elect two auditors. 4. To discuss and adopt measures for promoting the success of the object of the Fund. All subscribers are particularly requested to attend this meeting.

AN AGED OPIUM-EATER.—Dr. Mattison, of Brooklyn, gives (*New York Medical Record* for April 14) an account of a very extraordinary case occurring in the person of a Captain Lahrbush, a Londoner, now more than 111 years of age—a fact said to be well authenticated,—who, after some half-century of adventures in all parts of the world, settled down in New York. Becoming the subject of diarrhœa in India in 1807, on the relief of this by opium he took to the habit of eating this substance—a habit persisted in for *seventy years!* Beginning with only occasional half-grain doses, the amount he consumed up to the tenth year was only limited. From then the quantity taken was progressively increased until 1856, when the amount taken was *ninety grains per diem.* Placing himself then under medical care, the quantity was gradually decreased, so that by 1858 he took only thirty grains daily. Reduction was persevered in, so that for the last five years he has been content with a four-grain pill at bedtime. Alvine torpor has been a very constant accompaniment of the habit. Abstinence from opium has never been carried beyond forty-eight hours, and then has always been attended with diarrhœa and "profound malaise." No other ill effects have been produced by the opium, and up to quite lately the health of the Captain has been sufficiently good to allow of his passing several hours daily out of doors.

REPORT ON DIPHTHERIA IN FRANCE.—In his report to the Académie de Médecine on the epidemics which prevailed in France during 1875, M. Briquet arrived at the following conclusions respecting diphtheria:—1. Diphtheria was observed in 1875 in 100 communes of twenty-seven departments. 2. The localities in which it was observed were for the most part situated in the valleys of large rivers which were joined by numerous affluents. Still it was met with also in highly salubrious localities, and a commune adjoining one where an epidemic prevailed may remain intact during one visitation, and suffer severely during another. 3. Diphtheria attacks rural localities much oftener than towns—a fact proving the powerful effects of hygiene. But in large towns in which there is a large workman population—such as Abbeville, Havre, Rouen, and Paris,—and in which hygiene for certain classes is defective, diphtheria remains permanently established. As an exception to this rule, at Lyons, which is a very large and very populous city, situated in a deep valley traversed by large rivers, diphtheria is absent. Does it enjoy the same exemption from this disease as from cholera? 4. The epidemics, as a general rule, commence during the last three months of the year, after abundant rains, east winds, and a reduced temperature. 5. They have especially affected the poor, feeble, and lymphatic. 6. Children below twelve years of age are the ordinary victims, although in each epidemic adults and even some aged persons have been attacked. 7. In every locality females have furnished a much greater number of patients than males, the proportion being ten to six. This must be chiefly due to the more feeble condition of the former, and to the fact of their being more indoors and in contact with the sick. 8. In the epidemic at Bar there were 80 deaths in 833 cases; in another place 137 deaths among 569 patients; and in the Paris hospitals 416 deaths among 573 patients. 9. From one place it was reported that the children who contracted the disease at the end of the epidemic suffered as severely as those who took it at the beginning, so that the special miasm would seem to lose none of its power even at the end of a year, the epidemic only ceasing, in fact, when there are no longer any predisposed subjects.—*Union Méd.*, June 28.

NOTES, QUERIES, AND REPLIES.

"He that questioneth much shall learn much."—*Bacon.*

Dr. W. J. Branch, St. Kitts.—Received with thanks.

Mr. John Forster, Adelaide.—Received with thanks your favour of May 17; also that of December, 1876.

Dr. Henry Sorley, N.S.W.—Received with thanks.

S. B. E.—We suppose so.

W. Gregson L.—London covers within its jurisdiction 576 square miles; its area embraces 78,000 acres; it contains four millions of inhabitants, increasing at the rate of 75,000 a year.

Aubrey.—The so-called Turkish bath is no modern invention. Hot-air baths have been familiar for ages, in almost all the countries of the world. William Penn found them among the North American Indians. But it was the Greeks and Romans who brought the art of hot-air bathing to its perfection in their luxurious baths. The Romans introduced the practice as one of the fine arts into our country during their occupation of it. But it seems to have departed from our island with the conquerors. The so-called Turkish baths are in reality Roman baths; and their introduction in the nineteenth century is only a revival of a practice which prevailed 1800 years ago among our ancestors.

A TEMPERANCE COFFEE-HOUSE, NOTTING-HILL.

We are glad to notice that a new workmen's temperance club and coffee-house, known as the "Magdala Castle," was opened on Saturday evening by Lord Cairns. It is situate close to the Latimer-road Railway-station, Notting-hill. It may be observed that the "Magdala Castle" was originally intended to be used as a public-house, but a native of Notting-hill, having returned from Australia, after many years' absence, with a fortune, determined on applying some of it in benefiting his native place. With this view, and acting under the advice of a committee, he purchased the "Magdala Castle," and the house has been fitted out as a working-men's temperance club, reading-room, and coffee-saloon.

A Beer Drinker.—We have no historic account of the first brewer; but history tells us that brewing was practised more than 2000 years ago. Theophrastus, who was born nearly 400 years before Christ, described beer as the wine of barley. Egypt was the land in which it was first brewed.

AN UNWHOLESOME GOVERNMENT FACTORY.

The insanitary condition, from defective drainage or ventilation (especially), of our Government offices, buildings, and factories, has on several occasions lately been brought before the notice of the public, under circumstances involving, not only many cases of serious illness, but even of death. The following is another fatal instance from the like cause, and demands immediate action on the part of the Government authorities responsible for such a deplorable state of things. The coroner's inquiry into the death of an ironfounder in the Government employ at Keyham Factory, Devonport, after two days' sittings, has resulted in a verdict of "Accidental poisoning." It was shown that the deceased, without orders, went into a house where moulds are dried, and was there found dead. The medical evidence proved that death was caused by poisoning with noxious gases; and some of the jury who had, it seems, been in Admiralty employ, elicited from a witness that the ventilation of the whole factory was very defective, and that complaints had been made, but as yet with no result. The coroner was requested by the jury to direct the attention of the Admiralty to the necessity of improving the ventilation of the factory, which was dangerous to the health of the operatives.

COMMUNICATIONS have been received from—

Dr. JAMES RUSSELL, Birmingham; Dr. GAVIN MILROY, Richmond, Surrey; Dr. BARLOW, London; Dr. FRANCIS OOSTON, Aberdeen; Mr. JOHN CHATTO, London; Mr. T. M. STONE, London; Mr. G. HILL SMITH, Stevenage; Mr. W. COLLINGRIDGE, London; Mr. R. B. CARTER, London; Mr. GODLEE, London; Dr. PARKS, Homburg; Dr. BULKELEY, New York; Mr. WARRINGTON HAWARD, London; Dr. SEMPLE, London; Mr. J. FORSTER, Adelaide; S. B. L.; CARLSBAD WATER COMPANY; Dr. MORELL MACKENZIE, London; THE SECRETARY OF THE NAVAL SUPPLEMENTAL FUND.

BOOKS AND PAMPHLETS RECEIVED—

W. Wilberforce Smith, M.D., The Flat Roof as a Recreation Place in British Towns—S. O. Habershon, M.D. Lond., On the Pathology of the Pneumogastric Nerve—Thomas Hay, M.D., History of a Case of Recurring Sarcomatous Tumour of the Orbit in a Child—Herbert Tibbits, M.D., A Map of Ziemssen's Motor Points of the Human Body—Henry F. Campbell, M.D., Calculi found in the Bladder after the Cure of Vesico-Vaginal Fistula; Pneumatic Self-Replacement of the Gravid and Non-Gravid Uterus—T. Gallard, Clinique Médicale de la Pitié—Transactions of the Seventy-ninth Annual Session of the Medical and Chirurgical Faculty of Maryland—Charles Weber, M.D., Gout and its Treatment—E. Wyndham Cottle, The Hair in Health and Disease—Henry Heather Bigg, A. Inst. C.E., A Manual of Orthopraxy.

PERIODICALS AND NEWSPAPERS RECEIVED—

APPOINTMENTS FOR THE WEEK.

July 14. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

16. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

17. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

18. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

19. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

20. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1½ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, July 7, 1877.

BIRTHS.

Births of Boys, 1139; Girls, 1081; Total, 2220.
Average of 10 corresponding years 1867-76, 2112·3.

DEATHS.

	Males.	Females.	Total.
Deaths during the week	707	615	1322
Average of the ten years 1867-76	672·9	629·9	1302·8

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·82 in. The lowest reading was 29·70 in. on Friday, and the highest 30·01 in. at the end of the week.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

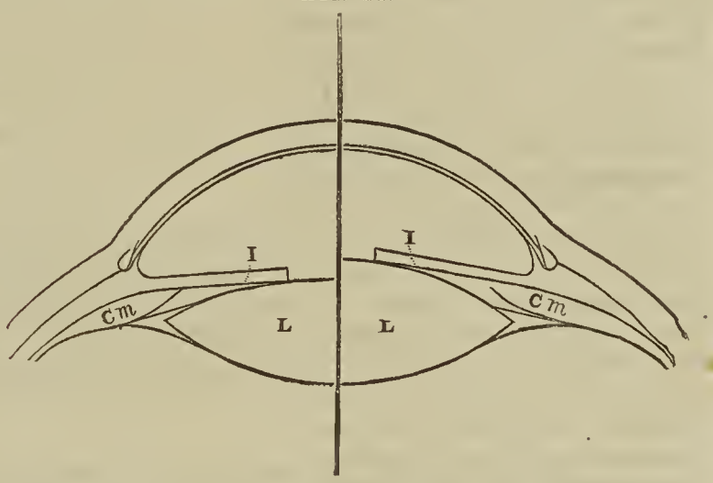
Lecture II.

Mr. President,—The two remaining factors of sustained clear vision, the accommodation and the convergence, require to be considered not only separately, but also in their relations to one another. The first of these two factors, the accommodation, was defined in my former lecture to be the power of adjusting the eye to see with equal clearness at distances within its far-point; and Mr. Hulke, when he held office as Arris and Gale Lecturer, fully described in this theatre the mechanism by which the function is performed. There is therefore no occasion for me to occupy ground which has already been so well covered; and I need only point out the necessity which there is for accommodation, and the nature of the change which produces it. Taking the emmetropic eye as a starting-point, with its capacity for uniting parallel rays upon its retina, it is obvious that rays coming from comparatively near objects will no longer be parallel, but divergent; and that the degree of their divergence will constantly increase as the object from which they proceed comes nearer and nearer. In order to overcome this constantly increasing divergence of the rays, and still to obtain clear images from near or from steadily approaching objects, the eye must possess the power of increasing its own action upon light. That it does possess such a power may be shown in many ways, among which that proposed by Donders is perhaps the most convenient. If we take a piece of net, and hold it between the eyes and a printed page, we may at pleasure see distinctly the fibres of the net, or the printed letters on the page through the interstices of the net; but we cannot clearly see both at once. When we are looking at the letters, we are only conscious of the net as a sort of intervening film of uncertain character; and when we are looking at the net, we are only conscious of the page as a greyish background. In order to see first one and then the other, we are quite conscious of a change which takes place in the adjustment of the eyes; and if the net is very near, and we look at it for any length of time, the maintenance of the effort of adjustment becomes fatiguing.

It has been thoroughly established, by the observations of Cramer, Helmholtz, Donders, and others, that the crystalline lens undergoes a change of shape in the act of accommodation; and there is abundant proof that this change of shape is brought about by contraction of the ciliary muscle. It appears, however, that the muscle does not act upon the lens directly, or alter its shape by virtue of any pressure or tension which it exercises, but that its action is to relax the capsule of the lens and the zonule of Zinn, and thus to allow the proper lens-tissue to undergo the necessary change by virtue of its own elasticity. When all parts are at rest, the capsule is believed to compress the lens, and to retain it in its state of greatest flatness; but when the ciliary muscle comes into play, it draws forward the ciliary body and makes tense the choroid, and so allows the lens to expand to the degree which the relaxation of its capsule will permit. The change of shape occurs chiefly in the anterior portion of the lens, although the posterior surface participates in a slight degree. Besides the principal alteration, that in the shape of the lens itself, there are other changes which accompany the act of accommodation, but which are not essential to its performance. The pupil contracts, and the iris-tissue is rendered more tense. The whole of these changes are represented in Fig. 14, in which L represents the lens, I the iris, and *Cm* the ciliary muscle. The left-hand half shows the parts at rest, and the right-hand half shows the changes which occur when accommodation is being exerted.

Putting aside the mechanism of accommodation, it may be broadly said that the effect of the effort is precisely that of placing an additional convex lens within the eye; and the amount of refracting power which can thus be added is very definite, and admits of easy and precise measurement. In every eye there is a point within which clear vision is no longer possible without optical assistance; and this, which is called the near-point, marks the limit of the power of accommodation. Still assuming the eye to be emmetropic, with its far-point at infinite distance, let us suppose that it can see small objects clearly at twenty centimetres, or one-fifth of a metre, but not at any shorter distance. The effort of accommodation, which is exercised in seeing at this near-point, produces precisely the same optical result which would be attained by placing within the eye a convex lens of the same focal length as the distance from the eye to the near-point. In the case supposed, therefore, the accommodation is equal to a lens of five dioptrics; and in the improved nomenclature it is expressed as being equal to five, and not, as would have been the case two years ago, by the focal length in inches, reduced to a fraction by placing unity as its numerator. The fifth of a metre being eight inches, the fraction would have been one-eighth; and in this distance, as in many others, the usefulness of the metric system in simplifying calculations becomes at once apparent.

Fig. 14.

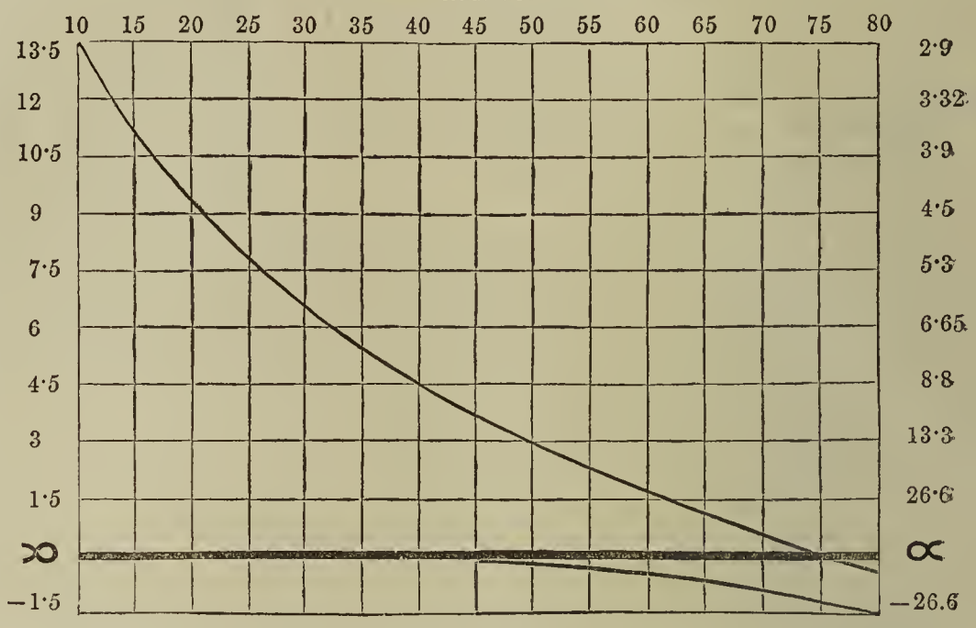


As life advances, probably on account of the regularly diminishing elasticity of the crystalline lens, the power of accommodation constantly diminishes, and the near-point consequently recedes farther and farther from the eye. The diagram in Fig. 15 is taken from Donders, and is only so far altered as to adapt it to the metric system, by expressing the accommodation in dioptrics, and the successive distances of the near-point in English instead of in Paris inches. It represents the ordinary course of the accommodation in an emmetropic eye from the age of ten years to the age of eighty. The figures at the top of the diagram show the years of life, and those at the sides the amount of accommodation, expressed to the left in dioptrics, and to the right in English inches. The larger curved line shows the course of the accommodation; and it is drawn as the mean of a great number of observations. We see that the emmetropic eye, at the age of 10, has a power of accommodation equal to $13\frac{1}{2}$ dioptrics; or, in other words, its near-point is a little nearer than the thirteenth part of a metre—a distance equal to 2·9 English inches. At 14—that is, before we reach the line marking the fifteenth year—the power of accommodation is reduced to 12 dioptrics, and the near-point has receded to 3·32 inches; at 18, the accommodation is 10·5 dioptrics, and the near-point is at 3·9 inches; at 21, the accommodation is at 9 dioptrics, and the near-point is at 4·5 inches; at 26, the accommodation is 7·5 dioptrics, and the near-point at 5·3 inches; at 32, the accommodation is 6 dioptrics, and the near-point at 6·65 inches; at 40, the accommodation is 4·5 dioptrics, and the near-point at 8·8 inches; at 50, a great change has taken place—the accommodation is only 3 dioptrics, and the near-point has receded to 13·3 inches; at 60, the accommodation is only 1·5, and the near-point is at 26·6 inches; at 75, accommodation is wholly lost, and the near point is at infinite distance; at 80, we have what Donders described as acquired hypermetropia, and, in the total absence of accommodation, a weak convex lens is required even for infinitely distant objects. It is probable that this phenomenon of acquired hypermetropia will be found to admit of a somewhat different explanation from that which Donders gave of it. The smaller curve on the diagram exhibits the course of the far-point during the same

succession of years, and shows that the hypermetropia which is said to be acquired is first traceable at about the forty-fifth year.

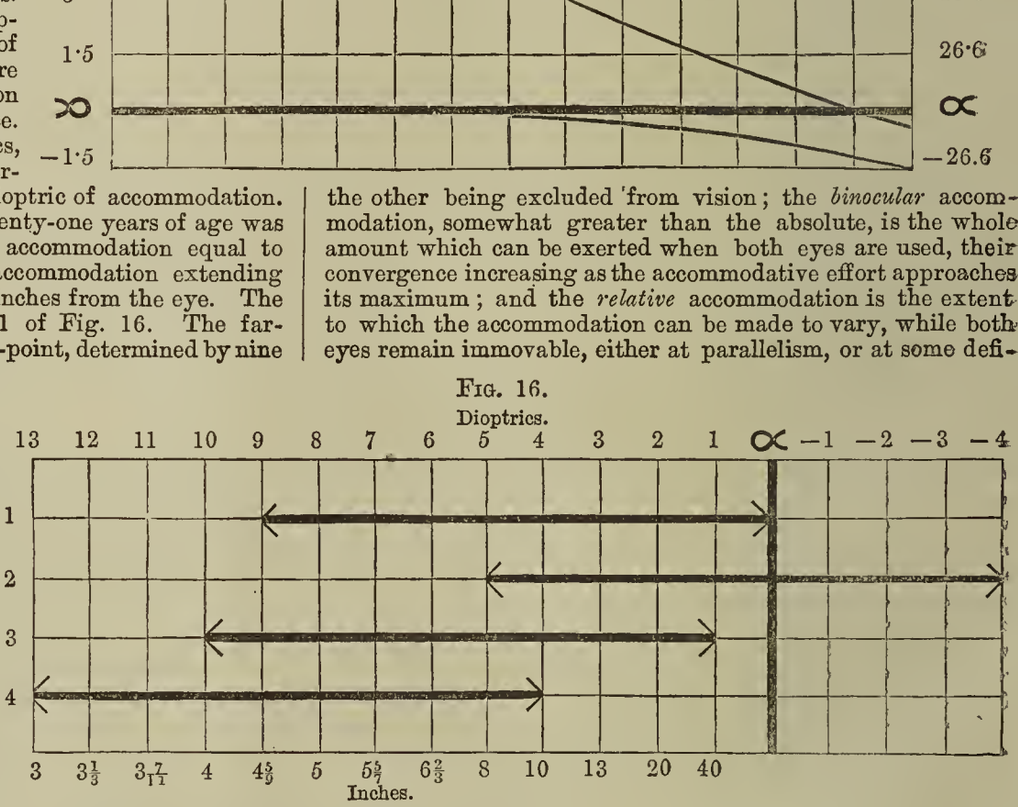
In speaking of the accommodation, there are two technical expressions in common use, which are somewhat liable to be misinterpreted, and about which it is very necessary to obtain perfectly clear notions. These are, respectively, the *range* and the *region* of accommodation. The range should be used as a synonym for the power of accommodation; that is, to express the number of dioptrics to which the power is equal. The region should be used to express the limits of space within which the power is exercised. In Fig. 16, the distinction is shown in a diagrammatic form. The horizontal lines, marked successively 1, 2, 3, and 4, exhibit, by their darker portions, the differences of region which will exist, with the same range of accommodation, in an emmetropic eye, an eye hypermetropic to four dioptrics, an eye myopic to one dioptric, and an eye myopic to four dioptrics. Each square is equivalent to one dioptric of added refraction—that is, of accommodation; and the squares are numbered both on the positive and on the negative side of infinite distance. The figures above indicate the dioptrics, and those below the position of the near-point, in English inches, for each dioptric of accommodation. In Fig. 15, the emmetropic eye at twenty-one years of age was shown to have a power or range of accommodation equal to nine dioptrics, and a region of accommodation extending from infinite distance to a point 4·5 inches from the eye. The same condition is exhibited by line 1 of Fig. 16. The far-point is at infinite distance; the near-point, determined by nine dioptrics of accommodation, is at 4·5 inches. On line No. 2 we have the same range of accommodation, but combined with four dioptrics of hypermetropia. Hence, the first four dioptrics of accommodation are required for parallel rays, or, in other words, to bring the far-point up to infinite distance; and only five dioptrics of accommodation remain for use in the ordinary way. The eye is in the position of an emmetropic eye which has only five dioptrics of accommodation; and the exercise of these five dioptrics places its near-point at eight inches. Moreover, as it is not generally practicable to employ more than half the accommodation continuously, the working near-point would be that given, at most, by five dioptrics of accommodation, and would therefore be forty inches away. On the third line, a myopia of one dioptric places the far-point at forty inches, and the nine dioptrics of accommodation must all be exercised within the limits thus imposed, that is, between a distance of forty inches and a distance of four inches, to which the near-point can be brought. The last example, an eye with four dioptrics of myopia, has its far-point at ten inches, and its near-point at three inches, the nine dioptrics of accommodation being all exercised on the nearer side of ten inches. As regards their near-points, the last two eyes are like emmetropic eyes which possess ten and thirteen dioptrics of accommodation respectively; and the four examples show that the same *range* of accommodation may be exercised in four widely different *regions*: In the first, the region extends from infinity to 4·5 inches; in the second, it is partly a mathematical negation, on the other side of infinite distance, and is partly between infinity and eight inches; in the third, it is between forty inches and four; in the fourth, it is between ten inches and three. The words "range" and "region" are not, I think, the best which could have been chosen for the purpose of expressing the ideas which they are intended to convey; and on this account it seemed desirable to explain them in some detail, and to endeavour to remove all ambiguity from their respective meanings.

Fig. 15.



We shall see hereafter that the power of accommodation is very much influenced by the convergence; and from this relation we derive other expressions, which hardly carry with them the senses in which they are used. The *absolute* accommodation is the whole amount which one eye can exert singly, the other being excluded from vision; the *binocular* accommodation, somewhat greater than the absolute, is the whole amount which can be exerted when both eyes are used, their convergence increasing as the accommodative effort approaches its maximum; and the *relative* accommodation is the extent to which the accommodation can be made to vary, while both eyes remain immovable, either at parallelism, or at some definite degree of convergence. Variations in the range, and in the region, of *relative* accommodation will be found to exercise a most important influence upon the power of sustained visual effort; but the consideration of this influence must be postponed until after the convergence function itself has been briefly described.

Fig. 16.

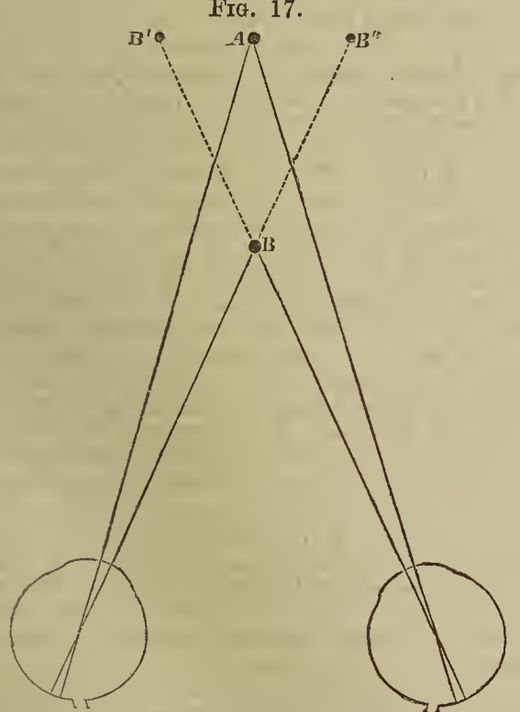


The convergence, the third factor of clear vision, is a term used to express the whole of that range of mobility by which the axes of vision are moved from parallelism, or even from a certain degree of divergence, to be directed towards some near point in space. The eyes may, of course, be directed convergently towards some lateral part of the field of vision; but such a direction is infrequent, and can scarcely ever require to be sustained. Practically, therefore, we mean by convergence the direction of the eyes to some point in a median plane between them, so that the muscles on the two sides are called into equal action for the maintenance of the effort. The conditions of human industry, moreover, generally require a downward direction of the gaze, so that the inferior recti muscles are brought into play; but convergence is mainly dependent upon the internal recti, and upon the state of equilibrium between these and their antagonists, the external recti. In a state of rest the optic axes, or rather the visual lines, which do not necessarily coincide with the optic axes, are at least approximately parallel, usually with a slight tendency towards convergence; and this must

be taken to be the state of equilibrium between the antagonistic muscles. The antagonism of these muscles, however, is of such a kind that it is constantly becoming co-operation; for, while each internal rectus, in convergence to the median plane, acts together with its fellow, and opposes, and is opposed by, its antagonist, yet in lateral vision, or in convergence towards any lateral portion of the field, each internal rectus acts in unison with the external rectus of the other eye. Dr. Broadbent has pointed out that the motor ganglia of any two or more muscles which are constantly called upon to act in unison have generally an intimate connexion; and we must assume, I think, that the stimulus to median and to lateral fixation must be derived from distinct centres. The actions themselves, although performed by the same muscles, are yet the results of combinations so entirely dissimilar in their character that no other hypothesis seems to meet the facts of the case.

As the perfection of accommodation for any object is shown by the clearness and sharpness of the vision, so the perfection of convergence for any object is shown by the singleness of vision, assuming it first to be ascertained that the person who is the subject of inquiry can see binocularly. If any object is in such a position as to be seen, and if the visual lines are not directed towards it, the images formed in the two eyes will not be on corresponding points of the retinæ, and double vision will be the result. A simple test of the possession of binocular vision is afforded by placing before one eye a prism with its base directed either upwards or downwards—an arrangement which, when both eyes are directed towards some moderately distant object, will produce diplopia if binocular vision exists. Another simple test is furnished by holding any slender object, such as a pencil or a knitting-needle, between the eyes and a printed page, nearly in the middle line. The observer should then read the print; and, if he has binocular vision, he will see two images of the intervening object, neither of which will shut out any letter from his view. He will be able to read as distinctly and as uninterruptedly as if the images were not there. If he has not binocular vision, or if he closes one eye experimentally, the intervening object will be seen single, and then it will shut out some portion of the page from his view. The reason of this is apparent from Fig. 17, in which

Fig. 17.



A represents the point on the page which is the object of vision, and B the intervening object. The rays from A fall upon the yellow spot of each eye; but those from B fall upon the outer side of the yellow spot of each eye, so that to the right eye B seems to be situated at B′, while to the left eye it seems to be at B″. An examination of the diagram will also render it obvious that, whether there be a printed page as background or not, the slender object will be seen double, with crossed images, if the eyes are directed to a point beyond it, and double, with direct or homonymous images, if the eyes are directed to a point nearer the observer. The purpose of convergence, it must be borne in mind, is the avoidance of double images, or the fusion of the images which are formed upon the two retinæ; and this can only be accomplished when the eyes are both directed to the same point. In estimating convergence, the apparent direction of the eyes is not always a perfectly safe guide, because this apparent direction will be governed by that of the axes of the eyeballs, and not by that of the axes of vision, which, as I have already said, do not always coincide with the former. The impulse to fusion, by which the convergence is governed or directed, can only be referred to the centres of visual sensation; and the urgency of the instinctive demand is shown by the giddiness and general disturbance of co-ordination which double images frequently produce. When single vision is maintained, and when it can be disturbed by means of a prism used in the manner already indicated, we have the best possible assurance that the demand for fusion exists in the nervous centres, and that the machinery for fulfilling the demaud is of natural strength and in full operation.

Having thus a test of the accuracy of the convergence for a given point, the power or range of the function may be estimated by two standards. The first of these is the distance of the nearest point for which convergence can be maintained, and the angle then contained between the visual lines. The average distance apart of the centres of the eyeballs is sixty-four millimetres, or nearly two inches and a half. The average reading distance may be stated at fifteen inches; and the nearest point at which I find it possible to maintain couvergence, even for a few moments, is twelve centimetres. The angle formed between the visual lines amounts only to 10° when the object is at fifteen inches, increases to 14° when the object approaches to ten inches; and becomes 28° at the distance of twelve centimetres, which I have mentioned as the limit of my own convergence. Mannhardt, in an interesting paper published a few years ago in the *Archiv für Ophthalmologie*, sought to attach great importance to this angle, and also to the increase of the angle which necessarily attends any increase of the normal width between the centres of the eyes. He endeavoured to show that people whose eyes were far apart must of necessity be more fatigued than others in using them for near objects; but he appears to have overlooked the obvious consideration that all such differences of original formation are likely to receive compensation from muscular attachments in harmony with them; and, as a matter of fact, I am not aware that Mannhardt's view has been confirmed by practical experience even in a single instance.

The other method of measuring the convergence-power, and certainly the most generally applicable, is by determining the capacity of the internal and external recti muscles for fusing together the double images produced by prisms. On a simple optical principle, which it is only necessary to mention, the rays of light which pass through a prism are deflected towards its base, so that any object seen through a prism is changed in apparent position, and seems to be displaced in the direction of the refracting angle. If the object is in the median line, and we look at it with one eye through a prism with its base turned towards the nose, the object appears to be displaced outwards towards the temple of the spectator; and if the base of the prism is turned towards the temple, the apparent displacement is in the opposite direction, or towards the median line. It follows, if we hold before each eye a prism with its base inwards, and look at a distant object in the middle line, we shall have to render our optic axes more divergent than the true position of the object requires, in order to see it singly; and the strength of the prisms which we can thus overcome by voluntary muscular effort is the measure of our power of voluntary divergence or abduction. In like manner, if we place the prisms with their bases outwards, we shall have to exert our converging power in order to see singly; and the strength of the prisms which we can overcome is in the same way the measure of the converging faculty. Taking as an object a flame at twelve feet distance, I find that I can overcome, for a short time at least, prisms of 22°—that is, two each of 11°, with their bases outwards, and two each of 6°, with their bases inwards. This is with fully relaxed accommodation, wearing convex spectacles of 0·75 to neutralise my hypermetropia. Great variations of power will be found in different persons, and I lately tested a gentleman who had no abduction or divergence power at all, so that he could not overcome two prisms each of 2° with their bases inwards, but who overcame all I could give him, amounting to an aggregate of 34°, when the bases were turned outwards, and his internal recti muscles came into play.

TABLE III.

	Overcame by adduction (bases outwards).	Overcame by abduction (bases inwards).
Case 1 . .	17° + 17° = 34°	3° + 4° = 7°
2 . .	17° + 17° = 34°	5° + 5° = 10°
3 . .	16° + 16° = 32°	5° + 4° = 9°
4 . .	15° + 15° = 30°	8° + 8° = 16°
5 . .	12° + 12° = 24°	4° + 4° = 8°
6 . .	10° + 10° = 20°	3° + 4° = 7°
7 . .	9° + 9° = 18°	3° + 4° = 7°

Table 3 shows the adduction and abduction powers of seven students at St. George's Hospital, taken at random. It will be seen that the adduction power ranges from a minimum of 18° to a maximum of 34°; the abduction from a minimum of 7° to a maximum of 10°. The object looked at was a flame eight feet away, and five of the students were presumably emmetropic. No. 3 was the subject of hypermetropia equal to 2·75 dioptrics; No. 7 of hypermetropia equal to 1·75 dioptrics.

(To be continued.)

CLINICAL LECTURE
ON A CASE OF
MULTIPLE ANEURYSMS IN THE HEART, THE LUNGS, AND CAVITY OF THE CRANIUM.

By HENRY THOMPSON, M.D., F.R.C.P.,
Physician to the Middlesex Hospital.

HENRY T., aged twenty, a draper's assistant, came under my care, in Cambridge Ward, January 12, 1876, with the following history, as recorded in the notes. The only serious illness he can recollect arose from the kick of a horse over the lower part of the chest, on the left side, between eight and nine years ago. Within half an hour of the accident he spat blood, but never afterwards. On this occasion he was confined to the house for six weeks. His present attack began about a month ago, with chest-pains and shortness of breath.

On Admission.—The cheeks were flushed purple; the general appearance was that of debility and emaciation. Complained chiefly of pain at the heart and across the loins. There was a loud blowing murmur of extreme intensity—loudest, indeed, over the upper and central regions of the præcordia, but loud everywhere in front, where it effaced the first sound altogether; and, again, well pronounced, although subdued by comparison, at the back. Coincidently with this murmur, a purring vibration, or thrill, could be felt at the base of the heart and over the whole of the right ventricle, but not beyond the boundary of the sternum; nor again, leftwards, so far as the outermost limits of the apex-beat. The second sound was unnaturally rough at the base, and both sounds obscurely expressed in the carotids. The murmur distinctly and entirely preceded the pulse at the wrist; it was synchronous with the pulse in the carotids, or in part antecedent to it. At the posterior base of the left lung the first sound could be heard, apparently prefaced by a brief tone or bruit. The superficial veins of the neck were enlarged, and beaded in places, but they presented no pulsation.

As the case progressed, the boy began to look gaunt, haggard, and extremely ill; he spat blood. He suffered for many days from pain in the upper part of the right chest; and, when that abated, from pain at the left posterior base, where the percussion-note was dull, the breathing tubular, and the voice-sound bronchophonic. All the while the original pain at the heart continued, and all the while he was losing flesh and strength. The urine contained a trace of albumen, with an admixture of blood, as shown by guaiacum.

Such is a summary of the case as far as February 11. From that date to February 17 the symptoms were chiefly those of dyspepsia—nausea, vomiting, and loss of appetite. On the 17th he coughed a good deal, spat blood, and suffered again from sharp pain near the right axilla. Temperature 104·4°—the highest on record. For many succeeding nights he required injections of morphia to procure sleep. The nausea, the vomiting, and the anorexia continued with interruptions; and it was not until the beginning of March that the pain subsided.

March 16.—A double murmur may be heard at mid-sternum; both sounds muffled, and murmur-like in carotids. Pulse jarring. Pain, aggravated by deep inspiration and by coughing, below left mamma.

April 8.—He has been wandering in the night, and even now seems confused. He speaks slowly, and with much thickness of utterance. His vocabulary is limited; for the most part he repeats a monotonous sound, which at times is clearly "Have mercy," and with this expression, plainly or indistinctly pronounced, he closes every sentence. The power of grasping is about the same in both hands, nor is there any want of symmetry in the lines of the forehead or face. The tongue, however, swerves in some measure to the right side.

9th.—Repeated the Lord's Prayer after the chaplain fairly well. On being asked how he was, he replied, with some hesitation, "I am first-rate." He cannot read audibly, however, nor could he repeat on dictation "A fine clear morning." Most of his sentences still relapse into the old "Have mercy." Wrote his Christian name, "Henry," quite well and legibly. When desired to write "morning" he failed altogether, but succeeded in copying a few letters of the word, presenting it under the form "mony."

20th.—Still there remain traces of aphasia, although, on the whole, he expresses himself with greater freedom and with a wider range of language.

27th.—Looks more and more ghastly, wan, and wasted.

May 18.—Seems in great distress, and complains of pain and tenderness in the left side of abdomen.

29th.—The physical signs have undergone a change. The original murmur is much softened, and the diastolic sound is clear everywhere over the chest and in the carotids. There is now pulsation in the cervical veins, and yesterday there was slight œdema in the right foot.

June 1.—After a long interval of clear, intelligible speech, he again miscalls many things. Looks deadly pale, and seems indifferent to life. Asked for a knife to cut his throat. From this time forth he sank, and died June 3.

Autopsy (abridged from the report of Dr. Sidney Coupland).—Beneath the arachnoid a large amount of fluid overspread the shrunken brain, the membrane itself here and there presenting patches of opacity with small plates of bony material. The left temporo-sphenoidal lobe, superficially orange-coloured, showed on section a cyst occupying the anterior half and containing a fluid like curds-and-whey. Seated on the middle cerebral artery, about half an inch from its origin, a saccular aneurysm, the size of a chesnut, blocked the entrance into the left Sylvian fissure. Internally, the aneurysm was found to consist of a compact mass of fibrine arranged concentrically in a laminated fashion, except in the innermost parts, where it was channelled and filled with soft black clot. The vessel was empty of blood. The heart weighed fourteen ounces and a half. On the right side the conus arteriosus was immensely enlarged; its walls were abruptly and inordinately thickened, and its cavity contained a mass of fleshy fragile vegetations, springing from the dense, irregular, milk-white endocardium, and spreading as far as the attached margins of the pulmonary valve. Half an inch below the attachment of the valve, the septum ventriculorum in its anterior part was the seat of two perforations—one circular, just admitting a crow-quill; the other triangular, measuring three-eighths of an inch in each direction. Both apertures were fringed with warty vegetations, but, in front and below, the margins of both were round, smooth, and continuous with the condensed endocardium of the conus. The foramen ovale was closed, and there were no traces of the ductus arteriosus. Projecting into the wide cavity of the left auricle, a group of vegetations arose from the adjoining borders of the two mitral curtains, close to the septum; and above, over the space of about a square inch, the opaque thickened endocardium was covered by vegetations. In laying open the left ventricle, a pouch was cut into, lined by a thick membrane, continuous with the endocardium through a smooth narrow orifice which occupied the interval between two diverging columnæ carneæ. The pouch was seated near the base of the heart, partly in the ventricular walls, but principally in the septum. The parietal portion was small; the septal division was oval-shaped, and measured an inch and a quarter in its long diameter from above downwards; its depth was half an inch; its smooth lining membrane was traversed by numerous folds marking the course of the muscular fasciculi which enclosed it on every side; it passed right through the septum, and opened into the conus arteriosus by the two foramina before described. All the valves except the tricuspid were competent to the water-test. The right lung was firmly adherent at the apex. Two cavities of large size

and long standing occupied respectively the upper and middle lobes. With these exceptions, the parenchyma of the lung presented no peculiarities of any moment. There were, however, five saccular pouches—true aneurysms—discovered on different branches of the pulmonary artery, all possessing walls of immense thickness, and all loosely attached to the tissues around. One was seated on the main artery supplying the middle lobe; it was of the size of a Barcelona nut, and lined by a layer of adherent fibrine. Four were found in the lower lobe, two as large as the last described, and two of smaller dimensions. They were nearly all engrafted on points of bifurcation in the artery, and, like the vessels, they were all empty of blood. No thrombi were found anywhere. On the left side, some recent lymph coated the lower lobe, which was in great measure solidified, showing numerous tracts of embolic pneumonia varying in size and appearance, some entire, some broken down into irregular cavities. Large firm fibrinous clots were seen to block the branches of the pulmonary artery in this lobe, and in one of these branches an aneurysm was situated—the only aneurysm discovered in the substance of the left lung. In the upper lobe, near the apex, was a recent infarction, of the size of a walnut, with a plug in the artery leading to it. The central third of the spleen was entirely composed of a large wedge-shaped buff-coloured mass, just beginning to soften in places. The remaining organs presented nothing that need be described.

Commentary.—Gentlemen,—Many a time and oft have I pointed attention to the foregoing case as a marvel and a mystery past all precise interpretation. During the lifetime of the patient I could only waver between two alternative hypotheses—congenital malformation with an unclosed interventricular septum; and aneurysm in some unwonted form or place. Strange to say, although the hypotheses in question together covered the main mischief in the heart, yet neither the one nor the other proved to be absolutely correct. In giving the diagnosis I never dreamt of aneurysm perforating the septum; still less could I foresee the discovery of eight disseminated aneurysms. There can be no manner of dispute as to the nature of the phenomena; the wonder is, how in the world they came into existence. As for the aneurysm in the septum, possibly it may owe its original development to the kick of the horse that occurred eight or nine years ago. Injury will cause laceration of the heart-fibres, and then, as you would naturally expect, it is the right ventricle which bears the brunt of the damage. Under these circumstances, let the heart-fibres be once torn, contused, or weakened on the right side of the septum, they will offer less resistance to the preponderating blood-pressure from the left heart. The blood bearing upon the intercolumnar spaces of the left surface will tell forcibly on the unresisting fibres of the septum; it will work its way into the substance of the partition-wall, and there excavate a chamber for itself, in close contiguity to the damaged structures on the right side. Given all these conditions, it is easy to imagine that the blood may break through the barrier altogether, and unite the two ventricles into one. Possibly the right ventricle may co-operate with the left, and excavations commenced at the same level on the two surfaces of the septum may in due course of time meet midway in its substance. On this view, or on any hypothesis implying time spent in development, the aneurysm in our own case, slowly tunnelling and at last perforating the septum, may have given origin to endocarditis, with its rank and exuberant overgrowth of vegetations. On another view the chain of causation may have been reversed, and endocarditis may have originated aneurysm in the acute form by a swifter process of disorganisation. The seat of the aneurysm might seem to bespeak an acute origin, but its characters conform expressly to the chronic type. A smooth, narrow mouth in the groove between two diverging fleshy columns, an expanded sac, a dense lining membrane continuous with the endocardium at the orifice, and plainly showing on the walls of the cavity the mouldings of the muscular fasciculi, which appeared to maintain their integrity unbroken, and simply to have given way before the advancing aneurysm: all these characters taken together present the very picture of an old formation. Moreover, the vegetations underneath the aortic valve, though, of course, near to the orifice of the sac, nowhere came into immediate contact with it—a circumstance almost, if not altogether, irreconcilable with the idea of acute ulceration of the myocardium beginning on the left side, where we commonly find the point of departure for the ulcerative process. In spite, then, of all plausible presumptions to the contrary, the intraseptal aneurysm must have been an old one, whether we derive the endocarditis from its rupture or not. As for the remaining aneurisms—the six that were discovered in the lungs, and the solitary one that existed on the brain-surface—we may fairly ascribe their genesis to embolism. *Primâ facie*, indeed, if we were to look at the lungs alone, we might demur to this opinion. The right lung, with its manifold aneurysms, offered no trace of plugging, infarction, or consolidation anywhere; the left lung, with its single aneurysm, displayed all these pathological changes on the amplest scale. Still, the drawbacks to the hypothesis are not insuperable. Emboli may give rise to aneurysms, exalting as they do the tension of the blood-pressure, and impairing the integrity of the vascular walls in their vicinity; and on a survey of all the circumstances the conclusion is irresistible that they have done so in the present case. Bear in mind the extreme rarity of aneurysm in one so young, the absence of any preceding flaw in the arterial system, the wide dissemination of the aneurysmal masses, coupled with the presence of a material at the heart, on the right side and on the left, ripe and ready for detachment and deposition anywhere at any moment—above all, bear in mind the preference shown for the bifurcations of the bloodvessels, the chosen sites of emboli—and you cannot fail to see in embolism the sole sufficient cause of all the phenomena under discussion. Gentlemen, you recollect well the mysterious murmur described in the notes. Are we in a position to interpret this murmur now, with the heart lying before us? I fear not. So multifarious are the sources of murmur that I find it impossible to recognise severally the part played by each in the production of the universal discord. Those who are familiar with malformations of the heart and its appendages may speak with authority on this point,—I dare not; I only venture, with many misgivings, to accord the foremost place to the pulmonary valve and the perforating aneurysm. In this connexion two circumstances deserve to be mentioned. There were undoubted evidences of aortic valvular incompetency, alike in the characteristic pulse and in the characteristic murmur. Now, both these characters vanished towards the close of life, about the time when the boy began to complain of pain in the left side of the abdomen. What is the inevitable inference? A considerable cluster of soft and fragile vegetations were found attached to the under surface of the aortic valve, which, however, was pronounced to be competent after death on the assurance of the water-test. The inference is this. There must have been a time when the valve put forth a more luxuriant growth of vegetations, large enough to encroach upon its free margins and to interfere with the due play of its mechanism. Soon the encroaching material lost its hold on the surface, drifted away in the current of the circulation, and became impacted in the spleen, thus restoring to the valve the competency it had destroyed. The overgrowth disappeared, the undergrowth remained. The second circumstance is the following:—The long loud murmur in part preceded the systole of the ventricle: this point was determined by comparison with the carotid pulse in front, where the first sound was inaudible. At the back it was ascertained by simple reference to the first sound, which was plainly distinguished at the left posterior base, and there only. The vegetations on the mitral valve and orifice, and on the adjacent surface of the left auricle, possibly explain the presystolic element in the murmur. Possibly, also, the blood streaming through the aneurysm may have developed sonorous vibrations there, even during the period of the auricular systole. I have spoken of the carotid pulse as a measure of time in the interpretation of a murmur; and this leads me to the lesson the case before us is pre-eminently calculated to teach. On applying the stethoscope to the præcordia with one hand, and placing the fingers of the other over the carotid, you at once recognised the rhythm of the murmur as systolic in the main. Again, when you laid your finger on the radial artery, the murmur seemed to fall within the diastolic or presystolic period. It concurred for the most part with the carotid pulse; it distinctly and entirely preceded the pulse at the wrist. You were enabled to verify this by determining the close coincidence of the apex-beat with the carotid pulse, in comparison with its marked priority in point of time to the radial beat. The radial pulse, you know, is a little later normally than the heart's impulse; but here the difference in time was abnormally great. You see, then, that in estimating the rhythm of any given murmur it is unsafe to rely on the pulse at the wrist. Whenever it comes to a fine point, and absolute precision is required, you should, as a rule, place your finger on the carotid while you are listening at the heart. Unfortunately, this is not always

an easy matter to accomplish, at least with the rigid stethoscope in common use. The attitude is awkward and embarrassing in the extreme, and cannot be endured for any length of time; the carotid itself is but feebly felt in many persons, and often the slightest movement of the neck may utterly derange the best concerted manœuvres. If, then, you are foiled in your manipulation of the carotid, try the subclavian, just where it is on the point of dipping beneath the clavicle. The interval between the pulses in the two arteries must be immeasurably small. The subclavian is the larger vessel, and presents a pulse less liable to change and less easily effaced by the movements of the muscles, while the clavicle offers a rest that steadies the hand and leaves the ear and the head at full liberty to pursue their investigations in peace and quietness, without let or hindrance. Enough of the heart: let us pass to the brain. I need not remind you that in the vast majority of cases of aphasia, understood in its widest sense, the lesion is on the left side, and that in the majority of such cases the seat of the morbid change is the convolution of Broca or its environment. Pathology, then, and, I may now add, direct experiment, would seem to mark this region as a great physiological speech-centre for the mass of mankind; in other words, as one of the main links in the long chain of succession, from the supreme centres downwards to the nerve-nuclei, that govern immediately the muscles engaged in the consummation of speech. Our own case is no exception to the rule in pathology. The Sylvian artery near its origin was blocked by an aneurysm, which lay embedded on the surrounding structures, among the rest, on the convolution of Broca. The branches to the corpus striatum ran clear of the block; they arose in front of it on the proximal side. The remaining ramifications encircled the aneurysm, and must have been submitted to strong pressure. The temporo-sphenoidal branch appears to have been absolutely closed in some part of its course. The branches distributed to the gyrus of Broca and the island of Reil would seem to have collapsed and expanded in a desultory manner by intermissions. In accordance with the varying fulness and force of the cerebral circulation, or with the changing bulk, form, and structure of the aneurysm itself, they were more or less open to the reception of blood flowing at times in a slender stream, at times in volume sufficient to maintain the normal activity of the speech-centre. Again, the pressure bearing upon the bloodvessels must have borne upon the brain-tissues around the aneurysm at the same time, in the same measure, and with the same variations. Hence it is easy to understand why the aphasia should appear, disappear, and finally reappear. I would willingly stop here, were it not that a distinguished professor—one of the foremost men of the day—by the mere ascendancy of his name has well-nigh thrown us back into chaos and confusion. Dr. Brown-Séquard denies to Broca's convolution and its surroundings all physiological power over the mechanism of speech. This doctrine is only part and parcel of a comprehensive scheme which aims at revolutionising the pathology of paralysis, as hitherto accepted—a scheme, indeed, which goes far to render impossible all localisation of brain-power. I am, however, only concerned with aphasia. Let us suppose, then, that our presumed speech-centre, now under controversy, is softened or otherwise damaged in its nutrition. You are called upon to believe that it is not the destruction of tissue, or the abolition of energy in the part diseased, that directly paralyses the apparatus of expression, but that the paralysis is owing to an irritation derived from the damaged spot, and conveyed away to nerve-cells in other regions, where it is empowered to put a veto on the operations essential to speech. The *modus agendi* is complex—first irritative, then inhibitory. Now, gentlemen, aphasia may last a man's lifetime without material change from beginning to end. Is it, then, conceivable that the processes described can go on for evermore without a break, and never let slip a single opportunity of silencing speech or circumscribing its scope? To my mind, unceasing, unchanging paralysis, the result of untiring excess or sustained perversion of energy in a nerve, is one of the hardest of all hard things to understand; harder by far than all the anomalies that beset the old belief in passive paralysis. Be that as it may,—concede, if you please, all the profound and enduring influences claimed for irritation and inhibition, operating intermediately upon nerve-cells scattered broadcast throughout the brain,—you are no nearer the mark practically. The region above defined is still in disease the main source of aphasia, whatever the nature and channel of communication may be. Even when robbed of all its authority over the utterances of health, it still remains a pathological centre—a centre of speechlessness, if not a centre of speech,—and for all practical purposes we are exactly where we were.

ORIGINAL COMMUNICATIONS.

REMARKS ON

UNUSUAL SLOWNESS OF THE PULSE,

FOUNDED UPON A CASE ILLUSTRATING THAT FORM OF DISEASE.

By JAMES RUSSELL, M.D., F.R.C.P.

In the *Medical Times and Gazette*, vol. i. 1864, page 7, is a very interesting paper from the pen of Dr. Peacock, on "Unusual Slowness of the Pulse." A case of this form of disease, which has lately occurred to myself, led me to examine other recorded instances; and, if I venture now to supplement Dr. Peacock's communication, it is not in the hope of strengthening his arguments, nor with the intention of amending his conclusion, with which my own examination of the subject leads me to coincide; but with the desire of offering such further illustration as the examples to which I am able to refer have placed within my reach.

It would appear that, just as abnormal depression in the temperature of the body is an occurrence much less frequent in disease than the opposite condition of elevated temperature, so the cases in which the frequency of the pulse is decidedly reduced below the normal standard bear an almost immeasurably small proportion to the number of those in which its rate is accelerated. I am, of course, not referring to a small reduction in frequency, with respect to which the analogy, drawn from the body-temperature, does not hold; but rather to such abnormal reduction as brings the rate of pulsation down below 50, or even below 30 per minute; and this reduction not presenting itself as a passing occurrence, but as a condition lasting through a protracted period. Cases of very slow pulse have, however, been mentioned or detailed in in some number, but unfortunately—so far, at least, as the printed records go—with too few particulars, in many of them, to render them available for practical use.

It is an interesting question, at the outset, how far slowness of pulse, such as that now contemplated, is compatible with health and activity. Dr. Peacock, in the paper already referred to, says that he never met with a case in which remarkable slowness of pulse had been ascertained to have been an original defect; but certain instances on record appear to intimate that marked slowness is not necessarily inconsistent with a considerable amount of mental and bodily energy. My patient had a pulse so slow as to have attracted the attention of a medical man, though its number was not stated, for seven or eight years before he came under the observation of Dr. Parkes, who sent him to me; and during that time he was not aware that he was in other than usual health; he worked as an engineer. Napoleon's pulse-rate of 40 has been frequently quoted, apparently on the authority of Rochoux; in the debate at the Clinical Society on Mr. Pugin Thornton's case (*Lancet*, vol. i. 1875, page 310), Dr. Southey referred to a man who lived to eighty years of age, his pulse having been only 20 for thirty years; and Mr. Hewan gave most striking testimony of a similar character from his own person. His pulse, he stated, had fallen in the course of eleven years from 72 to 24, and had remained at that rate for ten years, excepting for a brief rise to 64 during an attack of gout, yet he was capable of great physical exertion. At a meeting of the Harveian Society in 1864 (*Medical Times and Gazette*, vol. i. 1864, page 607), Mr. Adams mentioned that a hospital surgeon in London had habitually a pulse under 30, consequent on a fever caught in the Crimea (I presume ten years before); he suffered from cold, and was unable to take stimulants. Two cases are also quoted by Mr. Herbert Mayo in his well-known paper (*Medical Gazette*, vol. xxii., page 232)—one of a man in good health, aged thirty-five, who was aware of his pulse having been slow for fourteen years, and when counted, four years before the paper was written, it was found to be 40; another, of a man, aged thirty-two, whose pulse was 36,—his aortic valves were ossified, and he died of obstruction of the bowels, but his health is stated to have been excellent. Mr. Mayo adduces two other examples in men, aged respectively seventy-seven and seventy years: in the former of these the pulse had not exceeded 36 for ten years when it was first

counted, and generally was 28; in the second the rate was from 40 to 28, the reduction being apparently due to restricted diet five years before; the former of the two is expressly stated to have enjoyed good health. In what proportion of certain other cases which have been incidentally quoted on other occasions, and have been reported in the journals, the general health has been preserved, it is impossible to form an opinion on account of scantiness in the details; nor is any assurance afforded that the sensible beats at the wrist have not been supplemented by feebler contractions of the heart, insufficient to make an impression upon the finger placed over the artery. On the other hand, it may be added that in a large proportion of the cases, which will form the basis of the following remarks, the discovery of slowness of the pulse was made accidentally, attention having been called to the symptom through the occurrence of the sudden attacks which seem to be so general a concomitant of the condition, at least when existing in disease. How often the pulse may be morbidly reduced in frequency without producing a liability to these attacks, I have no means of judging.

Besides the examples I have already referred to, there are others mentioned incidentally (I have noted eleven), without information as to the circumstances under which the condition has occurred, whether in health or in disease. In the Index to the first fifteen volumes of the *Pathological Society's Transactions*, peculiarities of pulse are entered as having presented themselves in thirty-six of the cases: of these I have access to reports of twenty-five; unusual slowness was noted in two only (vol. vii., page 167; and vol. xv., page 87). It thus appears that slowness of pulse is one of the rarer accidents in pathology, yet is encountered with sufficient frequency to give it importance as a symptom of disease.

I have noted thirty-eight cases (including my own case) in which slowness of pulse appears to have been associated with disease, and in which sufficient details are afforded for the purpose of this communication. But in four of the thirty-eight the slowness was not so great as appeared at first sight, a weaker contraction of the heart, not marked by a sensible radial pulsation, supplementing the sensible pulse; in one of these four, however, the supplemental beats, when they occurred, merely raised the total number to 46, and in a second to 52; in a third the weaker beat occurred only every few seconds. Of these thirty-eight cases the highest rate of pulse recorded was 48—with one exception, a case of fat heart, with a pulse of 56. The number 40 was reached in four others; in the remainder the degree of frequency varied between 28 and 38, though in eleven of the patients a much lower rate was observed occasionally, falling to 20, 18, or even to 9 or 10; but it is to be specially remarked that this very great reduction of frequency took place exceptionally, and was not maintained in any instance. In five of the cases the former rate of the pulse is stated; it was from 60 to 70 or 80. I am unable to state the length of time during which this low rate of pulse was ascertained to have been present in several of the cases. In my own case the pulse had been discovered by a medical man to be "slow," without statement of number, seven years before my friend Dr. Parkes saw the patient; under our observation it has maintained a rate of 32 for the last eighteen months. In a case long watched by my colleague Dr. Fletcher, the man was under his observation for eight years, when the case ended in death; the pulse never exceeded 38, and sometimes was as low as 15. It is remarkable that this man became phthisical, and that when the symptoms of chest disease set in his pulse reached 120 or 130. A similar increase of frequency also occurred in another case—a case, probably, of fibroid degeneration of the heart,—in which, however, the reduction had been only of a few days' standing; the pulse had been at 10 in the night, but next day it ran up to 200, the patient dying two days afterwards without any further notice of the pulse-rate being made.

Besides the two cases just mentioned, the duration of the symptom in question was noted in seven others with greater or less exactitude during periods varying from two and a half to eleven years, or "several years," death closing the period in four. One only was a case of ascertained degeneration of the heart. In three of these cases there had been symptoms indicating a still longer duration of the symptoms with which the slowness of pulse had been associated—viz., from two to three years—making a total duration of four and a half, seven, and nine years respectively.

In six others (three of them cases of degeneration of the heart's walls) the known duration of the slowness of pulse was from four to eighteen months, three of the cases (those of degeneration of the heart) ending in death. Four of the patients, however, had suffered previously to examination of the pulse—for six months in two cases, for eighteen months in another, indefinitely in a fourth. I may yet add three other cases, two of them fatal, with degeneration of the heart, in which, although no indication as to the period during which the pulse had been slow was afforded, serious symptoms referable to the probable cause had been present for three, four, and seven years respectively.

Of the twenty remaining cases, of which ten were fatal from degeneration of the heart, and five others presented symptoms of "heart disease," many do not admit of any declaration as to the duration of the symptom of which I am now writing, nor indeed of the morbid state with which it was associated; but in four of them a limit is assigned, showing the symptom in question to have been acute in its production. The period was from five to eight days, the change of pulse being a precursor of death; symptoms had preceded for a short period, the longest term being six weeks.

Now, it is important to note how large a proportion of the cases of slow pulse, on which I am founding my remarks, have occurred in connexion with some kind of evidence proving the presence of organic disease of the heart; in fact, I can only point to seven cases in which no evidence of this kind existed. I may indeed add an eighth, in which the sole reason for inferring the presence of heart disease was the physical signs of "slight dilatation." The remaining thirty cases, with the exception of one, in which the details are defective, have all presented evidence of cardiac disease, either post-mortem or by a clinical history of that disease. It is at once granted that the different pathological conditions included under the common title of diseases of the heart stand in very different relations with reference to the peculiar change in the pulse which I am considering; still, it must be admitted that the very predominance of the cardiac element in these thirty-eight cases gives great significance to a diseased condition of the heart itself, as being an element of primary importance in our inquiry. This observation gains much additional force when it is added that in only four of the cases was there any evidence afforded of disease existing in connexion with the nervous system.

I may at once state what the evidence was in these four cases. In one (Mr. Holberton's) the antero-posterior diameter of the foramen magnum was much diminished, the odontoid process was pushed back, and its ligaments were thickened; the medulla oblongata was small and extremely firm; both pneumogastrics were large, and the right middle cervical ganglion of the sympathetic was unusually developed. The symptoms commenced two years after an injury to the neck. In the case of Dr. Fletcher's to which I have already referred, the cervical portion of the cord opposite the fourth, fifth, and sixth cervical vertebræ was uniformly atrophied and softened. The patient, aged fifty-eight, had suffered some injury to the occiput in early life; his kidneys were granular. In a case of fat heart, by Mr. Worthington, "the left branch of the basilar artery was dilated and thickened." And in a case of Dr. Spens', quoted by Mr. Richardson, about two ounces of watery fluid were found in the ventricles of the brain, and a gelatiniform appearance on some parts of the pia mater; "a small ossification also existed at the back of the pia mater;" there was nothing marked in the thorax. The author explains the cerebral changes—no doubt justly—by referring them to defective supply of blood to the brain. I may insert here a notice of a case of Dr. Chambers's, which is mentioned incidentally by Sir Thos. Watson in his Lectures (fourth edition, vol. i., page 132), in which the beats of the pulse were for some time as few as 9 in a minute; the gentleman, Sir Thomas was informed, had sustained some injury to the spinal cord, but no other particulars are given.

One very significant fact comes out in connexion with our present subject, from a further examination of the group of twenty-nine cases in which the heart was stated to have been diseased—namely, that in no less than seventeen had there been degeneration of the tissue of that organ. Of these seventeen cases, thirteen were cases of fatty degeneration or fatty growth, of which in one instance only had the diagnosis not been verified by a post-mortem examination; three were cases of fibroid degeneration, as ascertained by anatomical examination; and one was a case of aneurism of the septum of the ventricles.

Of the others, one patient is only reported to have had

granular kidney; two are stated to have suffered from "disease of the heart." In one case—that of Mr. Holberton's, referred to above (*Medico-Chirurgical Transactions*, vol. xxiv., page 77)—the heart was found after death to be large, the left ventricle rather thin, the auriculo-ventricular opening dilated; and in the discussion on the case more than one speaker expressed his conviction that degeneration of the heart-walls had existed. Still, it must be added that no proof of this having been the case is attainable, and that the case has been quoted by so high an authority as M. Charcot, in confirmation of the opinion that in certain instances of slow pulse that condition is due to the influence of the cervical spinal cord or medulla oblongata. Of the eight other cases, the proof of cardiac disease having been present, though decisive, was obtained from the symptoms or from the result of physical examination only.

With reference to the purpose for which I have adduced these cases, the group of degenerations of the walls of the heart has far more direct significance than any of the other forms of heart disease. Slowness of pulse is one of the recognised effects of degeneration of the heart. Dr. Quain speaks of irregularity being the change in the pulse most frequently observed, weakness a second, and slowness a third; and he adds that the slowness of pulse is sometimes quite remarkable. He further states that in his first two series of cases irregularity was noticed thirteen times, weakness fourteen, and slowness eight times. It thus appears that the mere fact of fatty degeneration being present does not render a complete account of the cause of slowness of the pulse, since it is by no means an invariable accompaniment; for it may be further noticed that through the three series of cases of cardiac degeneration given by Dr. Quain in his paper (*Medico-Chirurgical Transactions*, vol. xxxiii.), a number of the pulse as low as that which prevailed in the cases at present under consideration is given in four patients only. Dr. Peacock makes a remark to the same effect, and he adds that in the only case of slowness of pulse which he had examined after death the heart was in the opposite condition to degeneration—viz., that of great hypertrophy.

Dr. Quain observes that the mode in which the pulse is affected in fatty degeneration of the heart depends on the part of the heart affected, and on the degree and extent of the disease. Again, with respect to fibroid degeneration of the same organ, Dr. Ogle (*Pathological Transactions*, vol. xv., page 87), after reporting a case in which the pulse-rate averaged 38, refers to a report of other cases which he had drawn up in vol. viii. (which I do not possess), in which he "had suggested that the alteration of the heart's action, noticeable in many of these cases of fibrinous deposits in the heart's walls, might be explained on considering the acknowledged connexion which had been found by experiments on the lower animals to exist between the integrity of the great transverse fissure of the heart and the movement of the ventricles." Writing at a later period on the same subject, in the twenty-fifth volume of the same *Transactions*, Dr. Fagge concludes with these words:—"So far as I know, the only other suggestion that has been made for the recognition of this morbid condition (fibroid degeneration of the heart) is that the pulse is very slow in some cases. . . . My cases, however, do not at all support the opinion that a slow pulse is to be regarded as a constant or even a general result of fibroid disease."

A remark by Dr. Stokes (*Dublin Quarterly Journal*, vol. ii) has interest in connexion with the question as to the relation of cardiac degeneration to slowness of the pulse. Dr. Stokes refers incidentally to "typhoid softening of the heart" as co-existing with a pulse of 30 or 40. I need only add that a like degree of slowness has been noticed by other observers, specially by Dr. Murchison, as liable to occur in the course of that form of fever.

In this connexion I may notice one of Mr. Mayo's cases, which exhibits the direct effect of debilitating influences in retarding the action of the heart. The case was that of a young girl who had taken no food by the mouth for five weeks and three days, having been supported by enemata. Her pulse suddenly sank to 35, whence it slowly rose. But subsequently, having sat up for six nights successively, on the seventh the pulse fell to 30, and it was many years before it regained a frequency of 70.

On the whole, the conclusion respecting these cases of degeneration of the tissue of the heart must be, that although the degeneration does not offer of itself a full and complete explanation of the reduced frequency of the pulse met with in certain of the cases, yet that it constitutes a very important indication of the presence, in the heart itself, of some influence directly interfering with the irritability of its fibre; and thus these cases have much value in reference to the others already mentioned, in which evidence of other forms of heart disease was presented by the patient.

I may, however, select one of these last mentioned cases for special notice, as affording a transition from the cases of degeneration just referred to, so far as the apparently clear connexion goes between the state of the pulse and the condition of the heart. The patient is briefly stated to have presented embarrassed breathing, and was supposed to have water in his pericardium; his pulse was usually 29, and on some days was found to be as low as 14; in three months all his heart symptoms had disappeared, and the pulse had regained its natural standard.

(*To be continued.*)

NOTES OF A CASE OF

DIABETES MELLITUS IN AN INFANT.

By S. FULLOM CONOLLY, M.R.C.S. Eng., etc.

The following notes of a case of diabetes mellitus may possess some value, on account of the rarity of this affection among children, and the very early age at which symptoms of the complaint first discovered themselves. Two points of interest are, I think, suggested—one, the hereditary tendency of the child to the disease; and the second, the probability of this predisposition being developed into the actual disorder by the reflex irritation of teething.

J. H. P., a boy aged one year and nine months, had good health from his birth up to the date of the present seizure. When seven months old he cut his first tooth, and was weaned about the eleventh month, and appeared to thrive well upon the change of diet. Three months since (when the patient was about eighteen months old), his mother first noticed some failure in his previously healthy condition: that he suffered considerable thirst, passed water more frequently and in larger quantities, lost flesh and strength, and became irritable and capricious in temper. About this time, and during the following months, several teeth were cut at irregular intervals, and it was to their eruption the mother attributed the child's symptoms, so delayed obtaining advice until nearly three months after the first onset of the attack. His symptoms during this interval having got gradually worse—thirst more urgent, passage of urine more frequent and the amount greatly augmented, the wasting more decided,—his mother became alarmed, and first sought advice on December 30, 1876. His father and mother are healthy people, and have another child, a girl, in excellent health. There is no special feature in the family history, except the fact that a male cousin on the mother's side is at the present time suffering from diabetes, and his father was a diabetic, and died of that complaint.

Patient is fair, has grey eyes, and is very quick and intelligent; has a miserable expression, as if suffering from mesenteric disease; is pale, thin, and much reduced. One is struck immediately with the great thirst the child suffers, and his cry for "a drop of water" is almost incessant. His parents have measured the quantity of liquid he consumes in the twenty-four hours, and it varies between five and seven pints, but would be much more if they did not restrict the supply. Micturition is very frequent, the urine running away from him copiously as he stands, and drenching his mother when nursing him, notwithstanding her many precautions. It has not been possible to measure the amount of urine passed. The skin is not particularly dry or harsh. The appetite is very little altered—certainly never voracious. There is great muscular weakness and debility. The genitals are in a natural condition, but the nates, from the constant moisture, are reddened and covered with a lichenous eruption. The mouth is cool; tongue clean and moist; gums healthy. A bicuspid in the left lower jaw is just breaking the skin. The bowels have acted almost every day—sometimes natural motions; occasionally hard, dry, and scybalous. Rest disturbed at night by urgent thirst. Patient is irritable and capricious in temper; complains of pains in his limbs; the pressure of his mother's arms at times when nursing him appears to hurt him. His thoracic and abdominal organs are healthy. Pulse 80; temperature normal. Patient's urine exhibits all the usual characters of diabetes; it is of a pale

apple-green colour, faint sweet odour, no sediment or albumen, specific gravity 1032. On boiling with sulphate of copper and liquor potassæ a deep reddish-brown colour and deposit of the suboxide of copper are produced, indicating the presence of sugar. It readily undergoes fermentation when yeast is added to it. His mother's black clothes, after nursing him, show white powdery stains when dry.

On December 30 he was ordered a mixture composed of liq. sodæ, fer. ammon. cit., and syrup.

On January 8, three grains of an alterative powder, composed of hyd. c. cretâ, soda, and rhubarb, were ordered to be taken every other night. His diet was regulated to the exclusion of saccharine and amylaceous alimentaria; milk to be taken freely.

From December 30 to the next succeeding date his symptoms remained much the same; the specific gravity of the urine kept pretty constantly at 1032.

January 21.—Increased muscular weakness and debility. Thirst and micturition much the same. Was ordered a small quantity of cod-liver oil two or three times a day. Three grains of pot. bromid. with two grains of fer. ammon. cit. also exhibited. Drinks five pints of liquid in the twenty-four hours. Urine, specific gravity 1034.

25th.—Thirst and micturition less. Slept better since taking the pot. bromid.; evidently more reduced and weaker. Diet principally milk, eggs, and meat.

27th.—Was summoned to see the patient this evening. Had been very drowsy all day. Suffered less thirst; eaten nothing. Skin hot and dry; pulse 120, feeble; temperature 102·3°; mouth dry; lips cracked; tongue furred; breathing hurried; lungs healthy; bowels not moved for three days. Was ordered a purgative powder and a warm bath. Urine, specific gravity 1036, slightly opalescent, albumen a trace.

28th.—Bowels relieved; motion "like marbles." Pulse 90, very weak. Feverishness of yesterday abated. Mother has ceased giving him medicine. Patient is confined to cradle; too weak to sit up. Temperature 97°; urine, specific gravity 1032, albumen a trace.

30th.—Debility greater. Has a loathing for food, and his thirst is much less urgent; in fact, he often pushes necessary liquid nourishment away when offered him. Towards the evening his breathing became very hurried; was drowsy, intolerant of any movement, pale, and exhausted. Pulse 120, feeble and intermittent; extremities cold and slightly œdematous. Urine, specific gravity 1034, albumen increased. Was ordered warm milk, strong beef-tea, and wine negus.

31st.—When seen this morning he was comatose, surface of body very pale, extremities cold, legs œdematous as far as knees. Pupils strongly contracted; urine still passing from him, but in smaller quantities. Gradually sank, and died about 9 p.m. same day.

A post-mortem made thirty hours after death discovered the brain and its membranes very much congested only. The thoracic and abdominal organs healthy. The bladder contained about three ounces of urine of the specific gravity 1034.

Burford, Oxon.

The Meteorological Society has been placed under the management of a Council nominated by the Royal Society, and appointed by the Treasury. Its members are—Professor Henry J. Smith (chairman), Messrs. De la Rue, F. Galton, Professor Stokes, Lieutenant-General Strachey, with the Hydrographer to the Admiralty as *ex-officio* member.

The Lectures on Legal Medicine at the Morgue.—According to the *Gazette Hebdomadaire*, July 13, these lectures, to which we recently alluded, are fixed to commence when the Faculty opens in November next. It is to M. Devergie that their institution is chiefly owing, which is, in fact, a revival, for he instituted a kind of medico-legal clinic as long ago as 1834. His example was followed by M. Tourdes, of Strasburg, and such courses have since been instituted, and are well organised, in all the German medical faculties. Without any exactly known cause these lectures have been discontinued in Paris during the last fifteen years. They are in future to be delivered at the Morgue, where unclaimed bodies will be put at the disposal of the Professor of Legal Medicine. They will take place three times a week during the winter; but as the means of accommodation is very limited, only thirty advanced students will be admitted, and any practitioner who wishes to attend the lectures must apply to the Dean of the Faculty for permission.

REPORTS OF HOSPITAL PRACTICE
IN
MEDICINE AND SURGERY.

NORTHUMBERLAND HOUSE ASYLUM, STOKE NEWINGTON.

CASE OF HEMIPLEGIA AND UNILATERAL HYPERÆSTHESIA, WITH EPILEPSY, IN AN INSANE PATIENT.

(Under the care of Dr. WRIGHT.)
[Notes by Dr. Haggart.]

M. F., aged forty, a lady. Illness commenced June, 1874, with severe headaches, accompanied with epileptiform seizures. She became insane, and was placed under restraint in October, 1874, remaining under the same care till July 31, 1875, when she was transferred to Northumberland House. At this date the note of her appearance and condition is as follows:—She is a lady of clear complexion and fair hair, slightly built. She is somewhat feeble, and has a bedsore on the sacrum. She has left hemiplegia, with marked hyperæsthesia on the same side, so much so that she screams out, even at the slightest touch. She is alternately depressed and excited, her language is incoherent and irrational; at times she is violent. Her habits are wet and dirty. During the next few months after admission she slightly improved, her bedsore healed, and the epileptic attacks disappeared till January 21, 1876, when they returned in an exacerbated form, and with increased frequency. Just previous to this outbreak there had appeared on her face a small irritable ulcer, which, from the manner of its extension, was believed to be specific in its nature. From this time she gradually became weaker, both mentally and bodily, being at times so helpless that fears were entertained lest she should fall into the fire, or otherwise damage herself, during her aimless wanderings among the rooms. On this account she required constant attention. On the evening of November 10, 1876, she seemed more restless than usual, but not specially worse. She, however, became suddenly prostrate, and, notwithstanding the efforts which were made to sustain her, rapidly became worse and died. The immediate cause of her death was syncope.

Post-mortem Examination, twenty-four hours after death.—(Notes by W. H. Kesteven.)—Chest: Pleuritic adhesions at base of right lung; otherwise the lungs were healthy. Heart: Left auriculo-ventricular and aortic valves were thickened; there was a clot in the left ventricle, due to the slowness of the death, which was finally caused by syncope. Abdomen: Viscera generally healthy. Right kidney and supra-renal capsules larger than the left. On microscopical examination, however, the structure of each was found to be healthy. Cranial Cavity: Opacity of membranes all over cerebral surface. Right ventricle fuller of serum and more dilated than the left; the foramen of Monro was dilated. Right thalamus opticus was atrophied, and presented on its internal and posterior aspect a patch about the size of an acorn of greyish discoloration. On cutting into this it was found to be a cavity. The wall of this cavity which was towards the ventricle was about one-twelfth of an inch in thickness; it contained serum, and at its lower posterior border communicated by a small aperture with the ventricle. Internally its walls presented the appearance of broken-down and softened brain-tissue, of a brownish-grey tint. There was no pyogenic membrane. The corpus striatum on the right side had a cicatrix-like depression, just at the root of the narrow extremity which passes backwards external to the thalamus opticus. On cutting into this it was found to be the termination of a fistulous-like passage which led slightly downwards, inclining forwards and outwards into a cavity, situated partly in the substance of the lenticular nucleus of the corpus striatum, at its internal aspect partly in the island of Reil. This cavity presented a similar appearance to the cavity described in the thalamus opticus, with the exception that it presented from its reddish colouration the appearance of being of more recent origin than that in the thalamus opticus. Posteriorly, the right pair of the corpora quadrigemina were flattened, and had quite lost their natural contour, seeming like one soft square mass; these were blood-stained at the posterior aspect. The superior vermiform process of the cerebellum was softened. The ganglia in the

left ventricle were apparently healthy. Base of the Brain: The arteries seemed to be normal, nor could there be found any signs of rupture or occlusion of any of the larger branches of the arteries supplying the diseased parts. The right crus cerebri was discoloured and atrophied. On tracing it along its course beneath the thalamus opticus it was found to be implicated by the cavity of the corpus striatum above described. The softening and discoloration of the crus had evidently proceeded from this spot. The right side of the pons Varolii appeared slightly atrophied. The remaining parts of the brain appeared healthy so far as could be judged by the unaided eye.

Microscopical Examination of the Brain.—Superficial Convolutions, anterior and posterior: Throughout there was an atrophic condition of the nerve-cells, presenting itself in an increase of the size of the nuclei, with a shrinking, and in some cases a disappearance, of the cells in which they are normally embedded. Where the cell-substance had not disappeared it was seen to be of a different material from the nuclei, and also to differ from the same substance when healthy. This difference consists in its insusceptibility to the carmine dye with which the sections were stained, and which was readily absorbed by the nuclei. The result of this insusceptibility was a colourless appearance, contrasting strongly with the nuclei and the surrounding neuroglia. The bloodvessels of these convolutions were thickened as to their walls, and in many cases were lying loose in perivascular canals formed at the expense of the brain-tissue by their undue dilatation during life. On examining the parts lying in the neighbourhood of the cavities above described, the same appearances, so far as regarded the nerve-cells and the bloodvessels, were found. In addition to these changes, there were, more strongly marked in the white than in the grey substance, multitudes of spots of miliary degeneration. These seemed to increase in number as the walls of the cavity were approached. It appeared that these cavities, which were formed by the breaking down of the nervous tissue, acted as foci of degeneration. The medulla oblongata was too much damaged and softened to admit of examination, but it was evidently more affected on the right side than on the left. In the cerebellum the nerve-cells presented signs of degeneration. In this situation, however, it was the fuscous form of degeneration which presented itself. The walls of the bloodvessels also were thickened, and the vessels were lying in perivascular spaces. These appearances are all explicable by the condition of the bloodvessels, as they are all of them due to faulty nutrition. The origin of the whole disease, *fons et origo mali*, may, however, be attributed to the unstable condition of the nervous elements, giving rise to what Dr. Hughlings-Jackson has designated "nervous discharges." The evidence of these discharges was seen in the mania and convulsions of the patient. The more constant and the more powerful these discharges, the greater would be the inhibition exerted on the sympathetic or vaso-contractor nerves. The result of this inhibition would be dilatation of the vessels, followed by thickening of the coats, which might or might not be of an inflammatory nature. The effect produced on the nutrition of the nerve-cells by this atonicity of the vessels is not difficult of discernment, and fairly accounts for their degenerate condition. The cavities are also due to the condition of the vessels. There has evidently in each case been effusion. Some vessel, or vessels, under the continued abnormal pressure have given way, and the surrounding tissues have been destroyed. The point which strikes one most forcibly in this case is the connexion between the appearances found after death and the symptoms manifested during life. The patient had left hemiplegia and hyperæsthesia—hemiplegia on the left side on account of the extensive disease of the right corpus striatum and crus cerebri; left hyperæsthesia because of the disease found in the right thalamus opticus. The epilepsy, which, as we have seen, was, no doubt, the cause of all the mischief, might have been hereditary, or due to some cause connected, perhaps, with her time of life. The disease of the brain being in this case in the right hemisphere, and the paralysis and hyperæsthesia on the left side of the body, bear out the accepted teaching on these points.

RIGHT HEMIPLEGIA—EXTENSIVE LESIONS.

(Under the care of Dr. HUSBAND.)

X., female, aged sixty-seven. This patient had an attack of paralysis about seven years ago, of which there were no particulars obtainable. When first seen (about January, 1877) was just recovering from what was called a fainting fit, but which was accompanied by loss of power in the right hand. From this she recovered, but was attacked again in about six weeks in a similar manner. This also passed off, and six weeks later on she was prostrated by a serious attack, which deprived her of the power of speech and of swallowing, and entirely paralysed her right side. She died in about eight days of starvation; injections, etc., not being retained. Her mental powers had been impaired since her first attack.

Post-mortem Examination, twenty-four hours after death (made by W. H. Kesteven).—Lungs and heart healthy. Kidneys cystic and granular.(a) The contents of these cysts varied in consistency; some of them contained fluid resembling urine, others a brown pultaceous material. Microscopically, the semi-solid substance was found to consist of cholesterine, oily matter, and broken-down blood corpuscles. The fluid found in the other cysts contained blood corpuscles, epithelium, oil globules, uric acid, calcine oxalate, and cholesterine crystals. The striking peculiarities observed in microscopical examination of the kidney structure were frequent deposits of so-called "gouty" crystalline substance resembling calcine phosphate. The vessels did not appear altered, but the epithelium in the uriniferous tubes appeared to be detached. The remaining abdominal and thoracic organs were healthy. There were no coarse morbid appearances on the surface either of the brain or cord. On cutting down to the ventricles of the brain, they were found to contain blood. In the right lateral ventricle it would be more correctly described as bloody serum, and not in very large quantity. But in the left lateral ventricle there was found a large quantity of recent coagulum, which seemed to have burst open the sac of an old clot. This sac completely occupied the site of the thalamus opticus on the left side, to a large extent destroying the corpus striatum on the same side. The whole of the lower and lateral portion of the corona radiata was destroyed by this old standing lesion. The damage was found to travel downwards and backwards, implicating the left crus cerebri on its upper surface to within half an inch of the upper extremity of the fourth ventricle, and to a great extent destroying the left pair of the corpora quadrigemina. Anteriorly the lesion extended outwards, forwards, and slightly downwards, reaching as far as the island of Reil, which was itself to a large extent implicated. Where the brain-substance was attacked by this lesion it was utterly disintegrated; it was too soft for microscopical examination. On the right side the ganglia seemed to be atrophied, and were somewhat soft. They were not destroyed, but were deeply stained by the bloody serum which had penetrated the ventricle.

Microscopic examination of the spinal cord showed degeneration of the nerve-cells throughout, but only such as would be accounted for by the age of the patient. Some of the vessels were thickened, but not otherwise markedly diseased. There were large perivascular spaces round some of them, indicating undue dilatation. In the medulla, the floor of the fourth ventricle was found to have undergone degeneration on the surface, particularly that portion of it at which the nucleus of the vagus nerve comes to the surface. The nerve-cells of this nucleus were also very much degenerated, being in most cases nothing but conglomerations of pigment granules. The perivascular spaces as seen in the cord were also apparent in the medulla. There was also miliary degeneration. The brain showed, especially on the left side, large perivascular spaces, many of them containing hæmatin. There was also degeneration of the nerve-cells, and miliary degeneration. The symptoms observed during life, and the appearances found after death, in this case, seem to be well connected.

The history of the case shows that the patient had paralysis, and therefore cerebral lesion of old standing. The form of paralysis was that called hemiplegia. The lesion in the brain was found where such symptoms would have led one to anticipate them—that is, in the great motor ganglia on the opposite side of the body to that on which the hemiplegia appeared. The loss of power of swallowing would be accounted for by the condition discovered in the fourth ventricle, such lesion undoubtedly leading to paralysis of the glosso-pharyngeal nerve. Finally, the relaxed condition of the anal sphincter would be accounted for by the fact that the lesion in the brain would to a great extent cause unrestrained action of the inhibitory powers which the spinal cord possesses over the sympathetic nerves,

(a) For some years previous to her death she had complained of pain in the region of the left kidney. But this was the only evidence observed during life of the renal disease found post-mortem.

which nerves, normally, by their action, cause contraction of the involuntary muscular fibres; the result of such unrestrained action being to cause paralysis of the involuntary muscles.

SATURDAY, JULY 21, 1877.

POST-MORTEM EXAMINATIONS IN WORKHOUSES.

It cannot be denied that the changes made during the last few years in Poor-law Medical Relief have been for the better. The sick poor used to be in ill-planned and overcrowded wards, nursed by aged paupers nearly as feeble as the patients themselves, and attended by a doctor overworked and so underpaid as to be sorely tempted to choose his means of cure (most of which he had himself to find) for their cheapness. Now all this is gone, or going. We have in many London parishes, and shall have in others, infirmaries built on the best sanitary lines, with trained nurses, and a medical superintendent living in the house, giving his whole time to it, and not called upon to pay for what he orders.

But there is one direction in which no step forward has been taken, and in which, if the field were tilled, large harvests might be reaped. We are thinking of the making use of these great *special hospitals* (for they are really such) in the interests of science, and therefore of the nation, and of the world. The workhouse infirmaries are, in fact, in very large measure at least, hospitals for the diseases of old age. The morbid changes in this class of diseases are, as a rule, incurable and so chronic that the rules of our great hospitals forbid their being watched from beginning to end in them, even if they can be admitted for a time. Hence many common diseases of this kind are not so well understood as other rarer maladies, which run a shorter course. In illustration of this, we may refer to Mr. Hutchinson's work, now in progress, on Clinical Surgery, in which he devotes a plate and some letter-press to the changes met with in "deforming rheumatism," and in doing so remarks on the scantiness of our information on the subject. Dozens of cases of this affection may be found in any large workhouse infirmary, and yet comment of this kind is simply true. We need hardly insist on the importance of a knowledge of such morbid processes. All diseased actions are more or less related to one another, and it is not possible that one class of them should be well studied without light being thrown on others. To the public, our knowledge of such diseases is a benefit directly proportional to their commonness.

This will be enough to show that there is in these workhouse infirmaries a vast collection of disease well worth study, and at present largely in want of it. Seeing, then, the great value of the work which might be done in these institutions, we ask, why can it not be done? At one time some hoped that to these great hospitals there might be appointed a staff of visiting physicians and surgeons, who should make them useful for scientific research, and perhaps for medical training; so that these infirmaries should become pathological workshops, places from which should issue facts of value to the nation and to the world, as well as places in which the sick poor should have the benefit of thorough knowledge, skill, and attention. Perhaps, in the present state of public opinion on subjects of this kind, it is a Utopian idea to expect a Government to propose to spend public money on any plan of this kind; though it may be that in years to come we shall see each parochial hospital with a staff able to do scientific work, and provided with all necessary means.

But if this is but an idle fancy, if it is out of the question that any provision should be made to get more than local and temporary good out of these infirmaries, it is at least possible that each medical officer who has charge of the numerous interesting cases which a workhouse infirmary contains should throw in his mite to swell the sum total of medical knowledge. It is, therefore, not too much to ask that the zeal of those medical officers who do try to be of use beyond their immediate locality shall not be put down. But it unfortunately is. Medical officers have been plainly told by the central authority that the workhouse infirmary is not the place for scientific research. They are not allowed to make post-mortem examinations except by order of the coroner, or the board of guardians, or at the request of the patient's friends. Therefore, post-mortem examinations, like the use for dissection of unclaimed bodies, are practically at the discretion of the guardians.

Whether or not all the circumstances which now surround workhouse infirmary appointments are favourable to scientific work, we have not space here to discuss. There are many changes which might with advantage be made; and possibly at a future time we may point out some. But it is obvious that a post-mortem can be made on the body of a person dying in an infirmary with much less inconvenience to others and loss of time to the investigator than in the case of a private patient; and therefore that in this respect the workhouse medical officer is in an advantageous position. What we here call attention to is, that any attempt at making use of these advantages is at present nipped in the bud. We deplore the line taken by the Local Government Board, because if a medical officer spends time and trouble in examining the body of a pauper who has no friends whose feelings might be hurt, and whose corpse, had he happened to die in another parish, might have been sent for dissection,—he injures no one, but does good, possibly to the world, certainly to himself, and therefore, indirectly, to every patient who consults him. We base our objection to the rule, not only on the possible scientific results which might follow if medical officers of workhouses were encouraged to use their great opportunities for scientific research, but on larger grounds. Pathology is the foundation of medicine, and morbid anatomy is the alphabet of pathology. Diagnosis and treatment alike spring from pathology. All treatment depends for success upon correct

diagnosis; and morbid anatomy is the teacher and critic of diagnosis. A man who wishes to advance in diagnosis can only do so by habitually confronting his notion of the case formed during life with the revelations of the dead-house. The workhouse medical officer, therefore, who tries to correct his ideas about disease by post-mortem evidence, is walking in the only sure road to accuracy of diagnosis, and through that to skill in treatment. Every autopsy he makes renders him the more valuable servant of the public.

If public opinion could be so advanced that an autopsy should follow *every* death, incompetence and quackery would be unmasked with a certainty which would be greatly to the public good. Among ourselves more surely would success be the reward of skill, and ignorance and carelessness receive their deserts, while medicine would advance with rapid strides.

Putting aside visions, however, we come back to the practical question. Workhouse medical officers who make post-mortem examinations deserve all praise, and not blame. It is to the interest of their patients, and also of the nation, that they should do so. If the feelings of the surviving relatives be not hurt, no one else can justly complain; and such a body as a board of guardians ought not to have the power to put a stop to so enlightened and enlightening a practice. Workhouse infirmaries might be, and ought to be, made places for scientific research; and for the Local Government Board, supporting the prejudices of the ignorant and suspicious, to lay it down that they shall not be thus made fruitful is a most short-sighted and mischievous policy.

CHINESE MATERIA MEDICA.

It cannot fail to be an interesting subject of inquiry to investigate the sources from which the Chinese, who constitute so many millions of the human race, derive their supply of medicinal drugs; and this difficult problem has received some attention from recent pharmacologists. In particular, the late Mr. Hanbury, an esteemed, and indeed eminent, member of the Pharmaceutical Society, collected together a series of "Notes on Chinese Materia Medica," which he illustrated by some well-executed plates, and rendered very valuable by his great botanical and general scientific acquirements, and by his knowledge of the Chinese language, which he studied expressly for the execution of his self-imposed task. It may well be imagined, however, that this learned and elaborate contribution to Materia Medica resulted in very little practical information available for the medical profession out of China, and the details so skilfully brought together by Mr. Hanbury are perhaps more amusing and curious than instructive. But it is remarkable that at least a few of the substances commonly used in British pharmacy are to be found in the Chinese Materia Medica, such as the preparations of iron and mercury (as peroxide of iron, calomel, nitric oxide of mercury, and cinnabar) among mineral substances, the blistering-fly among animal bodies; and amidst a great host of substances of doubtful value from the vegetable kingdom are to be found galls, benzoin, and a kind of camphor.

But a still more recent contribution to the knowledge of Chinese Materia Medica has been made in the present year by the transmission of a collection of medicinal substances from Shanghae to the Earl of Derby, the Secretary of State for Foreign Affairs, and by him forwarded for investigation to the Society of Apothecaries. The specimens were obtained in 1875-76, in the course of a mission to the part of China called Yünnan, and the collection was accompanied by a printed copy of a report by Mr. Davenport, "On the Trading Capabilities of the Country traversed by the Yünnan Mission." The specimens are found to consist chiefly of such of the vegetable products of Yünnan as are applied to medicinal purposes by the inhabitants of that part of China, which is a very temperate region, being much elevated, sometimes rising to 6000 or 8000 feet, and situated in about 25° N.

There are no mineral substances in this collection, and the articles consist almost entirely of roots, stems, leaves, barks, and woods; there are but few fruits or seeds; and there are no gums or resins. The specimens are neatly put up in paper parcels, each of which is inscribed with the name of the contents in Chinese and English characters, and their local prices are added. There are 105 parcels, distributed into four packets marked with the locality from which they have respectively been procured, and they have evidently been put up by a skilled herbalist. A fifth packet contains eight specimens of native opium, each likewise marked with the locality from which it was obtained.

The examination, verification, and arrangement of these specimens (which we need hardly say have been carried out gratuitously as a mere labour of love) have been conducted by the present Master of the Society, Deputy Inspector-General Bradford, himself a botanist of no mean pretensions, assisted by Mr. Thomas Moore, the Curator of the Society's Botanic Garden at Chelsea, who has been able to determine the genera of most of them; and the chemical examination of the specimens of native opium has been made by Mr. A. Stewart, the principal Chemical Operator of the Society.

The detailed results of these rather laborious investigations are perhaps appreciable by few persons except professed botanists, but a general *résumé* is not without interest as showing the different value placed upon certain vegetable products by the inhabitants of the Chinese Empire, as compared with other countries. We find, then, that the plants professedly valued as medicines by the Chinese pharmacologists are those which are esteemed of little value in European medicine, although they comprise some fragrant and ornamental members of the vegetable kingdom, such as dendrobium, a beautiful orchidaceous plant; angelica, an odoriferous member of the *Umbelliferæ;* the lonicera, or honeysuckle; the beautiful clematis, and the fragrant and juicy mandarin orange; and various plants, abounding in volatile oil, from the natural order of *Labiatæ*, such as the sage (*Salvia*), the mint (*Mentha*), and the balm (*Melissa*). A few are known to be endowed with rather active properties, as the smilax, which yields sarsaparilla, if indeed this plant really has the active properties which some attribute to it; the uncaria, which yields a kind of catechu; the elaterium, the active character of which is indubitable; and beans, cowage (*Dolichos*), and wheat, rye, rice, and maize are among the medicinal drugs. Although not belonging to the vegetable world, there is a parcel of a coleopterous insect, the mylabris, used by the Chinese as a blistering-fly; and there are some nutgalls, apparently the product of some hymenopterous insect.

The properties ascribed by the Chinese to the specimens have been detailed, in many instances, in the "Contributions to the Materia Medica of China," by F. Porter Smith, M.B., and in the "Notes on Chinese Materia Medica," to which we have already referred, by the late Daniel Hanbury. It is needless for us to allude particularly to these properties, because it is evident that they are, for the most part, entirely fanciful. It is also remarked by the botanical investigators of the specimens that the members of the natural orders growing in temperate climates, and which possess active properties, are almost absent in the collection. There are no *Cruciferæ* or *Solanaceæ*, and scarcely any *Compositæ* or *Umbelliferæ;* there are no *Scrofulariaceæ* or *Euphorbiaceæ*, and there is only one imperfect specimen of rhubarb.

The most important part of the collection, both in a scientific and commercial point of view, is the opium. Mr. Davenport, in his report, repeatedly alludes to the enormous extent to which the poppy is cultivated, and this plant is said to be

probably indigenous in Yünnan. Unlimited quantities of the drug might be obtained if a demand existed.

The specimens of opium are of two kinds—namely, hard and soft—and it is supposed by Mr. Stewart that the soft samples are probably watery extracts, prepared from the hard specimens, with a special view to increase the percentage of morphia in the drug. It is found, in fact, that the soft specimens yield an amount of morphia nearly equal to three times as much as the dry ones. The latter, in their crude state, have neither the odour nor the general characteristics of Turkey opium, but have some of the qualities of Persian, Egyptian, and East Indian opium. The results of the analyses made by Mr. Stewart show that the hard specimens are inferior to Turkey opium in the yield of morphia, which is the standard of the commercial value of opium, the highest result obtained being 8·05 per cent., whereas from 10 to 14 per cent. is obtained from fine Turkey opium. The soft specimens, as we have just mentioned, contain much more morphia, but for general pharmaceutical purposes in England all the samples would be of little use, because in the British Pharmacopœia uniformity of quality is required in all officinal preparations of opium rather than high percentage of morphia. Mr. Stewart observes, with regard to the commercial aspect of the question, that, looking at the high percentage of morphia in the soft samples, and the low price, it is probable that these specimens might enter into successful competition, even in England, with Turkey or any other opium for the manufacture of morphia. The analytical results obtained from the samples of opium are appended to the report presented to the Secretary of State for Foreign Affairs, and they show the relative proportions of morphia, narcotine, extractive soluble in water, and water, contained in each; and, as we have observed, these proportions differ very widely.

A SUCCESSFUL CASE OF EXTIRPATION OF A KIDNEY.

We are pretty well accustomed in these times to new triumphs of surgical dexterity, and there is hardly any organ of the body a "successful removal" of which would greatly surprise us; yet the following case of extirpation of a kidney, reported by the operator, Dr. C. Langenbuch, Director of the Lazarus Hospital at Berlin (*Berliner Klinische Wochenschrift*, No. 24, 1877), deserves a brief narration:—The patient, Mrs. B., aged thirty-two, applied for relief at the hospital on November 10, 1875, on account of a painful tumour in the left side. She stated that for the last eighteen months she had suffered from dull pain in the region of the left kidney, which had rapidly increased in the last three months, and become so intolerable that she earnestly begged that something might be done for her. Within the last three months she had also first discovered the existence of a tumour. It should be noticed that her appearance was that of a strongly built and healthy woman.

On examination of the left renal region, inspection revealed nothing abnormal; but palpation at once detected a somewhat superficial tumour, apparently in front of the left kidney, but partly embedded in the lumbar muscles. It was a hard, tolerably smooth, globular body of about six to eight centimetres in diameter, tender on pressure, and which could be seized by the fingers pressed deeply down, as well as traced inwards for some distance, and moved to a certain extent from side to side. The patient stated that this tumour was the source of all her pain.

The diagnosis made was that of a new growth, probably a sarcoma, fibroma, or myo-sarcoma, springing from the connective tissue between and around the left lumbar muscles, or else from the muscles themselves. In spite of the pain, cancer could almost certainly be excluded by the appearance of the patient, whose hearty appetite and general state of health and vigour were strongly opposed to the idea of malignant disease. The condition of the urine seems to have to some extent diverted attention from the possibility of the tumour being of renal origin. The urine had its normal colour and specific gravity, and was completely free from blood, albumen, or any abnormal constituent or deposit. It was determined to extirpate the tumour, and the operation was performed on December 7. A careful examination of the tumour under chloroform immediately beforehand seems to have led Dr. Langenbuch to somewhat modify his opinion of its nature, and to think that after all there might be some connexion between the supposed growth and the kidney. The incision in the skin was made parallel to and about six centimetres from the spinal column, from the angle of the twelfth rib to the crest of the ilium. After dividing the subcutaneous cellular tissue and the superficial muscular fibres, the exterior of the tumour could be reached with the finger, but it was difficult to isolate it from the tissue of the surrounding muscles (sacrolumbalis and quadratus lumborum), with which it was connected by a tough cicatricial tissue, enclosing here and there a nodule of fat. After cutting completely through the quadratus lumborum, from which point onwards the finger alone was used to isolate the "growth," the termination of the latter in a "hilus-like cord" was finally reached. The latter was then ligatured and divided, though with some difficulty, owing to the great depth of the wound, and the tumour removed. The cord to which the ligature was applied, under the first impression that it was a large bloodvessel, turned out on closer examination to be the ureter, a thick-walled tube with a lumen about equal to that of the carotid artery. A moderate-sized bougie could be passed down it into the abdominal cavity for a distance of fifteen centimetres. The operation was conducted throughout with all the precautions of Lister's method, and the patient made an excellent recovery, which was only retarded by the rupture of the skin sutures, owing to incautious exertion on the part of the patient. She left the hospital, completely cured, in the beginning of January, 1876.

Unfortunately, she left Berlin shortly after without giving her address, and she has been lost sight of from that time. The condition of the kidney (for such it was) which was removed was as follows:—The whole organ (8 centimetres long, 5 centimetres broad, and 2·5 centimetres thick) was converted into a cavity whose walls consisted of a tough cicatricial tissue, the exterior of which still exhibited scattered remains of the fat in which the organ is normally embedded. The interior was lined with reddish floating shreds, the remains of the pyramidal substance. No microscopical examination of the kidney was possible, as, owing to the carelessness of a servant, the fate of many other pathological curiosities befel it, and it was thrown away. Dr. Orth, however, from a previous naked-eye examination, was able to state that the cyst-wall mainly consisted of fattily degenerated tissue with a fibrous layer externally, but that he could form no opinion of what the previous state of affairs had been. For Dr. Langenbuch's speculations as to the possible course of events in this case we must refer those interested to the original paper.

THE WEEK.

TOPICS OF THE DAY.

The movement for providing trained nurses for the sick poor of the metropolis is gradually developing; last week a meeting of gentlemen and ladies interested in the establishment of a District Nursing Home for the benefit of the poor in Lambeth and its neighbourhood, in connexion with the Metropolitan and National Nursing Association, was held, by permission of

the Archbishop of Canterbury, in the library of Lambeth Palace. The chair was taken by Mr. Robert Wigram in the first place, and afterwards by his Grace. Captain Fortescue, secretary to the parent society, explained its aims and operations, dwelling upon the great importance of having the sick poor tended by skilled nurses. The Association, he said, looked forward to the establishment, in the first instance, of one District Nursing Home for Central, East, and South London respectively. The Central Home had been fixed in Bloomsbury-square a year or two ago, and it was estimated that to maintain a home for Lambeth would require about £700 a year. Formal resolutions were moved for the appointment of a local committee to aid in raising funds for the support of the proposed home, and to interest persons in the neighbourhood in the work of the Association.

A committee convened by the Mayor, but in his absence presided over by the Rev. H. B. Boulby, was held at Birmingham last week, to consider the propriety of establishing a system of Provident Medical Dispensaries suited to the requirements of the town. The chairman, in opening the proceedings, pointed to the increasing abuse of medical charities, as shown by recently published statistics, in which the number of recipients of medical relief appeared to have risen within the last ten years from one in five to one in three. Many persons, he believed, who had recourse to the medical charities because of the excellence of the advice and treatment received there, were both able and willing to pay a small sum for that service if the opportunity of doing so were offered them through the establishment of popular dispensaries. Mr. R. W. Dale moved a resolution affirming the advantages of provident dispensaries for the industrial population, and this was unanimously carried.

Another case of poisoning by carbolic acid was heard before Dr. Hardwicke last week, at an inquest held at the St. Pancras Coroner's Court. The deceased, an old man, named Page, aged seventy-seven, an inmate of the infirm ward at the St. Pancras Workhouse, asked one of the helpers, named Kate Conolly, to give him some house medicine, upon which she went to a cupboard and took therefrom a bottle, and poured out a glassful, which Page took and drank off at a draught. He immediately found that there had been a mistake, and that instead of medicine, carbolic acid had been given him. Although everything was done for the deceased, he expired in five minutes. It was shown that it was against the rules of the house for anyone except the paid nurses to administer medicines. It was also stated that in this instance the bottles were of a similar kind. The jury returned a verdict of "Death from misadventure." They might have added a recommendation that carbolic acid should not be kept in the same cupboard with medicines for internal administration.

Some little time ago we commented on the decision of a judge who directed the acquittal of a prisoner who had administered cantharides to a young girl, on the ground that sufficient had not been given to cause actual harm. In a case recently tried at the Manchester Assizes, Martha Barker, a domestic servant, was charged with administering poison to her mistress, Mrs. French, at Manchester, with intent to murder her. Mrs. French being ill, the prisoner was sent to a surgeon's for some medicine; she returned with a bottle of liquid, which she said the doctor told her she must make her mistress take, although it would probably make her feel worse. Mrs. French took two doses, from the effects of which she became very ill, and it was afterwards found that there was red precipitate in the medicine. The medical man in question, who was called as a witness, denied that he kept this poison in his surgery; but as it was proved that there was not sufficient poison in the bottle of medicine to make it fatal to life, in accordance with Taylor's work on "Medical Jurisprudence" (which the judge consulted on the point), the jury acquitted the prisoner. There would appear to be something defective in the law as it now stands, if a charge of administering poison with a criminal intent is to break down because the would-be murderer just stopped short of the quantity necessary to produce death.

It is reported that information has been received at Devonport of an outbreak of Asiatic cholera which has occurred on board the *Arab* gun-vessel, Commander Broughton. One case of an artificer named Rose proved fatal five hours after the attack. The *Arab* is on the East India Station, and was commissioned at Devonport in July, 1875. Through deaths and invaliding only thirteen hands remain on board at the present time, out of the original complement of seventy-five men.

The humbler classes in the metropolis are undoubtedly acquainted with many "delicacies" in the way of food which are unknown to the more wealthy, but these are not always unaccompanied by drawbacks. Last week the Coroner for Central Middlesex held an inquiry at Haverstock-hill, touching the death of Lizzie Wilkinson, aged five years, who, it was alleged, had been killed by eating indigestible food, including an article known by the name of a "faggot." It appeared that deceased, who had always been a healthy child, was taken very ill soon after midnight on the Saturday, when she vomited; she lay down in bed with two other children, and seemed to be better, but at seven on the following morning she was found dead. Deceased had partaken of "faggots" the previous evening for supper, and she had also eaten some stale cherries. Dr. Rees, who was called in after death, and who had made a post-mortem examination, said he found the stomach greatly distended and inflamed, and it contained a portion of indigestible matter. He also found part of a rusty pin in the stomach. The cause of death was exhaustion from gastric irritation from taking indigestible food, accelerated by the unwholesome food taken for supper. The Coroner remarked that he thought faggots were not proper food for children. The vendor of the faggots of which deceased partook, who was on the jury, protested against the statement of the Coroner, and said he sold at least 100 of them each evening. They were made of the sinews of meat, bullocks' livers boiled down and chopped, with "pig's fry," seasoned with pepper, allspice, sage, and onions. After further discussion the jury agreed to a verdict in accordance with the medical evidence.

At the meeting of the London School Board held last week, the proposition brought forward by the Rev. John Rodgers—"That the playgrounds of the schools be opened to children from 5.30 p.m. on Mondays, Tuesdays, Wednesdays, Thursdays, and Fridays, and from 2 p.m. on Saturdays, up to the usual hour of closing"—was again submitted, and finally carried. Considerable discussion was evoked by an amendment to the foregoing proposition, which had for its object the opening of the playgrounds on Sunday afternoons. In the end, however, the opponents to this suggestion were too strong for those who think it better for children to play in a safe enclosure rather than in the gutters, and the amendment was lost, ten voting for it, and twenty-eight against. The opening of these playgrounds on week-days will at any rate be a great boon to the children of the working classes. Only last week the father of a child who was run over and killed in Theobald's-row complained at the inquest that the children of the poor had no place in which to play but the streets, and upon this occasion the Coroner suggested that the playgrounds of the schools might be thrown open, to obviate the dangers run by children playing in the London streets.

On Monday last the Bishop of London distributed the prizes to the successful students at St. Thomas's Hospital. During the proceedings it was stated that many of the students had

been to the East, and some had received Turkish and Servian orders for their services on the battle-fields. The Bishop congratulated the successful students, and dwelt feelingly upon the importance of the medical profession to mankind.

According to the monthly return of the Registrar-General for Scotland, it appears that in June last there were registered in the eight principal towns of Scotland 2178 deaths. Allowance being made for increase of population, this number is 426 under the average for the corresponding month during the last ten years. The zymotic class of diseases proved fatal to 338 persons, thus constituting 15·5 per cent. of the whole mortality; this rate was slightly exceeded in Glasgow and Perth. From violent causes 79 deaths resulted, of which 4 were suicides; 6 deaths were caused by delirium tremens, and 7 by the direct effects of intemperance. Two males and three females had passed the ninetieth year of life, the eldest of whom was a landed proprietor, aged ninety-eight years.

In order to extend and improve the elementary teaching of physiology and the laws of health in elementary schools, the National Health Society of Berners-street has placed at the disposal of the London School Board, in addition to a sum of £100 previously offered, a further sum of £25 annually, for four years, for premiums to teachers and children who pass the best examinations in these subjects.

A Convalescent Home has been erected at a considerable expenditure by Mr. W. H. Ripley, M.P., in a prominent position overlooking the valley of the Aire, at Rawdon, near Leeds; and the Marquis of Salisbury has undertaken to perform the opening ceremony in October next.

The fatal cases of small-pox in the twenty English cities and towns now included in the Registrar-General's weekly returns, which in the nine preceding weeks had steadily declined from 92 to 29, were 37 in the week ending July 14, and of these 32 occurred in London, and 5 in Wolverhampton. Of the 32 in London, 17 occurred in private dwellings, of which latter 2 happened in Shouldham-street, Marylebone, 2 in Poplar, and 3 in Camberwell.

PROFESSOR HUMPHRY AND THE VICE-PRESIDENCY OF THE COLLEGE OF SURGEONS.

At the meeting of the Council of the College of Surgeons on Thursday week, Professor Humphry, who stood next in order of seniority to the Vice-Presidents, stated that though there were many reasons to induce him to come forward for the Vice-Presidency, and in due time for the Presidency, such as the desire not to appear to shrink, without sufficient reason, from any duty which as a member of the Council he owed to the College; the consciousness that it would be agreeable to the Fellows and Members of the College resident in the provinces that one of their number should hold the highest offices in the College; the desire to promote a closer union between his University, as a representative of literature and general science, and the profession, and the feeling that it would be gratifying to the members of the University that one of its body should hold the offices of Vice-President and President of the College of Surgeons; and also the ambition, the honourable ambition, felt by all members of the Council and Fellows of the College, to occupy positions which place those who fill them at the head of the profession of surgery, and which give them the opportunity to do good work for the College and the profession;—still, before and above all these considerations he was bound to place the interests of the College, and to reflect whether he could fulfil in a satisfactory manner the duties of the office of Vice-President, and more particularly of President, without neglecting the duties which devolved upon him as Professor of Anatomy at Cambridge. This, he was forced to conclude, it would not be in his power to do. The duties of the Presidency are extremely onerous, requiring an almost daily attendance at the College for the transaction of business, an attendance at numerous committees, and an intimate acquaintance with the affairs and administration of the College which it was scarcely possible for him to possess. These duties had doubtless been increased by the zeal and assiduity in promoting the interests of the College which had been displayed by those who had recently held the office of President; but he should regret that an era of diminished zeal and lessened effort in such a cause should be inaugurated by himself. His labours at Cambridge as Professor of Anatomy and Surgeon to the Hospital were very considerable, and necessarily increased by the increasing number of students of medicine at the University, and were quite incompatible with that frequent attendance at the College which would be requisite for the efficient performance of the duties of the Presidency. He therefore felt sure that the Council and the Fellows of the College would agree that he was acting in the manner most conducive to the interests of the College in allowing the office of Vice-President to pass on to one who would be able to discharge its functions far better than it was possible for him to do.

DISTRIBUTION OF PRIZES AT THE LONDON HOSPITAL.

The Right Hon. W. E. Forster, M.P., presided at the annual distribution of prizes on Wednesday last, the 18th inst. After the more formal part of the proceedings had been gone through, the right honourable gentleman addressed the students and a numerous assemblage of their friends. In the course of his remarks he touched upon one or two subjects of great interest to the profession. He said that his duties in the House of Commons had taught him the absolute necessity of having well-educated medical men, especially at the present time. There was now going on in the House a perpetual war with disease, with a view to remedy as far as possible the mechanical ills which result from the existing circumstances of our present social system, and in the hope of making these conditions more favourable to life and health and happiness. In connexion with the Department of Health, with which he (Mr. Forster) while in office had had to deal, he referred to the services of Mr. Simon, "than whom a more able and more devoted public servant never existed." After thus paying a well-merited tribute to Mr. Simon, Mr. Forster went on to speak of the Vivisection Commission (of which he was a member) and its recommendations. He said he believed the Bill was necessary and useful; yet he had much sympathy with physiologists. He thought there was some ground for believing that vivisection cruelties had been practised on the Continent, but he firmly believed that there had been gross exaggeration as to what was done in England; he said the Commissioners had discovered that the reports of reckless cruelties in this country were absolutely unfounded. Mr. Forster believed "that vivisection may be of service, and that, under proper restrictions, it must be carried on. Restrictions were, however, necessary, as there was danger of becoming callous and indifferent, as the mere result of constantly experimenting. Hence he favoured the Bill, which allowed experiments, either with or without anæsthetics, provided there was some reason to anticipate fresh discoveries, but which forbids vivisection experiment as a mere demonstration to students." Mr. Hutchinson, in proposing a vote of thanks, which was carried by acclamation, said that he was pleased that the Council of the College had asked an "outsider" to preside on the occasion. Isolation was as bad for a profession as for individuals; and he knew of nothing which so tended to improve one as mixing with the world; and nothing assuredly would so help them, as a profession, as hearing what the outside world had to say of their doings. He was glad that Mr. Forster had been chosen, and he was greatly pleased to have heard from him the motives which had influenced

the Vivisection Commission in the drawing up of their recommendations. It was obvious that they had great sympathy with physiologists, and had worked in their interests. The proceedings then terminated.

TESTIMONIAL TO SEÑOR MANUEL GARCIA.

On Saturday, the 14th inst., at a meeting held at 21, Harley-street, a numerously signed address and a handsome service of plate were presented to Señor Manuel Garcia, in recognition of the services rendered by him to science and humanity by his discovery of the laryngoscope. In the unavoidable absence of Lord Coleridge, the presentation was made by Professor Huxley. He said that it was unnecessary for him to do more than remind the physician that in the laryngoscope he had gained a new ally against disease, and a very remarkable and valuable addition to that series of instruments, all of which, from the stethoscope downwards, had come into use within the memory of living men, and had effected a revolution in the practice of medicine. This instrument they owed to Señor Garcia, who had invented it a quarter of a century ago. Sweden and Germany had long since acknowledged their indebtedness to him on this account, and a feeling had arisen that Englishmen should not be behindhand in recognising the merit of one who had lived so long among them. Numerous representatives of the aristocracy and the commonalty, of the bench and the bar, of arts and of physic, and of the cultivators of the mathematical, physical, and physiological sciences, had therefore united in presenting him with this testimonial. Señor Garcia, in his very modest reply, said: "The idea of examining the interior of the larynx with a mirror during the act of singing had often presented itself to me, but was always rejected, as I believed it to be impracticable. It was not until September, 1854, that it occurred to me that the best way to resolve my doubts was to submit them to the test of experiment. I purchased a dentist's mirror, which, having heated it, I placed against the uvula; then, flashing upon it with a hand mirror a ray of light from the sun, I saw, to my intense delight, the larynx exposed. There my parts ends. If the laryngoscope has become a useful instrument, it is all owing to the skill of the men into whose hands it has fallen. The approbation of my simple idea by so many leaders of the scientific world is to me an honour as unmerited as it is unexpected."

THE HEALTH OF BRIGHTON.

Dr. R. P. B. Taaffe, Medical Officer of Health for the Borough of Brighton, has, in his annual report on the health of that locality for the year 1876, established the reputation for health which this well-known watering-place has so long enjoyed. From the tables which he has carefully prepared, it will be seen that Brighton takes the first place among the twenty large English towns, with a death-rate of 19·6 only, that of London for the year 1876 being returned as 22·3. In the first and second quarters of the year under notice, measles was prevalent in the town, and, in the last two quarters, scarlatina. This latter outbreak, however, which was much exaggerated, was not of a severe character, and soon died out. Dr. Taaffe, nevertheless, strongly impresses upon the authorities the advisability of being prepared with a hospital for infectious diseases, so that future epidemics may be instantly and efficiently dealt with. The County Hospital, he points out, cannot provide for the wants of an ordinary epidemic, so that he is dependent upon the kindness of the Board of Guardians for accommodation in times of zymotic visitations; and he remarks that the Sanitary Authority ought to be in a position to deal with epidemics more directly, by having a hospital and the necessary accessories at its own special command. As in former reports, Dr. Taaffe suggests that some steps should be taken to place prominently before the Legislature that persons barely convalescent from contagious complaints ought not to be allowed to travel from home and propagate them to communities at a distance. Brighton suffers heavily in this way, from the transmission into it of the zymotic class of diseases. Taking this fact into consideration, it speaks well for the sanitary condition of the town that it is enabled to present such a satisfactory report as the one under notice.

HARVEY TERCENTENARY MEMORIAL FUND.

A meeting of the London subscribers to this Fund was, by permission of the President of the Royal College of Physicians, held at the College on Wednesday last. In the absence of the chairman of the committee, the Earl of Derby, who sent a letter stating that he was unable to be present, Dr. Owen Rees occupied the chair. There were also present Sir Thomas Watson, Bart., Sir George Burrows, Bart., Dr. Sieveking, Dr. Barnes, Mr. Hilton, Dr. Hare, Dr. Glover, Mr. Ernest Hart, and others, with the Hon. Sec., Mr. G. Eastes. A report of the progress of the Fund was read, from which it appeared that, after the payment of all expenses hitherto incurred, a nett sum slightly exceeding £800 remains for the purposes of the Fund. As this amount is not sufficient, further funds are urgently required, in order that the statue may be completed by next year, which is the tercentenary anniversary of Harvey's birth. Dr. Glover and Dr. Hare were appointed auditors of the accounts. Sir George Burrows, Bart., M.D., and Prescott Hewett, Esq., were elected honorary treasurers; Sir G. Burrows, Sir W. Gull, Sir J. Paget, Sir F. Hicks, Sir S. Waterlow, Mr. S. Lushington, Dr. Quain, Dr. O. Rees, Mr. John Simon, and Mr. Prescott Hewett were nominated as an executive committee for London; and were requested to take immediate steps for securing further subscriptions, and to report progress to another general meeting of subscribers before the end of the present year. A resolution was passed, requesting the Earl of Radnor to grant a site of land at Folkestone on which the statue when completed might be placed. Votes of thanks to the President of the College of Physicians, to the Chairman for presiding, and to the Honorary Secretary, closed the proceedings.

ROYAL COLLEGE OF SURGEONS.

From the annual report on the finances of this institution, which has just been published, it appears that the receipts amounted to £16,266 11s. 8d., and the expenditure to £15,681 2s. 1d., showing a balance at the bankers of £585 9s. 7d. The largest amount in the receipts was in fees paid on admission to fellowship, membership, and for dental diplomas, viz., £12,372 10s. (the Midwifery Board having ceased to exist, there were no receipts for the licence in midwifery). The next largest sum appears to be derived from rents of chambers adjoining the College, and dividends on stock, viz., £2499 4s. 10d. The item of elections to the fellowship, which formerly produced a good income, is now reduced to only forty guineas. In the expenditure the largest item is in fees to Council, courts, and boards of examiners, viz., £6124 9s. Salaries and wages amounted to £3988 13s. 8d. For Government stamps, taxes, and rates, the large sum of £1250 2s. 10d. was required, not including postage-stamps. The Oration and Hunterian Festival this year amounted to £230 4s. 6d. It will be remembered that H.R.H. the Prince of Wales honoured both with his company. Pensions amounted to £287 19s. 6d.

ILLNESS OF PRINCE ALBERT VICTOR.

Prince Albert Victor, eldest son of H.R.H. the Prince of Wales, is suffering under an attack of continued fever. The symptoms date from Saturday, the 7th inst., hence it must be some days before there can be any important change for the better. The course of the disease has hitherto been very favourable.

A SUCCESSFUL ACTION FOR THE RECOVERY OF FEES.

An action was tried last week before the Lord Chief Justice and a special jury, brought by Mr. Wood, the senior Surgeon of King's College Hospital, to recover from a Mr. Mathias the balance of an account for medical attendance on the defendant's wife. The evidence showed that in the spring of 1870 the defendant's wife was sent up to London to be attended by the plaintiff for a serious illness; that she, having taken lodgings in the neighbourhood, underwent two operations, which ultimately proved successful; that the defendant, having paid the plaintiff £50 for the first operation, refused, except as to £20 which he now paid into Court, to pay the balance (which consisted of £20) for the second operation, and seventy-five guineas for seventy-five visits consequent upon it. The defendant's counsel admitted that he had no evidence to call to prove that the charges were improper; the defendant could only prove that he had no notion at the time that these would be the plaintiff's charges. His Lordship observed that that would be no answer; the defendant ought to have inquired. At his own request the defendant was sworn, and stated that the plaintiff had deceived him; he had been introduced to him by his brother, and he ought to have informed him that his charges were so high. His Lordship directed the jury that this was no defence, and the jury accordingly at once found a verdict for the plaintiff.

DEVONSHIRE HOSPITAL AND BUXTON BATH CHARITY.

Two important announcements were made at the meeting of the Committee of Management of the Devonshire Hospital and Buxton Bath Charity, held at the Hospital on the 7th inst. After adverting to the present position of the Hospital, the chairman stated that it was intended to organise a nursing department; a lady superintendent has been engaged, and, under her advice and supervision, trained and probationer nurses have been secured, and every expectation is held out that this part of the work of the establishment will be as satisfactory as can be desired. Further, the extension of the Hospital to the whole of the buildings and premises connected with it has now been secured. Under the easy requirement of providing similar stable accommodation, etc., elsewhere, the Duke of Devonshire has kindly conceded the whole of these buildings and grounds to the uses of the Hospital for ever, under certain restrictions. This extension will almost double the capacity of the Hospital; and the governors of the Cotton Districts Famine Fund have engaged to defray the whole expenses to be incurred (amounting to £10,650), subject to a prior claim on 100 additional beds to be created.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

The annual meeting of the Society of Medical Officers of Health was held July 11, when the following officers were elected for the year ensuing:—*President:* Dr. Thos. Stevenson, F.R.C.P. Lond. *Vice-Presidents:* Dr. G. Buchanan (late President), Dr. T. O. Dudfield, Dr. C. Meymott Tidy, Mr. E. L. Jacob. *Treasurer:* Mr. J. Liddle. *Hon. Secretaries:* Dr. J. Northcote Vinen, Dr. W. H. Corfield. *Council:* Dr. Bristowe, Mr. H. Leach, Mr. Lovett, Dr. Rygate, Dr. Tripe, Dr. Whitmore, Dr. Adams, Dr. Bond, Dr. Baylis, Dr. Philpot, Mr. Thomas, Dr. G. Wilson.

BRADFORD MEDICO-CHIRURGICAL SOCIETY.

This Society has just terminated a very successful session, and held its fifteenth annual meeting. The membership now includes a large majority of Bradford practitioners, and many of those from the populous districts surrounding the town. During the past session the Committee concluded an arrangement with the Board of the Bradford Infirmary, by which the Society finds a permanent home within the walls of that institution, obtains the use of a large and increasingly useful medical library, and secures facilities for the prosecution of pathology, and the formation of a museum. The Society has to deplore the loss of its President for the year, J. D. Lawrie, M.R.C.S., who died suddenly on January 1, 1877. The officers elected for the ensuing year are as follows:—*President:* R. H. Meade. *Treasurer:* W. Whalley. *Secretary:* D. Goyder, M.D. *Curators:* A. Rabagliati, M.D., and T. C. Denby. *Auditors:* J. Foster and J. H. Bell, M.D. *Committee:* W. Burnie, M.D., P. E. Miall, J. Arthur, and E. T. Tibbits, M.D.

PRESENTATION TO DR. WOLFE.

At a recent meeting in connexion with the Ophthalmic Institution, Glasgow, an address was presented to Dr. Wolfe on behalf of certain of the students of the University, thanking him for the trouble and pains he had taken in instructing them in ophthalmic medicine. Such a testimonial must be highly gratifying to Dr. Wolfe, and speaks well for the students themselves.

MEDICAL PARLIAMENTARY AFFAIRS.

London Water-Supply.—The report of Dr. Frankland concerning the Southwark and Vauxhall water-supply was alluded to by Colonel North, especially that part which stated that it was "full of moving organisms, and contained an excessive portion of organic impurity." Mr. Sclater-Booth explained that this water had been for some time in an unsatisfactory state, and the water examiner had been directed by the Local Government Board to communicate with the offending company. He had also directed a statutory inquiry to be made by Major Bolton under the 35th section of the Metropolis Water Act. He referred to the recent large expenditure of the company with a view to improve the quality of the water.

Small-pox in the Metropolis.—Authoritative contradiction to various floating rumours respecting the continued spread of small-pox was given by Mr. Sclater-Booth when he stated that there are now 483 vacant beds at the Asylums Hospitals; at the present time 621 patients are under treatment, as against 850 and 950 for May and June last. The experience already gained had been very salutary in keeping in check the existing epidemic.

Medical Department in India.—No conclusion has yet been come to, said Lord G. Hamilton, respecting the administration of the Army Medical Service in India. He could not state whether this department was to be in the hands of the Indian Government only, or what alterations were likely to be made.

Cattle Plague.—Allusion was made to the reappearance of cattle plague at Bethnal-green in a shed containing ten cows. Lord Sandon remarked that the whole stock were slaughtered after being condemned by the Privy Council inspector. Fortunately the orders of the Privy Council for effectually dealing with the disease in the metropolis were still in force. The order for restricting the removal of live cattle in the metropolis north of the Thames has been renewed. The Irish Privy Council have resolved not to relax the restrictions in the importation of live cattle into Ireland for the present.

St. John's House, Norfolk-street.—The annual meeting of this institution was held on Monday last, under the presidency of the Bishop of London. The report stated that there were now 138 nurses and probationers, and a large staff of nurses were satisfactorily employed at King's College and Charing-cross Hospitals. During the past eight years nearly 300 probationers had entered St. John's House for the usual three years' training. Of these many were now nurses of the House, while others had settled in England, or in different quarters of the globe, as nurses. During the same period 200 lady pupils had been trained, some of whom were now superintendents or matrons, and others have become sisters of St. John's House. More than 600 cases of illness had been nursed during the past year—many were fever, and some small-pox. A new branch of work had been commenced on a small scale in Ashburnham-road, Chelsea, in the form of a new Maternity Home and Training Sschool, the principal object of which was to provide means for the training of monthly nurses. The receipts and expenditure showed that £9972 had been received, of which £6761 was for nurses' services, and the total expenditure was £9465.

ANTI-VIVISECTION.

Mr. Charles Hawkins, a late member of the Council of the Royal College of Surgeons, in which he continues to take the greatest interest, has just presented to the Library the manuscript lectures of the late Sir Benjamin Brodie, which are of additional value as being in his own well-known and peculiar handwriting. The following lecture, which we are permitted to publish, will no doubt be considered very interesting at the present moment:—

"In the present, as in the other lectures, I have had frequent occasion to introduce the history of experiments on living animals, made with a view to promote our knowledge of the animal economy. But it is perhaps scarcely right that any one should refer to investigations of this description without offering some explanation or apology for what, in the eyes of many, may appear to be an abuse of the power which we are allowed to exercise over the other parts of the animal creation; and certainly it would but ill become the Professor of this College, addressing an audience in this theatre, to treat with indifference the question whether it be or be not allowable or proper to endeavour to enlarge the boundaries of our own knowledge by giving pain to other beings, and by sacrificing the lives of inferior creatures. Far be it from my intention to contribute anything towards suppressing the kinder feelings which nature has implanted in the human breast, and which ought to be especially cultivated and fostered by those whose profession leads them to be so conversant with human misery, and on whose active, zealous, and benevolent exertions depends so much of the happiness of their fellow-men. We must, however, on this, as on every other occasion, assume that we are justified in employing the animals which are below us, not only for the purposes of our instruction, but also for that of ameliorating the general condition of the human race. Without this assumption, indeed, man such as he now is, living in society and improving his intellectual and moral faculties, could scarcely exist. He is but ill calculated, especially in these northern climates, to live on a purely vegetable diet; and how could he support the storms of the autumnal season, or the low temperature and piercing winds of the winter months, if he were not to borrow from other animals their skins and furs and fleeces? and how cheerless and unprofitable would be his nights if he were not provided with that artificial light which makes them emulate the day, derived from the blubber of the whale, the tallow of the ox, or the wax of the bee! Besides, if we were not to obey that instinct which tells us that we are to exercise a dominion over all other beings endowed with life, we should soon discover that those other beings would exercise over us a dominion of a still more severe and arbitrary kind; and unarmed, feeble, and defenceless man would speedily vanish from the surface of the earth, or exist only in a few remote places whither his enemies have not yet been able to pursue him. If physiological experiments were intended merely to gratify an idle curiosity respecting that which it is of no import for us to know; if each experiment ended with itself leading to nothing of further interest, then must we esteem them as cruel and unjust, and the experimentalist must be placed on a level with him who trains his gamecocks to destroy each other, or his dogs to bait and torment the bull. But if such experiments enable us to obtain a more complete and accurate knowledge of the phenomena and laws of organic life; to take more enlarged and comprehensive views of the world which we inhabit, and of the general scheme of this vast creation; if they enable us better to understand the nature of disease, and to trace to their proper source the trains of morbid action on which our bodily infirmities depend, and thus to learn a better application of the remedies which may be resorted to for their relief—who then can doubt that we are as much justified in prosecuting our inquiries in this manner, as in slaughtering the sheep that we may eat his flesh, or enslaving the horse that we may avail ourselves of his bodily labour. Nor is this an exaggerated statement of the good which may be derived from physiological researches. How many lives have been preserved, which would otherwise have been lost from secondary hæmorrhage, in consequence of the modern observations on the ligature of bloodvessels! But I am not called upon to point out the particular advantage that may have been derived from each particular experiment. Those, indeed, have narrow views of science who are incapable of perceiving that, while each individual discovery contributes its own share to the general improvement, it is not from these considered separately, but from the increase of the whole mass of knowledge, that we are to deduce those principles which admit of a practical application for the benefit of the human race. The better pathology, the more accurate diagnosis of disease; the simpler, but more efficacious, remedies of modern surgery, all bear unequivocal testimony to the great importance of physiological science. And what would physiological science have now been, had it rested only on anatomical facts and speculative notions, unaided by physiological experiments? The arguments which may be urged against the inconsiderate making needless repetition of experiments, and a wanton sacrifice of animal life, do not apply to researches of this kind when conducted with proper circumspection, forethought, and attention to humanity; and if objections be made at all against researches such as these, let them come from the mild and peaceable Gentoo, or from the tender-hearted girl who steps aside that she may not injure the insect at her feet; not from those who rise in the morning elated with the expectation of hunting the timid and inoffensive hare or stag, or who catch the fox in a snare, and preserve him for a convenient opportunity when they may turn him out before their dogs to be pursued over the open country, that his terrors and bodily sufferings may be made the source of a barbarous amusement."

FROM ABROAD.

On Pilocarpinum Muriaticum.

Dr. Curschmann, Director of the Berlin City Tent Hospital, read a paper upon this substance at the Berlin Medical Society, which is published in the *Wochenschrift* for June 18.

Notwithstanding the enthusiasm with which jaborandi was received in the different clinics, a year and a half since, he observes, few practitioners now employ it, or only to a very limited extent. The chief causes of this are the inconstancy of its effects, and the vomiting, headache, and giddiness which often accompany its use. It was hoped that if its active principle could be separated, the results of its employment might prove more satisfactory. This has now been satisfactorily done by Merk, of Darmstadt, who designates it *pilocarpinum muriaticum*, after *pilocarpus pinnatus*, the name given by Baillou to the most important of the jaborandi group of plants. Weber and Bardenhewer having reported favourably of the employment which they have made of this new alkaloid, Dr. Curschmann instituted some trials, with results which corresponded with theirs. He has made ninety such trials on fifty-five adults, part of whom were ill, and part convalescent or in health. He employed a 2 per cent. solution, injecting from one to one and a half gramme, and therefore 0·02 to 0·03 of the pilocarpin.

The general effects which ensue correspond pretty exactly with those caused by the jaborandi; but they are produced more rapidly and more certainly, and are more durable. The first sign, observed in almost every case in the course of, or at the end of, the first minute, is turgescence and redness of the face, that soon spreads to the neck and chest—the carotids and temporals pulsating forcibly, and the latter appearing in many cases dilated and strongly prominent. Within from three to six minutes the increased secretions of saliva and sweat appear, the latter in almost all cases continuing longer than the former, sometimes for one or more hours longer. In all the ninety cases sweating was induced. The sweating begins on the face, and soon invades the chest and abdomen, whence it proceeds gradually, if sufficient pilocarpin has been injected, to the lower extremities. After a small dose, or when the patient is little sensitive to its action, the legs, or even the thighs, may remain quite dry, or only moderately damp. In several highly sensitive persons the highest point of its action was denoted by slight chills, and in two by decided shivering. In about half the cases there was more or less considerable increase of the lachrymal secretion, which, however, never was distressing. The contemporary discharge from the nose seemed dependent on this, for no independent secretion from the nose was observed, nor any from the remainder of the mucous membrane of the air-passages. In the great majority the pulse rose at the beginning of the action of the pilocarpin

five or six beats, and in a few cases twenty beats; but within the first half-hour it had usually resumed its normal condition. In a few instances its character remained unaltered, but in most there were dilatation and diminution of the tension of the arterial tube. No increase in the frequency of respiration was observed in either patients or healthy persons. A few cases in which the temperature was taken exhibited the same results as those obtained by Riegel and Bardenhewer—viz., that at the height of the influence of the drug the temperature sank half a degree.

Dr. Curschmann furnishes several details of the quantity of saliva discharged, which is shown to be dependent on the amount of the dose given. Some persons, however, are extremely sensitive to the action of the pilocarpin. Thus, a strong, healthy man who came into the hospital for some trifling external ailment, discharged in the course of two hours and a half 280 cubic centimetres of saliva after a single injection of 0·01 of pilocarpin. Sweating, which under jaborandi is not a constant occurrence, has always been produced abundantly by pilocarpin. In some very susceptible persons profuse sweating has been produced even by 0·01, and only one person remained exempt from it when the dose of 0·02 was employed, and he sweated abundantly on the dose being increased. The employment of 0·03 produced greater and more durable sweating than was required, and might be disadvantagous to feeble persons. The sweating under the full action of the remedy continues from one hour and a half to two hours, in many cases only an hour; and it is as profuse as from a vapour-bath, wetting through all the body- and bed-linen. In ten cases the persons were weighed, in order to ascertain the amount lost by sweating, all food and drink being in the meantime abstained from. After abstracting the weight of the urine and saliva discharged, that of the sweat was found to reach one or two kilogrammes, or even two and a quarter—showing that sweating is a most powerful factor in the action of pilocarpin, and not, as it has sometimes been considered with reference to jaborandi, an uncertain appendix to its sialagogue action. The pilocarpin does not seem to exert any direct influence on the secretion of urine, for although during the sweating and salivation its quantity is of course proportionately decreased, it is free from abnormal constituents. In thirty of the cases the condition of the pupil was carefully observed, and no decided influence was produced by the subcutaneous injections. But when a few drops of a 2 per cent. or stronger solution were brought in direct contact with the conjunctiva, decided contraction was induced in from five to ten minutes, which persisted for hours, and traces of which were even observable next day.

As to the accidental effects produced by pilocarpin, vomiting is the principal; but the frequency of its occurrence is much less than when jaborandi is employed; while by the observation of certain rules it is produced so seldom that it is of little consequence as compared with the advantages derived from the drug. This is brought about by careful dosing, and by desiring the patient to carefully avoid swallowing the increased saliva. In persons who have had vomiting after large doses, this may be often prevented by employing moderate yet effectual doses. From some comparative trials which he has made with the internal administration of pilocarpin, Dr. Curschmann believes that the infrequency with which it causes vomiting, as compared with jaborandi, is principally due to its being used hypodermically, and thereby avoiding direct irritation of the stomach. Some persons, especially those who have been weakened by prior disease, complain of a sense of debility, but this usually soon passes off; but in others a complete state of collapse is produced, which may or may not be connected with prior vomiting. The possibility of this occurrence must always be borne in mind. It is dependent upon the amount of the dose and the susceptibility of the individual. It is oftenest met with in women and in those whose strength has been greatly reduced; and when the patient's constitution is not known, the first dose of the medicine should not exceed 0·02, while its effect should be watched for a quarter or half an hour. As far as the trials have gone, pilocarpin does not seem to act dangerously on the subjects of heart disease, and, indeed, can be employed when no other diaphoretic procedure for so long a period would be ventured upon. Indeed, as a therapeutical agent for the production of diaphoresis, it is superior to any other method in use, being more easily employed, while its action is more certain and more complete, without being more or even so dangerous as most of these. Its superiority over the various sweating-baths in ascites, hydrothorax, asthma, etc., is most marked. It is true that diaphoretic treatment is thought less of than formerly; but in several cases the difficulty of its application, rather than its inefficacy, is the cause of its not being resorted to. Speaking from his own experience, Dr. Curschmann has found the pilocarpin very useful in œdema, in dropsy of the cavities from heart or lung disease, and in chronic nephritis, etc., and that after diuretic, drastic, and other means have failed. He believes that a large field for its employment may be found in pleurisy accompanied by serous exudation, both in promoting the absorption of this, and in preventing its re-accumulation after paracentesis. It is evidently indicated in chronic rheumatic affections, at least, so far as these are amenable to diaphoretic treatment.

Mortality Returns of the Paris Hospitals.

Dr. Ernest Besnier, in his report (*Union Méd.*, May 12 to 29) on the mortality for the first quarter of 1877, observes that so high a mean temperature—viz., 6·4° C. (42·10 F.)—has only been attained in this quarter on four occasions since 1819. The rainfall, too, was greatly above the mean, and the prevailing winds were W. and S. The general mortality of the civil hospitals (3438) has exceeded the mean of the quarter of the last six years by 390. A portion of this augmentation is accounted for by the great increase of population as contrasted with its diminution which followed the two sieges.

1. *Affections of the Respiratory Organs.*—In spite of the elevated temperature, these, as compared with the same quarter of the previous nine years, were very fatal, rising from the mean of 30·28 to 32·88. The deaths due to phthisis increased from 53·87 to 58·66, and to pneumonia from 35·73 to 41·72. It is to be observed that the hospital mortality from pneumonia is more than a third higher than the ordinary mortality from the disease, many of the subjects being the victims of alcoholism and various other diseased states disenabling them from resisting, while numerous aged persons are said to die of pneumonia which has only supervened on other chronic diseases. The fatality of bronchitis increased from 5·92 to 6·62, and of pleurisy from 11·91 to 15·96.

2. *Diphtheria.*—The usual melancholy account of this disease, and of the protests which have been addressed to the authorities respecting it, are repeated. In vain, Dr. Besnier observes, has he called attention during the last ten years to the increasing fatality of diphtheria, and its murderous propagation caused by the promiscuous introduction of cases into the ordinary wards. While during the first quarter of 1868 the number of cases was seventy-one, during that of 1877 there were 265 cases, with 220 deaths, or more than 83 per cent. The disease has been very fatal also among the town population, there having occurred 508 deaths, while the mean of the quarter of late years has furnished but 300 deaths. The entire mortality from diphtheria during the quarter, for the civil population, has reached the high figure of 728. It is observable that the higher parts of the town, which are generally spared by typhoid fever, were cruelly ravaged by diphtheria.

3. *Rheumatic Affections.*—Articular rheumatism occurs in pretty much the same proportion all the year round, but, although the number of cases is much the same in each quarter, the time of the year exerts an effect upon their gravity and upon the visceral complications that accompany them. Thus, Dr. Bucquoy, of the Cochin, and Dr. Lereboullet, of Val-de-Grâce, in the present quarter indicate the frequency of the occurrence, not only of cardiac complications, but also of pleurisy and pneumonia of a persistent character.

4. *Variola.*—The cases have amounted to 149, with twenty-two deaths, the number having been 141 in the last quarter of 1876. The excellent effects of isolation (recently established in the French hospitals) continue to be observed, the slightest infraction of the rule being followed by examples of manifest transmission. Dr. Lereboullet has communicated the successful results of 1290 revaccinations performed on 1290 soldiers at the Val-de-Grâce, but we have already (*Medical Times and Gazette*, June 16, page 657) brought these under the noticeo our readers.

5. *Typhoid Fever.*—Following its law of *évolution saisonnaire*, which has been frequently commented upon in these reports, and which is not departed from even during the most marked epidemic visitations, typhoid has undergone the normal diminution which always occurs in the spring, the deaths having fallen from 992 in the last quarter of 1866, by slow and

regular decrease, to 361—the numbers having been 114 in January, 118 in February, and 102 in March, and that in spite of a considerable elevation of the general mortality. Although the number of cases during the quarter has still been about three times greater than the corresponding mean of former years, the *relative mortality* has undergone an extremely remarkable diminution. Thus, while the mean mortality of the corresponding quarter of the eight preceding years was 20·86, that of 1877 was only 16·12. This diminution is due to two causes: there are many cases carried over from last quarter which after a long convalescence have recovered; and a considerable number of the cases occurring at the end of the epidemic are very benign and rapidly curable.

Prof. Germain Sée on Salicylic Acid.

Prof. G. Sée has just read, at the Academy of Medicine, an elaborate memoir (which is published in detail in the *Union Médicale* of July 3 *et seq.*) entitled, "Studies on Salicylic Acid and the Salicylates; and on the Treatment of Acute and Chronic Rheumatism, Gout, and various Affections of the Sensory Nervous System, by the Salicylates," in which he speaks of this new article of the materia medica in most enthusiastic terms. He treats at full length of the history, chemistry, physiological and therapeutical action of this substance; but we have only space for transcribing his conclusions as to its therapeutical effects.

"1. As an external antizymotic agent, salicylic acid has an incontestable action, but in nowise superior to that of carbolic acid, its only advantage being its privation of odour. As an internal antiseptic, it manifests no appreciable effect in either purulent affections or contagious and parasitical diseases—as diphtheria, or muguet, or gangrene, or finally in diabetes. 2. As an antipyretic, salicylic acid and the salicylates possess only transitory and doubtful properties, even when specific, miasmatic, virulent fevers, etc., are in question. Even the salicylate of quinine occupies no definite position in the treatment of marsh fevers. Powerless in the treatment of small-pox, the salicylate of soda has not been sufficiently tried in typhoid fever. Its febrifuge power is exceedingly limited. 3. It is in acute articular rheumatism that the most certain and most prompt effects are observed—so much so that we may promise with almost certainty the cure of febrile or apyretic acute rheumatism within a space of from two to four days. Fifty-one cases may be adduced in proof of this. 4. In simple chronic rheumatism the trials which I have made have proved most satisfactory. The same may be said of the acute crises which manifest themselves from time to time in simple rheumatism or in chronic rheumatic arthritis, the painful attacks of which cease as soon as in acute rheumatism. Moreover, the articular tumefactions considerably diminish, and the motions of the joints may become free even after years of pain, rigidity, and immobility—on the condition that the bony lesions have not become too deep-seated or too advanced. Twelve cases of chronic rheumatism either cured or ameliorated are adduced. 5. But it is in acute and chronic gout that the results are the most remarkable. From the commencement of my observations I was struck by the promptitude with which the most painful acute paroxysms were arrested. Within the space of two or three days the pains, the articular fluxion, the redness of the skin, and the sensibility to touch had all disappeared. Chronic gout is just as amenable to the salicylic treatment. Continued, even in moderate doses, it affords the patients absolute security from an acute attack. The tophi of the joints diminish in size, and cease to become inflamed—in a word, the cure is complete, and that without the production of any metastasis on the heart, stomach, respiratory organs, or the brain. Not once have I been able, among the twenty-one cases I have watched, to observe the slightest retrocession of gout inwardly. No other inconvenience has been produced than the production of some disturbances in the ear, and sometimes a certain amount of debility or narcotism. The two latter phenomena disappear when the dose is diminished; but the perturbations of audition are much more persistent. Among affections which are often of a gouty nature, gravel may be mentioned. This is favourably modified, or rather more easily eliminated, by the aid of salicylate of soda, which also has the advantage of allaying the nephritic pains. 6. The salicylic treatment has seemed to be of advantage in certain facial neuralgias; but its action in this affection is not definitively established, and the same may be said with regard to sciatica. 7. In painful affections of the spinal cord, the salicylate of soda produces calming effects which are distinctly appreciable; but by the continuance of its employment a certain amount of debility is produced."

REVIEWS.

A Handy Book of Forensic Medicine and Toxicology. By W. Bathurst Woodman, M.D., F.R.C.P., Assistant-Physician to the London Hospital, etc.; and Charles Meymott Tidy, M.B., F.C.S., Professor of Chemistry and of Medical Jurisprudence and Public Health at the London Hospital, etc. London: J. and A. Churchill. Pp. 1205.

In approaching such a book as this, more especially at the present moment, when the lamentable death of one of its authors is fresh in our minds, the critical inquirer labours under serious difficulties. One, at all events, has passed away, whom praise or blame would have influenced and affected. On him all praise is lost; dispraise we shrink from giving. Nevertheless, in the execution of our duty towards the public, we must do our best, whilst avoiding all extremes, to speak fairly of what is good and what is bad in the book. Shall we begin with the latter first? We fear that in one respect we are compelled to do so, for no one can look at, still less handle, the ungainly volume without making to himself the mental comment that it is eminently an *unhandy* book, from size, shape, and weight. But neither, on the other hand, can there be any doubt, on opening the book, of the immense amount of labour and pains bestowed upon it—often, we are sorry to say, needlessly, uselessly. The book might in more than one sense, unhappily, be termed monumental. It is dedicated to the memory of Dr. Letheby. Its appearance has been almost the signal for the death of one of its authors. Itself remains the monument of an immense amount of work—curious, learned, scientific, but very often for the medical jurist useless.

Throughout the work, or nearly so, the authors adopt the second person in addressing the reader: there can be no doubt of the value of this plan when addressing a class of students, but we question its utility when dealing with abstract principles or matters of fact. It may be said to begin with instructions as to how to give evidence, what courts a practitioner is liable to be called before, with the procedure of each; and this mode, which we think is a novelty in such treatises, is upon the whole a good one. It is better to learn by the concrete than by the abstract; and so this plan, if carried out perfectly and clearly, is likely to be of good service. The second chapter is devoted to instructions as to how to make a medico-legal or other post-mortem examination. Many useful hints are here given, but in thoroughness and completeness it is not to be compared to Virchow's famous post-mortem published in these columns, and afterwards as a separate pamphlet. Probably, however, this account appeared too late for the service of the authors.

Early in the volume come the chapters on poisoning, which, however, we shall meantime pass by, and proceed at once to chapter xix., which deals with the examination of hairs and stains. Here we find some very useful information. We have excellent figures of the microscopic appearances of many kinds of hairs, and a good account of the spectroscopic appearances of blood. These last are of the greatest possible importance; but they need not entail an account of the construction of the microspectroscope, nor of some hundreds of details of no practical importance. Nevertheless, we have no hesitation in saying that the practical description of the various steps to be taken for making out the various blood and other spectra liable to be mistaken for it, is one of the best we have seen. The chapter which follows, on "Life Insurance," is, if possible, too elaborate; it goes into details which have really no bearing on medical jurisprudence, many of them being purely physiological. Here, too, is to be seen, well marked, a tendency elsewhere manifest; there is no attempt to classify or group authorities—they are all given as of equal value, and are heaped pell-mell together throughout the pages. These useless details and most useful facts are mixed up in a very aggravating manner, for it is not possible to overlook what is really valueless to the medical jurist without also running the risk of overlooking something well worthy of attention. It is not a grateful task to find such faults, but when we bear in mind that the prime objection to the book consists in its unhandiness, we cannot help feeling how greatly it would have been improved by the omission of wholesale quotations from anatomical and physiological works. In the chapters which follow, on the

sexual relations, the same feature is equally marked. But the highest types of perverse ingenuity come further on in the volume; and as examples we might cite, under the heading of "Starvation," pages on "Some General Observations on Food"; or still worse, under the heading of "Gunshot Wounds," more than twenty pages on "The Weapons themselves and the General Theory of Projectiles," including elaborate mathematical calculations. Two other points, and we have done with this part of the volume. There are scattered throughout this part of the work a good many woodcuts. These are almost without exception such as are to be found in ordinary works on anatomy, and the accompanying explanations are purely anatomical, and such as are altogether useless in a work of this class. Such a book is not intended for a first-year's student; and to any other the anatomy of the base of the brain, the neck, the pelvis, and so on, should be sufficiently familiar to render the anatomical matter here altogether useless. There is, moreover, throughout the whole book a display of learning, which we cannot help calling pedantic. Quotations in half a dozen languages, *àpropos* or *mal-àpropos*, adding nothing to the clearness of the description, nor serving any good purpose which we can see, do not deserve any other name. Such little pettinesses are altogether out of place in works of this class; and the same may be said of the mock heroic style which is abundantly to be found throughout its pages. One very good feature in the volume is the collection of illustrative cases given in almost every department of the subject; but even here want of judgment has been displayed, for number seems to have been the aim of the authors, not aptness of illustration. But let us turn to the part relating to toxicology.

Here the authors—rightly or wrongly, we shall not pretend to say which—reject all schemes of classification, and deal with the various poisons simply as animal, vegetable, or mineral. They introduce the subject, however, by certain general considerations, followed by a scheme for a complete analysis in a toxicological sense of any suspected substances. Both of these chapters contain much sound matter, which it would be well to bear in mind; but the systematic analysis—largely founded, we are told, on the methods of Dr. Letheby,—is very imperfect, and in one instance, at least, illustrated by a dangerously inaccurate figure. Dr. Letheby's processes were often enough objected to while he was yet alive, and it is not well that they should be perpetuated; if the authors of a work like this take upon themselves the responsibility of doing so, it is as well once more to point out the inadequacy of these processes. We allude more especially to their acetate of lead process, which, as far as we are aware, is not now advocated by a single chemist or toxicologist of distinction.

Turning to the description of the individual poisons, we are again most painfully reminded of a fault of which we have already complained—the waste of space, and the superabundance of padding in the shape of details, useful no doubt to the student of chemistry, but utterly useless or worse than useless to the student of toxicology. Page after page is wasted in such matters as the various chemical compounds of metals, their atomic weights, their mode of manufacture,—we have hardly patience to say what-not,—whilst really important details are passed by. One most characteristic feature of the toxicological portion of the work now before us is the collection of cases of poisoning by various substances. In making this collection the authors have exercised a vast amount of patient research, but they have displayed little power of selection, and the analysis will be mainly of use as affording references, which, to render them useful, every real inquirer must verify for himself. It needs but a glance at these tables to illustrate and confirm what we are now saying. This part of the work is further illustrated by certain chromo-lithographs, about which a word may be said. They are supposed to represent the interior of the stomach in poisoning by certain substances; it so happens that we have seen the post-mortem appearances in similar cases of poisoning, and we can confidently say that in no one instance have we seen anything resembling the appearances here figured. This by no means implies that these are utterly inaccurate; it only means that hardly two cases present the same appearances. But when we come to consider the process through which these figures have gone, we can understand some at least of the sources of error. They are all described as from casts by Dr. Letheby. Now, to put it as mildly as possible, it is almost certain that Dr. Letheby's cast would not correspond in colouring to the original; and just as certain that the chromo-lithograph would not exactly correspond with the cast. This shows how dangerous it is in a subject like toxicology to attempt illustrations which cannot be made perfectly like the original.

In our general criticism of the book we have dealt with broad outlines; but in matters of detail it would be easy to go even farther than we have done. It is melancholy to reflect how much time and trouble have been wasted over the volume. Much of it, indeed, forcibly reminds us of that definition of dirt which describes it as matter in the wrong place. The waste of labour and of bodily and mental power which this book implies is enormous. The details entered into are, no doubt, useful in their proper place, but here they are out of place. The only thing wanting to make the book a good book, yea, a capital book, has been a stern and judicious editor. For it will be marked that throughout what we have said we have never said this is a "bad book"; we have not used even the milder form of expression, "this is not a good book." There is a vast amount of good in it, but the work has been conceived in a spirit which would require a lifetime to carry out, and a library to contain. No doubt the authors have done their best with the limited time and experience at their disposal; but these were not great enough for the undertaking, and it is much to be regretted that the work, as undertaken and carried out, was not more commensurate with these. Certain of the faults of the work we can trace distinctly to Dr. Letheby's teaching, especially in the earlier part of the volume. And in this respect it is perhaps hardly fair to visit the faults of the father on the children. Dr. Letheby, when alive, manfully fought his own battles, and as this work now remains a double monument of his labours, and of those of Dr. Woodman, so sadly and abruptly brought to a close, we shall say no more. In any subsequent editions we trust the surviving author will use the pruning-hook as judiciously as the pen of the ready writer.

The Endemic Diseases of Tropical Climates, with their Treatment. By John Sullivan, M.D., M.R.C.P.L., etc. London: J. and A. Churchill. 1877. Pp. 211.

As by far the larger part of this little work has already appeared in our own pages, we have given the best possible proof that we consider it worthy of the attention of the profession, and we therefore need not say much more now than that we are glad that Dr. Sullivan has collected his papers together, and republished them in this form. In his modest little preface, Dr. Sullivan says that his treatise "is the result of patient study and observation during a practice of many years in tropical climates," and it is this fact that gives a special value to the work. The subjects treated of are—Anæmia in Hot Climates; Marsh Malarial Fever; Latent or Masked Malaria; Pernicious Fever; the Bilious Fever of the Tropics; Marsh Diathesis and Marsh Cachexia; Dysentery, Acute and Chronic; Diseases of the Liver; Hepatitis; Jaundice; Yellow Fever; and Asiatic Cholera. Dr. Sullivan has kept himself well acquainted with the best and most recent writings on these diseases, but, as we have said above, the great value of his book consists in the fact that it is the outcome of his own experience and successful practice. In the chapter on dysentery it will be seen that he strongly advocates the employment of ipecacuanha in the treatment of the acute form of the disease. He does not propound any theory respecting the *modus operandi* of the drug, but says, "I only know that it cures dysentery. It is not necessary that it should act as an emetic; it acts best when absorbed. The properties of ipecacuanha are so defined, its effects are so certain, that I go so far as to assert that ipecacuanha is to dysentery what quinine is to malarial fever." In conjunction with ipecacuanha he relies most on manna in the mild, and on calomel, with a little opium, in the severer forms of the disease; but he uses calomel as a purgative only, and warns his readers to guard carefully against giving it to salivation. In Asiatic cholera Dr. Sullivan altogether rejects the treatment of elimination. The plan he has found most successful is—Firstly, to prescribe complete cessation from all labour and fatigue out of doors, and the adoption of the horizontal position on the very first appearance of diarrhœa. Secondly, arrest of diarrhœa, "whether it exists in the preliminary state, or whether it takes the form of rice-water evacuations"; and for this purpose he prefers the employment of opium or laudanum, by means of suppositories and enemata. And, thirdly, he endeavours to supply the loss of fluid, by giving *ad libitum* "iced or cold

water, cold tea, or chicken-tea; and a cordial astringent mixture, as in common diarrhœa." He says, "I believe that no purgative, however mild, should be administered in cholera. There is no danger in arresting diarrhœa, and no safety until it is arrested." Our readers will find Dr. Sullivan's book useful and interesting, as giving the results of the experience of a well-informed and observant practitioner.

Atlas of Skin Diseases. Consisting of a series of Coloured Illustrations, together with Descriptive Texts and Notes upon Treatment. By Tilbury Fox, M.D., F.R.C.P., Physician to the Department for Skin Diseases in University College Hospital. London: J. and A. Churchill. 1877.

This work, one of no ordinary enterprise and importance, has been issued and brought to completion with most commendable regularity and punctuality. It will be remembered that it was announced as intended to be a new and improved edition of Bateman and Willan's famous Atlas, no new edition of which had appeared for some sixty years; and the promise given of a complete and reliable Atlas of Skin Diseases has been very fully redeemed. The completed work consists of seventy-two plates, in which are given 100 different illustrations of diseases of the skin, representing both the most common and the rare forms of disease; and more than half the plates are new. Each plate is accompanied by explanatory letterpress, descriptive of the diseases represented, and briefly treating of the diagnosis and treatment. The whole of this part is entirely new, is clear and concise, and gives the now pretty well known views of Dr. Tilbury Fox. We pointed in our former notice to some of the plates that we thought particularly good, and among the later ones we would direct attention especially to the excellence of those illustrative of xanthelasma, leprosy, and diseases of the nails; but all are so good, that it may be fairly said of them that they could suffice to teach the diagnosis of the eruptions they represent, even without the aid of the text. The Atlas is altogether one of the, if not the, cheapest and best ever published, and reflects great credit on both the editor and the publishers.

A Practical Description of every form of Medico-Electric Apparatus in Modern Use; with Plain Directions for Mounting, Charging, and Working. Illustrated. By Salt and Son, of Birmingham. London: J. and A. Churchill. Second Edition. 1877.

This second edition of Messrs. Salt's "Medico-Electric Apparatus, and How to Use it," may be confidently recommended to practitioners who wish for information concerning the construction and working of the various forms of medico-electric apparatus now most in use. It is "intended to serve as a guide to medical men in the selection of their instruments, and as a handy book of reference for all mechanical details connected therewith," and it will serve these purposes excellently well. It gives full information as to shape, sizes, prices, portability, etc., of the instruments; is freely illustrated; and the description and directions are clear and concise.

The Hunterian Oration. Delivered in the presence of H.R.H. the Prince of Wales, at the Royal College of Surgeons, in 1877. By Sir James Paget, Bart., F.R.S., D.C.L. Oxon., LL.D. Cantab., Serjeant-Surgeon to the Queen, Surgeon to the Prince of Wales, etc. London: Longmans, Green, and Co. 1877.

The profession will gladly welcome this edition of Sir James Paget's admirable and eloquent Hunterian Oration, which is enriched by the addition of a large number of valuable and interesting notes. In giving these, Sir James says, "In studying the life of Hunter I found, or thought of, many things which could not be well used in the Oration, but may be worth printing, whether for the amendment of some of its defects or for subjects for the thoughts of others. I have therefore arranged them in the following notes." And in so doing he has indisputably conferred an additional, and by no means small, boon on his many readers.

The National Health Society, London, received a deputation last week from the London Schools Swimming Club, for the purpose of asking the support of the Society to promote the extension of the art of swimming amongst teachers and scholars of both sexes of the public elementary schools of the metropolis.

REPORTS OF SOCIETIES.

OBSTETRICAL SOCIETY OF LONDON.

Wednesday, July 4.

Charles West, M.D., F.R.C.P., President, in the Chair.

Occlusion of the Cervix Uteri from Cancer.

Dr. Galabin showed a uterus in the cavity of which suppuration had occurred from occlusion of the cervix, due to cancer. The organ had been punctured; a drainage-tube was afterwards inserted. The patient died with general purulent peritonitis. The specimen was referred to Drs. Roper and Galabin to report upon.

Cæsarian Section.

Dr. W. Squire (for Dr. Buckell, of Winchester) read the notes of and showed the viscera of a case in which Cæsarian section was performed twenty to thirty minutes after death. The child was saved. The mother died suddenly of dilatation of the aorta, rendering the aortic valves incompetent. At the post-mortem examination the viscera of the chest and abdomen were found to be transposed.

The President thought the case of interest, as showing that a child could be recovered a considerable time after the death of the mother.

Dr. Aveling said that it is believed that a child may be born alive an hour after the mother's death.

Dr. Playfair said he knew of one case in which a live child was born half an hour after the death of the mother.

Dr. Routh said that much depended on the cause of the mother's death. He had performed Cæsarian section in a case of death from apoplexy, but the child was dead from carbonised blood.

Dr. Daly saw Cæsarian section done twenty minutes after rupture of uterus, but child was dead.

Dr. Playfair showed a specimen of elephantiasis of the vulva, removed by him. It was amputated and the bleeding vessels tied.

Ovariotomy during Pregnancy.

Mr. T. Spencer Wells brought forward some additional cases of ovariotomy performed during pregnancy. The author had arranged in a table the particulars of all the cases in which he had performed ovariotomy during pregnancy. The age of the patient was given, the period of pregnancy when ovariotomy was performed, the weight of the tumour removed, and the results to mothers and children. Full particulars of four cases hitherto unpublished were given. The author concluded that as eight of the nine mothers recovered; as pregnancy proceeded in five, and living children were born after natural labour; as in two, where labour came on soon after ovariotomy, there was no unusual hæmorrhage nor difficulty; and as four of the patients had borne children at various periods since the labour which followed the ovariotomy,—these facts will have their just influence in the formation of professional opinion upon the best mode of treating cases of pregnancy complicated by ovarian tumour.

Dr. Playfair asked Mr. Wells what his experience was of tapping and induction of premature labour. Dr. Playfair was in favour of ovariotomy, because of the unfavourable results which followed when labour was allowed to go on with small ovarian tumours.

Dr. Murray related a case where he had induced labour at the eighth month, and later performed ovariotomy successfully. He thought that when the tumour was fluid it was safer to tap; and even if solid but small, and pregnancy far advanced, labour might take place before the tumour would cause great inconvenience.

The President said that Mr. Wells' results tended to show the comparative safety of ovariotomy during pregnancy. Probably the operation should be done early, for the advance of pregnancy may give rise to suppuration of the cyst, and death. If ovariotomy could not be done, owing to the nature of the tumour, or other circumstances, premature labour might be induced.

Mr. Lawson Tait had in several cases been able to push up small ovarian tumours impeding labour, and had obtained favourable results. He was of opinion that ovariotomy was better practice than the induction of premature labour. He had once performed the operation during pregnancy; mis-

carriage occurred on the seventh day after, and the woman soon died. The pedicle was found to be gangrenous.

Dr. CARTER had seen two cases of pregnancy with ovarian tumours. Both cases went to the full time and did well. Children were alive and healthy. He asked Mr. Wells what other cases he had been consulted about which had not been operated upon.

Dr. GALABIN asked if Mr. Wells attached any importance, in making the choice of operation, to the stage of pregnancy reached? In the cases tabulated, miscarriage had occurred in all in which ovariotomy had been performed later than the fourth month, but in none of the others. If this were confirmed, it would seem preferable at such a stage to induce premature labour, and not to delay ovariotomy if indicated in the earlier months.

Dr. HEYWOOD SMITH asked if rapidity of growth influenced Mr. Wells in his choice of operation? He considered that any operation was extremely hazardous during the puerperal state and for two months after delivery. Tapping might be dangerous, especially if cysts were forming rapidly, or if the tumour contained puriform fluid, for fluid might escape and set up inflammatory mischief.

Dr. ROUTH thought that more cases were required before an opinion could be formed on the subject before the Society. Seven cases had been mentioned this evening which ran natural courses without any interference. Dr. Routh had brought on premature labour successfully, and performed ovariotomy three months afterwards, but the patient died. Much depended on the size and rapidity of growth of the tumour.

Dr. CHAMBERS had seen a case of ovarian tumour associated with pregnancy. He tapped. A few days after, abortion took place at the fourth month. She recovered from the miscarriage and tapping, but the tumour began to grow again, and the patient to lose health. The tumour was removed in about six weeks from the tapping, but the patient died. He thought that had ovariotomy been performed instead of the tapping, the patient would have had a better chance of recovery.

Dr. SAVAGE saw no chance of obtaining a rule of practice in these cases from the present discussion. He asked if Mr. Wells would operate in a case of pregnancy complicated by a solid or cystic ovarian tumour when there was no suffering, and what operation would he choose if the patient suffered severely. Dr. Savage thought that ovariotomy was the only justifiable operation in the latter circumstances.

Dr. ROPER induced labour at the seventh month in a case complicated by an ovarian tumour as large as a fœtal head. The child was alive. The patient did well, and has had living children at full term since, the tumour remaining unaltered.

Mr. SCOTT said the propriety of performing ovariotomy during pregnancy depended mainly on two conditions—the amount of suffering and constitutional disturbance present, and the position of the tumour. If the tumour were wedged in the pelvis so as to impede delivery, early ovariotomy should be performed. If the tumour were well up in the abdomen, giving rise to no trouble, it may be doubted if operative interference be justifiable.

Mr. WELLS replied that the patient and her friends have an undoubted right to share in the discussion, and it is often not only advisable, but right, to give them some share of the responsibility when the decision involves a matter of life or death. He thought that to remove the fœtus, and soon afterwards to remove the tumour, was extremely dangerous. It was necessary to observe more cases to answer some questions. It is probable that early is preferable to late operation. If a tumour could not be reduced by tapping, and the woman was not suffering, the clear course was to leave her alone. Cases had gone on to term, and living children had been born, but the tumour still remained, and caused anxiety and suffering.

TREPHINING THE MEMBRANA TYMPANI IN OLD DEAFNESS.—Dr. Bonnafont, in a communication to the Academy of Sciences entitled, "Trephining the Membrana Tympani successfully in a case of old deafness that had resisted all treatment," lays down the position that all cases of deafness that are not due to an impairment of the sensibility of the auditory nerve (which may be ascertained by placing a watch on the cranium near the ear), and which have resisted all the ordinary modes of treatment, such as catheterism of the Eustachian tube, etc., may be cured or considerably ameliorated by trephining the membrana tympani.—*Gaz. Hebd.*, July 13.

NEW INVENTIONS AND IMPROVEMENTS.

HYPNOIPOIETIC.

UNDER the above name, the well-known manufacturing chemists, Messrs. Richardson and Co., of Leicester, have introduced a new solution of opium. It is of the same strength as the tincture of opium of the Pharmacopœia, but in its qualities is more like morphia; and it does not, so far as we have tried it, produce headache, nausea, or constipation. It has but little taste, is an elegant-looking, clear preparation, and mixes well with water.

ALEXIMORHYGIASTIKON.

THE apparatus with the above terrible name is a patent pocket inhaler, devised by Mr. James B. Austin, 7, High-street, Bloomsbury, and appears to us to be really an ingenious, handy little instrument, deserving of a less formidable title. It consists essentially of a core, composed of minute rolls of blotting paper, and enclosed within an impermeable circular case, open at the ends. The core is saturated with a solution of the drug to be inhaled, and then the air is inhaled through the tube. Two forms of the instrument are made, one for inhalation by the nostrils, and the other by the mouth. The case containing the inhaler carries also a small bottle of a solution of carbolate of iodine, and a twisted wire by means of which the fluid may be accurately dropped on to the bibulous core. The apparatus is very simple; is easily used; and we can well imagine that it may be found to be of good service. We have indeed received an indignant denunciation of it from an old friend, who suffers greatly from asthma and bronchitis, and had bought one of the bottle forms of the inhaler, hoping to get relief thereby. But we must in honesty add, as our friend did, that he had not tried it—he was kind enough to make us a present of it,—the sight of it having been enough to convince him that it was too small to be of any use. On this point, however, we think he is mistaken. It must be understood that our remarks respect the apparatus only, and have no reference to the medicinal value of the solution of carbolate of iodine supplied with it.

LACTOPEPTINE.

THERE is undoubtedly a very considerable and eager demand for artificial aids in the various forms of indigestion that result from the high-pressure life of nineteenth-century civilisation; and Messrs. Carnick, Kidder, and Co., of New York, and Great Russell-street, London, have brought out a new remedy, which they call Lactopeptine, to meet this demand. They state that this Lactopeptine is a combination "of the five active agents of digestion, in the same proportions as they exist in the human system"; that is, that it is composed of pepsin, pancreatine, diastose (or vegetable ptyalin), lactic and hydrochloric acids, together with sugar of milk; and the well-known analyst, Dr. H. C. Bartlett, confirms the correctness of the manufacturers' description of the preparation. We can add that Lactopeptine is pleasant to take, and that where we have had an opportunity of prescribing it, its employment has been decidedly beneficial. It is most useful, we think, in cases of *slow* digestion; and in dyspepsia attended with fulness, a sense of weight, and with flatulence. The dose required is large—not less than fifteen grains.

IVORY JELLY.

THIS jelly, which is prepared from pulverised ivory, is very palatable, and, as it contains the bone phosphates in (according to Mr. Dugald Campbell's analysis) a soluble condition, it may be very fairly supposed to possess, for some invalids, a higher nutritious value than that of ordinary jellies. It is manufactured and sold by Mr. T. K. Callard, Blenheim-terrace, St. John's-wood, and by Messrs. Callard and Callard, of Queen's-terrace, St. John's-wood.

KORFF'S CHOCOLATE.

FROM Messrs. Phillips and Co., 11, Great St. Helen's, London, we have received a sample of Korff and Co.'s Chocolate Powder. It is very agreeable and fragrant; and we believe that it is what it professes to be—viz., the pure powder of the bean, without any additional starchy matter, and without abstraction of the fatty matter natural to it.

VIN DE BAUDON.

"BAUDON'S WINE," which is proposed as a substitute for cod-liver oil in pulmonary phthisis and diseases of debility, is a medicated wine containing phosphate of lime and some antimony. It comes to us from France, and its usefulness is attested by the names of some French physicians and surgeons of high standing and repute. In our "Hospital Reports" of May 12, of this year, we also reported a case of pulmonary disease under the care of Dr. Andrew Clark, in the London Hospital, in which very marked improvement took place during the exhibition of this wine, without any other medicinal treatment. The "Vin de Baudon" is, at any rate, a very agreeable remedy, the basis of it being a pure muscat wine; but as this is a "generous" and rather potent wine, and it is given in considerable doses, "a claret-glassful, pure, or mixed with a little water, or seltzer water," being recommended to be given to adults before each principal meal, it may be questioned, perhaps, whether any good consequent on the use of it may not, in large measure at least, be due to the wine itself rather than to the phosphates, etc., with which it is medicated. Messrs. Pagny and Wallace, 3, Finsbury-pavement, are the agents for the wine in England.

OBITUARY.

CHARLES SCOTT, M.D., C.B., INSPECTOR-GENERAL OF HOSPITALS.

WE have to record the death of Dr. Charles Scott, which took place on the 9th inst., at St. Edmund's Villa, South Lambeth-road, at the age of seventy-four. The deceased entered the Army Medical Department in November, 1834. He was in medical charge of the 32nd Light Infantry for many years, and Surgeon to the regiment in the Punjaub campaign of 1848-49, and present at the siege and capture of Mooltan and the battle of Goojerat. He served with the force under Sir Colin Campbell against the Peshawur frontier hill tribes in 1852; and in the Indian Mutiny, as medical officer of the 32nd, in the defence of the Residency of Lucknow until its final relief by Lord Clyde, he distinguished himself. He was subsequently at the defeat of the Gwalior rebels at Cawnpore, and received official recognition in despatches "for eminent servicest hrough-out the whole siege of Lucknow." In 1860 he was appointed Honorary Surgeon to her Majesty, and in 1862 retired from the service.

MEDICAL NEWS.

KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND.—At the usual monthly Examination Meetings of the College, held on Monday, Tuesday, Wednesday, and Thursday, July 9, 10, 11, and 12, 1877, the following candidates were successful:—

Previous Examination for the Licence to Practise Medicine.

Waterston, Jane Elizabeth.

Final Examination for the Licence to Practise Medicine.

Charlton, Henry Arthur Herbert.
Clarke, John Patrick.
Clarke, Joseph.
Clinch, James Vincent.
Conry, John.
Delahoyde, O'Connell John.
Donaldson, Ebenezer.
Duigenan, John Joseph.
Fisher, Francis Charles.
Higgins, Samuel McCulloch.
Jennings, John Bray.
Kisby, George.
Lyndon, George.
Rowlands, William.
Rugg, James Foster.
Ryan, Walter Henry.
Sherrard, Henry Robert.
Smith, Richard Baker.
Thompson, John Henry.
Tyner, Richard Gelling.
Winter, Walter Henry Trimnell.
Wylde, James Harold.

For the Licence to Practise Midwifery.

Charlton, Henry Arthur Herbert.
Clarke, John Patrick.
Clinch, James Vincent.
Conry, John.
Croft, Freeman Wills.
Delahoyde, O'Connell John.
Donaldson, Ebenezer.
Duigenan, John Joseph.
Fairbank, William.
Fisher, Francis Charles.
Goodman, Francis George.
Hamilton, William.
Higgins, Samuel McCulloch.
Kisby, George.
Lyndon, George.
O'Dwyer, Malachi.
Rugg, James Foster.
Ryan, Walter Henry.
Sherrard, Henry Robert.
Smith, Richard Baker.
Thompson, James Edward.
Thompson, John Henry.
Tyner, Richard Gelling.
Westby, George.
Wylde, James Harold.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen passed their primary examinations in Anatomy and Physiology at a meeting of the Board of Examiners on the 12th inst., and when eligible will be admitted to the pass examination, viz.:—

Biden, Edward J., student of the Charing-cross Hospital.
Brockliss, Edward L., of Guy's Hospital.
Brown, Percy, of the London Hospital.
Charles, Henry, of Guy's Hospital.
Fulton, James, of St. Thomas's Hospital.
Gabriel, Samuel J., of St. Bartholomew's Hospital.
Hooker, C. Paget, of St. Bartholomew's Hospital.
Mark, Leonard P., of St. Bartholomew's Hospital.
Parish, Frank, of University College Hospital.
Pilkington, Francis S., of Guy's Hospital.
Ponsford, Leicester C., of University College Hospital.
Price, Arthur, of St. Thomas's Hospital.
Rushworth, Frank, of St. Bartholomew's Hospital.
Rushworth, Norman, of St. Bartholomew's Hospital.
Thomas, Stanley T., of Guy's Hospital.

Nine candidates were rejected. The following gentlemen passed on the 16th inst., viz.:—

Bampton, Augustus H., student of the Westminster Hospital.
Burrows, Henry C., of the Liverpool School.
Deane, Arthur D., of Guy's Hospital.
Humphry, Lawrence, of the Cambridge School.
Hunter, Vere E., of St. George's Hospital.
Moore, Stephen H., of Guy's Hospital.
Parker, William R., of University College Hospital.
Rees, Albert H., of University College Hospital.
Sage, Charles, of Guy's Hospital.
Shelswell, Oscar B., of Guy's Hospital.
Smith, Herbert, of St. Bartholomew's Hospital.
Wall, George B., of the Charing-cross Hospital.
Walters, Frederick R., of St. Thomas's Hospital.

Twelve candidates were rejected. The following gentlemen passed on the 17th inst., viz.:—

Balls, James, student of King's College Hospital.
Duncan, H. Montague, of University College.
Greensill, James H., of the Middlesex Hospital.
Griffiths, Herbert T., of St. George's Hospital.
Hodgson, J. Willoughby, of Guy's Hospital.
Hitch, Frederick, of Guy's Hospital.
Licard, William E., of the Charing-cross Hospital.
Mackrell, Alfred S., of St. Bartholomew's Hospital.
Outhwaite, William, of St. Bartholomew's Hospital.
Sainsbury, Harrington, of University College.
Smith, J., of the Westminster Hospital.
Stuart, Ernest O., of Guy's Hospital.
Watton, Robert S., of University College.
Webb, J. Gascoyne, of St. George's Hospital.
Williams, William, of St. Thomas's Hospital.

Nine candidates were rejected. The following gentlemen passed on the 18th inst., viz.:—

Brookes, Robert, student of King's College Hospital.
Buller, Audley C., M.A. Cantab., of the Cambridge School.
Dunn, Walter, of St. George's Hospital.
Heyland, Langford R., of St. George's Hospital.
Hine, John E., of University College Hospital.
MacDonald, Greville M., of King's College Hospital.
Shettle, H. Wynter, of St. George's Hospital.
Sutton, Samuel W., of St. Thomas's Hospital.
Tinker, T. Howard, of University College Hospital.

Fifty-seven candidates out of 136 examined having failed to acquit themselves to the satisfaction of the Board of Examiners, were referred to their anatomical and physiological studies for three months. With this the primary examinations for the present session are brought to a close. The next and ensuing weeks will be devoted to the pass examination for the diploma of Membership, for which upwards of 200 candidates have entered their names.

These examinations, as is now generally known, are open to all Fellows of the College; and distinguished foreigners introduced by them desirous of witnessing the mode of conducting the examinations for Fellowship and Membership. Amongst the visitors at the above examinations were Dr. Tripier, Professeur d'Anatomie à l'Ecole au Beaux Arts, Lyons, accompanied by a co-Professor, Dr. Wm. Darling, F.R.C.S. Eng. (exam.), Professor of Anatomy in the University of New York; Dr. J. E. Winters, the Demonstrator of Anatomy in the same University; Dr. Ambrose Lediard; Mr. A. P. Gould; Dr. Heiberg, Professor of Anatomy in the Royal University, Christiania, Norway.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, July 12:—

Green, Thomas Beaufoy, Kendal.
Fagg, Thomas William, Alkham, near Dover.
Rawson, Ernest, Taranaki, New Zealand.
Wakefield, Thomas, 37, Nottingham-place, W.
Wright, Arthur, 64, St. Mary's-terrace, W.

The following gentlemen also on the same day passed their primary professional examination:—

Bowlby, Anthony Alfred, St. Bartholomew's Hospital.
Fisher, Frederick Charles, St. George's Hospital.
Webb, Charles Alfred, St. George's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

BARNES, R. S. FANCOURT, M.B., C.M.—Physician to the British Lying-in Hospital.

PAXON, HERBERT E., M.R.C.S. Eng., L.S.A.—Junior House-Surgeon to the Cheltenham General Hospital, *vice* C. Greenwood, resigned.

BIRTHS.

DAVY.—On July 10. at Vue du Lac, Guernsey, the wife of Francis Arthur Davy, M.D., A.M.D., of a son.

DAWSON.—On July 12, at 5, Second-avenue, Queen's-gardens, Brighton, the wife of Richard Dawson, M.B., of a daughter.

MOORE.—On July 7, at H.M.'s Dockyard, Pembroke Dock, the wife of George Moore, M.D., Fleet-Surgeon, of a daughter.

OWEN.—On July 15, the wife of William Owen, M.R.C.S.E., of a daughter.

TAYLOR.—On July 11, at Champion-park, Denmark-hill, the wife of W. Bramley Taylor, M.R.C.S., of a daughter.

MARRIAGES.

BAINBRIDGE—MACKENZIE.—On June 21, at Dhulia, Khandeish, Bombay Presidency, George Bainbridge, L.R.C.P. Lond., M.R.C.S. Eng., H.M.'s Bombay Medical Establishment, to Jessie Beatrice, daughter of the late T. Mackenzie, C.B., Deputy Inspector-General of Hospitals, Bombay.

GRIMES—CROOKE.—On July 17, at Trinity Church, Brompton, John Grimes, M.D., B.Sc., of Grassendale, near Liverpool, to Emily, elder daughter of Reginald Crooke, of Mossley-hill, near Liverpool.

HEWSON—RICHARDSON.—On July 11, at Marylebone Church, R. W. Hewson, L.R.C.P. Edin., only son of J. Dale Hewson, M.D., of Coton Hill, Stafford, to Anna Maria, widow of the late H. Dallin Richardson, Esq., solicitor, York.

HITCHCOCK—HAILSTONE.—On July 12, at Bottisham, Lode, Charles Knight Hitchcock, Esq., younger son of Charles Hitchcock, L.R.C.P. Edin., of Fiddington House, Market Lavington, to Alice, younger daughter of the late Rev. J. Hailstone, M.A., J.P., of Anglesey Abbey, Cambs.

SMITH—CHAMPAIN-HALL.—On July 11, at St. Peter's Church, Paddington, Edwin Gilbert Smith, M.R.C.S. Eng., of Easy-row, Birmingham, to Florence, eldest child of William Champain-Hall, of Grittleton-road, Paddington.

WILMOT—WADDY.—On July 17, at Monkstown Church, county Dublin, Samuel Cusack Wilmot, Esq., B.A., barrister-at-law, eldest son of Samuel George Wilmot, M.D., of Dublin, to Annie Warren, younger daughter of Lieutenant-General Sir Richard Waddy, K.C.B.

DEATHS.

BOULTON, ROBERT GEORGE, M.D. and J.P., at Beverley, Yorkshire, on July 12, aged 72.

FRASER, MARGARET SKENE, eldest daughter of Robert W. Fraser, M.D., Staff-Surgeon, half-pay, at 13, Lloyd-square, Clerkenwell, on July 13, aged 32.

LAND, ARTHUR HOLMER SEYMER, child of Surgeon-Major J. Land, M.D., R.A., at Colaba, Bombay, on June 4, aged 2 years and 9 months.

MARCHER, HANS KOFOD, M.D., K. of D., at Copenhagen, on July 15, aged 81.

ROBERTSON, RICHARD H., M.D., at Carlisle Lodge, Howard-road, South Norwood, on July 16, aged 69.

POPE, EDMOND, M.R.C.S. Eng., of Brixton, on July 15, in his 41st year.

POWELL, HENRY, M.R.C.S., at Crawley Lodge, Crawley, Sussex, on July 10, aged 68.

STUCKEY, JOHN, M.R.C.S. Eng., of H.M.C.S., Colonial Surgeon, Accra, Western Africa, eldest son of Samuel Stuckey, late of Langport, and now of Worton Lodge, Devizes, on May 10, aged 34.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

HAVERSTOCK-HILL AND MALDEN-ROAD PROVIDENT DISPENSARY.—Medical Officer. Particulars may be had of the Honorary Secretary, to whom applications, with testimonials, should be sent on or before July 30.

ROYAL HOSPITAL FOR DISEASES OF THE CHEST, CITY-ROAD.—Two Assistant-Physicians. Candidates must be M.D. or M.B., and if not M.R.C.P. Lond., must undertake to become so within twelve months. Applications, with testimonials, to the Secretary, on or before July 31.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

VACANCIES.

Foleshill Union.—Mr. Charles H. Parsons has resigned the Shilton District; area 4,240; population 928; salary £15 per annum.

Holbeach Union.—Mr. Arthur B. Ewen has resigned the Tydd District; area 7229; population 1493; salary £25 per annum. Also the Lutton District; area 14,510; population 2900; £37 10s. per annum.

Manchester Township.—Mr. George R. Gowland has resigned the office of Assistant Resident Medical Officer at the Crumpsall Workhouse; salary £170 per annum and allowances.

North Witchford Union.—Mr. J. B. Pike has resigned the Fourth District; area 14,126; population 2905; salary £60 per annum.

Sleaford Union.—The Wilsford District is vacant; area 14,140; population 1920; salary £21 per annum.

APPOINTMENTS.

Brighton Parish.—Andrew Henderson, M.D. Glasg., L.F.P. & S. Glasg., to the Central District.

Droitwich.—Edward H. W. Swete, M.D., as Analyst for the Borough for two years.

Hastings Union.—Edward P. Thurstan, M.B. Cantab., M.R.C.S. Eng., L.S.A., to the Third District.

Llanelly Union.—John R. Thomas, M.R.C.S., L.S.A., to the Llanelly District. Lewis Jones, M.B., M.R.C.S. Eng., to the Pembrey District. John W. Morris, L.R.C.P. Lond., M.R.C.S. Eng., to the Llannon District.

SOCIAL SCIENCE CONGRESS.—The following are the special questions selected for discussion in the Health Department at the forthcoming Congress at Aberdeen:—1. What is the best mode of providing suitable accommodation for the labouring classes, and of utilising open spaces in towns? 2. How can the sanitary condition of the population engaged in the coast fisheries of Scotland and the United Kingdom be improved? 3. The present state of house accommodation in rural districts. Can its evils be remedied? Papers volunteered on other subjects coming within the range of the departments will be read and discussed.

HOSPITAL FEES IN DUBLIN.—A movement is at present in progress to consider the propriety of raising the fees payable by students in the clinical hospitals of Dublin. The hospital physicians and surgeons have already held two meetings at the College of Physicians, Kildare-street. To the second of these meetings a committee reported on the fees payable in the various London and provincial English and Scotch hospitals. It is suggested (1) that the fees payable should be uniform in all the hospitals; (2) that the fee for nine months' clinical instruction should be twelve guineas, that for six winter months should be eight guineas, and that for three summer months four guineas. Perpetual pupils are to pay a bulk sum of thirty guineas. These proposals were embodied in resolutions, which have been forwarded for discussion to the medical boards of the various clinical hospitals. If the increase of fees is agreed upon, it is not contemplated to make such increase retrospective.

TABULATION OF TEMPERATURE, ETC.—In the *Presse Méd. Belge* a case of Addison's disease is narrated by Dr. Carpentier, of the Hôpital St. Jean; but the reason of our noticing it here is to draw attention to the convenience of the tabulation employed for the exhibition of the temperature, pulse, and respiration, the initials for which are the same in all languages. The daily variations, given as a table at the end of the case, are much more readily appreciable and comparable than when diffused over the narrative of the case. For example:—

	Morning.			Evening.		
Dates.	T.	P.	R.	T.	P.	R.
March 16.. ..	37·9°	84	22	37·7°	78	18
„ 17.. ..	37·7°	76	16	37·8°	72	16

and so on as long as the case lasts.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

AN APPEAL.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—We venture to hope that you will kindly allow us, through your columns, to call the attention of the profession to the case of Dr. de Lisle Allen, who, after an illness of more than two years, is now an inmate of Bethlehem. During the whole of his illness Dr. Allen has been incapacitated from following his profession, and his family have been indebted to the kindness of private friends, supplemented by a grant from the Medical Benevolent Fund, for the means of defraying the heavy expenses necessitated by the nature of his malady. This appeal is now made to enable his wife and daughter to keep a home, and to put them in a position to earn a livelihood for themselves. Dr. B. W. Richardson, 12, Hinde-street, Manchester-square, will act as treasurer.

(Signed) BENJAMIN W. RICHARDSON, M.D., F.R.S.
J. HUGHLINGS-JACKSON, M.D.
J. E. ERICHSEN, F.R.C.S.
THOMAS SMITH, F.R.C.S.

Professor Vanzetti, Padua.—Received with thanks.

Recalcitrant.—A guardian, who has been a party to a resolution refusing to enforce the Vaccination Act, has given conclusive proof of his unfitness to be a guardian. A man who will not perform the duties cast upon him by statute ought not to be capable of election to the office with which these duties are associated. The business of a local authority is not to sit in judgment upon Acts of Parliament, but to execute them.

Sigma.—The term "census" originated at Rome, where the first took place B.C. 566, when the city was found to contain 84,700 citizens. After B.C. 432 it was held in the Campus Martius, and was generally taken every five years in Rome. The first census of Great Britain was made in 1801. The Act of Parliament, ordering a census to be taken every ten years, 41 George III., c. 15, passed December 31, 1800. Ireland was not included in this return, and the census for that portion of the United Kingdom was first taken in 1813.

SMALL-POX AND LIGHT.

Dr. Robert C. Croft, of the Camden-road, in a letter addressed to a morning contemporary, which deserves notice, asks those having the care of small-pox patients to try the plan of hanging the windows of the sick-chamber with yellow calico; preparing it, in fact, as if for photographic purposes. He states he does not know to whom the original suggestion is due, or from whom he heard of it, but the results in treatment have been so remarkable that he feels it a duty to call attention to it publicly. He adds—"We have yet a great deal to learn about the actinic properties of light, and we may some day find that the proper management of light will be a great aid in the treatment of disease."

TEMPERATURE OBSERVATIONS.

The mean temperature at the Royal Observatory, Greenwich, for the week ending the 7th inst. was 58·2°; 3·2° below the average in the corresponding week for sixty years.

COMMUNICATIONS have been received from—

Mr. ROBERT BRUDENELL CARTER, London; Dr. HENRY THOMPSON, London; Mr. KNOWSLEY THORNTON, London; Mr. E. L. HUSSEY, Oxford; Mr. S. FULLOM CONOLLY BURFORD, Oxfordshire; Mr. JOHN CHATTO, London; Dr. ROBERT HUNTER SEMPLE, London; Mr. T. M. STONE, London; Dr. THOMAS BARLOW, London; Dr. J. BURDON-SANDERSON, London; Dr. G. E. HERMAN, London; Dr. SPARKS, Crewkerne; Dr. HUMPHRY, Cambridge; Dr. GOYDER, Bradford; Dr. J. W. MOORE, Dublin; Sir WM. GULL, London; Dr. HANDFIELD JONES, London; THE SECRETARY OF THE OBSTETRICAL SOCIETY, London; THE REGISTRAR OF APOTHECARIES' HALL, London; Mr. R. KERSHAW, London; Mr. ERICHSEN, London; THE SECRETARY OF THE SOCIAL SCIENCE CONGRESS; Mr. J. S. JACK, Glasgow.

APPOINTMENTS FOR THE WEEK.

July 21. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

23. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

24. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

25. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

26. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

27. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, July 14, 1877.

BIRTHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·82 in. The lowest reading was 29·11 in. at the end of the week, and the highest 30·14 in. on Monday.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

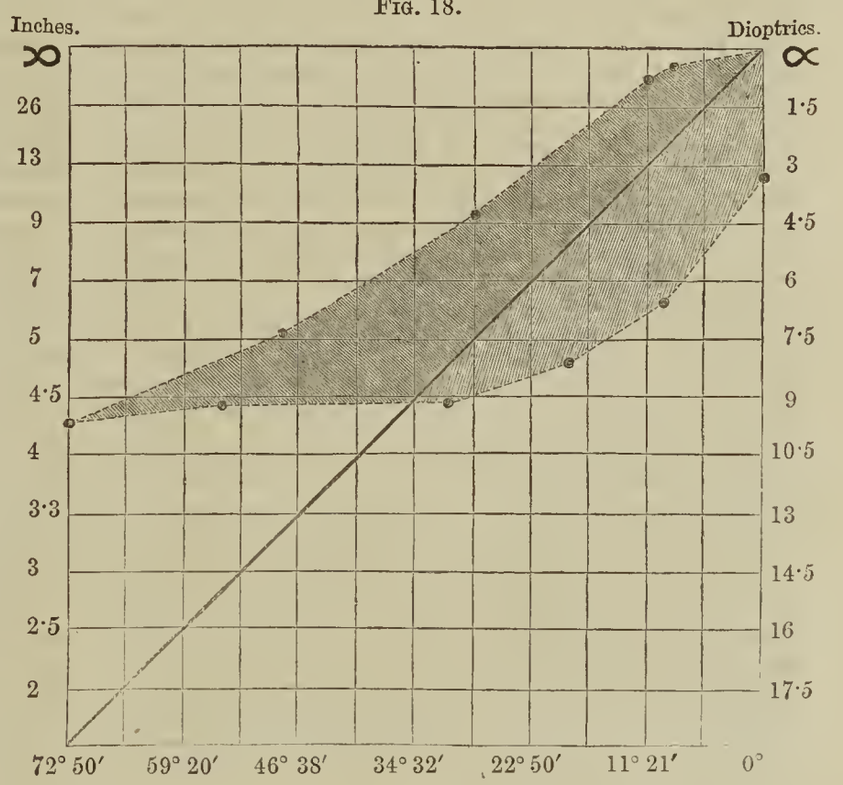
By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

Lecture II.

(*Concluded from page* 56.)

Although the object of convergence is entirely different from the object of accommodation—the former function being subservient to singleness of vision, or fusion; the latter to clearness or distinctness only,—yet it will be seen on brief consideration that the two functions must, in emmetropic eyes at least, almost always be called into action simultaneously. Accommodation is required only for near objects, and the nearer the object the more accommodation is necessary. The same is strictly true with regard to convergence; and hence, but only in emmetropic eyes, the two functions stand to each other in close and constant relationship, and, at least during the first forty years of life, are performed simultaneously and in strictly corresponding degrees. Convergence for a given point implies accommodation for the distance of that point, and the internal recti muscles and the ciliary muscles contract and relax together, as if by a common impulse communicated to the two. This harmony of action reminds us of Dr. Broadbent's doctrine, already mentioned, of the close connexion of the motor ganglia in such cases; and suggests the idea of a natural and complete co-ordination, common to the human race, and dependent upon the structure of the nervous system. If this be so, it is plain that such a co-ordination will not easily be overcome by changes in external organs—changes which, in their essential nature, are of an acquired or accidental character; and, although both myopia and hypermetropia derange the ordinary correlation between accommodation and convergence, yet the former of these errors of refraction is an acquired condition, while the latter, in its higher grades, is apparently an arrest of development, and neither of them can be expected to modify a ganglionic co-ordination equally in all cases; or even at all, except as the result of time, and of the gradual training of the muscles to adapt themselves to a disruption of their natural harmony. It was held by Porterfield, who published his treatise on the Eye in 1759, that "to every degree of convergence there is a fixed and absolute amount of accommodation"; but this view of the case is maintained by Donders not to be absolutely correct. In the first place, he argues, the two functions may be absolutely dissociated from each other, either by artificial means or by disease. Complete paralysis of the accommodation by atropine has no influence upon the convergence; and, although general paralysis of the third nerve would abolish both functions, there have been many cases of partial paralysis in which one of them has suffered alone. I have at present a patient in St. George's Hospital in whom the levator palpebræ muscle of the left eye is entirely paralysed, the superior and inferior recti are paralysed almost entirely, and the internal rectus is greatly weakened; but in whom the pupil is small and active, and the accommodation unimpaired. Quite lately, in private practice, I have seen the precisely opposite condition—the ciliary muscle and the sphincter pupillæ of one eye greatly weakened, apparently from intracranial syphilis, while the recti muscles were unaffected. Von Graefe has recorded a case of complete paralysis of all the external muscles without impairment of the accommodation; so that there is much reason to believe that the two functions, however intimately they may be associated in the healthy state, are physiologically distinct; and that the connexion between them is mainly of the character of an acquired co-ordination. Even in the healthy state, Volkmann showed that the interdependence of the two is not absolute; and Donders, who followed in the same direction, says—"It is easy to convince one's self that both eyes together, as well without as with slightly concave or convex glasses, can accurately see an object at a definite distance, and that, consequently, without change of convergence, the accommodation may be modified. With equal ease, we observe that, in holding a weak prism before the eye, whether with the refracting angle turned inwards or outwards, an object can be accurately seen with both eyes at the same distance, and that, consequently, the convergence may be altered without modifying the accommodation. When, therefore, it is required for the sake of distinct vision with both eyes, the connexion between convergence and accommodation can be, at least partially, overcome." Fig. 18 shows the diagram by which Donders illustrated these changes, as he found them occurring in the eyes of an emmetropic subject fifteen years of age. The diagram is altered by the conversion of the inches into dioptrics and parts of a metre, and by different shading of the positive and the negative parts of the relative accommodation; but in all essential respects it is the same. The diagonal line represents successive degrees of convergence; and the two irregular lines represent respectively the near-point and the far-point for each degree of convergence. An examination of the diagram shows that for all moderately distant points there was a play of accommodation on either side of that for which the visual axes were directed; but that the convergence power was in excess of the accommodative, so that the subject was able to converge to a point which the accommodation could not reach. The whole range of accommodation for each convergence is

Fig. 18.



called the relative accommodation for that point; and the diagram shows that not only the range, but also the region, of this relative accommodation differs according to the degree of the convergence. Thus, it appears that the eyes of this subject, whilst their axes were parallel, could accommodate from infinite distance up to a point which was only twelve inches away; and, when their convergence angle was 22° 50′, they could accommodate from twelve inches up to rather more than four inches and a half. With a convergence angle of 46° 38′, by which the visual axes were directed to a point only three inches distant, the accommodation had almost obtained its maximum, and was also entirely on the other side of the diagonal; so that it actually did not reach to the convergence point. With a convergence of 70°—that is, to a near-point of only two inches' distance, the absolute near-point of accommodation can be attained; but at this degree of convergence there is no longer any space for accommodation, and the lines of the far-point and of the near-point cut one another.

With reference to this diagram, Donders continues—"It

is of importance further to observe, that the relative range of accommodation consists of two parts—a *positive* part and a *negative*. The diagonal represents the convergence of the visual lines, and for each point of convergence the portion of the range of accommodation on the nearer side of this line is the positive, that on the farther side is the negative. The first represents what, reckoning from the point of convergence, we can accommodate still nearer; the second, what we can accommodate still farther off. For example, the emmetropic eye, at a distance of thirteen inches, is normally accommodated for this distance; but the accommodation may, with the same convergence, be made more tense—for a distance, namely, of six inches; and it may also be relaxed to distinct vision at a distance of seventy-two inches. The first is evident, since with negative, the second, since with positive glasses of definite strength, at the same distance of thirteen inches, with both eyes at once, accurate vision can be attained. The figure also shows that in the emmetropic eye, with parallel visual lines, the relative accommodation is wholly positive; that, with increasing convergence, the negative part rapidly increases, soon, also, at the expense of the positive; and that at a convergence of 36° the relative accommodation has become entirely negative. The distinction here made acquires importance from the fact that the accommodation can only be maintained for distances at which, as compared with the negative, the positive part of the relative range of accommodation is still tolerably great."

This subject of relative accommodation is one that underlies the useful employment of spectacles in almost all the cases which present any difficulty; and therefore, as at first sight it seems a little intricate, I may perhaps be excused if I dwell upon it with some minuteness. In the observations from which Fig. 18 was taken, Donders found that his patient, when the eyes were directed to a point thirteen inches away, and when by the maintenance of single vision it was certain that the convergence remained unchanged, was still able to overcome—that is, to see clearly through—convex glasses of 2·50 dioptrics, and concave glasses of 4·0 dioptrics. He found, also, by further observations, that work could only be maintained at distances at which the concave glass which could be overcome was greater than the convex glass; or, in other words, while the power of increasing the accommodative effort was greater than the power of relaxing it. Inquiries of this kind are more difficult than would at first sight appear, because they require a young subject, in whom the full vigour of accommodation has not begun to undergo curtailment from age, and who, nevertheless, is trustworthy as an observer. Moreover, they require the use of a very elaborate optometer, such that for every degree of convergence the lenses used may be placed at right angles to the visual lines, and also with their centres exactly opposite to the centres of the pupils. If the latter condition were not fulfilled, and if the patient were suffered to look through the lateral parts of the lenses, these would at once exert a prismatic action, which would vitiate the experiment by producing a displacement of the apparent position of the object, and, therefore, a corresponding alteration in the direction of the visual lines. For a description of the optometer, I can only refer to the great work of Donders; and, concerning the trustworthiness of the subject who was employed, we have no other ground of judgment than such as is supplied by the fact that Donders himself appears to have been satisfied upon the point.

The next inquiries in the same direction were made by Dr. Loring, of New York; and it is impossible even to refer to them without a passing tribute to the extraordinary care and diligence with which American practitioners have entered upon investigations of this kind, and to the success which has crowned their efforts. Dr. Loring was not satisfied with the then accepted view of a sort of fast and loose relation between accommodation and convergence—a relation which was intimate but not essential, which was to be explained no one exactly knew how, and which could be relaxed within the wide limits which are shown by Donders' diagram. He thought it more consonant with physiology to believe that there must be a close relation or none; and he tested the phenomena of relative accommodation from this point of view. He first showed, by an ingenious experiment which I will describe almost in his own words, that the tension of the internal recti muscles is modified by every change in the accommodation, and that the reason why such increased tension of the interni does not modify the position of the visual axes is to be found in the opposition of the external recti, which also become more tense, and which act as inhibitory structures against convergence in order to maintain the fusion of the two images which is necessary to singleness of vision. The experiment was conducted by placing letters of Snellen's test-types, No. 20, at a distance of twenty feet from the observer, while a lighted taper was so arranged as to be at the same level with the letters, and as nearly as possible in the same plane. The eyes being then fixed upon the letters, the visual axes were practically parallel, and the tension both of the interni and of the ciliary muscles was at the minimum. Binocular vision having been proved to exist by means of prisms, concave glasses of gradually increasing strength were successively tried, until the power was found which the accommodation, with parallel visual lines, could no longer overcome, and with which, therefore, vision began to be indistinct. Concaves of 2·25 dioptrics were the strongest glasses through which vision was distinct for both eyes. With these glasses binocular vision was also apparently perfect, as there was not a particle of diplopia or spreading of the rays of light. The glasses represented, therefore, the amount of relative accommodation which could be called forth independently of convergence, for, as the visual lines were parallel, the tension of the interni was apparently at its minimum. If every increased tension of the ciliary muscle were to be attended by increased tension of the interni, it would at first sight appear that this increased tension would show itself by increased convergence, which would then be expressed by diplopia. There was no diplopia. Did the assumption of an increased tension of the interni therefore fall to the ground? By no means; for if, under the foregoing conditions, a coloured glass was placed before one eye, diplopia followed immediately, with homonymous images separated to the extent of twenty-three inches. If the two images were then allowed to coalesce, by lessening the tension of the interni, so that binocular vision was restored, the letters and light became indistinct, showing that by lessening the tension of the interni the observer lessened at the same time the tension of the ciliary muscles, so that the concave glasses could no longer be overcome. The same result followed when weaker glasses were employed, only the separation between the images was not so great. With — 2·25, as already said, the images were separated 23 inches; with — 1·75, 12 inches; with — 1·25, 3 inches; with — 1·0, the images overlapped each other. With any weaker glass, actual diplopia was not produced; but with — 0·75, if a point of light was used instead of the flame, there was a perceptible widening of the point. The fact that the distance between the images corresponded with the strength of the glasses is very significant, and lends support to the belief that for every degree of tension of the ciliary muscle there is a corresponding degree of tension of the interni; while the reason why there was no diplopia with very weak glasses was evidently because the tension of the ciliary muscle in overcoming them, and consequently the corresponding tension of the interni, were so slight as not to be appreciable with the coarse test employed.

The explanation of the above-described phenomena is very simple. In order to overcome the concave glasses a certain amount of increased tension was required of the ciliary muscle. This latter contracted under nervous influence, and vision became distinct. If it be true that all nervous action imparted to the ciliary muscle is extended to the interni, then the impulse which called the ciliary muscle into contraction would be so extended, and an increased tension of the interni would be the result. The equilibrium between interni and externi (which was perfect before this increase took place) would necessarily be destroyed, and there would be a preponderance in favour of the interni proportionate to the increase of tension in the ciliary muscle. If such preponderance were produced, it ought to declare itself under the well-known test of the coloured glass and prism. We place the coloured glass before one eye (both eyes being, of course, still armed with the concave glasses), and homonymous double images are the result—proving, beyond doubt, the existing want of equilibrium.

It may be objected to the above reasoning that, when the eyes simply look through the concave glasses, the tension on the ciliary muscle, in order to overcome them—and, consequently, the tension extended to the interni—is just as great without the coloured glass as with it; and that the eye would have the same tendency to turn inwards whether the coloured glass were employed or not. This is true; the tension on the ciliary muscle, and that communicated to the interni, are just as great, and the tendency for the eye to turn in is also just as great, in

the one case as in the other; but this tendency is resisted and overcome by a factor which is in full force when the eyes are looking through the concave glasses alone, but which ceases to exist the moment the coloured glass is added. This new factor is the intuitive desire for single vision with the two eyes. So long as the images on both retinæ are equal in intensity, the desire for each eye to perform its share in the common act of vision is so great that every attempt to destroy this by a change in the direction of the optic axes is at once vigorously opposed. As soon as the increased tension of the ciliary muscle (called forth in order to overcome the glasses) is extended to the interni, the change in the visual axes, which would be the natural result, is counterbalanced by the desire for single vision, which, in this case, can only be retained by the agency of the external recti, the natural antagonists of the interni. Thus the equilibrium of the muscles, which would be destroyed by the increased action of the interni, is reinstated and maintained by a correspondingly increased action of the externi. As soon, however, as the image on one retina is reduced and altered, by placing the coloured glass before one eye, the instigation towards single vision is removed; and as soon as the desire ceases, the necessity for the muscular effort, by means of which the desire was fulfilled, ceases also; or, more plainly, the externi cease to act. Their relaxation destroys the equilibrium between the opposing muscles in favour of the interni, and homonymous images are the result. We have only to remove the coloured glass, or, in other words, to restore the power of, and with the power the desire for, single vision, and the homonymous images immediately become united; thus proving that when the eyes look through the concave glasses alone there is the same tension of the interni, and the same tendency for the eyes to become convergent, as when the coloured glass is added, but that this tendency is counteracted by the desire for single vision. Dr. Loring next turned his attention to the influence of increased convergence-effort upon the ciliary muscles. Making his own eyes the subject of experiment, he found, on directing them to a point eighteen inches distant, that he was able to maintain distinct and single vision through either concave or convex glasses. He took as his object a word printed in the smallest type which he could read at the specified distance, so that any imperfection in the image would immediately make itself felt, and he found that the strongest convex glass which he could overcome was one of 1·75 dioptrics, and the strongest concave was one of 2·50 dioptrics. This gave him a total of 4·25 dioptrics of relative accommodation—that is to say, of power to vary the accommodation while the convergence position remained unchanged. The convex of 1·75 dioptrics showed the extent to which the accommodation could be relaxed, or the negative part of the relative range; and the concave of 2·50 dioptrics showed the extent to which the accommodation could be increased, or the positive part of the relative range. The conditions are shown in diagrammatic form at A, Fig. 19, where O represents the object of vision and the point to which the visual lines are directed, O *p* the positive part, and O *r* the negative part, of the relative accommodation. So far, as in the earlier portion of the former experiment, the results appeared to bear out the view expressed by Donders. But Dr. Loring found, when he placed a prism of 5° with its base outwards before each eye, by which the convergence was increased, that, although the object still remained distinct, it could not be said that the accommodation remained unchanged. The strongest glass for which the accommodation could be relaxed was then 1·50 dioptrics, but it could be strengthened to overcome 3·0 dioptrics. The whole amount of relative accommodation was therefore increased from 4·25 to 4·50 dioptrics, and at the same time the proportion between its two parts was wholly changed. The object, instead of lying at the intersection of the optic axes, and at the line of division of the positive from the negative accommodation, was beyond the intersection, and wholly within the negative part of the range, as shown in Diagram B, Fig. 19. These changes in the conditions of the relative accommodation are exactly similar in kind, and very nearly identical in degree, with those which would follow if the eyes were rendered convergent to twelve inches naturally, instead of by means of prisms. When stronger prisms were employed—say of 10°—the changes which took place were the same in kind, but greater in degree. A convex of 1·25 dioptrics was then the strongest glass through which the object remained distinct, but a concave of 3·50 could be overcome, making the total relative accommodation again equal to 4·25. This is shown in C, Fig. 19. When the prisms were 12·5 the convex glass was 0·75, and the concave 4·0, the entire relative accommodation being 4·75, as shown in D, Fig. 19. When the prisms were 15, the accommodation could not be relaxed at all, even for so weak a glass as 0·50, which made vision indistinct. Hence the positive part of the relative accommodation became constantly smaller as the strength of the prisms was increased, until (in E, Fig. 19) the accommodation is all negative. And whereas, in the first diagram, the object was in the middle of the range, or at the very beginning of the negative portion of the accommodation, it ultimately came to lie at the farthest extremity of this portion. If now, instead of increasing his convergence by turning the bases of the prisms outward, Dr. Loring lessened it by turning them inward, a result identical in kind followed, only the optic axes intersected farther from the eyes, and the relative accommodation was likewise removed, and the proportions between its positive and negative portions modified. Fig. 20 represents the various changes produced by the prisms, the bases being placed inwards. Weaker prisms were employed in this case, as the optic axes are rendered parallel by prisms the united angles of which amount to 15°. Consequently, those were used whose united angles amounted to 5°, 10°, and 15°; instead, as in the former case, of 10°, 20°, and 30°. It will be seen that just as O was in the former arrangement always within the negative portion of the relative accommodation, so in the second series of experiments it was always within the positive portion; and just as *r* with increased convergence gradually descends to O, so *p* under diminished convergence ascends to O. It is very true that the object was distinctly seen at the same distance with all these different degrees of convergence; but this does not prove that the accommodation had not been modified, for with every alteration in the convergence there was a manifest and calculable modification of the accommodation, equalling in the aggregate a convex glass of 4·75 dioptrics. The reason why the object remains distinct while the convergence is changed by prisms is not because the accommodation has not been modified, but because the object remains within the limits of the modification; or, in other words, within the *region* of the relative accommodation, notwithstanding the alteration in convergence. From Fig. 19 it is evident that the convergence may be increased at pleasure, and yet the object will be distinctly seen as long as it remains in the region represented by the negative portion of the relative accommodation—that is, till *r* descends to O; while, on the other hand, Fig. 20 shows that the convergence may be diminished until *p* ascends to O. When, however, in either case, O passes outside the limits of the relative accommodation, the object at once becomes indistinct.

By the results of these experiments, Dr. Loring may, I

Fig. 19.

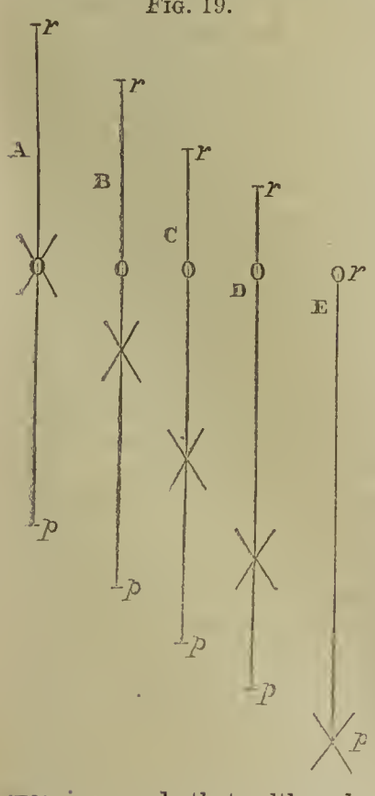


Fig. 20.

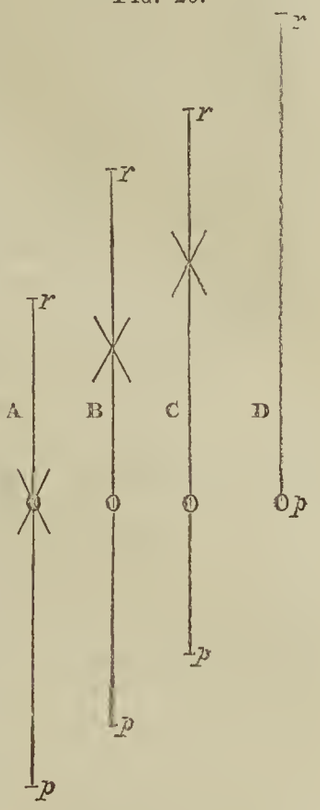

think, be taken to have proved that the earlier notion of an essential dependence between the ciliary muscle and the interni represents, at least, the physiological condition, and that the independence observed by Donders and others is more apparent than real; depending, in the case of the interni, upon the inhibitory action of the externi, and, in the case of the ciliary muscles, upon the latitude given by the extent of the range of relative accommodation. Muscular action, however, when regarded as a source of exhaustion or fatigue, must not be measured by the effect which is produced, but by the force which is exerted, and, when looked at from this point of view, I think we shall find, in the intimate and essential harmony between accommodation and convergence, and in the occasional disturbance of this harmony by the variations of either function, a full and sufficient explanation of many of the states which are productive of painful limitations of vision, and a key to their successful treatment. To these states, under the general name of asthenopia, I shall have to direct attention in a subsequent lecture.

ORIGINAL COMMUNICATIONS.

THREE CASES ILLUSTRATING SOME OF

THE VARIOUS RESULTS OF ROTATION OF OVARIAN TUMOURS.

By J. KNOWSLEY THORNTON, M.B., C.M.,
Surgeon to the Samaritan Free Hospital for Women and Children.

The three following cases illustrate so well the very different results of twisting of the pedicle of an ovarian tumour, that I think they are worth recording together. It is beyond my purpose to review the whole subject of twisting of the pedicle. Those who wish to see the present state of our knowledge will find some interesting cases and remarks on the subject in the works of Mr. Spencer Wells and Dr. Peaslee. I will first give a brief sketch of the three cases I have met with, and then endeavour, by comparing them, to bring forward some special points which may be of interest and value to us in the treatment of similar cases.

Case 1 has already been tolerably fully recorded in the twenty-seventh volume of the *Transactions of the Pathological Society*, so I will only briefly give its chief features here. The patient was twenty-eight years of age, pregnant four months and a half with her second child, the other being only fifteen months old. She was a bright, fresh-coloured, healthy little woman, but was suffering much inconvenience from the presence of an ovarian tumour along with the enlarged uterus. The cyst was in the right side, and freely movable; the uterus lay to the left and behind it. She was placed under Mr. Wells' care at the Samaritan Hospital by Dr. Parsons, of Wimbledon, and I tapped the cyst and removed ten pints of ovarian fluid on October 19, 1875. She suffered from cyst-inflammation after the tapping, and on the 26th, when turning over on to her left side, was suddenly seized with violent pain in the abdomen. I was sent for, and found her in a state of collapse. She got through the night tolerably well with frequent opiates and free stimulation, but in the morning was so ill that, after consultation with Dr. Savage (Mr. Wells being out of town), I advised immediate ovariotomy, to which she eagerly assented, saying she felt she was dying. The operation could not be performed till the afternoon, and she was then so ill I thought she would have died in my arms as I lifted her on to the operation-table. On opening the abdomen, I found the enlarged uterus in its normal position, surrounded by intestines much distended with gas, and the cyst, in a gangrenous condition, lying behind and to the left of the uterus. The pedicle was three times twisted on its axis; this twisting and the position of the cyst quite shutting off its blood-supply. There were no adhesions, but there was some red mawkish-smelling serum in the peritoneum, and its surfaces were dark and congested—a low, diffuse, and non-adhesive peritonitis. The patient rallied after the operation, and was bright and cheerful, and able to talk to her husband; then again fell into a state of collapse, and died in sixteen hours. It is worthy of remark that, during the whole illness, cyst-inflammation and gangrene, ovariotomy and death, there was no sign of abortion, and the child was alive a few hours before the operation.

Case 2.—An unmarried girl of twenty-four was sent to the Samaritan by Mr. Stevens, of Hoddesdon, Herts, in December, 1876. She resembled the last patient in being fair, with full colour and appearance of robust health. Six months before admission she had suffered from severe pain in the right iliac region during menstruation. This had recurred at the three following monthly periods, but less severely after the second attack. Mr. Stevens sent her to Mr. Wells, who discovered a small, firm, movable tumour on the right side, but was doubtful as to its nature. She came under my care on December 18, in the absence of Mr. Wells, and I kept her under observation for a month. At this time the pain at the periods was less severe, and the tumour increased but little in size; but ascitic fluid gathered somewhat rapidly round it, and her general health was beginning to suffer. On January 24, 1877, I performed ovariotomy, and on opening the abdomen found a dark-brown somewhat flaccid tumour on the right side (having much the appearance of liver), surrounded by brownish serum, free in the peritoneum. Some slight filmy adhesions to the cæcum were ligatured and divided, and the cyst tapped, dark tar-like fluid blood escaping from it. The cyst-wall was soft and sodden, and broke under the claws of the trocar. A short pedicle was then seen on the right side, tightly twisted twice on its axis; it was untwisted by turning the tumour round and round from behind forwards; it was transfixed, and ligatured in two halves, though it was so bloodless that I think it might have been simply cut and left without fear of hæmorrhage. The left ovary was represented by a small group of pediculated cysts, like a bunch of grapes; it was also removed after its pedicle had been transfixed and tied. The patient made a rapid recovery, the highest temperature recorded after the operation being 99·6° Fahr. The tumour proved on examination to be a multilocular one, all the cavities containing dark thick fluid blood, and the structure of their walls so destroyed by infiltration of blood that nothing but broken-up fibrous tissue, blood corpuscles, and granular *débris* could be found under the microscope.

Case 3.—An unmarried girl of nineteen was brought to me by Dr. De Lacy Lacy. She was a delicate, sallow-looking girl. On examination I found the abdomen large and distended, most markedly below the umbilicus, presenting on inspection the typical appearance of an ovarian tumour. No cyst-movement could be detected on deep inspiration, and dulness was continuous on the right side from the liver to the pubes, and was only interrupted on the left by what appeared to be the stomach and some adherent intestine. Both flanks were resonant. The uterus was anteflexed, and pressed down by the tumour, and closely connected with it. My diagnosis was ovarian tumour closely adherent to the parietes and closely connected with the uterus, there being no evidence as to the side from which it sprang. Mr. Spencer Wells kindly saw the patient with me, and agreed with my diagnosis. This patient had been tapped a year before I saw her, and twelve pints of greenish-yellow fluid had been removed. She recovered well after the tapping, and from first to last had never suffered any pain in the abdomen. I would call attention, especially, to complete absence of pain as of great interest when we consider the condition found at the operation. I performed ovariotomy on March 21, 1877, at the Samaritan Hospital, and was fully prepared for a difficult operation; but it exceeded all expectation. It was impossible to find any separation between the tumour and the parietes, even after my original incision of four inches had been prolonged to eight; and a large patch of parietal peritoneum was unavoidably removed on the left side before I could find any point at which to commence separating it from the tumour. I then found the cyst firmly adherent to everything it touched—parietes, omentum, mesentery, intestines, stomach, spleen, and liver. Both ovaries were involved in the tumour, and united behind the anteflexed uterus. The cyst-contents were pus and large masses of yellow lymph, which also lined all the cyst-cavities with a thick layer. The adhesions were everywhere firm and fibrous, evidently not recent. I at last freed the tumour below, after ligaturing and dividing two thick, twisted pedicles, which proved to contain the Fallopian tubes, etc. I was obliged eventually to leave portions of the cyst adherent to the spleen and liver, and both organs were somewhat peeled of their capsules. The patient seemed likely to do well for thirty-six hours, and passed a fair quantity of clear urine of good colour; then suddenly the kidneys ceased to act, and she died comatose at the end of another thirty-six hours, during which only about an ounce of urine was secreted, in spite of constant endeavours to restore the action of the kidneys.

When the tumour was examined after removal it was seen to be a large, single, rather thick-walled cyst, lined throughout by a thick layer of yellow lymph, which was also hanging into the interior in ragged membranous masses. When this material, which adhered very firmly, had been scraped off, the wall was seen covered with a dark red granulation material, and softened and friable, evidently in an actively inflamed state. Both ovaries were firmly attached to the posterior and under surface of the cyst, its peritoneal surface and theirs thick and opaque, and so smoothly continuous it was impossible to say to which ovary the tumour really belonged. The right ovary was smaller than normal, and very intimately blended with the base of the tumour, the left being plump and round, rather larger than usual, and containing healthy Graafian follicles. Both the pedicles were tightly twisted two times and a half on their axes, and in the same direction. Between the left ovary and the twisted pedicle, a small, clear broad ligament cyst about the size of a small marble was growing. No trace of the fimbriated extremity of either Fallopian tube could be found, but both pedicles were much thicker (nearly an inch in diameter) at their ovarian, and tapered towards their uterine attachments, forming, in fact, dense twisted cones of fibrous tissue, with the open ends of the tubes and vessels still to be seen when they were cut across. The compound mass which I have attempted to describe might have been either a multiple cyst of the right ovary in which the septa had disappeared; a unilocular cyst of that ovary; or an extra-ovarian cyst. I should have been inclined to adopt the latter view as most probable had the uterus not been entirely free from the tumour, except in so far as it was attached by the uterine ends of the pedicles. Had the cyst been a broad ligament, one pushing up between its layers, and thus becoming attached to both ovaries, the surface of uterus also attached must have been very extensive, and no twisting of the two pedicles would have been possible. I think the true explanation probably lies in considering the cyst as springing from the right ovary inflamed after tapping, and then adhering to the left ovary—the rotation occurring after the cyst had thus acquired its two pedicles,—a subacute inflammation, started by the tapping and increased by the rotation, continuing as the cyst gradually filled and distended the abdomen, and causing adhesion to each organ it came in contact with.

In the three cases the twisting of the pedicle led to very different results, not only before the operation, but during its performance and afterwards. I think we may trace the chief difference to the fact that two of the cases had been tapped. In them the effects of the twisting of the pedicle were very serious, though with well-marked differences.

In Case 1 tapping undoubtedly caused inflammation in the cyst; with the presence of more blood with imperfect circulation, fluid was rapidly secreted again, and the cyst became heavy, but before it was large enough to steady itself by its size, twisting commenced. This, of course, increased the inflammatory action and the weight of the cyst by hindering the flow of the venous blood. Then, before it was large enough to steady itself by contact with the parietes and surrounding organs, a sudden turn of the patient caused it to fall over and behind the pregnant uterus, and inflammatory congestion passed into gangrene. Twenty hours later the removal of the tumour and the fluid in the peritoneum which its presence had caused was already too late to save, though it undoubtedly prolonged life, and gave the patient a few precious hours of comfort, consciousness, and hope. Tapping in this case was clearly the cause of death; and I think, when we compare it with Case 2, the question at once suggests itself—Was there not something added to the simple inflammation? I will try and answer this question after considering the other cases.

In Case 2 I believe the cyst was as dead as in Case 1, and it was full of tar-like blood, and yet it remained for weeks inert in the abdomen, and only slowly, as its more fluid portion found its way into the peritoneum (which seemed incapable of absorbing it), did it affect the patient's health. It did not in itself possess sufficiently irritating properties to cause peritonitis and adhesions of neighbouring organs, and yet it must have been intensely inflamed before it became a multilocular blood-cyst, with sodden fibrous walls infiltrated with disintegrating blood. In Case 3, so far as we can read it, the sequence of events appears to be tapping, some inflammatory action, adhesion of cyst to other ovary, twisting of the mass with its two pedicles, and a prolonged and tolerably severe inflammation, causing adhesion to all neighbouring organs; the remarkable feature being that all this took place gradually and painlessly.

In Case 2, with the acute attacks of pain from which the patient suffered, one might have expected much adhesion, and there was none. How are we to account for these differences? I think it appears as if the more rapid and entire cutting off of the blood-supply, the acute process, with complete death of the tissues, is the least dangerous, provided there has been no tapping to complicate matters. In the more chronic process the whole substance of the cyst is inflamed, and still alive, and it attaches itself to all neighbouring parts by which it may maintain its life.

I cannot but think that in Case 2 the operation was happily performed when it was; for a mass of tissue such as I have described could hardly have ultimately been disposed of by nature unaided.(a) In the other two, I think, tapping must be credited with rendering two cases favourable for ovariotomy so unfavourable that the latter operation, when performed, could only be said to have failed to avert speedy death.

We may evidently have twisting of pedicle, either with or without tapping; but if the latter, it is a far more serious complication, and I think we must look to some septic mischief admitted from without to explain the difference.

No satisfactory explanation of the cause of rotation in these cases has been found, but I think it is possible that the peristaltic action of the intestines may start the process. A cyst flaccid after tapping and free from adhesions might be gradually turned over by the movements of the intestines; and so might a small tumour with a fair length of pedicle. The twist once started, the pulsations in the twisted cord would tend to increase it. This explanation would, I think, explain the most recent contribution to this subject. I refer to the case published by Dr. Malins, of Birmingham, in the *Lancet*, April 14, 1877. If the case is complicated by pregnancy, the fœtal movements may also play an important part.

CASE OF

POPLITEAL ANEURISM IN THE LEFT LEG, CURED BY PRESSURE,

FOUR YEARS AFTER SIMILAR DISEASE IN THE OTHER LEG.

By E. L. HUSSEY,

Senior Surgeon to the Radcliffe Infirmary, Oxford.

A MAN, about thirty-four years of age, rather below middle stature, a plate-layer on a railway, was admitted into the Radcliffe Infirmary, Oxford, on March 14, 1877, under my care, with an aneurismal swelling or enlargement of the popliteal artery of the left leg, about the size of a common hen's egg. It was hard, and could not be emptied by direct pressure. The deep parts around it in the popliteal space were somewhat thickened, and rather served to obscure the extent and character of the enlargement of the vessel. The pulsation can be stopped by making firm pressure over the femoral artery in the middle of the thigh; it is more easily stopped by making pressure in the groin. It is checked by bending the leg at the knee, but not completely controlled.

Upon examination made of the chest by Dr. Acland, a strong double blowing sound is heard over the region of the heart, extending along the course of the aorta and the innominata; but not any ordinary aneurismal whiz. In other respects the patient seems to be in good general health.

He had been under my care in July, 1873, with aneurism of the popliteal artery in the other limb (the right). This was cured by pressure. The particulars of the case are given in the *Medical Times and Gazette* of May 15, 1875, page 522.

History.—In the summer of last year, without previous symptoms to attract his attention, he was passing his hand down the back of his left leg, and found a small swelling under the knee. On making pressure with his fingers he found that it beat or throbbed in the same manner as the former swelling in the other leg. During the winter the foot was much swollen, and he suffered at times from pain in the back of the leg. The throbbing in the tumour was not continuous; it sometimes intermitted for several days. The swelling did not increase much in size, or did not seem to him

(a) There are undoubtedly cases on record in which a shrivelled fibrous mass, the remains of an ovarian tumour with twisted pedicle, has been found after death; but I think these must have been smaller tumours, and destroyed by the more gradual process with adhesions.

to be so large as the former aneurism in the other leg. He did not suffer from cold in the left foot, as he had in the right. Toward the end of February he became unable to continue at his work, and he applied to Mr. Drinkwater, of Bicester.

On Saturday morning, March 3, Mr. Drinkwater applied a tourniquet over the femoral artery in the middle of the thigh, and left the management of it to the patient himself. The tourniquet was kept on the thigh during the whole of the night; but the throbbing in the tumour was not completely stopped at any time by the pressure. The next morning the patient removed the tourniquet. During the two or three following days it was re-applied at different times, and for varying periods.

On Monday, March 12, a bag filled with sand and pieces of iron, weighing five pounds and three-quarters, was placed in the groin over the artery, and kept in position, under the superintendence of Mr. Drinkwater, by a relay of assistants, and at times by the patient himself. This was continued without intermission for eight hours. The pressure was attended with great pain in the leg and foot. The throbbing was not effectually stopped during the pressure. The pulsation continued after the weight was removed. Under Mr. Drinkwater's advice the patient came to the Infirmary for further treatment.

At the time of admission the skin of the thigh and groin seemed to be too tender to bear further pressure; the patient was therefore ordered to remain in bed, with the limb bent at the knee and resting on a pillow. By degrees he became able to bend the leg fully, so as to bring the heel almost to the tuber ischii, and to keep it in that position for several hours at a time. The pulsation in the swelling was checked, but never completely stopped.

March 19.—A large compress of flannel was placed under the knee upon the popliteal space, with the intention of making additional pressure upon the tumour; and the leg was bound, in the bent position, to the thigh by several turns of a flannel roller. The compress produced so much pain in and around the knee that the patient removed it in the course of the night. The large veins of the leg and thigh were observed next day to be distended; the roller was therefore removed, and the patient was trusted to keep the limb fully bent, the best way he could, by his own efforts.

On the 26th, about eleven o'clock in the morning, a narrow bag of canvas, having the pointed end filled with sand, was loaded with shot (to the weight of eleven pounds and a half), and suspended from the rod which supported the curtains at the head of the bed. A piece of wash-leather was laid loosely over the groin, and the weight, placed upon the artery where it passes over the pubes, was trusted to the patient, as on the former occasion. With the weight in position, the circulation was fully controlled. The pressure was continued with more or less efficiency during the day and in the night. The weight was not easily kept in place over the artery, nor was the pulsation in the tumour completely stopped with the limb in the bent position. After a trial of two or three hours the bent position was abandoned, and the limb was allowed to rest in an easy position, lying rather on its outer aspect.

About three o'clock in the following morning the patient thought that the pulsation in the tumour had ceased, and he took the weight off the groin. After breakfast he found the beating had returned, and he replaced the weight. In the middle of the day the swelling was examined by the house-surgeon. He found that the pulsation had ceased altogether, and he removed the weight. From this time there was not any return of it.

Although the patient was an intelligent man, taking an interest in the treatment, he became restless under a continuance of pain and confinement. A pill with morphia was given to him before the weight was put in position; it was repeated during the day and again at night. During the treatment morphia in solution was also several times injected under the skin.

On April 7 the patient was allowed to get out of bed, and to lie on the settle in the ward. He found the left foot to be much colder than the other, and he put on two worsted stockings.

He left the Infirmary on the 18th, able to walk well. The swelling in the popliteal space was much smaller than at the time of admission, hard, and not compressible. The anterior and posterior tibial arteries could not be felt at the ankle or in the foot.

Remarks.—In the former case (in the right leg) the aneurism was cured by rapid pressure, under which the flow of blood through the femoral and popliteal arteries was completely stopped during the treatment. In the present case a longer time was taken, and the exact period cannot be stated with accuracy. The pressure applied before the man came to the Infirmary helped, no doubt, in the cure.

Oxford.

A CRITICAL REVIEW OF THE

PREVAILING THEORIES CONCERNING THE PHYSIOLOGY AND THE PATHOLOGY OF THE BRAIN:

LOCALISATION OF FUNCTIONS, AND MODE OF PRODUCTION OF SYMPTOMS.

By EUGÈNE DUPUY, M.D. Paris, of New York;
Corresponding Member of the Paris Société de Biologie; Member of the American Neurological Association, etc.

Part I.

(*Concluded from page* 34.)

I HAVE come to the point where I must show that the last hypothesis of Drs. Ferrier and Hitzig, supported by pathological facts of Professor Charcot and his pupils, is only acceptable as any other former hypothesis; and even with less credit than the one with which Flourens has been accredited in science. I refer to the theory which maintains that the cortical motor centres are centres for movements *willed, executed towards an end, non-automatic.* Dr. Ferrier writes:—"It may be confidently asserted, and perhaps it may one day be resolved by experiment, that any special tricks or movements which a dog may have learnt could be effectually paralysed by removal of the cortical centres." That is equivalent to saying that all actions which are not automatic are impossible after removal of cortical centres. But even that hypothesis has no more value than the others; it is destroyed by facts. The experiment of Goltz previously cited is against it. I have between 1873 and 1876 had quite a number of dogs and cats under experiment, and I have *invariably* found these animals capable of using their would-be palsied limbs, not only for purposive voluntary movements, but for tricks. I remember a dog which would give the paw when asked, and stand on his hind legs and make salaams. I believe, therefore, that the counter-experiments which I have brought forward do not tend to show that the cortex cerebri is excitable by electricity, and also that certain convolutions in the neighbourhood of the Sylvian fissure and the fissure of Rolando contain psycho-motor centres composed of cells of grey matter.

Anatomy, normal and morbid, has furnished a good array of facts, which are brought forth to support the doctrine of localisation. That kind of evidence has been adduced chiefly by Professor Charcot and his pupils. I refer also to the discovery of giant-cells in the paracentral lobule by Betz and Mierzejewski. There is, however, no proof that those cells are motor. They are said to be motor; they are pyramidal, resemble those of the anterior horn of the spinal marrow, and they are found in a locality which is said to be motor—the paracentral lobule. But is that not again a *petition de principe?* For this is the argument: the paracentral lobule is a motor centre because it contains pyramidal cells which are motor. The pyramidal cells which are in the paracentral lobule are motor because that lobule is motor! That is the logic which has led to the adoption of the doctrine of localisation of functions on anatomical basis—from Luys and Meynert to Professor Charcot. But Professor Charcot has also pathological cases of the same nature as those of Hughlings-Jackson and Hitzig. I have not been able to collect all the cases reported, but I have carefully analysed those which are collected from different authors and gathered in the pamphlet of my friend Dr. Lepine.(a) I have found that there were *several lesions* in all the brains examined—lesions situated in *different parts* of the cerebrum. The convolutions, the crown of Reil, the several ganglia of the corpora striata and thalami optici, the pons, etc., were found diseased in both hemispheres sometimes. Yet those cases are given as proofs of the accuracy of localisation! The only reasoning which can have led to the rejection of all other lesions but those found in the convolutions of the paracentral lobule, in order to explain the production of the paralyses observed during the life of the patients, is the same through which the conclusion was gained

(a) Lepine, "Des Localisations Cérébrales," Paris, 1875.

that the said lobule is motor and that its cells are motor, and which I have just reported above; in fact, another *petitio principii*. Every one of the *other* lesions found in the brains examined, of those observations gathered in Dr. Lepine's pamphlet, have been known to produce paralysis—at all events, to have been found associated with paralysis. Why not ascribe to them also the phenomena observed during the life of the patients? There is no room for the statement that the great seeming relation of cause to effect which exists in the cases of lesions of the convolutions warrants the inferences drawn; the frequency of apparent relation of cause to effect is just as great (I was going to say greater) between the other lesions and the symptoms produced. The other cases, reported by other physicians as "illustrating the new discoveries of motor centres," etc., I found equally liable to the same criticism. Dr. Lepine has somewhere in his pamphlet said what is in the mind of all advocates of localisations, about aphasia—*i.e.*, that instead of looking out for cases of aphasia where there was no destruction of the insula or destruction of other parts, we ought to collect all the cases where there is disease of the convolutions of the insula, as the number would soon prove the localisation of speech beyond dispute. I believe now that that wish is accomplished. Cases are only reported partially, and only those which substantiate localisation; or when cases contain elements of both kinds (for and against), only those lesions which are supposed to bear out localisation are laid stress upon.

Another argument, however, has been adduced from his pathologieal eases by Professor Charcot.(b) It is, that disease of the paracentral lobule is accompanied by descending atrophy, which destroys those bundles of fibres supposed to be the conductors of the orders of the will to the muscles; and as, according to Professor Charcot, such descending atrophy is only met with in that region, therefore the eonclusion seems to force itself that the cells of the *cortex cerebri* are the centres of innervation of those degenerated bundles of fibres.

That theory cannot be entertained more than the others, notwithstanding the would-be elaborate logical inferences. It is, in essence, another example of begging the question. I explain. There are two systems of tissues to be considered here—the nervous and the connective (whatever may be the nature of this last, practically it must be considered as different from the first). The nervous tissues receive their blood-supply from vessels which penetrate into the cortex and somewhat deeper into the white matter from above, and from the arteries external of the ganglionic masses later in their progress; the connective tissues are fed by bloodvessels and capillaries, which are made up of anastomoses coming from the opto-striated system of arteries. It is now easy to understand how one kind of tissue can be *primarily* effected. To say nothing of former pathologists, let me remember that in a very elaborate paper Miezcrjewski(c) has again shown that in general paralysis, for instance (which gives rise to that kind of paresis which most resembles the one produced by destruction of so-called psycho-motor centres), the nerve-tissues become diseased only secondarily. Their supporting elements becoming diseased, they become altered and impaired. There is no temerity at all in asserting that there is no relation of cause to effect, coneerning the place where the disease of the supporting connective tissues is found, and nutritive disorder which has brought it on. Disease of the connective tissues follows no laws as to *direction* of its progress. The eases of Professor Charcot, therefore, I believe give no additional proofs that the atrophy of the fibres arose from disease of the convolutions with which they were connected. We are left in the dark as to the functions of the bundles of fibres destroyed, and unless we assume that the convolutions with which they were connected were *motor*, we cannot say what were their functions.

But it may be said that if those fibres were not motor, some other function which they did subserve would have been found impaired—which was not the case, as only motion was lost. Granted; but what physician does not know that parts can be destroyed, and yet no outward symptoms be produced? It is true that lesion of the *internal capsule* is always accompanied by loss of sensation. But the *internal capsule* is not a centre; it is only a tract of nerve fibres; it contains, moreover, blood-vessels, whieh traverse it, and go to some other region. When those fibres are destroyed, the bloodvessels are also destroyed. How can we know whether the symptoms which we observe in that case do not arise from the consequent impaired nutrition of the parts supplied by those vessels, and on the reflex or inhibitory actions which might then result? This point ought to be cleared.

Dr. Ferrier has, I am afraid, missed a fine opportunity of exercising his critical judgment through one-sidedness, when he has adduced as an argument, "*sans réplique*," the famous and much-to-be-regretted experiment of Dr. Roberts Bartholow, of Cincinnati. I am at a loss to discover how such an inaccurate observation (not to say more) can have captivated him to the point that he has laid stress upon it. He evidently believed that it constituted a good proof that irritation of the *cortex cerebri*(d) in man, in regions corresponding anatomically to the motor centres in the brain of monkeys, also gives rise to movements on the opposite side of the body.

Let us see. The experiment of Dr. Roberts Bartholow is the following, in his own words (as little abridged as possible, because I doubt that all those who quote it have read it); it is entitled "Epithelioma of the Scalp of Thirteen Months' Duration; Exposure of the Dura Mater; Experiments on the Function of the *Posterior Lobes*" (*sic*) (e):—"The part of the brain uncovered was about two inches in diameter in the postero-parietal region. The edge of the ulcer is thickened and hard; the excavation secretes a great quantity of pus. *Portions of brain-substance have been lost by injury or by the surgeon's knife, and as the brain has been deeply penetrated by incisions made for the escape of pus*, it was supposed that fine needles could be introduced without material injury to the cerebral matter. The needles being insulated too near their points, it was believed that diffusion of the current could be restricted. Observation 3. *Passed an insulated needle into the left posterior lobe, so that the non-insulated portion rested entirely in the substance of the brain.* The other insulated needle was *placed in contact with the dura mater*, within one-fourth of an inch of the first. When the circuit was closed, muscular contractions of the right upper and lower extremities ensued, as in the preceding observations; faint but visible contraction of the left orbicularis palpebrarum and dilatation of the pupils also ensued. Mary (the patient) complained of a very strong and unpleasant feeling of tingling in both right extremities, especially in the right arm, which she seized with the opposite hand and rubbed vigorously. The needle was withdrawn from the left lobe, and *passed in the same way into the substance* of the right. When the current passed, precisely the same phenomena ensued in the left extremities, and in the right orbicularis palpebrarum and pupil. When the needle *entered the brain-substance*, she complained of acute pain in the neck. In order to develope more decided reactions, the strength of the current was increased by *drawing out the wooden cylinder one inch.* When communication was made with the needles, her countenance exhibited great distress, and she began to cry. Very soon the left hand was extended as if in the act of taking hold of some object in front of her; the arm presently was agitated with clonic spasms; her eyes became fixed, with pupils widely dilated; lips were blue, and she frothed at the mouth; her breathing became stertorous, she lost consciousness, and was violently convulsed on the left side. After another experiment the patient remained in bed, and was stupid and incoherent; in the evening she had a convulsive seizure. She afterwards had profound unconsciousness, was paralysed on the right side of motion and sensation, had convergent strabismus. Autopsy: Before making an inspection of the needle wounds, the brain was placed for twenty-four hours in a solution of chromic acid. When sufficiently hardened, careful horizontal sections were made of the upper part of the hemisphere, to ascertain what injury, if any, had been done to the cerebral matter. *The track made by the needles could be distinctly traced on both sides.* On the left side the needle had entered the upper parietal lobule of Ecker, the gyrus centralis posterior of Henle, the postero-parietal lobule of Turner, one inch from the longitudinal fissure, *and had penetrated a depth of one inch.* The track of the needle was marked by some diffluent cerebral matter, two lines in diameter. On the right side the needle had entered the same convolution, but more posteriorly and one inch and a half from the great longitudinal fissure. *The needle on the right side had also penetrated to a greater depth, one and a half inch*, and its track through the lobe was marked as on the other side by a line of diffluent matter."

I have used Dr. Bartholow's *own phraseology all through* in order to be more accurate. I only beg the reader to notice that the needles being insulated up to their extremities and introduced to a depth of one inch and a half *into the substance of the brain, which had so much suffered by the surgeon's knife, etc.*, the aim of the experiment has been lost sight of, *as no cortical matter could possibly have been irritated.* I refrain from any kind of comment whatever. The case *in all its aspects* speaks too eloquently for me to say anything. This is the *experimentum in corpore vili* of which Dr. Ferrier has written(f)—"In addition to the pathological evidence of the existence of differentiated motor centres in the human brain supplied by the observations of Hughlings-Jackson and others, we have the experimental confirmation of the same in the investigations of Dr. Bartholow"!

I have another side of the question of localisation yet to examine. I have to speak of the centres of sensation, common and special. The localisation of the different senses is not supported by such an array of pathological facts as those regarding the motor centres. The sense of sight Dr. Ferrier localises in the angular gyrus. The experiments performed by him are of two sorts: he has irritated with electricity and destroyed with a cautery the area of the angular gyrus —the seat of the sense of sight. When he has used electricity, he has seen general movements of the head to the opposite side, and very often contraction of the pupils. These phenomena, he thinks, are purely reflex, consequent on the excitation of the subjective visual sensation. On destruction of the angular gyrus in both hemispheres, however, the loss of vision is complete and permanent (his animals did not survive long). I repeated the last-named experiment some time during the summer of 1875. I was successful enough to keep one dog alive several weeks, in the laboratory of the Muséum in Paris. Although the animal did not distinguish objects at first, he could see perfectly well at the end of that time. He *had his pupils widely dilated;* they returned gradually, with alternations of contraction and dilatation, to the normal state. At first no light could make them contract. In human pathology there is not a single case on record, *even unequally viewed*, of destruction of that angular gyrus followed by loss of sight. Dr. Hughlings-Jackson,(g) who the last ten years has been on the look out for such cases, says that he has never met with one. Diseases, such as tumours, produce blindness in a very *indirect* way, by leading to acute changes in the optic nerves, on which blindness may follow. There is not, he says, so far as he can judge, a particle of evidence from clinical medicine to prove that destruction of any part of the cerebral hemispheres produces defect of sight. Yet Dr. Ferrier gives it as a proven fact that there is a visual centre in the angular gyrus, and goes on to discuss the theory of decussation, complete or incomplete, of the optic fibres. He adopts Prof. Charcot's view of double decussation. How that hypothesis accounts for the various kinds of loss of sight, partial or total, I am unable to see. But one thing is certain; according to that theory, the angular gyrus of one hemisphere only animates the eye on the opposite side. I have taken out the left eyeball in a dog, and cauterised the right angular gyrus-centre. The animal *did see!* Goltz has performed a similar experiment, with identical result, I believe. Dr. Ferrier does not admit the so-called law of substitution, but he thinks that in his experiments there has been "a compensation from the centre in the other hemisphere." I only discover in that whole mode of reasoning the fatal recurrence of *petitio principii.* The experiments which I have made, and that performed by Goltz, dispose of even the theory of "compensatory action." It is needless to observe that there is no reason why the movements in the eyeballs, frequently associated with movements of the head to the opposite side, and which follow electrical irritation of the angular gyrus, as Dr. Ferrier has himself seen, should be reckoned by him to be only reflex—only due to awakening of subjective visual sensation. Unless the fact be granted beforehand that that gyrus contains a visual centre, the whole theory, as I have said, is a *petitio principii.*

The sense of hearing is found to be localised in a portion of the superior temporo-sphenoidal convolution; this conclusion has been reached through the two methods of investigation usually employed by Dr. Ferrier. Electrical irritation of this convolution in the monkey, he has found to result in certain definite phenomena—sudden retraction or pricking up of the opposite ear, wide opening of the eyes, dilatation of the pupils, and turning the head and eyes to the opposite side. All these phenomena, like *similar ones* noticed in the experiments on the sense of sight, are said to be of the same nature—reflex. Destruction with a cautery of both angular gyri renders the monkey deaf altogether. I have seen all the phenomena described by Dr. Ferrier, except the *complete deafness*, after destruction of both gyri. I have experimented on dogs and rabbits. I have seen the dogs recover the faculty of hearing after some weeks. The only cases of destruction through disease of the acoustic nerves, involving their whole course up to the fourth ventricle, in man, that I know of, have been put on record by Dr. Luys. I have reported them earlier in this paper. Luys has seen that the lesion consisted in the destruction of the grey matter of the occipital lobule; he has given a plate which leaves no doubt as to this localisation. (I do not wish to be understood to accept Luys' localisation.) I believe that it is not unjustifiable to ascribe loss of hearing, in the experiments reported above, to another cause than destruction of the centre of that sense. When I come to state what I think is the most acceptable provisional theory, I shall try to explain what that cause is. As I have no desire to swell this review into a volume, I shall enter into no further details concerning the other senses—those of tact, and of taste, and of smell. Their existence being localised in different regions of the cortex by the same order of facts as are used by Dr. Ferrier with regard to the other senses, already spoken of, the same kind of arguments can be raised against the validity of the proofs adduced.

I will, however, note one fact to show how deductions are drawn, as to function of parts, on bad premises. I choose the sense of smell, because it is a typical instance of what I advance. Dr. Ferrier, after relating the experiment of Magendie which showed disappearance of the faculty of smelling after section of the trigeminus, remarks that the experiment did not prove that the fifth nerve was the nerve of smell properly so called, but that the integrity of the fifth nerve was necessary to the due functional activity of the olfactory nerves. But he also says that when the tactile sensibility was entirely gone in the nostril, the *vapour of acetic acid* (!) caused copious lachrymation—a fact which shows that some afferent fibres still remained functionally active in the nostril, "evidently the olfactory nerves," which, however, owing to the loss of common sensation, were not of themselves sufficient to convey the impressions of odours. If, notwithstanding destruction of the sensitive nerve, *acetic acid* induced lachrymation, it must be through a reflex of the olfactory nerve, as Dr. Ferrier shows; and if the olfactory *can* give such a reflex action under such circumstances, it is evident that it is impressed in the same manner as a sensitive nerve. Now, what signifies his postulate that the integrity of the *sensitive* nerve is necessary for the conveyance of the impressions of odours?

Absence of the fifth nerve does not destroy the faculty of tasting nor the faculty of seeing. It does so in some cases where there are reflex actions at play—inhibitory actions. On the other hand, there are cases on record of destruction of the first pair of nerves, and yet preservation of the sense of smell. The celebrated case reported by Claude Bernard is in the memory of all. He mentions the case of a woman, who during life disliked the *smell of tobacco* (it requires a special sense to smell tobacco, whereas *acetic acid* acts on the fifth nerve as well!), who knew that a *sink* near her bedroom was dirty by its smell, etc., in whom the remarkable fact was discovered of the congenital absence of the olfactory nerves! How to explain this case? Is it explained in accordance with what Mr. Lewes maintains, that *neural processes* are uniform in character, the diversity of their results (sensation, motion, or secretion) depending on anatomical connexions? Is it explained by the theory of *organised past experience* of the fifth nerve from childhood upwards?

Another very original part of Dr. Ferrier's work is the one in which he treats of the occipital lobes. Dr. Ferrier believes that the viscera have fibres which transmit their special sensations to the sensorium,(h) and that the centres of these fibres are in the occipital lobe. The sense of *hunger* has its seat there. So we have a *sense of hunger.* The reasons given by Dr.

(f) Ferrier, *loc. cit.*, page 296.

(g) J. Hughlings-Jackson, "Clinical and Physiological Researches on the Nervous System," (reprint,) page xli., *note.*

(h) Compare Hughlings-Jackson, *loc. cit.*, page xv., *note, et seq.* He says that the arteries, the heart, and the different viscera, etc., are represented in the highest nervous process.

Ferrier for this new discovery are, that his animals could drink, but *refused to eat*, when the occipital lobes had been destroyed. At first sight I suspect that the animals in this experiment do not eat for the same reason that they do not when they have had both angular gyri destroyed—because the masseter muscles have been cut through or separated from their occipital-parietal insertions; which is a sufficient cause to explain the difference as to taking food between this experiment of removal of the occipital lobule, and destruction of the anterior lobes when the animals do eat (the masseters are not cut away so extensively from their insertions then). In fact, the animals cannot masticate. Dr. Ferrier says himself that one animal which was kept alive on the *fifth* day after the operation of removal of the occipital lobule, and which had up to that day refused food, "took a cold potato offered, smelt it several times, and at last, as if struck by a new idea, began to eat with great relish. From this time it began to take food, and recovered." As it is impossible to suppose that within five days after their destruction the anatomical tissues in which the sense of hunger is localised could have been regenerated, I cannot understand how the reappearance of that sense can be accounted for. Let us not forget that on anatomo-pathological evidence Luys has localised in these same occipital lobules the sense of hearing,(i) and that Dr. Joffroy,(k) one of the ablest pupils of Professor Charcot, and once a *collaborateur* of Duchenne, has localised trophic centres; lesions of that lobule, he thinks, bring on sloughing of the sacrum, etc. It is needless for me to add that there are at least twenty-five cases *above criticism* of lesion of those lobes, without any phenomena whatever but hemiplegia.

I think that with regard to the motor centres of the cortex cerebri of the monkey and of man Dr. Ferrier is at variance with what observation teaches. I have had no opportunity to experiment on monkeys, but Dr. Ferrier agrees that in the other animals the so-called lost psycho-motor functions of that region can be recuperated, while in man loss of the cortical centres leaves lasting paralysis. I do not know of one single case of destruction of the so-called motor centres in the brain of man having caused lasting paralysis. My experience goes the other way. The cases which I shall report, and which belong to those series published by Professor Charcot and others, will bear out my statements.

I have now reached that interesting chapter of Dr. Ferrier's treatise where he considers the hemispheres psychologically. I have little to say in respect to that matter on account of my little familiarity with it. It appears to me that the whole of it, in its masterly exposition, is one continuous begging of the question. All his psychological deductions, I own, are based upon physiological facts; but those facts I have proved, I trust, to have been considered only in a one-sided way—viewed unequally, as the phrase goes. I know that I am liable, on *primâ facie* evidence, to be charged with levity for this statement, considering that there is a seeming concordance between the theories of the advocates of the localisation doctrine and the deductions of Herbert Spencer, of Professor Bain, and of others. But let it be remembered that this concordance only proves that we have several valuable *similar or identical* deductions, reached through different processes of reasoning; it does not prove that any one of the theories advanced is better grounded. The two eminent philosophers whose authority is adduced by Dr. Ferrier seem to me to have availed themselves, in lieu of premises from which to evolve their powerful reasoning, of results of the physiological and anatomical researches of Professor Laycock, Dr. Carpenter, Dr. Hughlings-Jackson, Professor Broca, Professor Helmholtz, Professor Brown-Séquard, Professor Ferrier himself, Professor Hitzig, etc., —which results, notwithstanding their extrinsic value, are still *sub judice*. The foregoing considerations warrant me, I presume, in pointing out the strangeness of adducing authority of such an origin by way of philosophical confirmation of their theories by the advocates of the localisation doctrine.

Here I relinquish this theme, for fear of being lost if I once launch into a subject too unknown to me.

I have next to expose what views are held concerning speech. The question of aphasia is one which, for the last thirteen years, has agitated pathologists, physiologists, and psychologists equally. Dr. Ferrier has handled this subject in the same manner that he handled the others.

FATAL CASE OF HYDROPHOBIA.

By JAS. D. GUNNING,
Surgeon, Army Medical Department.

Butwee, a dhobie, aged forty years, robust, was brought to me on Christmas-day, 1876, walking. Stated that about four months before he had been severely bitten above the left knee by a dog, supposed to have been mad. The wound healed up readily, and a large scar was visible. Up to three days prior to my seeing him he had enjoyed his usual health, when he lost his appetite, could not sleep, and complained of spasmodic pain of a burning character, referable to the diaphragm. On December 24 his aversion to water was first noticed. On being handed a lotah (a brass drinking-vessel) with water, in my presence, he made an attempt to drink, but was unable to do so, throwing the vessel from him, screaming, his countenance horror-stricken, and trembling all over —a most pitable sight. I tried to induce him to come to hospital, or else go to the Charitable Dispensary, but he refused; so I determined to watch the case and do what I could in his own house. At 4 p.m. I ordered plenty of strong mutton broth to be prepared (beef not being procurable just then), and at 6 p.m. he had some, which he swallowed with difficulty, about one-half dribbling from the corners of the mouth. Thirty grains of hydrate of chloral were given. Temperature 97·2°; pulse 64. At 10 p.m. I saw him again; had not slept; chloral (thirty grains) repeated, and mutton broth to be given very frequently; the chloral to be given again at 2 a.m., and repeated at 6 a.m. if he had not slept in the meantime.

December 26.—At 8 a.m. went to see him; up to this hour he had not slept, although 120 grains of chloral had been administered. His pupils were dilated, and he had a drowsy look; complained of a spasmodic burning pain in the epigastrium. Had plenty of the mutton broth. He, however, expressed himself as much better, and to show that he was so asked for a drink of water, which he took tremblingly, but swallowed fairly, and without exhibiting the same violent emotion as yesterday; only a little escaped from the corners of the mouth. At 9 a.m. I went with Surgeon-Major Gribbon to see him. Pulse 96, weak; hands cold. While telling us how much better he was, and after showing us how well he could now drink the water, he suddenly fell back, and, after a few convulsive struggles, died in about five minutes, restoratives being administered without any avail. He never at any time exhibited any symptoms of delirium, nor was there any flow of saliva. The chloral in this case seems to have overcome the spasm of the glottis very considerably. I was very anxious to get a post-mortem, but was unable to induce the friends to allow it.

Fyzabad, Oudh, E.I.

Surgical Examinations.—The following is a copy of the paper on Surgical Anatomy and the Principles and Practice of Surgery submitted to the 200 candidates at the pass examination for the diploma of Membership of the Royal College of Surgeons on the 20th inst., when they were required to answer at least four (including one of the first two) out of the six questions, viz.:—1. Give the relations of the common femoral artery; and mention the branches by which the collateral circulation would be carried on after ligature of that vessel. 2. Mention, in order, all the structures which must be divided in excision of the eyeball. 3. Describe the methods of ossific union of simple fracture under varying conditions of movement and coaptation of the fragments. 4. Describe the injuries of the elbow-joint which are liable to be confounded with dislocations. 5. Describe the symptoms of inherited syphilis, and mention the periods of life at which they are liable to appear, and the suitable treatment. 6. In a case of strangulated inguinal hernia, state the symptoms which would lead you at once to perform an operation, and those by which you would be induced to postpone it. The following is a copy of the paper on Medicine submitted the following day:—1. Discuss the causes, morbid anatomy, symptoms, and diagnosis, together with the complications and sequelæ, of cirrhosis of the liver. 2. What are the causes, symptoms and diagnosis, and results of pneumothorax? How would you treat it? 3. What medicinal plants belong to the order *Solanaceæ?* What are their several physiological and therapeutical properties? and what the doses of their Pharmacopœial preparations.

NOTES OF A CLINICAL LECTURE ON ACNE.

By JONATHAN HUTCHINSON, F.R.C.S.

When the face is covered with pimples, some of which are red, some contain pus, and others show only black points in their centres—all kinds being present, and all slow in progress,—it is commonly agreed to call the condition Acne. If the spots are angry and suppurate quickly, it is acne pustulosa; if they are small, very florid, and not prone to suppurate, it is acne rosacea; if there is great thickening about them, and again little tendency to suppurate, it is acne tuberculata; if there are numerous black points to be seen, it is acne punctata; lastly, if no ono of these features be in excess of the others, it is common acne—acne vulgaris. Now, let us first understand clearly that these various adjectives do not denote different diseases, but merely different conditions of the same disease, which may be frequently met with in one and the same case. Next, we will observe that all forms of acne are inflammations of sebaceous follicles. I have already said that, when a follicle inflames, three results ensue—a thickening of its gland tissue, deposit and congestion of the cellular tissue around it, and accumulation of its secretion in its interior. Now, we have in acne all shades of variety as to these three results. Everyone is familiar with the little black dots so frequent in the skin of the face of those who have rather coarse complexions. In degree they may perhaps be found in the skins of most persons, especially about the nose. If you squeeze them, little black-headed "maggots" are ejected. These maggots, or grubs, are not living, but consist of half-dried sebaceous matter, which had accumulated in the cavity of the gland, and which has been moulded into the pellet form in passing through the constricted opening. The black head is the end of the pellet, which, having been long exposed at the mouth of the duct, has gathered soot.

It is not always that the end of the pellet gets blackened; sometimes, and especially in young persons, the mouth of the follicle is closed by a delicate membrane, and then the secretion collected beneath it is seen under its transparent covering, and remains quite white. In infants this distension of closed follicles constitutes what used to be known as strophulus albidus; in adults it is more frequently seen on the eyelids than on other parts.

Sometimes the interior of the follicle suppurates, and, after removal of the pellet, pus escapes. This constitutes pustular acne.(a)

It is a peculiar feature of the condition known as acne, that at one and the same time, in the same patient, you will find the follicles in all stages of disease, some simply distended and free from material irritation, others congested also, others suppurating. In this it differs much from lichen.

Acne is emphatically a disease of coarse skins; or rather, perhaps, we ought to say that the term "coarse skin" usually applies to integument in which the sebaceous follicles are larger than ordinary, and have gaping mouths. This causes the skin to look rough and pitted. It is a state of skin the tendency to which is often hereditary, and it is thus often seen in several members of the same family.

Acne spots cause more annoyance on the face than elsewhere, and hence an exaggerated impression as to their great relative frequency on this part. Although there is no doubt that the face and shoulders are their usual sites, yet, if you will examine the general surface of acne patients, you will very frequently find the spots, in smaller numbers, on the trunk and the upper arms also.

Having asserted that all persons of coarse skin are liable to have their sebaceous follicles take on occasionally the acne inflammation, we may suitably ask what are the causes which induce the more severe forms of the disease. For clinical purposes we may recognise acne chiefly in two forms—first, the acne of young persons; and second, the acne of those past middle life. It is in young persons that we meet chiefly with the pustular, punctate, and vulgaris types, whilst in the elderly we encounter the acne rosacea and tuberculata. Respecting the acne of the young, there is a very widespread opinion that it is usually the result of sexual disturbance. I have no doubt that this belief is well founded to some extent, but we must beware of exaggerating it. The eruption is chiefly met with in young celibates, whilst it is very rare under the age of puberty, and is often benefited by marriage. It is possible, however, that its comparative rarity in the married may after all be a coincidence and not a sequence, and that we ought to consider it not so much a disease peculiar to celibacy as to the special age at which a large majority of the population are celibates. It may certainly occur before puberty. I have seen it not very infrequently in children, and once in a very marked form in the face of an infant of six months. It is also frequent in married persons of both sexes, and sometimes originates after marriage. I have known it occur in ladies who were bearing children, and in whom the sexual functions appeared to be in perfect activity.

Making full allowance for a considerable number of acne cases in which there appears to be no sexual cause, there are yet, I think, good grounds for accepting the general belief that in a majority of instances such is the fact. The remarkable influence which the sexual functions exercise upon the general health and upon the state of the nervous system is amongst the secrets known unto all men. That they should have the power of making the sebaceous glands of the skin enlarge and suppurate is certainly, if thought about, one of the most strange. I suspect that, when it occurs, it is brought about through the agency of the nervous system rather than of the blood. Women who are not liable to acne at other times sometimes have a few spots appear at each menstrual period, and that whilst in excellent general health. I have been assured by gentlemen liable to nocturnal emissions that they invariably had an increase of acne spots after such occurrences, and sometimes so immediately, that it was impossible to believe that any material change in the blood had occurred. In other cases sexual intercourse may produce the same result.

It is certainly not in cases of extreme sexual exhaustion that acne is most common. I have seen many such patients, both with and without spermatorrhœa, who had not a spot of acne, but, on the contrary, had skins which were perfectly smooth—in some instances florid, in others earthy pale. It is, perhaps, rather a condition of sexual irritability than of exhaustion which produces acne. I do not think that the severity of the acne eruption bears any relation to the degree of sexual disturbance. In the worst cases that I have seen the patients often seemed to be in good health.

To dismiss this subject, we may remark that the prescriber ought, in respect to the acne of celibates, to bear in mind the possibility of a sexual cause. He will advise the adoption of measures likely to improve the general vigour, he will caution against any possible causes of debility, and he may, in some instances, suggest matrimony as the remedy most likely to prove successful. Derangements of stomach and liver stand in about the same relation to the acne of middle-aged persons that sexual causes do to the acne of early life. Manifest dyspepsia (often the result of intemperance) is present in perhaps half the cases of acne rosacea, whilst in the other half it is exceedingly difficult to assign any cause. The same remark applies also to the indurated and tuberous form of acne, which produces the thickened, bossy condition of skin familiarly known as "grog-blossoms," and usually considered to be proof of intemperance. In many cases such suspicion is most unjust. At any rate, of this you may be sure—that in persons congenitally of coarse skin very slight indulgence at the table may produce results in the way of acne, which would not ensue in others whatever the amount of provocation afforded. As I asserted in reference to sexual exhaustion, so I may say here again, it is common enough to see the most intemperate escape scot-free. Nothing would be more unjust than to allow ourselves to entertain the belief in the one form of acne, that it is certainly due to sexual causes, or in the other that intemperance or gluttony is the cause. We will freely admit a frequent connexion, but strongly deny that it is invariable. For the worst forms of acne of either variety you will be able to discover in the patient's state of health or antecedents no cause whatever, and you will be compelled, in considering your measures of treatment, to regard it chiefly as a local disease.

The rules for the constitutional treatment of acne patients follow easily from what we have said. If the patient be young he should be made to use a cold bath every morning, to take

(a) By some authors called Milium *seu* Grutum.

plenty of exercise, to live liberally as regards meat diet, with a fair allowance of stimulants; and he should be cautioned or encouraged, as the case may be, in reference to sexual matters. As to medicines, a long course of small doses of arsenic will often be of great use. If constipation be present, the habitual use of a chalybeate aperient should be prescribed. You may do all this, however, most sedulously, and gain nothing whatever, if you neglect local measures; whilst with the latter only, and without any change in the patient's habits, you may often get an acne eruption so nearly well that he will regard it gratefully as a cure. The chief local measure consists in destroying, by means of a fluid caustic, the inflamed follicles. With a fine-pointed glass brush, or a bit of soft wood cut to a point, you touch the inflamed spots from day to day. Take great care not to apply too much. In the left hand should be a roll of blotting-paper with which to absorb the fluid if it has been deposited too abundantly. The best fluid to use is the acid nitrate of mercury. It will usually be necessary to repeat the touching once a week for a month or two, carefully seeking out every fresh spot. After that the patient should still see you once a month, in order that the cure may be kept up. The acid thus used does not leave larger scars than the spots would themselves do.

In acne rosacea the use of the caustic will again serve an excellent purpose. You may not only touch the spots themselves, but also pencil out the stray vessels which add so much to the patient's disfigurement. He, or more usually she, will gladly exchange a few slight and scarcely perceptible scars for the angry and very suspicious-looking redness of face which the disease causes.

NORTH-EASTERN HOSPITAL FOR CHILDREN.

DIPHTHERIA AND BRONCHO-PNEUMONIA—SUBSEQUENT PARALYSIS—RECOVERY.

(Under the care of Dr. SANSOM.)

Annie K., aged six years, was admitted as an out-patient on January 6, 1877. Her previous history was as follows:—Fourteen weeks ago she had a severe attack of scarlatina, and had never been well since. No dropsy had occurred after the fever; but three weeks from the present time she suffered from a bad throat, similar to that which was now troubling her. She complained of dyspnœa, cough, and pain, with difficulty in swallowing.

On Examination.—Tongue very brown, with exudation on the left side, covered by white false membrane; and the left side of the buccal cavity was also thickly covered by false membrane.

Physical Signs.—Dulness over the upper and back part of the left lung; dense tubular breathing and râles. Her urine was very scanty, and contained no albumen. Prognosis seemed very bad. Broncho-pneumonia and diphtheria were diagnosed. During the next fortnight, patient greatly improved under the exhibition of the sulpho-carbolates (sodic sulpho-carbolate, gr. xij., every four hours), her throat becoming much better. On January 31 there was deficiency of resonance over right base, and dulness with tubular breathing as before at the left apex, and in addition the following interesting symptoms:—Well-marked ptosis on the left side, with contraction of the left pupil to not more than half the size of the right. From that time she improved a little; and on February 14 the ptosis was much less, while on the 28th it was almost imperceptible; but the contraction of the pupil remained for a much longer period. Ophthalmoscopic examination showed abnormal redness of the optic discs; otherwise fundus of each eye healthy.

On March 7, symptoms appeared of the palate being affected, the voice becoming very nasal, though the child's health at this time seemed a good deal better, and the chest complications were much improved.

On April 4 the uvula appeared distinctly drawn to the right side; hearing also impaired on that side, and a purulent discharge from the same ear. During the next two months she became slowly convalescent; and on May 30 all symptoms of paralysis had disappeared, the pupils were of the same size, and the patient was able to articulate quite clearly, neither was there any impairment of the hearing.

General health and appearance were also greatly improved. The treatment consisted of sulpho-carbolates during the first few weeks, followed by a long-continued course of iron and quinine.

SATURDAY, JULY 28, 1877.

THE CRUELTY TO ANIMALS ACT.

We live in an age of Congresses. "Association" appears to be too small a title for new societies to take nowadays, and accordingly "Congress" takes its place; and on the 19th inst. a new society, the "Domestic Economy Congress," held its first meeting, and a successful one, in Birmingham. One would perhaps have hardly looked for an address in physiology at such a congress, nevertheless the first paper read in "Section B"—we do not know the title of the section—was one, by no less a *savant* than Professor Huxley, on "Elementary Instruction in Physiology," for the pleasure of a perusal of which we are indebted to our contemporary *Nature*. The learned Professor had, of course, no difficulty in giving good reasons for his appearance on such an occasion. He pointed out how "eminently desirable" it is "that the hygienist and the physician should find something in the public mind to which they can appeal; some little stock of universally acknowledged truths, which may serve as a foundation for their warnings, and predispose towards an intelligent obedience to their recommendations." He spoke of the existence of "a strong, though perhaps an unavowed and half unconscious, undercurrent of opinion that the phenomena of life are not only widely different in their superficial characters and in their practical importance, from other natural events, but that they do not follow in that definite order which characterises the succession of all other occurrences, and the statement of which we call the law of nature;" and hence, he said, arises that want of heartiness of belief in the value of knowledge respecting the laws of health and disease, and of the foresight and care to which knowledge is the essential preliminary, which is so noticeable; and hence a corresponding laxity and carelessness in practice, the results of which are too frequently lamentable. But, in fact, there is, the Professor said, "a vast and increasing mass of evidence that birth

and death, health and disease, are as much parts of the ordinary stream of events as the rising and setting of the sun, or the changes of the moon; and that the living body is a mechanism, the proper working of which we term health; its disturbance, disease; its stoppage, death." The business of the hygienist and of the physician is to know the range of the modifiable conditions upon which the activity of this mechanism is dependent, and how to influence them towards the maintenance of health and the prolongation of life; and "the business of the general public is to give an intelligent assent, and a ready obedience, based upon that assent, to the rules laid down for their guidance by such experts." But an intelligent assent is "assent based upon knowledge, and the knowledge which is here in question means an acquaintance with the elements of physiology." Mr. Huxley then asserted that though "the most highly trained and best furnished intellect may find all its resources insufficient when it strives to reach the heights and penetrate into the depths of the problems of physiology," yet its "elementary and fundamental truths can be made clear to a child"; and that elementary physiology may be taught in such a way as not only to confer real, practical, and useful knowledge, but also to serve as a training in accurate observation, and in the methods of reasoning of physical science. Of course he insisted, however, that if children are to be taught a little physiology, the instruction must be real, "based upon observation, eked out by good explanatory diagrams and models, and conveyed by a teacher whose knowledge has been acquired by study of the facts, and not the mere catechismal parrot-work which too often usurps the place of elementary teaching." This very important and most necessary requisition is enough to explain why it is, as yet, impossible, or almost impossible, to make elementary physiology a part of general education, however desirable this may be thought: the skilled teachers cannot be had. Into this Professor Huxley did not enter, nor do we mean to. Our chief interest in his address lies in the latter part. Speaking of the teaching he advocated, he said he hoped it was unnecessary to give a formal contradiction to the silly fiction, assiduously circulated by fanatics who not only ought to know, but do know, that their assertions are untrue, that he had advocated the introduction into elementary teaching of that experimental discipline which is absolutely indispensable to the professed physiologist. And then, referring to the Vivisection Act, he added, "But while I should object to any experimentation which can justly be called painful for the purpose of elementary instruction, and while, as a member of the late Royal Commission, I gladly did my best to prevent the infliction of needless pain for any purpose, I think it is my duty to take this opportunity of expressing my regret at a condition of the law which permits a boy to troll for pike, or set lines with live frog-bait for idle amusement, and, at the same time, lays the teacher of that boy open to the penalty of fine and imprisonment if he uses the same animal for the purpose of exhibiting one of the most beautiful and instructive of physiological spectacles—the circulation in the web of the foot. No one could undertake to affirm that a frog is not inconvenienced by being wrapped up in a wet rag, and having his toes tied out; and it cannot be denied that inconvenience is a sort of pain. But you must not inflict the least pain on a vertebrated animal for scientific purposes (though you may do a good deal in that way for gain or for sport) without due licence of the Secretary of State for the Home Department, granted under the authority of the Vivisection Act." And so it comes about, he said, "that, in this present year of grace 1877, two persons might be charged with cruelty to animals. One had impaled a frog, and suffered the creature to writhe about in that condition for hours; the other had pained the animal no more than one of us would be pained by tying wet strings round his finger, and keeping him in the condition of a hydropathic patient. The first offender said, 'I did it because I find fishing very amusing,' and the magistrate bade him depart in peace; perhaps even wished him good sport. The second pleaded, 'I wanted to impress a scientific truth, with a distinctness attainable in no other way, on the minds of my scholars,' and the magistrate fined him five pounds." The Professor naturally observed that he could not but think this an anomalous, and not wholly creditable, state of things.

Mr. W. E. Forster spoke on the same subject at the distribution of prizes at the London Hospital, and we last week reported part of what he said, to which we will add that he dwelt upon the high character of the medical profession and the benevolence so widely spread among its members; and observed that "medical men, in striving for knowledge, were carrying on a desperate war against a desperate enemy, and they had to wrest out the secrets of disease and the secrets of life as best they could." Mr. Forster did not, however, think fit to explain how it was that, notwithstanding all this, he had done his utmost in Parliament to make the Vivisection Act most mischievously and powerfully restrictive on physiological research. But it must have been in the minds of some of his hearers on that occasion, and will be remembered by medical men when hampered and impeded in their efforts to "wrest out the secrets of life and the secrets of disease," that it was Mr. Forster who, at the last moment, compelled the Government, in spite of a promise to the contrary, to substitute the word "invertebrate" for "cold-blooded" in the Bill, and so to place the frog and other reptilia under the protection of the Act. The terms of the understanding upon which the opposition of the profession, and other scientific workers, to the Bill had been withdrawn having been thus broken in this most important point, the Bill passed; and, even so passed, it was accepted frankly and loyally, in the hope and belief that it would be administered in a wise and liberal spirit.

But in this respect, again, the expectations of the profession have been cruelly disappointed. It will be remembered that during the late session of the General Medical Council a communication was received by that body, complaining that applications, duly supported by certificates signed in accordance with the Act, for permission to conduct physiological or medical researches, had in some cases been refused; and in other cases the certificates had been indefinitely suspended, without cause assigned. We learn now that among the researches thus prohibited by the Home Secretary is the continuance of Professor Rutherford's and M. Vignal's researches into the action of various drugs upon the secretion of the bile, and that the research has in consequence been transferred to Paris. Thus the worst fears as to the possible effects of the Act are being realised; and it seems probable, already, that England will lose her rank among European countries as a fountain of scientific progress. The Medical Council passed a resolution expressing their regret that the Act was being administered so as to seriously impede highly meritorious cultivators of physiology and pathology in this country in their legitimate studies, and directed their Executive Committee to bring this to the notice of the Home Secretary, if complaints continued; but if this has been done, it seems, at present, to have had no effect.

THE MADRAS FAMINE.

When we last wrote, a fortnight ago, on the subject of the famine in Madras, we were able to say that "rains had already fallen in some districts of the Madras Presidency," and that there was reason for hoping that the amount of suffering and distress would be rapidly reduced. But the favourable weather lasted but a short time, and the hopes raised by it have been bitterly disappointed. The *Times* published, on the 24th, a telegram from Calcutta, dated July 22, in which the food

prospects for the Madras Presidency are depicted in the darkest colours. It says, "The latest news from the famine districts is most gloomy, owing to the almost entire cessation of the rains. The situation is critical in the extreme, and is causing much anxiety. From Madras we hear of crops suffering and pasture failing, and an extensive failure of unirrigated crops is inevitable"; and the report adds, "if rain does not fall within the next few days, in all probability the next week or two will decide whether Madras and Mysore are doomed to undergo the terrible calamity of a second year of scarcity." In Bombay and in the Malabar coast districts everything was going on satisfactorily; but from Nepaul, Assam, the Central Provinces, and the North-west, complaints of want of rain had been received; and in Calcutta prices had risen greatly owing to the large exports of rice to Madras. The telegram concludes with, "The next week or two will decide the fate of Southern India. There is still hope, but we must be prepared for the worst." Even before this failure of the monsoon rains the prospect was gloomy enough. Writing from Madras on June 22, the correspondent of the *Times*, after saying that they had had so far in Southern India "splendid rain," and that agricultural operations were being actively pursued, points out the mistake of supposing "that after good rain the tension of famine is at an end," and adds, "If one may judge from facts and figures, the distress is greater now than during the intense heat of April and May," and "for the next four months the populations of our actual famine districts, and of others that have been partially distressed, will have to depend to a very great extent on imported food." We must be thankful in the midst of this gloom to learn that one calamity, which would have been simply overwhelming, has been averted. The *Madras Weekly Mail* of June 27 tells us that, a few days before, Southern India was threatened with a water famine, and it was feared that the railway would come to a dead standstill by the failure of the wells at stations at which the engines were watered. "That would have meant nothing more nor less than the depopulation of Cuddapah, Bellary, Kurnool, and half Mysore," and excessive mortality in North Arcot and other districts. Enough rain had, however, fallen to replenish the wells and tanks "for some months to come," and grass had sprung up rapidly enough, and in sufficient abundance to save, for some time longer at any rate, the cattle that had survived the many months of drought. The danger of a loss of the great means of carrying and distributing food has, we may therefore hope, passed by; but it is abundantly clear that the supreme Government must be prepared to meet enormous demands for food for several months to come; and it does not appear that this necessity is yet at all fully recognised. The *Times'* correspondent says that in June the Madras Government was supporting one and a quarter million of the population; and it is calculated that at least ten millions of the population of the Presidency and Mysore are dependent on imported grain for their daily food; so that "it is quite possible that the next three months may demand an importation of 200,000 tons of grain per month to keep the people alive." It is easy enough to see, therefore, that there is a risk—and a very serious risk—of some millions of people being absolutely short of food; and to understand that it is idle to trust to private trade and enterprise to meet such emergencies. Yet the Supreme Government does appear to insist still on the propriety of relying on the resources of private trade. And we are told even that "the Madras Government has been soundly rated both by Lord Lytton's Government and by the Marquis of Salisbury for their very modest precaution of securing 30,000 tons of grain and placing it in regions inaccessible by railway, or by ordinary road in bad weather, as an insurance against possible calamity. Indeed, orders were sent down some time ago to sell off this stock in the open market, but the Madras Government declined." The *Times* may well add to this the comment that, if reliance on economical doctrines has been carried to this extent, it appears extremely rash.

The mortality in the famine districts has been fearful. We could give terrible reports of this from Madras papers, but we prefer to quote from the correspondent of the *Times*, as it might be supposed that the accounts in the Madras journals are coloured by the feeling that exists against the Supreme Government. It is satisfactory to know that "the Temple rate of wages" has been abandoned, but the disastrous effects of the "experiment" remain—effects which, it must be remembered, were most clearly predicted by Dr. Cornish in his Minutes. The *Times'* correspondent states that the mortality in the relief-camps was at the frightful rate of 100 per cent. In the month of May, out of a strength of 50,254 in those camps, "there were 4037 deaths, almost entirely due to starvation diseases." In other words, if that rate of mortality were continued, the present occupants of the "camps" would be entirely swept away within twelve months! No more evidence can be required to prove that the relief allowed had been fatally inadequate, and that the mass of the population had been reduced to the lowest point of vitality. The *Times* acknowledges that relief which produces such results is scarcely deserving of the name of relief at all; that we are responsible for saving the lives of the vast population who seem actually dependent on us; and that there does seem reason to fear that far more energetic—and, we may add, more liberal—measures are necessary than have yet been taken. And the *Madras Mail* observes, "It is a choice of two evils—a great outlay of public money, and a ghastly loss of human life. No time is now left for argument as to the responsibility of this or that Government, or of this or that official." There can be no doubt about what the English public will say: they will utterly repudiate any determination to incur a risk of the population of Southern India running short of food lest the Government should expend more money than may prove to have been absolutely necessary.

THE DISPUTE IN THE UNIVERSITY OF LONDON.

The extraordinary meeting of Convocation of the University of London, which is summoned for to-day (Friday), will be a memorable one in the history of university freedom. For the first time since its creation, more than twenty years ago, Convocation of the University of London will meet upon special and urgent business. Our readers have had the opportunity of following with some closeness, from week to week, the various steps of the unfortunate difference which exists between the Senate or executive body of the University and its Convocation or parliament; and these need hardly be again reviewed. Arising out of the question of the admission of women to degrees in medicine, the dispute now occupies much higher ground—namely, the respective rights of the two bodies in the introduction and rejection of changes affecting the constitution of the University. Stated concisely, the matter which Convocation will have to consider and settle to-day is, whether the Senate acted rightly, justly, and honourably, when it took advantage of an Act of Parliament to effect a change in the constitution of the University without consulting Convocation, and persisted in its course against the express desire of that body. This comprehends the substance of the dispute, although there are certain other points bearing on it which cannot fail to be dwelt upon. Thus it will probably be urged against the conduct of the Senate that the Act which it has been so eager to use is a permissive one, passed hastily through Parliament as an innocent measure; that it was drawn by a member of the Senate who is one of the most active of the unconstitutional party, and that a "university" which is enabled by the Act to use powers that it embodies is consti-

tuted, not by the Senate alone, but by all graduates. In still another aspect this matter will have to be regarded by Convocation. We understand that certain flaws have been discovered in the words of the Act, and that the special provision which it contains *against* the admission of women-graduates to a seat in Convocation is so carelessly expressed as to be virtually invalid! Convocation may be called jealous of its privileges, but we question whether even the majority of the Senate will care to proceed in their present course when they discover that it may end in giving women the right to canvass the first vacant seat amongst themselves. These several points may, as we have said, have a certain amount of influence on the minds of the graduates to-day; but the principle at stake, and which Convocation meets to uphold, needs no support from accident, from legal interpretations, or, for that matter, from Acts of Parliament. It is the principle of freedom of speech and of action in their own affairs possessed by the members of a University—the principle of the right of a body of nearly 2000 highly educated men to protest successfully against the action of a narrow majority of eight or ten senators.

It is to be feared that some of the acerbity that was developed during the discussion of the women's question has been transferred to the more general one, where it is even less becoming. Indeed, as might have been expected, the unconstitutional party, who would allow the Senate to override the privileges of Convocation, are trying their hardest to secure on this occasion the support of the graduates who may be in favour of the admission of women, by representing the present agitation in Convocation as nothing but a side move of the anti-women party, skilfully got up in order to arrest the further action of the Senate. It is much to be hoped that no member of Convocation will allow himself to be blinded by this very transparent design, and that at the meeting to-day the constitutional question will be fairly discussed on its own merits, quite apart from the other question of sex—which, we doubt not, will be adroitly introduced, but ought not to receive a moment's consideration.

THE WEEK.

TOPICS OF THE DAY.

The Council of the Social Science Association last week presented to the Secretary of State for the Home Department a document containing three resolutions on the subject of the office, duties, and jurisdiction of coroners, which had been adopted by the Council. They are as follows:—1. That in the opinion of this Council a Parliamentary inquiry into the mode of appointment, the office, duties, and jurisdiction of coroners is imperatively demanded. 2. The Council draw attention to the fact that the office of coroner is one of high antiquity and high utility; that it has been the subject of much and intricate legislation, and has come in process of time to be attended with inconveniences in respect of the constituencies by which the coroner is elected, the manner of election, the mode of administration and procedure, the place for holding the court, as well as of many points relating to functions, procedure, and responsibility. The Council are of opinion that in consequence of various social changes since the time of the original creation of the coroner's office, the expediency of obtaining a coroner's jury, either at all, or in its present form, the existing relations of the coroner to the justices of the peace, and the provision for the use of expert witnesses, have become matters requiring fresh and special arrangements. 3. That the question of inquiry into the causes of fires is one of urgency, and should be considered in regard to the appointments, duties, and functions of coroners.

A serious interruption has taken place at the outfall works of the King Sedgmoor main drain at Dunball, near Bridgwater. The new auxiliary cut, constructed at a cost of between £4000 and £5000, suddenly collapsed, owing, it is supposed, to the shifting of quicksand beneath, and to the combined action of the tide and fresh water accumulated by the late heavy rains. Several massive iron pipes, six feet in diameter, burst with a loud report. A considerable portion of the turnpike-road was carried away, and a house in the vicinity was undermined to such an extent that its fall is anticipated. Traffic on the turnpike road has been diverted for more than four miles in consequence of a bridge being rendered unsafe by the accident.

At the inaugural meeting of the Domestic Economy Congress, held at Birmingham last week, Prof. Huxley, in addressing the meeting, remarked that if anyone is interested in the laws of health it is the working-man, whose strength is wasted by ill-prepared food, whose health is sapped by bad ventilation and bad drainage, and who loses half his children by disorders which might be prevented. He further pointed out that not only does our general primary education carefully abstain from hinting to the workman that some of his greatest evils are traceable to mere physical agencies, which could be removed by energy, patience, and frugality, but it does worse, it renders him, so far as it can, deaf to those who would help him, and tries to substitute an Oriental submission to what is falsely called the will of God for his natural tendency.

The Mayor and Town Council of Leamington, acting as the urban sanitary authority for the borough, last week applied to Vice-Chancellor Sir Charles Hall for an injunction to restrain the contractors who supplied the town with water, from supplying water in an unfiltered state. In June, 1856, the defendants entered into a contract to construct works and supply the town with 500,000 gallons of water a day, properly cleansed and filtered; and the plaintiffs complained that recently, owing to the water being permitted to pass through a certain culvert, it had been by no means free from impurities. One witness had found at dinner a live leech an inch long in his water-bottle, and another was ready to testify to the presence of a decomposed eel in the water supplied to him. The defendants denied that the water was supplied in an unfiltered state, but eventually they gave an undertaking which was substantially in the terms of the notice of motion, and the motion was allowed to stand over to the hearing, with liberty to advance the cause.

The debate in the House of Commons, last week, on the vote proposed to be taken for the Broadmoor Criminal Lunatic Asylum, was satisfactory, in so far that it elicited a full explanation of what at first sight appears a very large expenditure of public money. Mr. Walter, as one of the Council of Supervision, laid before the House several particulars not before generally known. Broadmoor, he pointed out, was essentially a place for the reception of persons who were not criminal, but who had committed, in a state of insanity, acts which would otherwise have been criminal. The policy of the State had been to treat these persons not as criminals, but as patients, and unless that distinction were kept in view, they would argue the question on wrong premises. An objection was made to the dietary of the prisoners; but it was acknowledged by medical men that the recovery of these unfortunate people greatly depended on good living. Again, the attendants at Broadmoor were 20 per cent. of the inmates, whereas in ordinary county asylums the attendants were only about 10 per cent. This arose from the immense proportion of male patients at Broadmoor, and the dangerous nature of their peculiar form of malady. As a set-off the mortality is only $2\frac{1}{4}$ per cent., and there is no institution in the kingdom of a similar kind which can show so small a mortality amongst its patients. The cost of maintaining the buildings is very heavy, but the present estimate is less than that of last year, as that was less than the one preceding it. The present asylum at Broadmoor might be sold, Mr. Walter added, but

he believed the sacrifice would be very great, and any new site would be dearly purchased. Eventually the vote was agreed to.

The annual Conference of Sanitary Engineers was held last week at Bristol, under the presidency of Mr. F. Ashmead, C.E., Borough Engineer of Bristol, who delivered an address, in the course of which he reviewed the several modes of treating town sewage, arriving at the conclusion that the best and cheapest mode was by discharging it into the sea. With regard to the question of ventilation of sewers and drains, Mr. Ashmead said that Bristol stood almost alone in this matter, its sewers having been worked successfully for upwards of twenty years without ventilation. He was of opinion that if the original construction of sewers was effectual, and the supply of water ample, ventilation was rendered unnecessary. The borough of Bristol extends over an area of 4687 acres, or nearly eight square miles, with an estimated population at the present time of 202,950. For drainage purposes it has been divided into six districts. The average death-rate before the construction of these works was 28 per 1000, and for the year ending January, 1875, it was 22·7.

The Stafford House Committee for the relief of sick and wounded Turkish soldiers have determined to send out four more surgeons, in addition to the five who have already arrived in Turkish territory fully equipped. Mr. Barrington Kennet is superintending the distribution of appliances, and the establishment of hospitals, of which three are in working order under other doctors at Shumla, Varna, and Rustchuk. Mr. Pratt, of Royston Hall, Norfolk, has volunteered to proceed to the East as assistant commissioner, and will take out the next supply of stores. Lord Blantyre has also sent out a number of medical men at his own expense.

The *Gardeners' Chronicle* states that the Society of Apothecaries, in addition to the usual medals and prizes for botany and chemistry given to medical students, intends to offer a silver medal for proficiency in botany, to be competed for by ladies only.

The report of the Water Examiner for the month of June last presents no new feature of interest. Attention is again called to the fact that the deterioration of the waters of the Thames and Lea continues, sewage pollution being found in both rivers, principally from the fact that the dwellers on the upper reaches of these streams treat them as common sewers. Moreover, as the population of the districts through which the Thames and Lea flow is rapidly increasing in density, this pollution is more likely to increase than to diminish, and points to the urgent necessity which exists for at once adopting measures to prevent the contamination of the water from which most of the metropolitan water companies draw their supplies. As a result of the analyses made by him, Dr. Frankland reports that the river waters delivered by the Chelsea, West Middlesex, Grand Junction, Lambeth, and East London Companies were all efficiently filtered, and contained about the average summer proportion of organic impurity. That delivered by the New River Company was also efficiently filtered, and contained a remarkably small proportion of organic matter. On the other hand, the Southwark Company's water was slightly turbid from inefficient filtration, and the suspended matter was full of moving organisms.

It is stated that the attendance of representatives of the medical and other officers, and of the members of the provident dispensaries in London, has been invited by the Medical Committee of the Charity Organisation Society at a conference to be held at the rooms of the Medical Society, Chandos-street, with a view to consider what steps should be taken to strengthen and consolidate the movement in London. Mr. Timothy Holmes is announced to take the chair, and Dr. Ford Anderson will open the discussion.

During the week ending July 21, the deaths from small-pox in the twenty English towns included in the Registrar-General's weekly report were 41, against 37 in the previous week. Of the 41 deaths, 35 occurred in London, against 32 in the week ending July 14; 4 occurred in Liverpool, 1 in Brighton, and 1 in Leeds.

THE PURPLE OF THE RETINA.

Boll's discovery, or rediscovery, of the see-purple (*Sehpurpur*) of the retina, of which we gave a brief account in vol. i. 1877, page 291, still attracts attention, and is the subject of much investigation in Germany. Professor Kühne gives some very interesting observations of his own in the *Centralblatt Med. Wiss.*, March 17 and April 14, 1877, and points out that the red colour of the retina was first observed as early as 1839 by Krohn in the eye of the cephalopods; in 1857 it was seen by Leyden in the eyes of *Rana* and *Pelobates;* and in 1866 by Schultze in the retina of the rat and the owl. To Boll, however, is due the merit of the discovery of the distinction of the see-purple by white light, and its regeneration in darkness. Kühne finds that the purple, or red colour, which undergoes these curious changes, is only present in the outer (posterior) portion of the rods (*Stäbchendussenglieder*), and that its intensity varies directly with the proportion of rods present in a given part of the eye. It is never found in the cones; and where only the latter are present, as in the macula lutea, there is no purple; and similarly, where the cones predominate over the rods, as in the immediate neighbourhood of the yellow spot, the purple tint is very slightly developed.

In only a few animals which have been as yet examined was the see-purple found completely absent from the posterior portion of the rods—*e.g.*, in the bat, pigeon, and fowl. In the owl, and especially in one species (*Athene noctua*) which has very long rods, the purple tint is deeper than in any other animal as yet observed. Apparently there is an inverse relation between the amount of pigmentary absorptive material present on the retina, and the intensity of the purple.

The red colouring matter of the rods is due to a peculiar body, which can be isolated, both in solution and in the solid form. Its only solvent, as far as is at present known, is the bile, or a purified salt of cholic acid. The clear filtered solution of see-purple is at first of a magnificent carmine-red colour, but it quickly turns chamois-yellow in the light, and finally becomes colourless. As long as it retains any red tint at all, it allows yellow, orange, and red, and possibly a little violet, light to pass through it, but absorbs all rays from yellowish-green to violet. The solar spectrum affects it as follows:—The portion from yellowish-green to pure green bleaches it completely in fifteen minutes; from bluish-green to violet the action is less intense, and lasts much longer; yellow and orange act much more feebly; and red and *ultra*-violet, in the period above named, not at all. The purple, however, appears to be affected by very long exposure to the red portion of the spectrum.

Kühne finds that the range of vision of a rabbit's eye, whether extirpated or allowed to remain *in situ*, is from nineteen to twenty-seven centimetres. If objects cut out in black paper be placed on the ground glass cover of a black box of this height, and the sensitive eye be placed at the bottom of it, very well-defined "optograms" can be obtained, and fixed by immersion in a solution of alum. They can be preserved for a long time, if dried in the dark on slips of porcelain. In fresh ox-eyes, the pictures obtained by this method can be seen immediately after exposure, by isolating the retina in the dark, or with the aid of yellow light, in a weak solution of common salt.

The *regeneration* of the see-purple is effected in less than an hour after extirpation, and preservation in the dark, in a hog's eye previously deprived of its purple by long exposure to bright sunlight before the animal's death.

The question whether the retinal purple is visible *intra vitam* seems at present an open one, some observers—*e.g.*, Dr. Adler, of the Wieden Ophthalmic Hospital, Vienna (*Centralblatt*, No. 14, 1877),—describing cases in which it was supposed to have been seen even without the ophthalmoscope; and others—Drs. Diett and Plenk, of Innsbrück (*Centralblatt*, No. 16, 17),—denying that it can be seen by ordinary artificial light, even with Jäger's ophthalmoscope (where the illumination required is very weak), although its presence was afterwards proved by anatomical examination.

HOME HOSPITALS FOR THE MIDDLE CLASSES.

The Committee recently appointed to consider the scheme for the promotion of home hospitals for those who are able to pay, held a meeting last week at the Mansion House, under the presidency of the Duke of Northumberland. It was resolved to establish an association to provide Homes which should be self-supporting, for the treatment and cure of disease, as in hospitals, by skilled nursing, and regulated diet, under proper sanitary and hygienic conditions, with the comforts of home, for the benefit of all classes when attacked by illness who could afford to pay in various degrees for such advantages. Upwards of 200 well-known members of the medical profession and others had testified to the necessity of such institutions in a population like that of London, amongst whom a large number existed whose homes or lodgings were incapable of affording to them the comforts, nursing, and regular attention which were essential in cases of sickness. To successfully establish Homes to meet this want it would be necessary to provide sufficient funds to meet the first outlay for buildings, fittings, furniture, and other essential appliances. For that purpose the Committee decided to make an appeal to the public for funds (say £20,000) to enable them to open one or more Homes filled with every requirement of modern times. They had decided to solicit contributions either as subscriptions, conferring certain privileges, or as free gifts. They proposed that every contributor of fifty guineas and upwards should be a governor of the Association, with eligibility to serve on the committee of management, priority of admission to the Homes, and power to nominate patients; other donors to have privileges equal to the amount of their donations. It was believed that the Invalids' Home Association would thus be the means of relieving the present hospitals from much of the pressure which now existed. Should the scheme succeed, it was intended to combine Invalid Homes in town with similar institutions in the country, where the cure of convalescent patients might be completed. The Committees of Management and Finance were then appointed, and it was resolved to invite the Bishop of London, Monsignor Capel, and several other representative men, to join in the movement.

VACCINATION VIGILANCE IN WHITECHAPEL.

In publishing his report on the sanitary condition of the Whitechapel district for the quarter ending March 31 last, Mr. John Liddle, the Medical Officer of Health, attributes the comparative freedom from small-pox which that portion of London has enjoyed, during the period in question, to the satisfactory manner in which vaccination has been carried out in the district. In all cases where the inspectors ascertained that children had not been vaccinated, information was immediately given to the vaccination officer; and in nearly every instance it was found that the children referred to had neither been born nor registered in the district of the Whitechapel Union. Mr. Liddle further states that Mr. Coombes, the vaccination officer, has, during the last half-year, been the means of securing, by visitation in the localities, the primary vaccination of 360 children whose births had not been registered in the district. The inhabitants of Whitechapel are reported to be generally favourably disposed to vaccination, but the migratory habits, necessitous circumstances, and foreign nationality of many of them, involve a great amount of labour and time in explaining and effecting the desired end. Out of 1471 births registered during the past half-year, Mr. Coombes succeeded in obtaining and recording certificates of the successful primary vaccination of 1400 children. In every house where small-pox existed, parents were cautioned not to send other children to school during the prevalence of the disease; and information of the existence of small-pox was, in every case, reported to the schoolmasters and mistresses of the schools where the children attended. Consequent upon this vigilance, only sixty cases of small-pox were reported to the inspectors of the district from February 11 to May 4; of this number ten were attended by private practitioners, and four occurred in the registered common lodging-houses.

MEDICAL CORONERS.

At an inquest held at Oxford last week, by Mr. Hussey (surgeon), Coroner for the City of Oxford, the Coroner, in charging the jury, said that in that case, as they had heard, he had seen the deceased. No other medical practitioner, he believed, had seen him. After they had heard the particulars of the accident from those who were present at the time, he did not suppose they would desire to have medical testimony; but it would be for them to say so if they thought it necessary. They knew that there were many of the coroners throughout the country who were members of the medical profession; and they had, no doubt, heard it publicly suggested that, when a medical practitioner was the coroner, he should absent himself, and appoint a deputy to hold the inquest, if he (the coroner) had himself attended the patient whose death was the subject of inquiry. He need hardly tell them that the coroner's office was an office of great trust and importance, the duties of which he was bound to execute in person; and, indeed, if he were to shrink from the responsibilities incidental to the proper discharge of those duties, he would be liable to censure, and even to removal. Moreover, if he did absent himself for such a cause, he would be liable to be brought back at the instance of the jury to give his testimony as a witness, and his presence at the inquest would at once put an end to the power of his deputy, and would make the inquiry by the deputy altogether invalid. It seemed to him that it was best in such a case for the coroner himself to put the facts before the jury, and for them to say what they thought was necessary as medical testimony.

NEURIN AS A REMEDY IN DIPHTHERIA.

From experiments on the action of this body on albuminous substances, and from experience of its antiseptic action, Professor E. Ludwig, of Vienna, was led last year to recommend a trial of it as a local application in diphtheria. His advice has been followed at the Crown Prince Rudolf Children's Hospital, and, according to the reports of the physicians, Drs. Hanke, von Becker, Brezma, and Winiwater, neurin, when applied to the affected parts every two hours in a 3 to 6 per cent. aqueous solution, gave "good results, even in the severest cases." The membranous exudation was soon detached, the inflammation limited itself to the most superficial layers of the mucous membrane, and a remarkable improvement in the general appearance of the patient was observed. Similar results were obtained with solutions of tetræmethyl ammonium-hydroxide, and tetræthyl ammonium-hydroxide. Neurin, it may be mentioned, is a product of the decomposition of protagon, a phosphorised constituent of the brain, and is known to modern chemists under the prodigious name of *trimethyl*-

oxethyl, ammonium-hydroxide $(CH_3)_3N,C_2H_4O,H_2NO$. It can be synthetically prepared by the action of a concentrated solution of trimethylamin on ethylene oxide.

PETER SQUIRE.

Mr. Peter Squire, who has for forty-two years filled the office of Chemist on the establishment of the Queen, has now resigned the appointment; and her Majesty has been graciously pleased to confer it on Mr. Squire's son. This is not the time for noticing all that Mr. Squire has done for pharmaceutical chemistry, but we cannot, when recording his retirement from her Majesty's service, refrain from just referring to the fact that many important improvements in the various preparations of the Pharmacopœia are due to his practical skill and industry. Some of his own preparations, and especially his extracts, have almost a world-wide fame. The extracts of the London Pharmacopœia were entirely remodelled under his superintendence, and now the extracts of the British Pharmacopœia are made according to his processes—that is to say, mainly *in vacuo*. He rendered real and great service to the profession by the production of his "Companion to the Pharmacopœia." From the moment of its first appearance it has commanded the attention of the profession; it is met with everywhere; and the great number of large editions it has rapidly passed through attest the high value and favour with which medical men regard it. Let us add a word on our own behalf—that is, on behalf of our profession. To medical men Mr. Squire was ever most liberal, most painstaking. If there was a new remedy to be tried, Mr. Squire would get it for you, and would take the greatest interest in the investigation. Was a new or more accurate preparation of any drug wanted, Mr. Squire would put all the resources of his establishment at your service, and when you came to ask for the bill—well, there was nothing to pay.

THE CONVOCATION OF THE UNIVERSITY OF LONDON.

At a recent meeting of the Standing Committee of Convocation of the University of London, the following motion was adopted by fifteen against seven:—"That the Annual Committee request the chairman to summon an extraordinary meeting of Convocation at as early a date as may be convenient, with a view of considering how far the constitutional privileges of Convocation have been superseded by the Senate in adopting a permissive Act of Parliament by which the constitution of the University would be materially altered, without consultation with Convocation." A large number of the graduates contend that by the charter of the University the Senate are not entitled to make any decided change in the constitution of the University without the sanction of Convocation; and that the Senate have acted contrary to the spirit of the charter in availing themselves of the permissive Act of last year, under the provisions of which any of the medical licensing bodies might, if they think fit, admit women to examination; but were in no sense compelled to do so. The question in dispute between the Senate and Convocation will not now be that of the admission of women to degrees, but the more important one, the privileges of Convocation.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

At a quarterly court of the directors of the Society, held on Wednesday, July 11, the President, Sir George Burrows, Bart., in the chair, a sum of £1324 10s. was distributed among sixty widows and thirteen orphans. The new grants made at the meeting amounted to £172 per annum. Three widows and one orphan were admitted as recipients of grants. Two new members were elected. The deaths of five members were reported, that of Mr. George Cooper, Vice-President, being one of the number.

HOSPITAL FEES IN DUBLIN.

At an adjourned meeting of the clinical physicians and surgeons of the Dublin hospitals, held at the King and Queen's College of Physicians on Monday, July 23, Dr. C. J. Nixon, one of the honorary secretaries of the movement to increase the hospital fees, reported that the honorary secretaries to the medical boards of the following Hospitals had agreed, on behalf of their respective boards, to adhere strictly to the terms of the proposed new scale on and after October 1, 1877—viz., the City of Dublin, Meath, Sir Patrick Dun's, Mercer's, Steevens', House of Industry, Mater Misericordiæ, St. Vincent's, and Jervis-street Hospitals. The Adelaide Hospital agrees to the scale, but not to the arrangement made with regard to the method of payment of the perpetual pupils' fees. The new scale is as follows:—For the winter (six months), eight guineas; summer (three months), five guineas; winter and summer sessions (nine months), twelve guineas; for perpetual pupils, thirty guineas. Perpetual pupils are required to pay at least half the fee on entrance. Pending final arrangements the meeting was again adjourned.

"GO YE AND DO LIKEWISE."

The following is from our "inestimable" contemporary, the *Home Chronicler*:—

"We wish every clergyman would follow the example of the Rev. J. Strickland, B.D., who, having made a collection on Hospital Sunday, refused to hand over the money until he had received a positive assurance that no hospital, within whose walls vivisection is carried on, or abetted, should receive a single penny of it. This pledge was readily given; and we were glad to see another 'sign of the times' in an advertisement that appeared on the front page of the *Times* last week:—'*Vivisection*.—In reply to numerous inquiries, I am instructed by the Committee to state that vivisection is never practised at the Metropolitan Free Hospital.—Geo. Croxton, Secretary, 81, Commercial-street, Spitalfields, E., June 26, 1877.' The 'Metropolitan Free Hospital' must not be confounded with the 'Royal Free Hospital,' in the Gray's-inn-road, which has not made a similar declaration."

The whole performance is so lovely that it deserves—what shall we say?—at all events a slight notice in our columns. The Metropolitan Free Hospital is in such sweet odour with the profession that it can afford to do anything; but nobody ever supposed that either the authorities or the officers would indulge in vivisection (so-called) within its threshold. The arrangements for post-mortem examinations have been so good that it must be quite unnecessary to indulge in vivisection within its walls. But let the reader read. We are quite sure that it must be a great pleasure and satisfaction to those connected with the Royal Free to be thus carefully separated from their immaculate brethren of the Metropolitan Free Hospital.

ANOTHER "BON MORCEAU."

This *Home Chronicler* is really too good! We fear it would exhaust our readers should they attempt to read it in its length and breadth, but we hardly think that select extracts administered cautiously now and again will do much harm. Well, then, for one more quotation:—

"The election of three members of Council by the Fellows of the College took place on Thursday. The Editor of *The Home Chronicler*, who is a Fellow (by examination), appended the following memorandum to his voting-paper:—'I regret that I feel myself compelled to withhold my vote from Mr. Erichsen. I will not support a candidate for the Council of the Royal College of Surgeons of England who is identified, as Mr. Erichsen is, with the practice of Vivisection.'"

We have been most cautious; we have run through in our mind all the most important Fellows (*by examination*, mind you!—none of your mere respectabilities), and our intellect has got confused. Jenner, Paget, Gull, Prescott Hewett, George Pollock, Hancock, Risdon Bennett, John Hilton, Quain—in

fact, all the names of those most eminent in medicine and surgery,—it could not possibly be that of any secondary luminary! —Oh, it is quite clear we are wrong, they have got mixed up. Could it be that Erichsen is the man after all, and that he has in this base way advertised himself as Editor of the *Home Chronicler?*

HEALTH OF H.R.H. PRINCE ALBERT VICTOR.

The course of the fever under which H.R.H. Prince Albert Victor is suffering has during the past week been favourable. The symptoms have been but moderately severe.

MEDICAL PARLIAMENTARY AFFAIRS.

Science and Art.—Mr. Chamberlain drew attention to the expenditure for the promotion of science and art, contending that the grants should not be exclusively confined to institutions in London, Edinburgh, and Dublin. He was anxious to see established in every one of our great cities a museum devoted to the art and manufacture appropriate to the district. These institutions were much appreciated by the public generally, and he thought that a portion of the money for which they were taxed ought to go to towns in the provinces. Lord Sandon said that large grants from the public funds were voted yearly for the purpose of loan supplies of art treasures to provincial museums. He reminded the House of the advantage of keeping collections in the large centres of population, in contrast to distributing rare specimens among various local museums. By the present arrangement all may in a short visit to London, etc., see much more than by travelling about to smaller towns for this purpose.

Public Health.—Foremost among the measures doomed for the current session to be thrown overboard is the Public Health Bill for the metropolis. Mr. Sclater-Booth on Thursday, the 19th, informed the House that he must withdraw the Bill for the present Session. This Bill, he said, was prepared last year, at the instance of the Statute-Law Revision Commissioners, in order to supplement the work done by the Consolidation Act of 1875, which put together the substance of thirty Acts of Parliament, so far as they applied to the country at large. This year certain provisions had been added to the Consolidation Bill that experience had shown to be desirable. Many of the local authorities within the metropolis, however, objected to the consolidation of the existing laws, and hon. members representing metropolitan constituencies were not satisfied to allow the Bill to proceed unopposed. His only object had been to introduce a measure of consolidation, but, under the circumstances, he felt it would be better to withdraw this Bill for the present session. If he were to re-introduce a Bill on this subject, he could not bind himself to make it merely a consolidation Bill, but he would feel it to be his duty considerably to amend the sanitary laws so far as they affected the metropolis.

The works at the projected "Hygieopolis" or City of Health, at Courtland, near Worthing, will probably be commenced in the autumn. The architect and engineer are both busily engaged on the plans, and estimates will shortly be obtained for making the roads and parade, and for erecting the pier and protected bathing areas.

Thermo-Cautery in Lithotomy.—Thermo-cautery seems now to be the order of the day in Paris. At a recent meeting of the Société de Chirurgie, M. Verneuil stated that he had employed it in three cases of lithotomy with advantage. It is used, however, not for effecting the operation itself, but for the performance of its preparatory stage in order to discover the urethra more easily. Its employment, which is extremely easy, facilitates this very much, while it prevents urinary infiltration. Sometimes, however, a fistula persists for a long time—viz., for seven weeks in one of these cases, and three months in another. M. Anger observed that the track caused by the thermo-cautery is a very clean one, and greatly facilitates the penetration of instruments into the bladder. The incision should be made by rapid strokes, which are to be followed by irrigation with cold water. In his case, although the wound did not cicatrise for thirty days, no urine had escaped after the tenth or twelfth day. The *passage* of urine over the wound, it is true, is not dangerous, but under the ordinary mode of procedure the different planes of the perineum are retracted irregularly, and *stagnation* of urine taking place, infiltration, or at the least maceration, of the wound may occur.—*Gaz. des Hôp.*, July 21.

THE LOCAL GOVERNMENT BOARD AND ASSISTANTS AT CAPITAL OPERATIONS.

The following letter has been addressed by the authorities to the Secretary of the Poor-law Medical Association:—

"Local Government Board, Whitehall, S.W.
July 17, 1877.

"Sir,—I am directed by the Local Government Board to state that they have had under their consideration the grounds stated in your letter of May 10 last, upon which the Council of the Poor-law Medical Officers' Association base their application for the issue of a general order fixing the remuneration of medical practitioners called in to assist Poor-law medical officers in performing capital operations.

"The Board have very carefully considered the representations contained in your letter; but, as at present advised, they do not think that sufficient reasons have been adduced to render it expedient to alter the existing regulations on the subject.

"The circumstances connected with each of the capital operations referred to in your letter are, in practice, so different as to render it impossible to lay down a fixed scale of remuneration, such as would be just alike to the medical practitioner and to the ratepayer. Moreover, the Board consider that it would be undesirable to encourage the performance in the dwellings of the poor of such serious operations, sometimes involving danger to life, as those referred to. When operations of this nature are performed at the pauper's house, neither the constant care and nursing, nor the means and appliances for carrying the operation to a successful issue, can as a general rule be provided.

"For the comparatively few exceptional cases in which it is absolutely necessary for the district medical officers to perform capital operations, and for the right means of dealing with such grave contingencies, the law and the regulations of the Board, as has been already pointed out, appear to make sufficient provision. "I am, Sir, your obedient servant,

"(Signed) H. Owen, Jun., Assistant Secretary.

"To J. W. Barnes, Esq., F.R.C.S.,
"Hon. Sec., Poor-law Medical Officers' Association,
"3, Bolt-court, Fleet-street, E.C."

NOTES ON THE

SANITARY STATE OF MOORISH TOWNS, AND ON THE CLIMATE AND DISEASES OF MOROCCO.

(*From a Correspondent.*)

Fez, June 27.

The opportunity of visiting the Moorish cities of Fez and Mequinez under favourable circumstances seldom presents itself. Your correspondent, therefore, gladly availed himself of the departure from Tangier of a Portuguese Embassy, of which he was appointed physician, to congratulate the Sultan on his accession to the throne. A short account of the experience gained, from the medical standpoint, will perhaps interest your readers.

One thing must at once occur to the mind of the medical observer in Morocco. If there is any truth in the influence of sanitary arrangements on the public health, how is it that health is preserved at all in the Moorish towns? Take, for example, this capital. Fez is a town of about 45,000 inhabitants, surrounded by high walls. So narrow are the streets that in many of them it would be impossible for two people to walk abreast. Even the principal streets in which business is conducted are not more than ten feet wide. Owing to the height of the houses, many of which are of three storeys, and the practice of covering the street on a level with the first storey with reed roofs, and often with vines, the rays of the sun never reach the streets, except here and there in some more open spots. The consequence of this is that the inhabitants of Fez—hardly ever exposed to the sun—are a comparatively light-complexioned race of Moors. Many, indeed, present a pallid etiolated appearance. The shops are mere cells, placed about five feet from the ground, and in these the

owners sit crouched up the whole day, waiting for customers. The walls of the houses and shade-roofs spoken of are covered with dust and festooned with cobwebs.

The streets are rarely swept, and bad smells are prevalent. It is noteworthy, however, that one never experiences the smell of sewage. The reason is not far to seek: Fez, like other Moorish towns, possesses a system of drains and an abundant and continuous water-supply. Every house of any pretensions is provided with a fountain in its courtyard, by which the drains are constantly flushed. Moreover, there is no communication between the streets and the sewers. The surface-water finds its way out of the streets by other channels. The closet is usually placed just inside the street entrance of the dwelling-houses, and too often makes its presence known by a vile smell. But it is, no doubt, due to the abundance of water that the bad effects of sewage fermentation are not severely felt, since the sewers open only into the houses. In proof of the absence of epidemic diseases, it may be mentioned that whereas, since his arrival in Morocco, your correspondent has been consulted in hundreds of cases, none of them except one was a case of fever, or indeed of acute disease. And in the case of the exception the remittent fever seemed to be the revival of a previous attack contracted at Jaffa. It occurred here in the person of a Jewish priest, on a mission from Jerusalem to his brethren in Morocco. Outside certain of the city gates there is a vast accumulation of rubbish, consisting amongst other things of vegetable and animal offal—dead dogs and cats, and even dead horses. The stench from these is very bad, yet the people living in the neighbourhood do not seem to suffer in health.

The drinking-water of Fez is procured from a river which flows by the town, and which receives its drainage subsequently. This water almost invariably induces diarrhœa in strangers. The members of the Spanish and German Embassies, which immediately preceded us, suffered severely from this cause. At your correspondent's suggestion, the drinking-water used by the Portuguese Embassy was conveyed from a source at a considerable distance, and we escaped almost entirely. The only casualty which has hitherto occurred to the Embassies was to a servant belonging to the German Embassy, who died from the effects of a sudden escape of the vapour of ammonia from an ice-making machine.

The journey to Mequinez, a distance of about 160 miles from Tangier, was performed by easy stages, as the weather was very hot—in one place the thermometer stood at 100° Fahr. in the tents; and it is worthy of remark that on arriving at Fez (about thirty-five miles from Mequinez), where we encamped outside the walls by the river's side, almost all our party of about 150 persons—Moors as well as Europeans—were attacked by catarrhal symptoms which continued some days.

There can be no question about the healthiness of the climate of Morocco, notwithstanding the great heat of summer in the interior of the country. And yet, unfortunately for the peace of mind of the European medical man, he is sure to have a larger practice amongst the natives than he desires. As soon as it becomes known that a *tabeeb*, or doctor, is amongst a travelling party, his fame travels before him. From this it generally happens that on arriving at a stopping-place the doctor alone is compelled to exert himself, while his companions are taking well-earned rest. The *clinique* of your correspondent was often extensive, and a few deductions and observations from notes made from time to time will probably be of interest.

It is certain that phthisis is very rare in Morocco. Three cases only were met with; one was that of a man who seemed to have contracted it from a rigorous imprisonment of thirteen years at Mequinez. This is the more remarkable, because scrofula in its external forms is not uncommon in children. Bronchitis is not unfrequent, and the same may be said of chronic rheumatism. No case of acute rheumatism was met, and diseases of the heart appear to be unusual. Dyspepsia, often of a severe kind, is exceedingly common, and is to be attributed to the voracity with which the Moors devour their *kuscusoo*, and, amongst the better classes, to the practice of drinking very hot, very sweet, and very strong green tea several times in the day. Cases of diabetes were also seen. The Moors lay great stress on fatness in their wives and concubines; and the ladies who have the misfortune to be thin form a large proportion of those applying for medical aid, with the hope of being able to attain the proper *embonpoint*. Barrenness is a frequent subject of complaint, and in the case of old men increase of virile power to a most unreasonable extent is also demanded. Skin diseases are very common, especially of the scaly class. But leprosy, which prevails in the city of Morocco, seems not to be indigenous at either Fez or Mequinez. A curious skin affection was met at Mequinez; it was that of a young man, a Jew, the cuticle of whose palms and soles had long continued to be shed in large thick flakes, as sometimes occurs after scarlet fever. He denied having had syphilis. Notwithstanding that the heads of all young males are invariably kept more or less closely shaved, scurfy ringworm (*tinea tonsurans*) is so prevalent that it may be safely said to be universal amongst children. Its commonness prevents its being regarded as worth interfering with; and one is never asked to prescribe for even the worst cases. After puberty it wears out, and it is rare to see an adult affected. Ophthalmia of a virulent and (most likely) highly contagious kind is frightfully common. Flies, which swarm everywhere, may be seen crowding round inflamed eyes, the owners of which are too indolent to be at the constant trouble of driving them away. These insects are probably a constant means of communicating the disease. The number of people who have lost an eye one meets is remarkable, and besides these there is a larger number affected with opacities of the cornea in one or both eyes. Except in the case of beggars, the totally blind are not much seen in the streets. Another thing which calls the attention of the observer is the number of people who have lost noses. This, of course, points to the prevalence of syphilis. Notwithstanding the jealous way in which women are guarded in Morocco, prostitutes, Moorish as well as Jewish, exist in all the towns, and syphilis prevails among them. In the absence of all proper treatment, the ravages of the disease are very marked.

The state of medical jurisprudence amongst the Moors may be judged of from what follows:—A young negress died suddenly in the Royal harem, and your correspondent was sent for by the Sultan to investigate the cause of death. All that could be ascertained was that the girl was in good health on the morning of the day she died, and that there were no marks of violence about the body. Particular attention was requested to be given to the neck in reference to strangulation. But the great point to be determined was whether poison had been used. This, it was supposed, one could determine by inspecting the tongue. It was in vain that an examination of the interior of the body was requested. The Sultan would not sanction a thing so contrary to Mohammedan prejudice. The cause of death remained therefore a mystery. It is more than probable that poison—in the use of which the Moors are skilled—was employed. But great caution was necessary, lest even an expression of suspicion might cost some possibly innocent persons the loss of their heads.

The American Medical Association and Total Abstinence.—In his address as President of this body, Dr. Bowditch, of Boston, at the recent meeting at Chicago, proposed that in future total abstinence from all intoxicating liquors should be observed during their annual meetings. He justified this extraordinary proposition on the following grounds:—"It seems to me that every one of us, even if he disagree to the proposition of total abstinence, and regards a prohibitory law as simply impossible, would be willing at these meetings to forego the use of any stimulants, for the sake of not leading some weaker brethren into mischief, and because such a position, taken by this great Association, would have a most important, though indirect, effect on the noble cause of temperance throughout the land. I would submit, therefore, whether we, as a body of physicians believing in a true temperance, although varying in our views of what that may mean, should not declare that hereafter we will respectfully but decidedly decline any public or private entertainment, for our whole body, where intoxicating drinks are to be offered." Respecting this singular proposal, the editor of the *Boston Medical Journal* (June 7) observes—"The proposal to forbid the use of any intoxicating drink at all social gatherings in which the members of the Association take part somewhat surprises us, for we had looked on Dr. Bowditch as the apostle of beer and light wine—of temperance, in a word, as opposed to prohibition. (He has written some excellent papers to this effect.) It seems to us that the best example that the Association can set is that of moderation in conviviality, and that if it cannot partake of wine without such a display as was witnessed in Boston in 1865, it is a conclusive proof that the Association is not formed of the proper material."

FROM ABROAD.

Teaching Pathological Anatomy.

M. Cornil, in a recent number of the *Journal des Connaissances Médicales*, of which he is the editor, thus describes the mode of teaching pathological anatomy employed by the newly appointed Professor, M. Coyne, at Lille:—

"We have several times spoken of the teaching of pathological anatomy and autopsies, and shown how in that respect our institutions are behind those of Germany, Switzerland, Italy, and all the countries of the North. We must, however, make an exception as regards the teaching adopted at the State University recently established at Lille; and we beg leave to initiate our readers in the mode of procedure adopted by Dr. Coyne, Professor of Pathological Anatomy in the Medical Faculty of that University. On accepting the chair which was offered him, he stipulated for the right of making the autopsies in the clinical services. He well knew that a merely theoretical course of lectures could not impart complete instruction or even prove interesting, and that demonstration and the technical teaching of autopsies must constitute an essential part of his functions. He, moreover, felt convinced that he ought not to confine himself to the delivery of the three hours per week regulation-lectures during one-half of the scholastic year; but that, besides his lectures, he owed it to himself and the students to continue throughout the year, in the post-mortem theatre and in the laboratory, the practical demonstration of the subjects relating to his speciality.

"In order to fulfil this programme, Prof. Cornil, who has no clinical service, attends at the hospital amphitheatre every morning, and makes the autopsies himself before the pupils, dictating the particulars, which are inserted in a special register,—the results of ulterior examination of parts selected during the autopsy being inserted opposite the general account. The whole statement is placed at the disposal of the Clinical Professor, who, on his part, supplies a note relating the case. After the autopsy, which is accompanied by practical comments of the greatest utility to the students who are present, the portions which require histological examination are put aside. This demonstration continues for a longer or shorter period, according to the number of autopsies that have to be made. About one o'clock the Professor repairs to the laboratory, and describes to the students following the laboratory practice the various parts which have been reserved from the morning. These parts are distributed among the pupils, who make preparations under the direction of their teacher. About four o'clock, just before breaking up for the day, the Professor goes round to each pupil, and examines the work they have done, and places some two or three of the preparations under the microscopes, explaining them by the aid of sketches on the board. This instruction is to be pursued daily throughout the year; and during the winter session, in his formal lectures delivered at the Faculty, the Professor endeavours to render his instruction as fruitful as possible, by exhibiting and demonstrating fresh specimens at the end of each lecture.

"This we do not hesitate to affirm," M. Cornil concludes by stating, "is the best, and, we might add, the only, manner in which pathological anatomy can be taught."

Diagnosis of Diabetes.

In a clinical lecture upon this subject (*Gaz. des Hôp.*, May 22), Prof. Hardy, after narrating the particulars of a case of diabetes, made some useful practical observations upon the signs by which it may be recognised. Some thirty years ago he observed that almost the only physical characteristic relied upon was the sugary taste of the urine; but since then the progress of science has enabled the practitioner to dispense with this procedure, chemistry having placed at his disposal a number of means, of which the most simple, which are also those most employed, may be mentioned. First, there is caustic potash, either in solution or in granules or solid fragments; heated with urine containing sugar, it immediately produces a more or less yellow or brown colour, the intensity of which is proportioned to the quantity of sugar. This is an excellent procedure, which Prof. Hardy prefers to all others, and which enables extremely minute traces of sugar to be detected. Another method consists in adding to the urine a small quantity of bismuth, potash, or carbonate of soda, when a black colour indicates the presence of sugar. Barreswill's and Fehling's solutions of copper, from which sugar precipitates the copper, are not always at hand; and another procedure which has been recommended to country doctors is the employment of pieces of wool, which have previously been dipped in a solution of bichloride of tin. If one of these be placed in the urine while it is heated, a black colour is produced, which is due to the precipitation of the tin. But this is a defective procedure.

In order to be induced to examine the urine for sugar, our attention must have been drawn to some of the circumstances indicative of diabetes. This is, indeed, a disease which is often overlooked, so that the patient may suffer from it a long time before either he or his attendant suspects its existence. Still, there are indications which ought to arouse the attention of the intelligent practitioner, some of which have been wrongly called fundamental, the others only being met with from time to time. The fundamental characters are five in number—viz., glycosuria, polyuria, polydipsia, polyphagia, and autophagia. There is only one of these that can justly be called fundamental—glycosuria,—as the others may be absent, or only so slightly marked as to escape observation. The presence of sugar in the urine is revealed by many indications. We may often recognise it by greyish patches on the clothing or linen, which are reduced to powder when scratched with the nail. In women the chemise, from prolonged contact with the urine, may become spotted and stiffened as if by drops of syrup. Another circumstance indicating the sugary savour of the urine, especially in the country, is the great number of flies or ants that will be attracted around the vessel containing it. As to polyuria, it must not be thought an easy matter to decide when a patient passes more than the normal quantity of urine, for it is very rare for him to complain of this, so that we may be led to the suspicion of diabetes only by his frequent retirement to pass urine. Polydipsia is a very important sign, concerning which patients often say nothing unless interrogated. We then learn that they are constantly thirsty, and especially at night. Persons who cannot go to bed without a bottle of water at their side are almost always diabetic. Although polyphagia exists to a very great extent in diabetics, it is not a fundamental sign, as some of them have an invincible repugnance for food. Persons who are called "great eaters" not infrequently become diabetic. Autophagia is shown by muscular debility, emaciation, and anæmia, which are observed in most diabetics. Indeed, whenever an individual manifests this condition without any cause discoverable in the condition of the organs, on examining his urine it will almost always be found to contain either sugar or albumen.

Besides these signs, there is another observed in the patient the subject of the lecture, of great diagnostic value—viz., genital impotence, which is one of the first signs of approaching diabetes; and whenever individuals are met with who, previously virile, become weak and impotent without coinciding disease, especially of the spinal marrow, diabetes will usually be found to be the cause. Then, again, valuable information is derivable from the mouth, for besides the insatiable thirst and dry mouth, some patients complain of a disagreeable taste, which is sometimes acrid, and at others faint or bitter or sugary; and it is this perverted taste which contributes to maintain the thirst. It must not, however, be thought that the taste of sugar, complained of by some diabetics, is a constant thing, for, on the contrary, it is that which is most rarely met with. The mouth also frequently exhibits an aphthous condition, while the edges and tip, and even the whole surface of the tongue, may present a red aspect, as if the aphthæ had been removed. The gums also are often softened, fungous, or bleeding; while in some the teeth become loose or fall out without being decayed, and in others become carious. The breath is frequently of a bad, acid smell, and the saliva on examination is acid instead of neutral. Another fact which is not much known, and which has sometimes led to the diagnosis, is the existence of intertrigo at the commissure of the lips. This intertrigo labialis is not exclusively connected with diabetes, but when met with should always lead to an examination of the urine. With regard to the digestive organs, bulimia on the one hand, and

a complete repugnance for food on the other, with dyspepsia, should lead us to suspect diabetes. The skin also presents some valuable indications, most diabetics having it very dry, with an absence or singular diminution of transpiration. This is, however, only observed when the diabetes is advanced and there is a considerable quantity of sugar in the urine. This is not the case with furuncles, which may recur eight or ten times in the course of six months; and with these may be mentioned anthrax, affecting the nape and other of the upper parts of the body—which is very common in diabetes. There is also an eruption peculiar to these patients, a gangrenous ecthyma, which appears on the legs, and is characterised by more or less considerable pustules, which are surrounded by a gangrenous circle. The pustule breaks, and the eschar falls, leaving an ulceration. But a much more important occurrence is the diffused phlegmon which supervenes on the slightest cause in diabetes, and frequently proves fatal. Spontaneous gangrene, chiefly occurring on the upper limbs, has long been a sign by which the existence of diabetes has been indicated. There are other cutaneous affections, which are much less known, and which are yet of importance, as their presence alone has often led Prof. Hardy to the diagnosis of diabetes. Thus, in women, there may be pruritus of the genital organs, which is accompanied at first by a kind of redness around the meatus, the erythema gradually extending to the labia, the entire vulva, the groins, and often over the whole belly. "It has happened to me to diagnosticate diabetes pretty frequently in women by the existence of erythema in the supra-pubic fold. In such cases, whether the redness exist alone, or is accompanied by a slight transpiration, always examine the urine. It is an almost constant sign of diabetes. The knowledge of the fact is of interest, because it is a means which, although indirect, is certain of arriving at a diagnosis. It has been sought to explain this occurrence by the contact of the parts with the saccharine urine, but I have seen the affection occupy regions of the body which the urine never approached. I have seen this eruption, in fact, between the two breasts, in the armpits, behind the ears, and at the commissure of the lips. There is, then, some peculiar condition of the economy and of the blood characterised by this eruption, as also by the insupportable itching which accompanies it. These phenomena do not exist only in women, as analogous ones are observed in men. Thus we observe affections of the glans and prepuce, especially when this is somewhat long. Between these there is a purulent secretion, a peculiar balano-posthitis, which induces extremely distressing itching. So also the glans may, although rarely, become the seat of a special phenomenon, a kind of greyish-white thick pseudo-membrane covering the whole or part of the glans. Frequently, also, we may observe an erythematous inflammation of the scrotum, and especially a pruritus analogous to, and in all respects comparable to, the vulvar pruritus."

As other signs of diabetes we have also affections of the eye. A variety of soft cataract is, in fact, proper to this affection. It is also often accompanied by amblyopia, due to changes in the optic papilla, deposits in the retina, etc. Lastly, in certain diabetics, intense neuralgic pains have been noticed, which are more persistent than those ordinarily observed. These pains especially manifest themselves in the calves, and in the articulations of the foot. They are prolonged sometimes for months; and if in cases of obstinate neuralgia the urine is examined, sugar will frequently be found to be present.

"Such are most of the principal signs," Prof. Hardy concludes, "which may reveal the presence of sugar in the urine. There are some among them which may seem to you at first insignificant; but still, they have a very great value if you know how to apply them. In these cases, the physician in face of his patient resembles the *juge d'instruction* in presence of the criminal: he seeks for indications on every side, and invokes the means to put him on the true path. Here the crime is diabetes, and the urine is the criminal. Search about, then, for indications in this direction, sometimes even for the slightest, adding one to another, and, especially if you take care to examine the urine, they will lead you to the diagnosis. Lastly, recollect this well—that of all diseases which are overlooked, diabetes is the most common, although its history has been written so long ago. There are cases, indeed, in which it may be unrecognised, where the disease conceals its symptoms; but it is in such cases that we find the sagacity of the physician brought into play, and that he ought to know how to profit by the slightest indication in order to enable him to establish his diagnosis."

REVIEWS.

Fownes' Manual of Chemistry, Theoretical and Practical. Vol. I. Physical and Inorganic Chemistry. Twelfth Edition, revised and corrected by Henry Watts, B.A., F.R.S., etc. London: J. and A. Churchill. Pp. 551.

Take it all in all, there is no book of chemistry like Fownes's, and it has certainly lost nothing under the editorship of Mr. Watts. It is in every way up to the time. We think the publishers have done well to divide the work into two separate parts, each complete in itself. The work thus gains decidedly in compactness and convenience. In itself it needs no commendation.

St. George's Hospital Reports. Edited by W. Howship Dickinson, M.D., F.R.C.P., and Timothy Holmes, F.R.C.S. Vol. VIII. 1874-6. London: J. and A. Churchill. Pp. 580.

The present volume of these reports has been so long delayed that we had almost fancied they had ceased to exist; even now, when they appear, we miss the names of several old and esteemed contributors. Nevertheless, the present volume contains some admirable matter. Let us cite Barnes on Retro-Uterine Tumours, Blandford on Nerve Degeneration, Clifford Allbutt on Menière's Disease, Holmes on Amputations, etc. The volume is, however, richest as regards the Annual Reports of the Registrars. Here, in a compact space, are collected a vast number of facts available for comparison and reference. The volume is very well worthy of attention, and is invaluable for reference.

Traité du Microscope et des Injections. Par Ch. Robin, Membre de l'Institut. Deuxième edition. Revue et augmentée. Paris: J. B. Baillière et Fils. 1877. Pp. 1100.

Treatise on the Microscope and Injections. By Ch. Robin, Member of the Institute. Second Edition. Revised and augmented.

M. Robin states in his preface that though but a few years have passed since the first edition of his book was published, the march of scientific microscopy has been so rapid that important alterations and additions have had to be made to this new edition. The principal alterations concern what he calls "technical micrography."

The volume is divided into three parts. In the first part, the construction of microscopes is exhaustively treated of, and it embraces the productions and peculiarities, *quâ* the microscope, of England, France, America, Germany, etc.; also descriptions of all the accessory apparatus, and the methods of using it, of microtomes, and, indeed, of the whole mechanical art of microscopy. Part II. points out the application of microscopy to anatomy, physiology, medicine, natural history, chemistry, and agriculture. It is, indeed, in this part of the work that the chief changes and additions have had to be made; it now forms more than one-half of the entire book, and embraces a very large field of work. The student or practitioner will find this chapter of the greatest value, including as it does instructions for the microscopic examination of the blood, bile, saliva, urine and urinary deposits, and fæces, as well as of parasites of all kinds, human as well as animal. Part III. treats of the subject of the manipulative part of microscopy, and especially of injections. The whole book is richly illustrated with figures, the execution of which deserves our highest commendation. We have thus given a sketch of the general plan of the work; it is a perfect encyclopædia of microscopy, and for the advanced student a work which is almost indispensable to his laboratory. For beginners it is decidedly too bulky, and contains too many methods to be of much service. There is an "*embarras de richesses*," which, while it delights a man who knows his subject practically, simply overwhelms a learner. The optical part of it, enriched with figures, is very well done, and very clearly expressed, and cannot fail to interest all who read it. We notice in the chapter on the hardening of objects ready for cutting, that the obsolete method of coction is still retained, and that the still more useless plan of desiccation finds a place. One of the chapters with which we are least pleased is that on making sections. Here it is that the variety of methods already alluded to renders selection of the proper one too much a matter of chance. There is a little too much taken for granted. Thus,

when speaking of cuttingvery delicate structures (we venture to think that all structures ought to be considered and treated as delicate), our author says, "It is seized with the fingers of the left hand, and the required sections are made by drawing the razor with its edge turned towards one, or otherwise, *according to circumstances, and the nature of the organ.*" The italics are our own: we would ask, How is a beginner to know the circumstances which require that the blade shall be turned towards him or from him? Indeed, we are quite at variance on this point: some operators cut from, while others cut towards, themselves. It is a matter purely of accident which method is adopted; but whichever way one begins with, it is probably used irrespective of the material to be cut. We should have been pleased to see the use of the microtome more generally advocated. There can be no doubt that by its aid time is saved, the art of cutting sections is more quickly attained, the sections are more uniformly thin, and they are larger. In pathology the size of a section is a matter of some moment; for it is necessary, in order rightly to appreciate the diseased part, to see it side by side with the healthy structure, and to study also the boundary-line between the two. On these, among other, grounds we strongly advocate the use of the microtome; like everything else, however, it requires practice. The chapter on micrometry is ample and clearly written. This is a subject which is often left out of such books, though it is one of the very greatest importance. We cannot go further into the book. Enough has been said to show its scope, and the manner in which the author's task has been accomplished. The book is exceedingly well got up, and does credit to the well-known firm of publishers by whom it is issued.

The Treatment of Spina Bifida by a New Method. By James Morton, M.D. Glasgow: Maclehose. 1877. Pp. 120.

Writers on spina bifida for the most part state that the tumour is covered by healthy skin, but Dr. Morton finds that in the majority of cases the skin has been more or less altered; usually it is much thinned, and hence translucent. This is our own experience also. Indeed, in many cases the skin has been so thin as to give rise to the fear of immediate rupture. The sac may be said to consist of the membranes of the cord; its neck is formed by an opening, the result of non-union in the laminæ and spinous processes of one or more vertebræ. The contents of the sac are—first, the spinal or subarachnoid fluid, an albuminous liquid, more or less watery, alleged by some to contain a saccharine substance; second, a portion of the cord itself, or cauda equina, or some of the spinal nerves. In dorsal cases the cord usually projects in the form of a curve into the sac, and usually this projection is in the middle line, and closely applied to the back of the sac. Having thus described the nature and anatomy of this peculiar malformation, our author passes in review the various kinds of treatment which have been suggested and tried. He says, "Operations may be either palliative or radical. Among the palliative may be named pressure, although the name of operation can hardly be applied to it, which has been proposed to be gradually and cautiously applied. We have heard of no good result from it, and fear it would be likely to hasten the bursting of the sac, and the mischief invariably attendant upon this. Repeated tapping with a fine trocar, followed by pressure, is said to have been followed by two successes in the hands of Sir Astley Cooper." Attempts at radical cure have been made by ligature, excision, and injection. The first of these methods is almost invariably fatal. As regards excision, Dr. Morton says, "With the knowledge now possessed of the anatomy of this malformation, surely no one would think of excising the sac; and yet we are told that it has had a few successes." Injection is obviously the treatment least open to objection; and it is the one which has been most frequently resorted to, and the most successful. Our author has placed it last on his list, because he has most to say about it. His "new method" is itself injection of an iodine solution. The fluid is also new, and he calls it "iodo-glycerine solution"—so named from its component parts. It consists of iodine gr. x., pot. iod. gr. xxx., glycerine ℥j. The main points in this treatment are—"the prevention of the continuous loss of the subarachnoid fluid, which must be regarded as essential to the integrity of the spinal cord, and a necessary part of the contents of the spinal canal," and the employment of a fluid of less diffusibility than usual for injection; and he advises the use of a medium-sized trocar and canula, on account of the thickness of this fluid. It will be seen that Dr. Morton insists on three points chiefly—the prevention of the loss of spinal fluid by the application of collodion or otherwise; the withdrawal only of a portion of the contents of the sac at one time; and the use of the iodo-glycerine solution. Dr. Morton's book contains, in the concluding chapter, statistics of the operation to the present time. The statistics of the cases subjected to this plan of treatment, so far as known or recorded, are these:—Fifteen cases in all, of which twelve have been successful and three unfortunate. All his own lumbar cases have been fortunate. Of the three cases which died, one was the case of a child hopelessly deformed and paralysed—a class of cases as yet completely beyond the resources of our art; another died from causes altogether unconnected with this special deformity; while in the third case it was not conclusively ascertained whether it was a true case of spina bifida, or a case of encephalocele, situated, as it was, high in the cervical region. Thus it will be seen that none of the three fatal cases died from the operation. Such figures speak for themselves, and best tell their own tale. The book is very suggestive, and we hope the success which Dr. Morton has had may induce others to try this "new method," for the invention of which Dr. Morton deserves no little credit, the treatment of spina bifida having hitherto been a very thankless task.

Diseases of Women. By Lawson Tait, F.R.C.S., Surgeon to the Birmingham Hospital for Women, etc. London and Edinburgh: Williams and Norgate. 1877. Pp. 304.

There are few branches of medicine our knowledge of which is more modern than is that of gynæcology; there is, therefore, much to be written about it. In the great work of Dr. Barnes we possess a book which represents the present state of science in this department, but the size and fulness of which make it a volume ill-suited for the average student. For such we want a book clear enough to be readily understood, brief enough to be quickly mastered, and yet complete and accurate.

Judging from its size, and from some advertisements which have appeared, the book we are noticing seems designed to supply this want. It is a work which treats of the diseases peculiar to women from the point of view of the practical surgeon. Anyone who opens it expecting to find a careful summary and comparison of different theories as to pathology and modes of treatment, will, however, be disappointed. But anyone who wants to know what Mr. Tait has seen, what his opinions are, and what is his practice, will find all this dogmatically stated. The diseases which it describes are arranged strictly according to locality. Mr. Tait begins at the mons veneris, and ends at the pelvic bones; and as he writes upon each part, he puts down his recollections of the different sorts of disease he has seen in it, and the treatment which he thinks has done them good. Of the pathology and the natural history of the diseases of women, of their relations to one another and to derangements of other parts of the organism, we find very little. Nor, when the author puts forth opinions not identical with those generally accepted, do we find any exposition of his reasons for doing so, except that sometimes he refers to work of his own published elsewhere.

The distinguishing merit of the book is its originality and its practical character. The subject is considered from an independent standpoint, and the exigencies of practice are always kept in mind. We find a description (the first we have seen, and certainly the first at all full account yet given) of that curious affection of the vulva, marked by exceeding tenderness, and the presence of patches of purplish-red discoloration round the vaginal orifice. But we cannot help thinking that Mr. Tait has generalised from too few cases, and has consequently described the malady with a precision that the facts as yet known about it hardly justify, for we have seen cases which did not in all points conform to Mr. Tait's statements concerning them. Nevertheless, we are much indebted to Mr. Tait for what he has given us.

While we desire to call attention to the fact that there is much good matter in Mr. Tait's book, yet we must permit ourselves to say that we think the manner is not quite that in which scientific works ought to be written. He on all points lays down the law in an *ex cathedrâ* fashion, without condescending to exhibit the foundations on which his faith is built. His

statements are at times too forcible to be accurate—*e.g.*, we are told that in chronic metritis iron is a poison. This style of writing detracts much from the value of the book. Then we are often told that this or that can only be diagnosed by means of the "*tactus eruditus*," an art impossible to convey to others; and we find the same as to treatment, certain modes being described as only safe in "skilful hands," without explanation why. "*Tactus eruditus*" in this sense may be vulgarly translated—rule of thumb. It means that the author on these subjects has only confused, unanalysed impressions, and therefore has not attained exact knowledge. We hope that, should a future edition be called for, Mr. Tait will not let the profession into the secret that this is his method of diagnosis. Passages like these make us ask, if the author cannot explain his method of diagnosis, or the principles which should guide the skilful hands, why write a book? or, if a book must be written, why not omit the subjects on which he can throw so little light? And lastly, nearly all the illustrative cases which are referred to in the book were seen in private practice, in consultation with another medical man whose name is given. As we presume they were only seen once, or, if more than once, at comparatively distant intervals of time, we cannot but think such cases inferior in value to those observed under the conditions of strict management and keen criticism which obtain in a good hospital.

This book is distinctly not one written for the public; but in the points on which we have remarked it bears an unfortunate resemblance to books of that class. We therefore hope that, should a future edition be called for, Mr. Tait will remove the blemishes which remind the reader of such works. We cannot call this a good students' book, not only on account of the want of exactness of its style, and the unscientific references to the *tactus eruditus*, but because students need a book giving what is generally accepted on the subject; not one reflecting exclusively the idiosyncrasies of the author. And further, because we expect a good students' book to not merely present facts, but to teach a scientific method of work. We fear that students who read this book will gather the idea that the only test of accuracy is the opinion of Mr. Tait, or of someone who possesses the so-called *tactus eruditus*.

But the work, representing as it does the impressions of a surgeon of considerable experience, great ability, and independent judgment, is worth the perusal of all who practise this branch, and are therefore able to judge for themselves of what is said in it.

OBITUARY.

FREDERIC TICEHURST, M.R.C.S., ETC.

IT is with deep regret we record the death of Frederic Ticehurst, Esq., which took place at his residence, Carlisle-parade, shortly before two o'clock this (Friday) morning. As most of our readers are aware, the deceased gentleman has been seriously ill for several months past. The internal malady from which he suffered was so severe that it gave little or no hope of his recovery. In his death Hastings has lost one of its most skilful medical practitioners and one of its most useful public men. For nearly half a century the name of Ticehurst has been a "household word" in the borough, and those whose memories and local knowledge extend over the period we name best know the worth of that active life which has now been brought to a peaceful close. Mr. Ticehurst was formerly one of the Medical Officers of the Hastings Union, and his unvarying kindness to the poor made him deservedly popular. He was several times elected Mayor of Hastings, for a series of years he faithfully and zealously acted as an Alderman of the borough, he has long been one of the most esteemed of our magistrates, and besides his lengthened connexion with the medical charities and other local institutions, he was Coroner for the Borough until failing health led him to resign. His death will be mourned over a wide circle in both public and private life, and the deepest sympathy will be felt for his widow and family.

THE International Statistical and Meteorological Congresses, which were to be held at Rome in September, have been postponed for a year, on the representation, it is stated, of England and Austria.

MEDICAL NEWS.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College at a meeting of the Court of Examiners on the 24th inst., viz.:—

Ainsley, T. G., West Hartlepool.
Armstrong, G. R., L.K.Q.C.P.I., Kingstown, Dublin.
Ashworth, J. Wallwork, Manchester.
Briggs, H., M.B. Edin., Prestwich, near Manchester.
Devis, C. J., Birmingham.
Drinkwater, H., M.B. Edin., Sunderland.
Dumbleton, E. H., Southampton.
Evans, H., Barmouth.
Fairclough, J. J. K., M.D. Queen's Univ. Ire., Manchester.
Fenwick, B., M.B. Durham, Harley-street.
Gomes, D. A., L.R.C.P.L. and L.M., Bombay, Bombay.
Harrison, D., L.K.Q.C.P.I., Liverpool.
Jones, C. L., B.A. Cantab., L.S.A., Blackfriars-road.
Jones, R. H., Liverpool.
Jones, W. F., Bangor.
Kirker, G., M.D. Queen's Univ. Ire., Belfast.
McClelland, J., M.D. Queen's Univ. Ire., Liverpool.
Norton, T. C., Bristol.
Pilkington, J. E., Manchester.
Rose, J., Liverpool.
White, H. H., M.B. Camb., Corwen.

Five candidates who passed in Surgery at previous meetings of the Court, having subsequently obtained medical qualifications, were admitted Members of the College, viz.:—

Gristock, W., L.S.A., Blandford-sq.
Prytherch, H., L.R.C.P.E., Anglesey
Scott, W. G., L.S.A., Bedford.
Symington, J., M.B. Edin., Fenny Stratford.
Walcott, H. L., L.R.C.P.E., Tenby.

Two candidates who had previously qualified in Surgery, having passed in Medicine, were also admitted Members, viz.:

Bowen-Jones, L. M., Gwarmacwydd-Narberth.
Cooper, T. H., Hampstead.

Three candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College. The other two candidates were referred to their professional studies for a period of not less than six months.

The following gentlemen were admitted on the 25th inst.:

Allard, J. H., L.R.C.P. Ed., Tewkesbury.
Bartlett, F. P., Brixham.
Benham, F. L., Gloucester-terrace.
Bowen, O., L.S.A., Llandilo.
Bradford, C. L.S.A., Birmingham.
Dennis, F. S., M.D. New York, New York.
Harris, G.F.A., Sutherland-gardens.
Jewell, C. C., Brighton.
Messum, J. A. B. G., L.S.A., Champion-hill.
Morgan, E. S., Swansea.
Prowse, A. B., Cambridge.
Shaw, C. T. K., St. Leonards-on-Sea.
Sidebotham, G. W., L.S.A., Hyde.
Smith, A. J., Ladbroke-crescent.
Smith, H. U., Basildon.
Steele, C. E., L.S.A., Liverpool.
Turner, G. R., Sussex-gardens.
Uhthoff, J. C., Penge.
Whittle, E. M. G., M.D. Dub., M.B. Camb., Cambridge.

Four candidates who passed in Surgery at previous meetings of the Court, having subsequently obtained medical qualifications, were admitted Members of the College, viz.:—

Brock, A. C., L.R.C.P. Lond., Guernsey.
Galloway, A. W., L.R.C.P. Lond., Fitzroy-road.
Langdon, J. S., L.R.C.P. Lond., Queen's-square.
Wright, A., L.S.A. Lond., Paddington.

Two candidates who had previously qualified in Surgery, having passed in Medicine, were also admitted Members, viz.:—

Prior, E. T., Talbot-square.
Vasey, S. W., Cavendish-place.

One candidate passed the examination in Surgery, and when qualified in Medicine will be admitted a Member of the College. The other six candidates were referred to their professional studies for a period of not less than six months.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, July 19:—

Flewitt, Walter, Birmingham.
Giffard, Henry Edward, Hersham, near Esher.
Weekes, Francis Henry, Auckland, New Zealand.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Baird, Andrew, St. Mary's Hospital.
Bower, Arthur E. R., St. Thomas Hospital.
Devis, Charles James, General Hospital, Birmingham.
Fairer, George Albert, St. Bartholomew's Hospital.
Fallon, Joseph Septimus, Westminster Hospital.
King, W. H. Tindal, St. Mary's Hospital.
Pardington, George Lucus, St. Bartholomew's Hospital.

BIRTHS.

ATKINSON.—On July 16, at Clydesdale, Kingston-on-Thames, the wife of Frederick P. Atkinson, M.D., of a daughter.

DUNCAN.—On July 22, at 139, Buckingham Palace-road, the wife of H. M. Duncan, M.D., of a daughter.

HAMILTON.—On July 17, at 30, Northampton-park, Canonbury, the wife of Thomas Hamilton, M.B., F.R.C.S. Eng., of a son.

PRIESTLEY.—On July 17, at Halstead, Essex, the wife of C. E. Priestley, M.R.C.S., of a son.

SIMPSON.—On July 19, at 52, Queen-street, Edinburgh, the wife of Professor Simpson, M.D., of a son (Alexander Rudolf Virchow).

SHEARMAN.—On July 17, at The Hollies, Swinton, near Manchester, the wife of W. H. Shearman, M.R.C.S. Eng., of a son.

WALKER.—On July 20, at 58, Ladbroke-grove-road, the wife of A. Dunbar Walker, M.D., of a son.

MARRIAGES.

BEVAN—COCKELL.—On July 24, at St. John's, Hackney, Richard Bevan, M.R.C.S. and L.S.A., of New Romney, to Annie, eldest daughter of Frederick E. Cockell, M.R.C.S., of Hackney.

CHAPMAN—BRIDGE.—On May 15, at St. James's Church, Southbridge, Leeston, near Christchurch, New Zealand, Henry T. H. Chapman, M.D., M.R.C.S.E., to Fanny Woodyatt, daughter of the late C. J. Bridge, Esq., J.P., of Hornebrook, Southbridge.

GIBSON—VALLANCE.—On July 19, at St. James's Place U.P. Church, Edinburgh, George Gibson, C.E., to Maggie, eldest daughter of the late George Vallance, Esq., of 1, Gayfield-square, Edinburgh, and relict of Angus Macgregor, M.D., F.R.C.S.E.

LEWIS—DOWNING.—On July 17, at the parish church, Falmouth, Lewis Lewis, L.R.C.P. Lond., M.R.C.S. Eng., to Annie, daughter of the late J. V. Downing, of Falmouth.

O'SULLIVAN—MOORE.—On June 23, at Ercaud Church, Shevaroy Hills, Madras, Patrick O'Sullivan, barrister-at-law, of Madras, to Sydney, daughter of the late William Daniel Moore, M.D., of Dublin.

PORTER—MAYON.—On July 18, at St. Mary's, Crumpsall, Charles Frederick Porter, M.R.C.S.E., youngest son of William Porter, of Fleetwood, to Elizabeth Mary (Bessie), daughter of John Mayon, of Higher Crumpsall, and granddaughter of the late George Mallalue, of Wigmore-street, Cavendish-square.

TRIMMER—WELSH.—On July 17, at St. Luke's, Westbourne-park, London, Francis Trimmer, M.R.C.S., youngest son of the late Edward Trimmer, Esq., of Gloucester, to Mary Ball, only daughter of the late Thomas Inman Welsh, M.R.C.S.E., of Southsea, and granddaughter of the late Captain George Wilson, R.N., of Kelso.

DEATHS.

ANDERSON, JAMES DOUGLAS, youngest son of Dr. J. Anderson, at 1, Newcross-road, S.E., on July 20, aged 12.

BELLYSE, EDWIN SWINFEN, M.D., F.R.C.S.E., L.A.C., at Oakfields, near Nantwich, on July 21.

COCKS, ANNIE, eldest daughter of the late Jordan Roche Lynch, M.D., at Murrumburrah Vicarage, New South Wales, on June 1.

COOPER, BARBARA, the wife of Frederick Cooper, Inspector-General of Hospitals, at the Clifton Down Hotel, Clifton, on June 23, in her 81st year.

COPLAND, JAMES HAWKINS, eldest son of James Charlesworth Copland, M.R.C.S.E., L.S.A., at Ladbroke-grove, W., on July 22.

COTTERELL, CHARLES EDWARD, M.R.C.S., eldest son of the late C. E. Cotterell, Esq., R.N., aged 43.

EATON, FREEMAN, M.R.C.S., L.S.A., at Ancaster, on July 3, aged 69.

ELLIOTT, JOHN, M.R.C.S.E., L.S.A., late of 2, Finsbury-pavement, and upwards of fifty years an inhabitant of the Ward of Coleman-street, at his residence, The Ferns, Belgrave-terrace, Upper Holloway, on July 22, aged 81.

JACKSON, EDWARD HENRY, son of the late Dr. Jackson, of Warley Barracks, Brentwood, at Victoria, British Columbia, on June 27, aged 43.

LAMBERT, EDMUND, M.D., formerly of Cheltenham, at 23, James-street, Bath, on July 20, aged 82.

LITHGOW, JAMES, M.D., F.R.C.S., at his residence, 10, Royal-terrace, Weymouth, on July 20, aged 58.

MENZIES, ALEXANDER, son of the late Robert Menzies, M.R.C.S., L.S.A., of Stamford-street, London, and of Mary Menzies, of Bedford-park, Croydon, lost in a hurricane off the Friendly Islands, while in command of the *May Queen*, with all on board, about March 19, aged 30.

PAUL, JOHN GRANT, son of James Paul, M.D., of The Hermitage, Isle of Wight, and Barnes, Surrey, on July 19, aged 32.

POPE, EDMUND, M.R.C.S., L.S.A., of Brixton, on July 15, in his 41st year.

TICEHURST, FREDERIC, J.P., M.R.C.S., L.S.A., at Hastings, where he practised for forty-five years, on July 20, in the 68th year of his age.

WINN, WILLIAM, Captain in the Royal Scots, and formerly of the 29th Regiment, son of Dr. Winn, of Harley-street, at Dublin, after a short illness, on July 18.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

HAVERSTOCK-HILL AND MALDEN-ROAD PROVIDENT DISPENSARY.—Medical Officer. Particulars may be had of the Honorary Secretary, to whom applications, with testimonials, should be sent on or before July 30.

ROYAL HOSPITAL FOR DISEASES OF THE CHEST, CITY-ROAD.—Two Assistant-Physicians. Candidates must be M.D. or M.B., and if not M.R.C.P. Lond., must undertake to become so within twelve months. Applications, with testimonials, to the Secretary, on or before July 31.

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL, WOLVERHAMPTON.—Physician's Assistant and Pathologist. Qualifications must be satisfactory to the Medical Committee. Salary £50, with board, washing, and furnished rooms. Appointment for one year. Applications to the Chairman of the Medical Committee, Mr. Vincent Jackson, 46, Darlington-street, Wolverhampton.

FARINGDON UNION.—Medical Officer and Public Vaccinator for the Shrivenham District. Must reside in the district, be duly registered, and enter into a contract. Salary £70, with extra fees for operations and services allowed under the Poor-law Board, with vaccination fees. He will also have to undertake the duties of Medical Officer of Health for the above district, the salary for which is £10. Applications, with testimonials, under seal, by Tuesday, the 31st inst., 10 a.m., to George J. Haines, Clerk, Faringdon.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Cosford Union.—The Bildeston District is vacant; area 16,375; population 4343; salary £78 13s. per annum.

Coventry Union.—Mr. E. Bicknell has resigned the Workhouse; salary £60 per annum.

APPOINTMENTS.

Faversham Union.—Wm. E. Dring, L.R.C.P. Edin., M.R.C.S. Eng., L.S.A., to the Third District.

Freebridge Lynn Union.—John D. Alexander, L.R.C.P. Edin., L.F.P. & S. Glasg., to the Second Eastern District and the Workhouse.

Gravesend and Milton Union.—Richard O. Arnold, L.F.P. & S. Glasg., L.S.A. Lond., to the Milton District.

Hoxne Union.—Frederick W. Friend, M.R.C.S. Eng., L.R.C.P. Edin., to the Hoxne District.

Mitford and Launditch Union.—Irvine K. Milne, B.M. and M.C. Aber., to the Shipdham District.

AT Sheffield, last week, a prosecution was instituted by the Treasury, the defendant being a medical student, by name William McIrvine, of Stockbridge, near Sheffield. He was formerly in the employ of a medical man there, but being dismissed, he commenced practising as a surgeon on his own account, and in the case of three burial certificates it was proved that he had forged the name of a medical man in Sheffield. He was committed for trial at the assizes.

CONSUMPTION OF HORSE-FLESH IN BRESLAU.—Breslau has had a public municipal horse-slaughterhouse placed under veterinary supervision since 1869. During 1875 there were 1379 horses slaughtered, 1846 during 1876, and 703 until April in 1877. Among the horses thirty-nine were slaughtered on account of fracture, and three for lameness, the rest having reached the honourable old age of from sixteen to twenty years. Forty-four were rejected on account of disease.—*Deutsche Wochenschrift*, July 7.

A SURGICAL "SEA-SERPENT."—During a discussion on the treatment of varicocele and varicose veins by the iron injection, Prof. Dittel remarked that the radical cure of varicocele is the "sea-serpent" of surgery, which from time to time was always cropping up with some new modification. Two circumstances had always prevented him from adopting these procedures—viz., the constant occurrence of relapses, and the danger to the patient from the introduction of coagulating substances into the veins. He referred to two cases of teleangiectasis in which the perchloride was injected, and in one of these it caused immediate death, and in the other sudden blindness. This production of acute thrombosis had always something so deterrent for him that he had always avoided these procedures.—*Wien. Med. Zeit.*, June 5.

CREMATION IN PARIS.—That somewhat restless body, the Paris Municipal Council, has, according to the *Gazette Hebdomadaire* (July 13), taken up the subject of cremation with great eagerness, proposing to offer large prizes for the best procedures. The Préfet de la Seine has recommended that these shall be considerably reduced in value, and moreover considers the matter to come more within the province of the Préfet de Police than his own. One of the speakers declared that no law or permission was required, for cremation is like a particular mode of embalming, for which no law is required. Another (M. Cadet) observed that the only plausible objection offered to cremation is that the detection of poisons after death would not be possible; but this is a mistake, for the discovery of poisons would be rendered more easy, and the crime of poisoning become less frequent. By experiments on animals he had found that all the mineral poisons which are met with after inhumation are found among the ashes after incineration. It will be easy to impose upon inventors the necessity of showing that such detection of poisons swallowed experimentally does take place. The resolution was carried to open a *concours* for the best mode of effecting cremation, or any other procedure attaining the same result. It must insure the transformation of organic matters without the production of smell, smoke, or deleterious gases. It must guarantee the identity and the total preservation without admixture of fixed matters; it must be expeditious and economical, and it must offer no obstacle to the celebration of religious ceremonies. The question of the prizes to be offered, and carrying out of the *concours*, to be referred to the Préfet de Police.

THE GERMAN CONGRESS OF PHYSICIANS AND NATURALISTS.—The next meeting of this body is to be held at Munich from September 17 to 22, Professors Pettenköfer, Waldeyer, and Klebs being announced as taking a prominent part in the arrangements. Quite rightly it has been determined that every predominance shall be given to the scientific character of the meeting, reducing the pleasuring to the smallest proportions. Avoiding grand festivities and entertainments, it has been resolved to renounce any of the subventions from the city or the Government which have been hitherto given, all expenses being defrayed out of the resources of the Congress.—*Deutsche Med. Woch.*, July 7.—[We congratulate our German colleagues upon the resolution they have come to; for it has always seemed to us somewhat derogatory to accept from the municipalities and governments sums of money to be spent in festivity.]

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Charity Electioneering.—We find that in November, 1868, there were 30 candidates for the Hospital for Incurables at Putney, many of whom had undergone that ordeal from ten to sixteen times. In November, 1871, there were 298 candidates, several of whom had been beaten at seventeen, eighteen, or nineteen half-yearly elections. On the former occasion forty, and on the latter only twenty, candidates were elected.

Paterfamilias.—No; in Germany one *never* sees *children* acting as monitors or pupil-teachers.

S. H. I.—The Metropolitan Board was created by Sir Benjamin Hall's Act of 1855. Prior to 1855 the administration of London was entrusted to a vast number of trusts under local Acts. There were nearly 150 such petty corporations, each having separate and independent management. In addition, there was the Sewers Commission, under district commissioners nominated in the days of Elizabeth, or earlier. There were nine Commissioners of Sewers so recently as 1847. A practical consolidation of these was effected in 1848.

*** We understand that Sir Joseph Hooker, President of the Royal Society, has gone to the United States on a botanical tour, during which, in company with Professor Asa Gray, he will examine the flora of Colorado and other regions in the north-west.

F.R.C.S., Manchester.—We are indebted to the kindness of Mr. William Allingham, the late honorary secretary of the Festival of the Fellows of the College of Surgeons, for the information you desire, and which, no doubt, will be interesting to other readers in this metropolis, from whence the next chairman will be selected—the rule being to elect metropolitan and provincial Fellows alternately. (Those gentlemen whose names appear in *italics* have all served the office of President of the Royal College of Surgeons.) The first chairman was *Mr. Benjamin Travers, F.R.S.*, in 1846, succeeded the following year by Mr. J. S. Soden, of Bath; *Sir Benjamin Brodie, Bart., F.R.S.*, in 1848; *Mr. Joseph Hodgson, F.R.S.*, of Birmingham, in 1849; *Sir William Lawrence, Bart., F.R.S.*, in 1850; Mr. J. H. James, of Exeter, in 1851; *Mr. J. H. Green, F.R.S.*, in 1852; Mr. Wilson, of Manchester, in 1853; *Mr. Edward Stanley, F.R.S.*, in 1854; Mr. Norman, of Bath, in 1855; *Mr. J. F. South* in 1856; Mr. Smith, of Leeds, in 1857; *Mr. Cæsar H. Hawkins, F.R.S.*, in 1858; Mr. Thomas Paget, of Leicester, in 1859; *Mr. James Luke, F.R.S.*, in 1860; Mr. J. Wickham, of Winchester, in 1861; *Mr. F. C. Skey, F.R.S.*, in 1862; Mr. Thomas Turner, of Manchester, in 1863; *Mr. J. M. Arnott, F.R.S.*, in 1864; Mr. P. C. De la Garde, of Exeter, in 1865; Mr. T. Wormald, in 1866; Mr. Thomas Green, of Bristol, in 1867; *Mr. Richard Partridge, F.R.S.*, in 1868; Mr. Thomas Nunneley, of Leeds, in 1869; *Mr. John Hilton, F.R.S.*, in 1870; Mr. H. D. Carden, of Worcester, in 1871; *Sir William Fergusson, Bart., F.R.S.*, in 1872; Professor Humphry, M.D., F.R.S., of Cambridge, in 1873; Professor Erasmus Wilson, F.R.S., in 1874; Surgeon-General Thomas Longmore, C.B., of Netley, Southampton, in 1875; *Mr. T. B. Curling, F.R.S.*, in 1876; and Mr. E. L. Hussey, of Oxford, in 1877. These gentlemen have been ably supported in their duties by the following honorary secretaries:—Mr. Charles Hawkins, a late member of the Council, from 1847 to 1849 inclusive; Mr. W. W. Cooper, 1850 and 1851; Mr. J. Newton Tomkins, 1852; Mr. William Adams from 1853 to 1862 (ten years, the last conjointly with Mr. G. W. Callender, F.R.S.), who was succeeded in 1864 by Mr. E. C. Hulme, who held the office for five years, as did Mr. T. C. Jackson from 1869, when he was succeeded by Mr. William Allingham, who resigned the office at the conclusion of the last banquet, when Professor B. T. Lowne was appointed.

A Tutor; A Parent.—Why not consult the advertisement-sheets of this journal?—from which you will learn that the next preliminary examination in Arts, etc., for the College of Surgeons will take place at Burlington House in September next, and not at Christmas.

Mr. Williams, Bristol.—Mr. John Birkett, the Government Inspector of Provincial Medical Schools, was elected President of the College of Surgeons a week or two ago, in succession to Mr. Prescott Hewett; he is a Jacksonian prizeman, for his essay on "Diseases of the Male and Female Breast." Formerly the Presidents of the Royal Colleges of Physicians and Surgeons respectively received a special honorarium of one hundred guineas annually from the Government as members of the National Vaccine Board.

Dr. Johnson.—The annual meeting of the British Medical Association will be held early in the ensuing month at Manchester. Write at once to Messrs. Cook and Sons, Fleet-street, who are organising interesting excursions to the Lakes immediately after the meeting.

EFFECTS OF YELLOW LIGHT IN DISEASE.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—You were good enough to call attention last week to a letter of mine in the *Daily News*, in which I suggested the use of a yellow calico blind in cases of small-pox. Will you kindly further bring before the notice of the profession the advisability of trying the same plan in cases of inflammation of the eye, whether after operation or idiopathic. I quite believe that if patients, instead of being kept in profound darkness, were placed in a room where none but yellow rays penetrated, and used *yellow spectacles*, not only great comfort would be felt, but a more rapid cure would be induced. At any rate, the plan is so simple that it deserves a trial.

204, Camden-road, N.W. I am, &c., ROBERT CHARLES CROFT.

AN OPENING.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I beg to call your attention to the fact that in the town of Newport, containing, with its suburbs, a population not far off 4000, there are only three medical practitioners—and between two of these, I believe, a co-partnership exists. There is no resident surgeon within half a dozen miles of the town, and only five or six in the whole Poor-law union, comprising sixteen parishes, with an aggregate population of at least 16,000. There are many gentry in the district, and a large proportion of well-to-do farmers. The town is a prosperous one, and is steadily though not rapidly increasing. There is an excellent grammar-school, at present free for eighty boys resident in the town and immediate neighbourhood; and under a new scheme for its management just propounded by the Charity Commissioners, a girls' school is likely to be established in connexion with the foundation. These educational advantages are likely to attract many respectable residents to the neighbourhood. I am, &c.,

July 21. PRO BONO PUBLICO.

LEAD POISONING.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I have three people in one family suffering from lead poisoning—one very ill. Being unable to trace the source of the lead other than by the use of zinc buckets, I shall be much obliged to you to tell me—first, if zinc will give rise to symptoms similar to lead; and second, if lead in combination with zinc is used in making the buckets before-named.

July 23. I am, &c., INQUIRER.

THE NEW METROPOLITAN FREE HOSPITAL.

The Lord Mayor presided at a meeting, held at the Mansion House on Monday, to promote the movement to rebuild the Metropolitan Free Hospital, with accommodation for not less than 100 beds. The cost of the building is estimated at £30,000, of which £11,000 is already subscribed. A site has been obtained in Half-moon-street, Bishopsgate-street.

AUCTIONEERS' CATALOGUES.

The art of making an auctioneer's catalogue is not, apparently, among those that are lost. We had a sample the other day when Albert Grant's house was for sale, but the following "bit," as painters say, cut from the *Times*, is in its way unique. The sale took place at Lancaster, and the catalogue commenced with the following headnote:—"The effects comprised in this catalogue represent an aggregation of trophies unparalleled of their kind, the fruits of Mr. Sly's life-long lore-chase, in which that gentleman's æsthetic proclivities have been plied with the assiduity of an instinctive connoisseur and a devotion that counts no cost. They are now submitted to the strife of new competitors, in consequence of Mr. Sly's retirement from business." Lot 241 was entered in the catalogue as—"Hansome (*sic*) carved oak sideboard, middle of seventeenth century, with fittings for modern convenience, including cupboards, drawers, and veined marble top, 6 ft. 6 in. long, 2 ft. 2½ in. deep, 3 ft. 2 in. high to top of marble; extreme elevation of back, 6 ft. 4 in., the front richly decorated with boldly-executed heraldic insignia." Then followed in smaller type:—"This imposing item formerly graced the mansion of Alderman Proctor, one of the early merchant princes of the then rival maritime borough of Liverpool."

"ALL THINGS TO ALL MEN."

We give the following correspondence without comment. Mr. W. E. Gladstone, M.P., has just replied to a letter from Mr. Wm. Burgess, of Liverpool, who presided at a recent open-air meeting of Deptford Working-men, agitating for the repeal of the Contagious Diseases Acts. The letter is as follows:—

"Sir,—I have been indisposed to-day, but will not waive a hasty acknowledgment of your letter. I will not fail to present the petition, and have seen no cause to change my views since the proposal of Lord Aberdare on behalf of the late Government. Apart from all shades of opinion, the feeling shown by such numbers of working-men on this question is, without doubt, most honourable to them.

"July 18, 1877. Yours very faithfully, W. E. GLADSTONE."

Some time ago, Mr. F. W. Lowndes, the Liverpool Secretary of the Association for Promoting the Extension of the Contagious Diseases Acts, forwarded to Mr. Gladstone a copy of a pamphlet on the subject, which had then been just published. The following was the ex-Premier's reply:—

"Sir,—I beg to thank you for your tract, which I have not failed to peruse. My own opinion on the subject coincided very much with the proposal of the late Government, which did not in full satisfy either extreme view, and did not become law. "Your faithful servant,

"W. E. GLADSTONE."

The proposal of the late Government was that the Acts should be modified and extended, not repealed.

AN APPEAL TO THE HUMANE AND BENEVOLENT.

This appeal is made on behalf of a lady and her little helpless children. Her husband was a surgeon attached to one of her Majesty's infantry regiments, and was obliged to retire from the service in consequence of his health having been very greatly impaired whilst on duty with his regiment in an African station. He died shortly after his retirement from the service, leaving his wife and children sadly unprovided for. She is now in urgent want of assistance to meet present necessities, and to enable her to make arrangements for earning, by her own exertions, means to support and bring up her helpless little children.

Reference kindly permitted to the following, by whom contributions will be thankfully received and acknowledged:—George W. Abraham, LL.D., etc., 2, Oakland-villas, Rathgar; E. D. Mapother, M.D., F.R.C.S. Ire., 6, Merrion-square North; Thomas M'Nally, A.M., T.C.D., 77, Lower Gardiner-street; Austin Meldon, F.R.C.S. Ire., etc., 15, Merrion-square North; Joseph Manly, Esq., Manager, Hibernian Bank, 21, Lower Sackville-street; Arthur H. Lynch, Surgeon, Army Medical Department, Killester, Raheny; Major A. H. Lynch, Killester, Raheny.

N.B.—Subscriptions will be acknowledged in *Irish Times* each Saturday.

COMMUNICATIONS have been received from—

Mr. EDWARD LAW HUSSEY, Oxford; Mr. JOHN CHATTO, London; Dr. BARLOW, London; Mr. JONATHAN HUTCHINSON, London; Dr. R. SHINGLETON SMITH, Clifton, Bristol; Dr. FRANCIS OGSTON, Aberdeen; Mr. A. de WATTEVILLE, London; Mr. TENDALL, Hastings; Messrs. CLIN and Co., Paris; Messrs. ALLEN and HANBURY, London; REFORMED FUNERAL'S COMPANY, London; Mr. J. BOND, London: LOCAL GOVERNMENT BOARD; Mr. F. W. LOWNDES, Liverpool; Dr. E. SPARKS, Crewkerne; Mr. W. E. PORTER, Lindfield; Mr. J. W. BARNES, London; APOTHECARIES' HALL, London; Dr. R. F. E. LYNCH, Killester; Mr. H. W. BELLEW, Punjaub; Dr. W. J. FLEMING, London; PRO BONO PUBLICO, Newport, Shropshire; Mr. T. M. STONE, London; Mr. J. B. BLACKETT, London; Dr. R. C. CROFT, London; ROYAL COLLEGE OF SURGEONS, London; Messrs. COOK and SON, London; Sir WILLIAM GULL, London; Mr. H. C. BURDETT, Greenwich; NORFOLK AND NORWICH HOSPITAL.

BOOKS AND PAMPHLETS RECEIVED—

J. Gibbs Blake, M.D., The Place of the Law of Similars in the Practice of Medicine—Harry Leach, A Bit of Bulgaria—Charles Darwin, M.A., F.R.S., The Different Forms of Flowers on Plants of the same Species—J. Beattie Crozier, M.B., L.R.C.P., etc., God or Force—L. Duncan Bulkeley, M.D., Analysis of Seven Hundred and Seventy-four Cases of Skin Disease—Dr. Whitmore's Monthly Report on the Health and Meteorology of the Parish of St. Marylebone—Thirty-eighth Annual Report of the Registrar-General of Births, Marriages, and Deaths in England—W. J. H. Lush, F.L.S., M.R.C.P., etc., Examination Papers for the Use of Medical Students—Tenth Annual Report of the Victoria Hospital for Sick Children, Chelsea and Margate.

PERIODICALS AND NEWSPAPERS RECEIVED—

APPOINTMENTS FOR THE WEEK.

July 28. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

30. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

31. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

August 1. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

2. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

3. *Friday*.

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1½ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, July 21, 1877.

BIRTHS.

Births of Boys, 1226; Girls, 1189; Total, 2415.
Average of 10 corresponding years 1867-76, 2152·8.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·53 in. The lowest reading was 29·07 in. on Sunday morning, and the highest 29·87 in. on Saturday morning.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

LECTURE III.—PRESBYOPIA.

MR. PRESIDENT,—Having in the former lectures briefly sketched the chief features of the three great factors in sustained vision—the refraction, the accommodation, and the convergence,—and having described the manner in which these may severally be estimated and measured, I may now pass on to the consideration of the principal forms of what I have already termed "conditioned vision," that is to say, a state in which the patient, although able to use his eyes at certain distances, or for limited periods of time, is not able to use them at all distances, or for all periods; and is constantly reminded of their existence by the very fact of the bounds which are set to his power to employ them. The form of conditioned vision to which I shall first refer is the least important of any as regards the structural states on which it depends; but it may be considered the most important on the ground that it is common to the whole human race, and that it befalls the eyes of all persons who reach middle age, whether those eyes are normal or abnormal, emmetropic or ametropic. I refer, I need hardly say, to the condition of presbyopia, or aged sight.

I have already mentioned that the faculty of accommodation, the power to adjust the eyes for clear vision at distances nearer than their far-point, is gradually curtailed as life advances, and I have already shown you (see Fig. 15) the diagram in which Donders has traced out the natural progress of the change. The cause of the change is probably diminished elasticity of the crystalline lens, which obviously undergoes progressive molecular changes of a marked character. In infancy and childhood it is brilliantly transparent, and even its presence can scarcely be recognised by any kind of direct examination. After a few years, if we dilate the pupil and throw a fine pencil of rays into the eye, we shall observe more or less fluorescence in the lens-tissue, the light breaking up against its inequalities, and the blue waves being returned to the spectator. Later still, if we examine our own eyes by looking at diffused light through a very fine perforation, we shall see, besides floating fibres or bodies in the vitreous, stationary granules in the lenticular substance—granules which, being opaque by comparison with the parts around them, cast shadows upon the retina and appear as dark spots in the illuminated field. Later still, the fluorescence passes into what appears to be a very manifest cloudiness by reflected light, although to transmitted light the lens may yet be perfectly transparent; and this cloudiness is often traversed by brighter lines which mark the divisions of the sectors of which the structure is built up. Later still, the lens becomes more or less of a yellow or an amber tint, even though it may never undergo the changes which constitute cataract. Assuming, as already stated, that the increased convexity of accommodation is the result of a change of shape which occurs spontaneously as soon as the lens is released, by the action of the ciliary muscle, from the restraint exercised upon it by its capsule, it is easy to understand how alterations in its molecular structure may involve a progressive loss of its elasticity; so that, although the capsule may be relaxed, the change in the curvature of the lens may become less and less, and ultimately altogether ceases. Hence, at the same time, the refractive power which the changed curvature was wont to add, becomes diminished in a corresponding ratio; and the near-point of distinct vision recedes slowly but steadily from the eye. During many years, although this change is occurring, it is not felt to be a source of inconvenience; but by-and-by a time comes when very small objects, in order that they may be clearly seen, must be held so far away that they either subtend a visual angle which is too small to allow them to be recognised with facility, or else sufficient light for the requirements of vision is no longer reflected from their surfaces. The amount of light reflected from any point, and falling upon a given area, such as the pupil of the eye, varies, it need hardly be said, as the square of the distance between the two; so that an object which is only twelve inches distant gives the pupil four times as much light as it would do if it were removed to a position twenty-four inches away. Hence, those who are becoming presbyopic in an inconvenient degree first feel the effect of the change by twilight, or by artificial light of any kind, which, however good it may be, and however dazzling when near the eyes, never approaches in its general illuminating effect to that of even a feeble degree of diffuse daylight. By the age of forty-five, or thereabouts, it is generally necessary for the possessor of emmetropic eyes to hold very small print so far away (especially in the evening) that it becomes difficult to decipher. It will help us to realise the progress which has been made, during the present century, in the art of artificial lighting, if I remind you of Dr. Kitchener's well-known saying, that people who were fifty years old began to "bless the man who invented snuffers." At the same period, or somewhat later, we often see an artificial light held between the reader and his page, so as to increase the illumination of the latter to the utmost, without unduly taxing the accommodation.

The term presbyopia, in former times, has been used with a good deal of latitude, or rather with a complete absence of anything like scientific precision; but now, in accordance with the teaching of Donders, it is used only to signify the alteration of vision which is produced by the recession of the near-point, or the gradual curtailment of the power of accommodation, which is incidental to advancing life. It is evident, therefore, that the term, used in this sense, cannot be defined except in an arbitrary manner; for the degree of presbyopia which is felt as an inconvenience will be mainly determined by the nature of individual pursuits or employments, or even by such an accidental circumstance as the character of the illumination of the room which is chiefly inhabited. In order to meet this difficulty, Donders suggested that presbyopia should be looked upon as established when the binocular near-point had receded to eight inches; that is, when it was no longer possible, by any effort of voluntary adjustment, to read the smallest type, such as No. 1 of Jäger's scale, at a shorter distance than eight inches. This limit is probably as good a one as can be fixed, and it has the advantage of attaching a definite meaning to the word.

By the time that the binocular near-point has receded to a distance of eight inches, the convenient near-point at which any visual effort can be sustained will have gone a good deal farther away. It is seldom possible to use more than half of the actual range of accommodation for more than a short period of time; and hence, if a person has only five dioptrics of accommodation—the amount which would bring the near-point to eight inches,—he will only have two and a half dioptrics, or say a near-point at sixteen inches, really available for continuous effort at his occupation. For some occupations this may be sufficient, but for others it will clearly not be sufficient; and in cases of the latter kind, remembering that accommodation is practically the addition of a convex lens to a passive eye, we supply by art the deficiency of nature, and give such lenses as may be enough to bring back the near-point, without effort to the user, to the place or distance at which it is wanted. We say that the patient requires spectacles; and in a vast majority of instances we see that he can be effectually supplied with them by a sort of rule of thumb of an extremely simple character. Those who deal in spectacles sell what they call glasses of first or of second sight; and they recommend one or other of these accordingly as the patient has or has not worn spectacles before. In many instances the necessary relief is at once obtained; and the patient feels no farther inconvenience for perhaps two or three years. After some such period of time his former difficulties return, and he again obtains relief from them by using glasses somewhat stronger than those which he procured in the first instance.

It has long been a tradition among opticians that people who were advancing in life should be very chary of employing spectacles of too great magnifying power—partly because it was believed that such spectacles were likely to be injurious to the eyes, and partly lest the desire of the eyes for more power should grow with indulgence, until it might at last outstrip the resources of the spectacle-grinder. These opinion were much confirmed, and were widely diffused among th

public, by an elaborate essay on spectacles which was published in the *Quarterly Review* some sixty years since, and which was commonly attributed to the late Sir David Brewster. The writer, whoever he may have been, was not in advance of his time, and had little or no knowledge of the changes which occur in the eye, or of the altered conditions of vision which they entail. He approached his subject from a standpoint of pure optics, and did little more than give a new lease to some prevalent errors and misconceptions. Convex spectacles, of whatever power, cannot do more than place the far-point at the distance of their own focal length; and, in an emmetropic eye, with restricted accommodation, the near-point would not be very much within the far-point. The only harm done by spectacles which were too strong, or stronger than was needful, would be so to approximate the visual distance as to call upon the internal recti for a fatiguing effort of convergence in order to maintain binocular vision; and this effort would in any case be relinquished, because it would be fatiguing, long before it could by any possibility become injurious to the eyes of a person of mature age. The excessive convergence which, as we shall see, is incidental to the higher degrees of myopia, is often injurious in youth, when the ocular tunics are yielding and extensible; but seldom or never becomes so at an advanced period of life, if no harm has previously been occasioned by it. Apart from forced convergence, the use of high magnifying powers is absolutely harmless. I have often had occasion to remark to students how rarely it happens that we see at the hospital any persons who follow the trades, such as watch-making, wood engraving, and the like, which require the constant use of a single magnifying-glass; and I believe the tradition about the ill-effect of powerful convex spectacles is mainly due to the fact that a premature and rapidly increasing presbyopia, such as to call for constantly stronger and stronger glasses, is one of the early symptoms of approaching glaucoma. The demand for strong spectacles has itself, in these cases, been merely a sign of the impending destructive disease; and, before the symptoms of the disease were understood, the resulting blindness, although perfectly independent of the spectacles, was often erroneously attributed to their influence.

We may therefore, as far as the safety of the eyes is concerned, give to the presbyopic person spectacles which are strong enough completely to supply his deficiency; so that, without any strain upon his accommodation, his work may be brought near enough to be seen under sufficient illumination. The annexed table, taken from Professor Donders, but translated into dioptrics, gives approximately the strength of the lens which will be necessary for an emmetropic person at each age of life, and also the strength which will be required for those whom the author regards as having been originally emmetropic, but ultimately the subjects of acquired hypermetropia; a doctrine upon which I shall have more to say in the sequel. A third column states the distances at which the specified glasses should give clear vision.

Table IV.

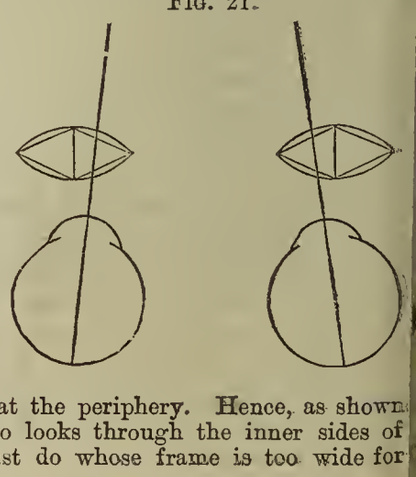
Years of age.	In present emmetropia. (Dioptrics.)	In original emmetropia. (Dioptrics.)	Distance of distinct vision in inches.
48	0·75	0·75	14
50	1·0	1·0	14
55	1·25	1·50	14
58	1·75	2·0	13
60	2·0	2·25	13
62	2·50	3·0	13
65	2·75	3·50	12
70	3·50	5·0	10
75	4·0	5·50	9
78	4·50	7·0	8
80	5·0	8·0	7

I have never myself found it necessary or useful to prescribe glasses so strong as those here suggested for emmetropic persons of seventy years old and upwards; and it must, of course, be remembered that age does not by any means furnish a certain criterion of the power of the accommodation. Before prescribing, it is always necessary to test the state of the patient, and to be guided by the distance to which his near-point has actually receded.

It will often happen, however, that the lenses which a presbyopic patient would himself choose by reason of their immediate effect, and which may afford him the best and most comfortable vision for a time, will yet become sources of strain or inconvenience if their use is continued; and this result is usually traceable to the way in which the glasses disturb the previously existing relation between accommodation and convergence. As presbyopia becomes declared, its inevitable tendency is to call for a stronger effort of accommodation than before, in order that the eyes may be adjusted for any given distance; and, in this way, as the measure of the accommodation exerted must be the amount of effort, and not the amount of result, it is manifest that the patient will be called upon to exert a greater amount of accommodation than before, for any given amount of convergence. In other words, for any given convergence, say to eighteen inches, he will have to strain the positive part of his relative accommodation; and the effort to do this, although in itself more or less irksome, would within certain limits become more easy by practice. Let us now suppose that he puts on a moderately strong pair of spectacles, which enable him, at the same distance of eighteen inches, to read almost without exercising his accommodation at all. The relation between the two muscular functions is suddenly reversed; and, having for some time been gradually accustoming himself to use accommodation in excess of his convergence, he is all at once compelled to maintain a degree of convergence which is in excess of his accommodation. In other words, his work is almost wholly in the negative part of his relative accommodation; and this, especially whilst it is a new condition, is apt to be a very irksome one. I may somewhat vary the illustration by pointing out that, when presbyopia first becomes an inconvenience, the book or newspaper, held at eighteen inches distance, requires as much accommodation effort as would have sufficed a short time before for a distance of thirteen inches, but it still requires, of course, only the old convergence effort for the actual distance of eighteen inches. The eyes, therefore, may be regarded as accommodating for thirteen inches, while they are only converging to eighteen. Convex lenses outside the eyes rest their accommodation by rendering an equivalent quantity of increased convexity of the internal lenses unnecessary. Convex lenses of three-quarters of a dioptric almost precisely represent the difference between accommodation for thirteen inches and for eighteen, and such lenses, therefore, restore the equilibrium which has been disturbed, and render the accommodation effort and the convergence effort the same in quantity. Anything weaker than these would fail to remedy the inconvenience; and anything stronger—lenses of a dioptric and a half, for example—would afford over-compensation, so as to require an accommodation effort less than that of the convergence, and to produce strain by this new disparity. If presbyopia were a fixed instead of a progressive affection, the lenses of 0·75 would cure it once for all. In actual fact, they only correct the accomplished portion of a progressive change, and they leave the eyes still on the threshold of presbyopia, compelled to use a considerable accommodation effort. After a short time, this again creeps so far ahead of the convergence effort that the disparity once more becomes painful, and then stronger spectacles are required in order to redress the balance.

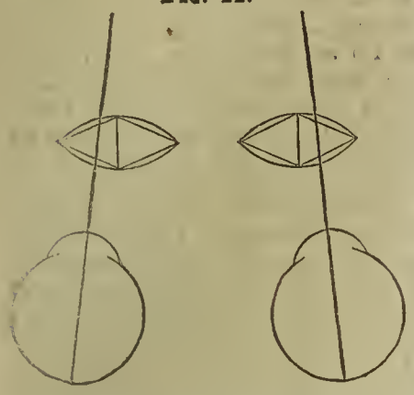
It has long been known to opticians, as a matter of empirical observation, that the discomfort arising to the presbyopic from glasses of too high a power is much increased if these are mounted in frames a little too wide for the patient, so that the eyes look through the outer sides of the lenses instead of through their centres; and also that the discomfort is diminished, or is less likely to arise, if the frames are somewhat narrow. When the relation between accommodation and convergence became known, the action of misfitting frames was rendered easily intelligible. A convex lens, within its curved surfaces, may be regarded as being made up of an infinite number of prisms with their bases meeting at the centre; and a concave lens is in like manner made up of an infinite number of prisms with their bases outwards or at the periphery. Hence, as shown by Fig. 21, a person who looks through the inner sides of convex lenses, as he must do whose frame is too wide for

Fig. 21.



the distance between his eyes, is looking not only through convex lenses, but also through prisms with their bases outwards; and he who looks through the outer sides of the lenses, as happens when the frame is too narrow, and as shown by Fig. 22, looks through prisms with their bases inwards. The former arrangement, it will at once be manifest, calls upon the convergence muscles for still greater effort, notwithstanding that the accommodation is almost entirely relaxed; and the latter rests the convergence together with the accommodation. Dr. Giraud-Teulon was, I believe, the first to suggest that this action of eccentrically placed lenses should be systematically utilised in the manufacture of spectacles; and after him the same subject was carefully considered by Dr. Hermann Scheffler, of Brunswick, whose treatise on ocular defects I translated nine or ten years ago. Dr. Scheffler approached the subject almost entirely from a geometrical point of view, and I gather from his various writings that he is not even a practitioner. He expresses the opinion that "the accommodation and the convergence are two primitive independent visual faculties, directed to the attainment of two wholly distinct and definite purposes, through efforts after wholly distinct and definite sensory impressions. By reason of the original independence of these faculties, every pair of eyes possesses the power to accommodate more or less with the same convergence, and to converge more or less with the same accommodation; as also to exert accommodation and convergence voluntarily, without the stimulus of light or of an external object of vision, and to increase the degree of this voluntary exertion by practice. Notwithstanding this original independence, the two faculties pass into a secondary dependence upon one another, caused either by congenital organisation, or in consequence of their usually coincident exercise, or as the result of an induction framed by the sensorium, as a higher central apparatus dominating over all the visual processes. From this secondary dependence, it follows that, in voluntary convergence, even when the eyes do not fix any object, the accommodation, if unstrained, involuntarily keeps pace with the convergence; and inversely, that in voluntary accommodation without the stimulus of light, the eyes involuntarily assume a corresponding degree of convergence. So long as this secondary proportionate dependence between accommodation and convergence, in regarding an object, is such as corresponds to the normal relative proportion of the functions in the pair of eyes concerned, the visual process is carried on without strain and with entire completeness. So soon, however, as the eyes are called upon for an abnormal relative proportion, the visual process is attended by strain."

Fig. 22.



In order to bring this view of the matter to a practical bearing, Dr. Scheffler suggested that every spectacle-lens should be used eccentrically, and should be looked upon as a combination of a convex or concave lens, destined to influence the refraction or the accommodation, with a prism destined to influence the convergence, and that each of these two elements should be studied and calculated, in every case, with an equal degree of care. He described, as a standard combination, spectacles which he called "orthoscopic," and which require a moment's consideration. It is manifest that every prism, say with its base inwards, will produce a certain definite degree of divergence, or at least of alteration from convergence, of the visual lines, just as every convex lens will place the far-point at some definite distance. Orthoscopic lenses are pairs in which the two elements are so combined that they are precisely coincident in their action—that is, that the prisms produce convergence of the visual lines precisely to the distance of the principal focus of the lenses. An instance of such a combination is furnished by two convex lenses, each of 1·25 dioptrics, ground upon prisms of four degrees and a half of angular measurement, and combined in a spectacle-frame with their bases inwards. A person wearing these spectacles, and looking at an object eighty centimetres distant, would have absolute repose both of the convergence and of the accommodation. The prisms would render the pencils of light which reached the two eyes from an object at that distance precisely parallel, so that the visual lines must also be parallel in order that single vision might be maintained; and the lenses would render the component rays of each pencil also parallel, so that an emmetropic eye would not be called upon for any effort of accommodation. The eyes would be perfectly passive, directed to the horizon and accommodated for infinite distance; and yet clear and single vision of an object thirty inches distant would be obtained. Such spectacles are, in fact, component lateral parts of a larger lens, out of which they may be cut; and the same effect is produced when we look with both eyes through a large lens, such as forms part of the instrument called the graphoscope, at an object placed in its principal focus. Each eye then looks through a lateral part of the lens; and, if we were to cover most of the lens with paper, leaving two holes at a proper distance apart for the two eyes to look through them easily, we should have the same thing as a pair of orthoscopic spectacles. Hence the two lenses, whatever their angles and foci, are only orthoscopic when fixed at some definite distance apart; and a simple test of the orthoscopic character of any spectacles is furnished by the fact that, if they are so, the two images of a flame, thrown upon a screen by the two lenses, will be combined into a single image at their focal length. This again follows from the fact that the two lenses are parts of a larger one. The larger one itself would cast only one image, and two of its component parts, when they retain their original relations, act in a precisely similar manner. The annexed table shows six combinations of lenses and prisms which are orthoscopic when the centres of the glasses are sixty-six millimetres apart.

Orthoscopic Combinations.

Dioptrics.	Degrees.	Dioptrics.	Degrees.
0·5	1·30	1·75	6·0
1·0	3·0	2·0	7·30
1·25	4·30	2·50	9·0

The orthoscopic spectacles were not found, in practice, to fulfil the expectations of their inventor, because they possess a property upon which he had not sufficiently reckoned. When we look through the lens of a graphoscope, at a painting or other plane surface bounded by straight lines, the surface appears convex, and the boundary lines appear concave. Orthoscopic convex spectacles produce the same effect. They are necessarily very heavy, from the thickness of their basal sides and from the amount of glass which they contain; and they cause the centre of a page to appear prominent, while at the same time they distort its outlines. To spectacles which are composed of lenses and prisms, but which are not orthoscopic, Scheffler gave the name of combination glasses; and he went so far as to assert that they should be used in almost all cases. His general principle was that we should test, for every pair of eyes, the full amount of their convergence range, and for each eye singly the full amount of its accommodation; and that we should then give such a combination that the pair, for any desired distance at which the objects of vision were to be held, should use exactly half of their accommodation and exactly half of their convergence. The principle will not admit of being fully carried out in practice, for the reason, if for no other, that the range of accommodation is constantly being curtailed as life advances, and that the combination necessary to fulfil Dr. Scheffler's requirement would therefore be constantly changing; but it is none the less worthy of being held in remembrance, on the ground that a disruption of the accustomed harmony between accommodation and convergence is in most cases at the root of any discomfort which emmetropic persons, when they become presbyopic, receive from spectacles, especially if the latter are at all stronger than they need be. Such discomfort may often be relieved by the simple expedient of having the centres of the lenses displaced inwards, so that they exert a prismatic action of a kind to diminish the convergence strain. When I myself first used spectacles, and had all my needs fulfilled by glasses of one dioptric, I have often tried the experiment of putting on stronger ones, say of two dioptrics, and I invariably found, after using them during a few minutes for objects at their focal length, that weariness and discomfort of the eyes was produced. If now I added to the lenses a pair of prisms of seven and a half degrees, with their bases inwards, so as to form with the lenses an orthoscopic combination, all discomfort was at an end. There was the nuisance of weight, and there was the nuisance of the convexity and altered shape

of the page; but, except for these, the comfort was complete. I have read for hours with such glasses without experiencing a single sensation which could remind me that I had eyes. As a general rule, we may satisfy all the wants of the presbyopic by glasses of such moderate power that the consequent disruption of the previously existing relation between accommodation and convergence is not sufficient in degree to be a source of discomfort; but we shall sometimes meet with a case in which the patient is unusually sensitive upon this point, or in which the nature of the occupation is such as to render an unusually high magnifying power desirable. In either of these cases we may overcome the difficulty by having the glasses decentered—that is to say, so cut that the patient, at the accustomed line of his convergence, does not look through the centres of the two lenses, but through a portion at the outer side of the centre of each, in the manner shown in Fig. 22. It is immaterial how much the lens is decentered, the effect being much the same as long as the visual line passes through it to the outer side of its axis. Each glass is then a prism with its base inwards, and the pair enable the eyes to obtain single vision of an object which is nearer to them than the point to which they are actually directed. In other words, the prismatic element in such spectacles diminishes the demand for convergence, just as the convex lens element diminishes the demand for accommodation. It is not necessary that the lenses should be orthoscopic, should diminish the two demands precisely in the same degree, because there is, as we have seen, a certain play, or relative range, of each function independently of the other. As long as we keep the two so nearly together that the limits of this range are not exceeded, nor even too nearly approached, we shall find that the eyes, supposing them to be emmetropic and presbyopic, can be used for all ordinary purposes and for any reasonable time.

On the grounds thus stated, therefore, I should put aside entirely, as an exploded error, the still prevailing notion that middle-aged or elderly people, previously of good sight, are liable to injure their eyes by the use of strong spectacles; and instead of allowing them to remain—tottering, so to speak, on the brink of their constantly increasing presbyopia, I am accustomed, as soon as the change becomes an inconvenience, to prescribe glasses sufficiently strong to relieve them completely, and for some little time to come. If I may venture to quote a passage which I have already published, it will be to point out that the effect of the gradual impairment of accommodation becomes harassing, to persons who are engaged in sedentary occupations, generally between the forty-fifth and the fiftieth year; but very frequently the use of glasses is still improperly deferred. It is important for it to be understood that spectacles, instead of being a nuisance or an encumbrance, or an evidence of bad sight, are to the presbyopic a luxury beyond description, clearing outlines which were beginning to be shadowy, brightening colours which were beginning to fade, intensifying the light reflected from objects by permitting them to be brought nearer to the eyes, and instantly restoring vision to a standard from which, for ten or a dozen years previously, it had been slowly and imperceptibly, but steadily, declining. This return to juvenility of sight is one of the most agreeable experiences of middle age; and my general principle, therefore, is to recognise presbyopia early, and to give optical help liberally, so as to render the muscles of accommodation not only able to perform their tasks, but able to perform them easily. When, as will happen after a time, more power is required, the stronger glasses should at first be taken into use only by artificial light; and the original pair should still be worn in the daytime. If the glasses fail to relieve discomfort, or if they become sources of discomfort themselves, the strength of the convergence muscles should be taken into account, and an endeavour should be made to give relief by means of decentred or prismatic lenses. It is seldom worth while to begin the treatment of presbyopia with lenses weaker than a dioptric; and lenses stronger than three dioptrics will scarcely ever be required, except possibly in extreme old age. Between these limits I generally make four gradations—namely, 1·5, 1·75, 2·0, and 2·50. With these six powers nearly every case of emmetropic presbyopia may be successfully treated; and the ametropic forms will require a separate consideration.

When I first called your attention to the diagram in Fig. 15, in which Donders has drawn the curve of gradually failing accommodation which constitutes presbyopia, I mentioned his belief that the emmetropia of adult age often, or even generally, passes into hypermetropia as life advances. In other words, we often find that, after the age of fifty, distant vision is in some slight degree improved, or at all events is not impaired, by looking through a weak convex glass. The smaller curve of the diagram shows what is the ordinary course of things; that is to say, that a convex quarter dioptric is tolerated at the age of sixty, half a dioptric at sixty-five, 0·75 at seventy, 1·0 at seventy-five, and 1·50 at eighty. There can be no doubt about the facts; but I venture to think there may be doubt about the right interpretation of them. I am disposed to regard such cases not as instances of acquired hypermetropia, but as instances of manifest hypermetropia which was previously latent, or entirely concealed by the accommodation. Donders assumes that emmetropic eyes are not uncommon; I almost doubt whether they exist. I use the term, in common parlance, to include all those very small degrees of hypermetropia which are not disturbing to vision, and which are perhaps too slight to be readily estimated or even identified; but, speaking with precision, I can hardly imagine an eye that is truly emmetropic. We talk about men who are six feet high, but the chances against any particular man being precisely of that height are so great as to be almost incalculable. So they are, as it seems to me, against the focal distance and the axial length of any eye being precisely identical; and, of the two forms which ametropia may assume, hypermetropia is greatly the more common. When Dr. Cohn first investigated the refraction of children in the schools at Breslau, he found only 239 in 10,060, or 2·38 per cent., who were hypermetropic; but it has since been well established that the tests which he used were not fine enough for the discovery of the slighter grades of the condition; and that, in children who are not myopic, a slight degree of hypermetropia is the rule. I have lately been told, by Dr. Hirschberg, of Berlin, of some investigations, the precise reports of which I have not yet been able to procure, but according to which the hypermetropic eye is the normal formation in children, and in all the lower animals as far as they have been examined; and I strongly incline to the belief that it must also be regarded as the normal formation in the human adult, and that we must be content to look upon emmetropia as a merely ideal standard, constantly and closely approached, but seldom or never attained. We shall often find that even high degrees of hypermetropia are completely concealed, and rendered latent, by the accommodation; and it need not be a matter for surprise if the slighter grades, even up to an advanced period of life, remain entirely unsuspected.

We have already seen, in the first lecture, that the measure of hypermetropia is the power of the lens which will correct it; that is to say, which will render parallel rays just so far convergent that the refracting media of the passive eye may bring them to a focus upon the retina. We have also seen that the effort of accommodation is practically the addition of a lens to the eye; and, for the correction of hypermetropia, it is a matter of indifference, optically speaking, whether the required lens be added externally, by art, or internally, by natural effort. The eye shown in the second line of Fig. 16, which is hypermetropic to four dioptrics, would be undistinguishable from an emmetropic eye if it were exerting four of its nine dioptrics of accommodation; and, as with an emmetropic eye, its vision for distant objects would be impaired by even the weakest convex glass, unless a part of the accommodation effort could be relaxed. It would only be distinguishable from an emmetropic eye by the circumstance that it would have less than the normal amount of accommodation for divergent rays; so that its near-point would be farther away than that of an emmetropic eye at the same period of life. Taking the conditions shown in the figure, it would have only five dioptrics of working accommodation, and its near-point would be at eight inches instead of at four inches and a half. Even this condition might be due to weakness of accommodation; and, while it could hardly fail to excite suspicion of hypermetropia, it would by no means afford certainty. Such cases would be sources of great embarrassment in practice, were it not for the power which we possess of paralysing for a time the accommodation by the application of atropia; so as to obtain an absolutely passive eye, the refraction of which may be accurately tested. It is manifest, however, that the examinations thus made will be misleading, if any part of the accommodation should be still retained, in cases in which it was supposed to be entirely set aside.

Now, Donders taught, and writers generally have followed him, that the instillation of a drop of a solution of sulphate of

atropine, of the strength of four grains of the salt to the ounce of distilled water, would completely paralyse the accommodation of the eye so treated. He says that the accommodation begins to diminish in from twelve to eighteen minutes, that the diminution is still trifling at the end of twenty-six minutes, that it then proceeds, at first rapidly and afterwards more slowly, until, at the end of one hundred and three minutes, the near-point and the far-point coincide, and the accommodation is *wholly removed*. This statement was published in 1864, and it is repeated, word for word, and without comment, by Mauthner, one of the most recent writers upon the subject of the defects of accommodation. At the Royal London Ophthalmic Hospital, however, it has long been the custom of the staff to act upon the assumption that Donders was in error, and that the accommodation cannot be completely paralysed thus easily. It is not uncommon for them to apply a solution of atropine three times a day for a week or longer; and they confidently affirm that in this way they bring out, and render manifest, degrees of hypermetropia which were still concealed by the accommodation after a single application. I am not aware that anything has been written upon this subject, or that any precise data have been placed on record with regard to it; but I have myself often followed the practice of saturating the eye with atropine, and I entertain no doubt that this practice affords the only means of paralysing the accommodation entirely. I think that the eye clings, so to speak, to the last shred of its accommodating faculty, and surrenders it tardily and unwillingly; and I feel sure that many eyes have been pronounced to be emmetropic, because they rejected the weakest convex glass for distant objects after a single application of atropine, which were really hypermetropic to the extent of a dioptric, or of a dioptric and a half. The latent hypermetropia of such eyes would be disclosed by perseverance in atropinisation; and it is disclosed also, in course of time, by the total loss of accommodation which occurs at advanced periods of life. It must be remembered that the optical effect of a dioptric, or of a dioptric and a half, of hypermetropia, would be extremely small. A reference to Fig. 16 will show that a hypermetrope of one dioptric, with nine dioptrics of accommodation, would have his near-point at five inches instead of at four and a half; and that an additional half-dioptric of defect would remove the near-point only one-third of an inch farther away. With ordinary accommodation such a degree of hypermetropia as this would entail no inconvenience; or at most would cause presbyopia to become declared a year or two sooner than in an emmetropic eye.

It may further be remarked, with reference to the view expressed by Donders, that this appears to have been founded upon experiments upon the eye of his assistant, Mr. Hamer; and it by no means follows that what was true of Mr. Hamer must be true universally. It follows still less, because Mr. Hamer is in a slight degree myopic; and the recent researches of Iwanoff tend to support the belief that the structure and strength of the ciliary muscle, in the two forms of ametropia, differ materially and in opposite directions from those of the emmetropic standard. Fig. 23, which is taken from Iwanoff's

Fig. 23.

drawing, represents a diagrammatic section of the ciliary region of the eye, and shows the outline of the muscle in emmetropia, in myopia, and in hypermetropia. The thick continuous line shows the emmetropic muscle, the dotted line the myopic, and the broken line the hypermetropic. It will be seen that the anterior border of the emmetropic muscle is nearly at right angles to the sclerotic; while that of the hypermetropic muscle comes more forward, and that of the myopic muscle recedes. The hypermetropic muscle is more bulky than the emmetropic by the whole mass of the triangle A; and the emmetropic muscle is more bulky than the myopic by the whole mass of the triangle B. The anterior portion of the muscle, moreover, contains nearly the whole of the circular fibres; which in the hypermetropic eye are more numerous, and in the myopic eye less numerous, than in the emmetropic; and it is reasonable to suppose that these circular fibres may be the chief agents in the work of accommodation, and that in this muscle, as in all others, work is a stimulus to development. It is intelligible that in the hypermetropic eye, which has constant need to exert its accommodation, the muscle subservient to the function should be stronger, better nourished, and less ready to yield up all its power under the influence of atropine, than the corresponding muscle of a myopic eye, in which the demand for accommodation would be only of an occasional and comparatively trivial nature. So far as this we should be led by reasoning, even if Iwanoff's investigations had not been made; and it must be admitted that these investigations still need confirmation, and that Iwanoff himself does not assert that the proportions above stated are of invariable occurrence. He asserts that they are the rule; but the rule is not without exceptions. Still, even if the sections made by Iwanoff were wholly deceptive, any error into which he may have fallen would not invalidate the evidence of analogy; and on the ground of analogy alone the frequent latency of the smaller grades of hypermetropia must be regarded as highly probable. The higher grades of this form of defect, which are discoverable always and without doubt, must be reserved for consideration in the next lecture.

SELECT LECTURES ON MEDICAL JURISPRUDENCE.

By FRANCIS OGSTON, M.D.,
Professor of Medical Logic and Medical Jurisprudence in the University of Aberdeen.

Lecture XVII.—WOUNDS—*Continued.*

(*Concluded from page* 29.)

As regards *the mere colour* of the blood, too much stress should not be laid on the distinction betwixt *blood recently effused* and that which is *older*, as sometimes drawn from the respective appearances of different stains or blood-spots. For, while it holds good generally, that recent stains are *red*, and older stains *brown*, the change of colour is influenced by other circumstances than *age alone*. Thus, the same change is more speedily induced by *warm* than by *cold weather*. Thus, too, the colour will more speedily darken where the layer of blood is thick, than where it is thinner. The nature of the stuff, and that of its surface, will further influence the shade of colour of the stain. "Thus," from their relative *porosity* or *the reverse*, as well as from contrast, "marks of blood upon *white stuffs*, and upon *light wood*, are *paler* and *duller* than those *on articles of greater density*, as varnished or painted wood, iron, and stone."—(Wharton and Stillé, page 557.)

To Ollivier d'Angers we owe the notice of the important fact, that "on coloured stuffs, especially on those which are brown, blue, or black, the spot is more easily recognised by *candle-light* than by *daylight*. He had been directed to re-examine the room of a person accused of murder. Having already visited it in the day-time, his second examination was conducted at night; and he *now discovered*, by holding a lighted candle near to the paper-hangings, which were of a pale blue colour, a number of drops of an obscure dirty red, which by day had the aspect of small black specks, and were lost in the general pattern of the paper. On a further examination, other spots of the same kind were found on the furniture. On the chimney-jamb, which was painted blue, there was a large stain of blood, which appeared red by the light of the candle. The next day, by daylight, Barruel and Lesueur could not find these spots, and were obliged to make use of artificial light to discover them.—(*Id.*, page 557.) "The same remarks will, of course, apply to spots of blood upon dark woollen cloth."

It is necessary, however, here to suggest to you that broad daylight *should, in the general case*, be preferred to artificial light in the search for obscure traces of blood. I have failed

to detect some of these stains at night which came out distinctly on the following day. Once more, it may not be useless to warn the medical jurist to search for traces of blood in places where it would be apt to escape the notice of a person wishing to obliterate all traces of it; such as in the seams of clothes, the soles and seams of shoes, etc.

Every such stain or appreciable trace of blood, unless washing or friction has been previously had recourse to, will present some sensible characters which may be deserving of being attended to. "Thus," as remarked by Dr. Taylor, "the crimson stain of blood is unlike that of any other colouring matter, and when the stained portion presents the character of a dry coagulum, the stain cannot be easily mistaken by a practised eye for that caused by other red colours."—("Principles and Practice," page 445.) To bring this out, where the stain is of minute size, recourse may require to be had to a strong light, under the low power of the microscope. In this case, on the stained part, or at least on its fibres, if on cloth, a shining glossy film will either be detected, or a dried jelly-like clot will be seen investing the cloth or its fibres, these having a more or less deep shade of redness.

Some other stains, however, approach on some points to those of blood.

Thus, as pointed out by Lassaigne, *the dejections* of *fleas*, *bugs*, and *flies*, on undyed stuffs, correspond pretty closely with the stains produced on these by small drops of blood, as far as their ground tints are concerned:—

The stains from the flea and the bug agree with those from blood, in yielding to water a rich colouring matter and traces of albumen. The respective shades of colour differ somewhat, however: that from the parasites being *a currant red;* while that from blood verges more or less to a *brownish or greenish red.* A better distinctive mark is afforded, according to Lassaigne, by the characteristic odour of the two insects, which is brought out readily by merely moistening the stain with water.

The reddish *stain produced by crushing the common fly between folds of cloth*, Lassaigne found to be caused by the escape of the red-coloured *aqueous humour* from their *large compound eyes.* From *its appearance alone*, he found that this could not be distinguished from the stain caused by a drop of blood. On macerating it in water, however, the water took an *orange-yellow tint*, and was found to contain *no albumen*, leaving the original stain of a *yellowish brown.* The colour of the fluid, thus obtained, was *discharged by chlorine*, without affording any precipitate. On touching the fly stains with various agents, this observer also obtained characteristic results, such as a *deep violet* with sulphuric acid, and a *bright red* with nitric acid.—(*Ann. d'Hyg.*, January, 1866, page 204.)

When due care has been taken to obviate chances of mistaking such sources of reddened stains as the above, and where the quantity of blood has been such as presents its more obvious characters, nothing further than a mere inspection may be required. It will often happen in practice, however, that, either from the minuteness or indistinctness of the stains, or from their having been interfered with by wetting, rubbing, or otherwise, more rigid methods will be required for their verification and discrimination.

For the ready verification of doubtful blood-stains on articles of dress, the following steps may, in the first instance, be taken. The stained portion of the stuff should be cut out and suspended by a thread in a small test-tube containing as much distilled water as will cover the stain. On standing, if the stain is from blood, the colour speedily detaches from the cloth and gravitates to the bottom of the tube, leaving the supernatant fluid nearly clear, and any fibrine which may have been present originally on the cloth remains still adherent to it in the form of a soft greyish or slightly reddish film. The reddish fluid at the bottom of the tube, on being now heated, if a mere trace of albumen merely is present in it, becomes milky; but if albumen is more abundant, it will yield a coagulum of a dirty greyish or greenish colour, all trace of redness in the fluid having by this time disappeared. The clot re-dissolves on the addition of caustic potass, the solution taking on a reddish-yellow hue by refracted, and a green colour by reflected light.

In order to strengthen the proof of the colour of the stain being from blood, other processes supplementary to or in lieu of the above procedure have been advised. Of these, writers on chemistry and physics have spoken with most confidence of—

(1.) *Teichmann's test*, which, as modified by Buckner and Simon, is substantially as follows:—The stained portion of the stuff is to be cut away from the rest—if recent, *macerated*, and if old, boiled with an excess of glacial acetic acid, till the acid is coloured, when it is to be evaporated to dryness on a watch-glass. When now placed in the field of the microscope, the matter in the watch-glass will be found to present *hæmine*, in the form of rhomboidal tabular, or indeterminate crystals, varying in colour from a faint yellowish red to a deep blood red. As the presence of *the saline matter of the blood is* requisite to the success of this process, and as this may have been previously all washed away, the advice has been given, to add a *very small particle* of common salt to the acetic acid before the maceration or boiling, in order to insure the appearance of the crystals.—(Caspar, vol. i., pages 199-201.) Dr. Taylor and others have dispensed with *the common salt* in this process, as unnecessary, and as liable to encumber the field of view with cubic and other crystals of chloride of sodium.—("Principles and Practice," page 261.)

(2.) In 1861, Schönlein announced a new test for blood. He found that *peroxide of hydrogen or antozone* had *no action* on *tincture of guaiacum*, but that in the presence of blood in the fluid a blue colour was produced. Hence, he concluded that there could be no blood present when there was no blue reaction, and that the production of a blue colour, though it might not lead to a positive conclusion as to the presence of blood, yet was a sufficient corroboration of other tests of blood.—(*Ann. d'Hyg.*, vol. xxxiv., pages 431-2.)

Dr. Taylor goes farther than this, and adopts Schönlein's conclusion without any qualification. He employs an etherial solution of the peroxide of hydrogen, and takes up the blue precipitate with an excess of alcohol or ether, when he obtains a deep sapphire blue solution.—("Principles and Practice," vol. i., page 527.)

(3.) Some reliance was formerly placed upon the colour test brought out by the addition of caustic soda to the stain taken up with water, which brings out a play of colours, from brown to green, and these changes occupying some time. The same effect is producible with concentrated sulphuric acid; an effect, however, which is equally yielded by this acid with albumen alone, or the bile acids, and even fat.

(4.) Some chemists have proposed to extract first the animal matter from the stain by potass, to throw it down by nitric acid, and subsequently to take up the iron from the colouring matter by hydrochloric acid, and to test the solution for this metal by ferrocyanide of potassium.

(5.) Once more: it has been proposed to apply the process of *spectrum analysis* to the detection of the blood in suspected stains.

Now, to the best of these tests it has been shown that serious, if not fatal, objections admit of being urged. To bring out their expected results, the quantity of colouring matter on the stains falling to be examined would require to be more considerable than is sometimes found to be present on those stains submitted to the medical examiner. Nor is this the sole objection to their use on such occasions. Teichmann's test, for instance, has been shown by Roussin and Kunse to be liable to much uncertainty. Both these persons have come to the conclusion that spots of human blood, or even the fluid itself, in appreciable quantity, may fail to yield any hæmine crystals whatever, or only such as are of so indefinite character as to be utterly worthless as a diagnosis.—(*Sydenham Society's Year-book*, 1864, page 456; Roussin, *Annales d'Hygiène*, vol. xxiii., page 142.) Similar failures have been found to follow the attempts at bringing out the polychroism of the blood, even in the hands of competent experimentalists. In the hands of Liman, again, and others, Schönlein's test yielded very doubtful results; while they found that the many substances belonging to the three kingdoms of nature yielded the blue reaction with guaiacum. The whole question has recently been examined by Pinard in France with substantially the same results.—(*Ibid.*)

As regards the *spectrum analysis*, it has been admitted by those who have examined it in connexion with blood-stains that they found it difficult to extract the *cruorine*—the colouring matter on which the process hinges—from stuffs of various kinds; and further, that *with the cruorine*—even when successfully extracted—foreign matters are usually found mixed, whose presence either hinders the production of the spectrum altogether, or renders the fluid so turbid as to interfere with its distinctness.—(*Journal of Science*, No. 1, pages 212-3.)

All this being admitted, it has been proposed by Roussin, who has carefully investigated the subject, to *dispense altogether with the chemical proof* of doubtful blood-stains, and to trust entirely to the *microscopical examination.* For this purpose,

this expert advised "that the stained stuff should be carefully examined; that a separate, distinct, and well-defined spot should be selected, choosing a part which has escaped traction and friction; that from this a portion not exceeding the breadth of a twenty-centime piece (the breadth of the nail) be cut out with blunt-pointed scissors, or the point of a scalpel, and spread out on a glass slide. On this from a pipette is to be dropped a few drops of a fluid composed of three parts by weight of glycerine, one part of concentrated sulphuric acid, and as much distilled water as will bring the compound to the specific gravity of 1028, leaving the stuff to imbibe the fluid for about three hours. At the end of that time two glass rods drawn out to fine points are to be used to press the stuff and move it about, and afterwards to disentangle its separate threads; when the threads are to be collected and withdrawn, and the fluid immediately covered with a cover-glass, when it is ready for placing in the field of the microscope."

By this process, the blood-globules will be easily recognised, of their natural size and shape, with a stain of even a smaller size than that prescribed by Roussin, provided the stain be recent and tolerably distinct. As admitted by its author, the success, however, will be interfered with where the stuff has been previously submitted to traction or friction. I have found, also, that it succeeds best with recent stains.

In practice, on some occasions, I have attempted to combine the whole or the greater number of the above tests as follows:—

The stained portion of the cloth is to be cut out, and suspended by a fine thread in a test-tube containing distilled water. If the stain has been from *rust or red paint*—the peroxide of iron—the cloth will yield *no colour* to the water; the addition to the contents of the tube of hydrochloric acid will destroy the colour of the cloth and render the fluid yellowish; and the yellow fluid, on the farther addition to it of ferrocyanide of potassium, will indicate the presence of perchloride of iron by the production of Prussian blue.

If the stain has been *from blood*, the colouring matter will detach itself from the cloth in the form of reddish striæ, and collect at the bottom of the tube, while the water will assume a reddish colour more or less pronounced.

(*a*.) A portion of the contents of the tube may now be used for the spectroscope. (*b*.) Two or three drops of the fluid from the bottom of the tube may be cautiously withdrawn by a pipette and placed in the field of the microscope, and the slide examined for blood-discs, epithelial scales, or fragments of capillary tubes. (*c*.) Two or three more drops similarly withdrawn from the bottom of the tube may be placed on a glass slide, glacial acetic acid added, and be left to spontaneous evaporation, or gently heated, and when dried looked at by the microscope for traces of blood-crystals. (*d*.) A little of the fluid may be dropped on white filter-paper and submitted to the guaiacum test. (*e*.) A little more of the fluid, after the addition of ammonia, may be watched for any change other than a heightening of its colour. (*f*.) The remainder of the fluid in the tube may now be heated, without or with nitric acid, for albumen, which if present will render it milky or throw down a coagulum from it, of a dirty grey colour, leaving the water without any trace of red. (*g*.) The turbidity or coagulum, if from albumen, will disappear or be re-dissolved on the addition of caustic potass, and assume a brownish-red by refracted, and a green colour by reflected light. (*h*.) When a stain has arisen from a layer of blood of perceptible thickness, the cloth, after maceration, may exhibit a soft, white, greyish, or rosy adherent matter, which, when removed and placed under the microscope, will prove to be the fibrine of the blood.

If, in place of stains on clothes, *a liquid, supposed to be blood*, has to be submitted to examination, by adding a drop or two of the suspected fluid to distilled water in a tube, the various steps of the above method will give the same results, with, of course, the exception of the last, or *the discovery of the fibrine*.

To insure the success of the above method several precautions require to be taken, and allowance made for some modifications or shortcomings in the results. To obviate these, the quantity of water employed should be as small as possible, and but little delay in the examination of the contents of the tube permitted. Thus, the fresher the fluid the better will the colour tests come out. Again, with (*b*), while the blood-discs in any case will not, as in Roussin's process, be found to have retained their natural size and form, from their imbibition of water and endosmose, they may be expected, if the examination is delayed, to be found of irregular shape, or even altogether broken up. Once more, to render the spectroscope (*a*) available in this way, the contents of the tube may require previous dilution, or their transference to a tube of very thin glass.

In the *detection of blood on weapons or instruments*, the medical examiner has to guard against some chances of mistake. Thus, on steel instruments, the presence of *rust spots* and *certain vegetable salts* of *iron* present very much the aspect of blood. A case in point is adduced by Orfila:—

A man in Paris was suspected of having murdered another; and a knife, apparently spotted with blood, was found in his possession, and regarded as a strong circumstantial proof of his guilt. The weapon was sent to the Laboratory of the Faculty for examination, when it was ascertained that the supposed spots of *blood* were nothing more than *citrate of iron*. The instrument, it appears, had been used some days previously for the purpose of cutting a lemon. Not having been wiped before it was put aside, a simple chemical action had gone on between the acid and the metal, which gave rise to the appearance in question.

Though, as already pointed out, the distinction is easily established betwixt stains of blood and stains by the salts of iron, when *either of these exists singly* on weapons, Lesueur and Robin, in 1856, found that some difficulty may be encountered in deciding on the real character of a stain on a weapon compounded of the two. To obviate this, in a case in point, they scraped off a portion of the stain, dropped it on a solution of sulphate of soda rendered slightly alkaline by caustic soda or potass with or without the addition of glycerine, when the substance examined under the microscope resolved itself into blood-discs on the one hand, and brownish-red particles of carbonate of iron on the other.—(*Ann. d'Hyg.*, July, 1856, pages 134-5.)

Lassaigne found that blood-stains on articles of steel, kept for six days in a humid atmosphere, failed to yield albumen or its colouring matter to water, from, as he supposed, the hæmatine and albumen forming with peroxide of iron a compound insoluble in water, and that such stains on wood containing much tannin—such as the common birch—may yield no albumen to water, owing to the previous formation of the two. To obviate this last difficulty, he suggests that the surface of the stain only should be employed; the compound in question originating only with the portions of the blood which have had time to penetrate below the surface of the wood.—(*Id. op.*, January, 1856, page 199.)

The medical jurist may be called on, in some instances, to discriminate betwixt *blood and other animal matters*, such as cerebral matter, menstrual fluid, etc.

(1.) In the case of cerebral matter, Orfila, besides the use of the microscope, proposes that the stain should be moistened, when hydrochloric acid will give a dull reddish grey with the brain matter, passing, ultimately, into a Malaga red; and sulphuric acid a violet colour, without any charring. Lassaigne considers the sulphuric acid test sufficiently characteristic, and found that it first yielded a sulphur yellow, speedily passing into a vermilion red, followed in two minutes by violet, which disappeared on exposure in about half an hour.—(*Ann. d'Hyg.*)

(2.) The question of the possibility of distinguishing betwixt *menstrual blood* and that which had flowed from an *ordinary wound* was mooted in a trial in France in 1858. In this instance, a person had been found dead, at some distance from his own house, with numerous large wounds on the head, shoulders, and other parts. Circumstances, not detailed, led to the suspicion that the murder had been committed *in the man's house*, and the body subsequently *carried to the spot where it had been found*. Large spots of blood were found in *the bed usually occupied by the man and his wife*. The woman was suspected of the murder; but on being charged with the crime she affirmed that the blood in the bed had proceeded from herself, and that she had been recently *menstruating*. This circumstance led, amongst other inquiries, to certain experimental researches on the part of MM. Mannoury, Salmon, and Robin, with the view of deciding as to the true source of the blood in question; the result of which was that in all their investigations, they found—first, that *menstrual blood* differed from that drawn from the vessels of the body, in containing a mixture of *epithelial cells and mucous globules*, the former derived from the utero-vaginal lining, the latter from the mucous covering of the genital membrane; secondly, that these bodies were never found in blood issuing directly from the vessels of the body; and thirdly, that by comparing the two forms of blood by the microscope, their respective characters could always be distinctly ascertained.—(*Ann. d'Hyg.*, 2me série, vol. x., pages 434-5.)

Few experts, however, I imagine, would be disposed to rely on such a test. I have met with epithelial cells in blood-stains from different parts of the surface, while mucous globules so closely resemble colourless blood-corpuscles, that if not, as held by some, identical, they differ so little from them as to render the discrimination of the two all but impossible.

(3.) No difficulty would present itself in the discrimination of the blood on a stain, whether from the mammalia other than the camel and the blood of fishes, birds, and reptiles, the shapes of the discs differing so much from each other. When, on the other hand, the discrimination has to be made betwixt human blood and that of the mass of the mammalia, the only assistance would lie with the determination of the respective measurements of the discs—a task which none but a practised microscopist would be authorised to attempt, even if he could do so successfully, dealing, as he would have to do, not with fresh blood, but with that altered by drying.

In the case of the murder near Kintore, previously referred to, the accused alleged that stains on his frock coat had been caused by swine which he had been carrying for a flesher a few days before, and we declined to give our opinion on the point raised in consequence on the precognition.

ORIGINAL COMMUNICATIONS.

STATISTICS OF DISEASE IN KING WILLIAM'S TOWN, BRITISH KAFFRARIA.

By CHAS. JAS. EGAN, A.B.T.C.D., M.R.C.S., etc.

In examining the statistics of disease in this country, in reference to its fitness as a health-resort for phthisical patients, it is of most importance, first, to consider the diseases of the respiratory organs.

The total number of cases of these diseases, attended in the six years 1870 to 1875, and from which the following statistics are drawn, are 1837—divided as is shown in the following table:—

Table I.

	1870.	1871.	1872.	1873.	1874.	1875.	Total.
Disease of respiratory passages	102	89	85	122	86	150	634
Bronchitis	33	67	100	85	111	111	507
Pneumonia	21	5	20	32	23	31	132
Croup	1	5	3	4	8	26	47
Influenza	17	81	109	53	121	95	476
Phthisis	4	9	8	4	5	11	41
	178	256	325	300	354	424	1837

Under the heading of diseases of the respiratory passages are included cases of common catarrh, relaxed throat, chronic and acute tonsillitis, cynanche pharyngea, and cynanche laryngea (with the exception of croup).

Table II. shows the number of these cases that occurred in each quarter of the year (the quarters being the same as given in the meteorological statistics at page 362 of the last volume of this journal), and the percentage for each quarter on the whole number of cases:—

Table II.—*Respiratory Passages.*

	1870.	1871.	1872.	1873.	1874.	1875.	Per-centage.
Spring	27	15	13	31	23	46	24·45
Summer	16	15	19	24	28	30	20·80
Autumn	30	30	25	45	21	32	28·70
Winter	29	29	28	22	14	42	26·86
	102	89	85	122	86	150 = 634	

This table shows that this class of disease is most common in the autumn months—viz., March, April, and May—which is the season in which the most sudden changes of temperature take place, and when fogs at night are most common. At this time of the year the epidemic "house sickness" is prevalent, which is a form of acute bronchitis or suffocative catarrh.

The number of deaths registered under this class was only 2, giving a percentage on the total number of cases of 0·31. One of these fatal cases was of a very unusual character; death resulting from hæmorrhage, derived from ulceration of an artery in the throat, with rapid sloughing of the right tonsil.

The other death resulted from cynanche laryngea in a boy fourteen years of age, on whom I performed the operation of tracheotomy.

The disease next in order to the above is bronchitis, of which 507 cases were attended during the six years. In this number, of course, there are included very mild as well as severe cases, and both acute and chronic.

Table III. shows the distribution of these in the different quarters of the year, and the percentage on the whole number:—

Table III.—*Bronchitis.*

	1870.	1871.	1872.	1873.	1874.	1875.	Per-centage.
Spring	10	28	34	19	21	36	29·20
Summer	5	13	31	31	27	17	24·50
Autumn	5	9	22	18	26	24	20·51
Winter	13	17	13	17	37	34	24·00
	33	67	100	85	111	111 = 507	

The number of deaths that occurred among these cases was 4, or about 0·79 per cent., which shows that bronchitis cannot be considered a very fatal disease in this country.

The next table shows the statistics of pneumonia:—

Table IV.—*Pneumonia.*

	1870.	1871.	1872.	1873.	1874.	1875.	Per-centage.
Spring	10	1	8	12	14	14	44·70
Summer	1	1	4	4	4	3	12·88
Autumn	5	1	3	8	2	5	18·18
Winter	5	2	5	8	3	9	24·24
	21	5	20	32	23	31 = 132	

From this we find that while diseases of the respiratory passages are most frequent in the autumn months, bronchitis and pneumonia are more common in the winter and spring. The number of deaths that occurred in this class was 14, or 10·60 per cent.

Croup is the most fatal of these diseases, and I have therefore separated it from the diseases of the respiratory passages, and given a separate notice of it.

Many cases of this disease, of which no registry is kept, take place in the country districts, where the disease comes on suddenly, and death ensues before any medical assistance can be obtained; and some are brought into town in a hopeless and dying state, which circumstance increases the mortality shown in these reports.

Table V.—*Croup.*

	1870.	1871.	1872.	1873.	1874.	1875.	Per-centage.
Spring	—	—	—	—	1	4	10·62
Summer	1	—	1	—	5	7	29·78
Autumn	—	—	1	2	2	11	34·06
Winter	—	5	1	2	—	4	25·53
	1	5	3	4	8	26 = 47	

The number of deaths that occurred from this disease was 13, or 27·66 per cent.; and it will be seen that it is most prevalent in the autumn and winter, the same seasons in which the respiratory passages are most affected by disease.

Nearly every year some cases of influenza occur, but occasionally a regular epidemic sets in, as in the years 1872 and 1874, when nearly everyone in the community suffers more or less from it. This very year (1876) there has been a widespread epidemic of the disease all over the colony, attacking both natives and Europeans.

Of course the number of cases attended by me, and reported in these statistics, does not show the number of cases that actually occur, as all the milder ones take care of themselves, without applying to any medical practitioner; and often when called to see one member of a family, the prescription given is used for each succeeding case that may occur.

The following table gives the statistics of influenza:—

Table VI.—*Influenza.*

	1870.	1871.	1872.	1873.	1874.	1875.	Per-centage.
Spring	4	37	76	24	38	17	41·35
Summer	4	21	22	—	22	2	14·96
Autumn	6	15	—	12	39	30	21·09
Winter	3	8	11	17	22	46	22·55
	17	81	109	53	121	95 = 476	

One death occurred among these cases, giving a percentage on the whole number of cases of 0·21.

Having now given statistics of the principal diseases of the respiratory organs, I come to phthisis, the disease for which especially patients are recommended to come to South Africa.

The total number of cases of this disease that have come under my notice in the six years 1870 to 1875 is 41, and of these 13 cases were colonial-born persons, and 28 came from England, some of them especially on account of disease of the lungs.

According to my experience, cases of phthisis in colonial born persons are more rapid, and give less hope of amelioration by treatment or change of climate, than in home-born persons.

Patients who come here with slight deposits of tubercle at the apex of the lung, but where softening has not taken place, and cavities have not been formed, have a very good chance of a healthy life by taking ordinary care of themselves: by not exposing themselves to the night-air after a hot day, nor suddenly changing their clothing because the weather has taken a sudden change, and especially by always wearing, both in summer and winter, flannel underclothing—underclothing made of *wool*, not mixed with any cotton.

No person should be recommended to come here in whom the disease is much advanced. The climate is good for such cases, but the manner of living here is much rougher than at home; and to a stranger coming here the want of home comforts cannot be supplemented.

Travelling by cart over rough, stony roads is very wearisome to a person in health, and the jolting is peculiarly bad for invalids.

The hotels, except in the large towns, are not comfortable for invalids; and, even in the best hotels, very little trouble is taken to make an invalid comfortable. Besides, the cooking is not of a very superior character—well enough for persons in health, but unsuited for a phthisical patient with a weak digestion.

Travelling by bullock-waggon, as described in a recent work on South Africa as a health-resort, is very pleasant for persons in health, and even for an invalid while the weather keeps fine; but should rain set in, all the pleasure will disappear. Besides, the pleasure of such travelling depends on the number of your servants, and cannot be easily undertaken without a good outlay of money.

To asthmatical patients, who have no organic disease of the lungs, this open-air life of waggon travelling is very beneficial. I have met cases of this kind, who never had a single attack of asthma while living in a waggon, but who suffered severely as soon as they resided in a house.

Among the native population (the Kaffirs), cases resembling phthisis are often met with; but I believe that most of these are cases of pneumonia becoming chronic through neglect. This is more especially the case among the Christianised Kaffirs, because the wild Kaffir wears only a blanket, and when he gets wet, as soon as he returns to his hut he throws off his blanket, and does not sit or sleep with the wet blanket round him, but lies naked on a mat before a fire. But the Christianised Kaffir, who wears European clothes, does not change them when he gets wet, as it is too much trouble, but keeps them on and sleeps in them, and is thus, through the help of civilisation, more subject to bronchitis and pneumonia, the latter often, through neglect, terminating in abscess of the lung.

The Hottentots and Bushmen are nearly all scrofulous, and phthisis is very common among them.

To sum up this paper on the diseases of the respiratory organs, we find that, out of the total number of cases of disease observed in the six years (viz., 1837), 369, or 20 per cent., occurred in the summer months; 440, or 23·9 per cent., occurred in the autumn; 458, or 24·9 per cent., occurred in the winter; and 570, or 31 per cent., in the spring; but the most serious forms of the disease, except croup, occurred in the winter and the autumn.

The total number of deaths that occurred, including 13 from phthisis, was 47, or a percentage of 2·55 on the whole number of cases. As an appendix to the diseases of the respiratory organs, I may mention that pertussis, which is such a dangerous disease at home, is not at all so here when children are taken ordinary care of. There was an epidemic of the disease during the spring and December, 1870, and January and February, 1871, during which I attended over 100 cases of the disease, and only three deaths occurred; and during the autumn and winter of the year 1876 there has been another epidemic, and at the same time a violent epidemic of influenza, and yet I have not heard of any deaths. In my own practice I have been called to see over 120 cases. I hope shortly to be able to add to these statistics reports of disease of the abdominal organs.

King William's Town, British Kaffraria.

CASE OF ACUTE ORCHITIS.(a)

By H. K. HITCHCOCK, M.D.,

THE case which I have the honour of bringing before your notice this evening is one of acute orchitis occurring in, and influenced by, a strumous diathesis.

Acute orchitis, as I need scarcely remind the members of this Society, is generally a sequel of gonorrhœa, occurring coincidently with the cessation or diminution of urethral discharge, usually terminating in resolution, seldom going on to suppuration. Orchitis also less frequently results from local injury (a blow or kick) to the testicle. I make these preliminary remarks because this case differs in several important points from an ordinary acute orchitis, both in its history and course, inasmuch as (1) it was not connected with gonorrhœa, (2) it did go on to suppuration within the testicle, and (3) for some few days I was unable to obtain any history of local injury.

On February 16, 1877, I was called to see W. P., aged fifty-four, married, with grown-up family, an auctioneer, house-agent, etc., a rather stout, flabby man, of average height, with fair complexion, reddish-brown hair, etc.; has a phthisical family history, several brothers and sisters having died of phthisis, and all the members of his own family exhibit more or less signs of struma. He has had very fair health, chiefly suffering from external piles, which he has had the last sixteen years. On this date (February 16) I found him in bed, complaining of pain in the right testicle, which, on examination I found slightly enlarged, red, very hard, and exceedingly painful to the slightest touch. There being no urethral discharge, and the man's history putting gonorrhœa out of the question, I endeavoured to obtain some history of local injury, but he could remember none, merely saying that for a day or two previously the testicle had ached very much, and then suddenly became worse. Every day I jogged his memory, until at last (about the fourth day) he told me that he was in the habit of collecting rents and putting the money into his right trousers pocket, where, oftener than not, he had two or three large door-keys, and that he had often noticed, when moving about quickly, this weight swing and strike the testicle, causing it to ache for some little time after; and he also said that eight days ago his dog sprang heavily against it, causing him to feel so sick as to oblige his sitting down. So there was the local injury established. I ordered four leeches to the right scrotum, followed by linseed-meal poultice, and pil. opii gr. j. statim sumendus.

February 17.—The leeches had bitten well, and poultices had been constantly applied, but the testicle was still enlarging and acutely painful. In the evening, the swelling and pain increasing, I adopted Mr. Henry Smith's plan, and punctured the testicle at its lower and back part with a tenotomy-knife, which was followed by the escape of some black, treacly-looking blood. Linseed-meal poultice was then applied; pil. opii. gr. j.

19th.—He told me that the agonising pain disappeared soon after the puncture of the previous evening, enabling him to sleep, and had not returned since, the pain now being dull and aching; size of testicle, an average hen's egg. Linseed-meal poultice continued.

23rd.—Testicle still continued large, but scarcely any pain, even on handling; so I strapped it, hoping to reduce its size. He bore the strapping well, and the scrotum was suspended in a bag.

25th.—Strapping removed; size about the same. From the tension, redness, and swelling not subsiding, although no acute pain existed, I concluded that some deep-seated suppuration must be slowly going on.

28th.—There has been a gradual increase in size, but very little pain; it is now equal to a *large* hen's egg, and at one place, high up, the scrotum appears thinning and shiny. Mr. Wagstaffe, of St. Thomas's Hospital, saw the patient with me in the afternoon, and with a very narrow lancet (one-eighth of an inch in breadth) punctured the testicle from above downwards, in perhaps a dozen places, inserting the blade trans-

(a) A paper read before the West Kent Medico-Chirurgical Society, at Greenwich, Friday May 4, 1877.

versely. From all the punctures very dark blood escaped, mixed at some points (especially the upper) with curdy pus. The blood coagulated almost directly, and was in quantity, I should think, about five or six ounces. The patient bore the operation well, without chloroform or ether spray. Linseed-meal poultices were then re-applied.

From this date (February 28) no further punctures were required, for those made kept on discharging pus in small quantities, gradually closing, one after the other, from the bottom of the testicle upwards. Three of the first-made punctures at the top remained discharging long after the rest, and from these *débris* of convoluted tubules escaped. These finally closed, and on April 5 the scrotum was quite sound, and, except that the testicle was a little shrunken, nothing abnormal could be perceived.

The treatment during this long period (from February 28 to April 5) comprised poultices of various kinds—viz., carrot, linseed, bread, yeast, figs, etc.,—alternating with warm water and olive oil dressings, and, finally, cold sea-water baths; tonics internally, and purgatives when required. I may mention that the amount of nourishment consumed by the patient appeared enormous, and yet he seemed unable to do with less. I will now, gentlemen, draw your attention to what I consider points of interest in the case. First, its obscure origin shows what slight injury will, if continued, suffice to set up inflammation in a strumous subject, and it also shows the importance of making diligent inquiry of the patient; secondly, what a low type of inflammation, insidiously going on to suppuration, occurs in these cases; and thirdly, what a long time suppuration continues—well exemplifying the pyogenic tendency in struma.

With regard to treatment, I wish, first, to call attention to the rapid relief (without return) of the intense pain afforded by puncturing the testicle in the acute stage; and secondly, to the splendid results obtained by the multiple punctures carried out by Mr. Wagstaffe—a result which, I think, could scarcely have been obtained by any other means, inasmuch as each lobule of the testicle being separately tapped, afforded a free and simultaneous exit for all discharges until the end of the case, thereby obviating any skin-sloughing or fungoid growth, either of which results are common in suppurative orchitis, and would, I fear, have inevitably occurred in this case, either if the abscess had been allowed to break spontaneously, or if it had been lanced in the usual way by free incision; thirdly, the advantages of ringing the changes on poultices of different materials, and alternating them with water or oil dressings, as the patient tires of one dressing so long continued, and I believe the changes, by preventing soddening of the skin, obviate skin-sloughing.

St. Clare, College-park, Lewisham, E.C.

CASE OF

CYANOSIS, WITH GREAT DEVELOPMENT OF THE RIGHT SIDE OF THE HEART;

INTER-AURICULAR SEPTUM PERFECT, AND NO INTERMIXTURE OF ARTERIAL AND VENOUS BLOOD.

By R. SHINGLETON SMITH, M.D. Lond., B.Sc.,
Physician to the Bristol Royal Infirmary.

T. W. J., AGED thirteen, an errand-boy, admitted to the Bristol Royal Infirmary on December 19, 1876, with cardiac symptoms. His mother says that he has always been delicate, and that he was always "of a blue colour." He states that his breath used to be good, and that he could run uphill well till within the last two years. Was not laid up at all till two months ago, when he caught cold, had "bronchitis," and soon after lying up it was noticed for the first time that the feet were swollen.

On admission he was observed to be a thin, ill-nourished, and small-sized cyanotic boy. There was excessive œdematous swelling of both legs, and a considerable degree of ascites. He complained of dyspnœa, and was not able to lie back. The heart's impulse was found to be entirely on the right side of the sternum; there was marked percussion resonance over the normal cardiac area, but a dull patch was found on the right side, extending from the third rib down to the line of liver-dulness, and continuous with that of the liver, its outer limit being a vertical line though the right nipple, its inner limit being the middle line of the sternum. A diffused heart-impulse was felt over this region, and a distinct thrill could be felt to the inner side of the nipple. A loud systolic bruit was heard over the cardiac area, loudest below, but indistinct above; the point of greatest intensity was an inch below and half an inch to the inner side of the right nipple. The chest expanded fairly. Total size round the line through the nipples was twenty-eight inches; the right side measured fourteen inches and a half, and the left side thirteen inches and a half. The left side was unduly resonant everywhere, almost tympanitic; the right side beyond the cardiac area had normal resonance. Occasional rhonchus was heard on both sides, front and back, and some loose crepitation at the bases; but in front, in the infra-clavicular regions, loud puerile breathing was audible. The boy always lay on the right side; the right elbow and the right hip had become sore from his constantly lying in this one position. He complained of troublesome cough. Pulse was very small and compressible; 120. Hands and feet felt cold. Tips of the fingers were very blue, and there was a marked condition of clubbing, with incurvation of the nails. The veins in neck were much distended, and pulsated synchronously with the heart's action. Urine was acid, clear, specific gravity 1025, free from albumen. His temperature was 96° Fahr. Measurement round abdomen was thirty-two inches.

January 8, 1877.—The swelling of the legs had decreased, and he could lie down in bed more comfortably, but the abdomen measured thirty-three inches at the largest part. He passed twenty to thirty ounces of urine daily. His mental condition had improved; he seemed much brighter and more cheerful than on admission. There was no marked irritability or irascibility. The temperature varied from 96° to 97°.

13th.—He was not so well; was very drowsy, and much more blue. Had been sick frequently, and his bowels were much relaxed. Anasarca had increased; the abdomen measured thirty-four inches, both hands had become œdematous, and the face also was puffy. Pulse 108, very small and weak.

18th.—Drowsiness had passed off. Urine scanty (only about sixteen ounces), and contained a trace of albumen. The hands were not swollen, but prepuce was so swollen that it was freely punctured. Abdomen measured thirty-four inches and a half.

25th.—An incision was made above each ankle. Temperature 95·8° in the evening.

26th.—A large amount of fluid had drained away. The hands and feet were very cold, and pulse was only just perceptible; but he seemed more comfortable. Urine clear, specific gravity 1015, with no albumen.

29th.—Fluid still draining freely. Can now lie on his back and move about a little in the bed. Breathes very comfortably, and is less blue. Abdomen measures thirty inches and a half.

February 1.—His strength very gradually diminished, and he died at 10.15 p.m.

Post-mortem Examination, fourteen hours after Death.—Pericardium and both pleuræ full of serum. A small quantity of lymph (œdematous) on the parietal surface of left pleura. Heart situated entirely on the right side of median line; anterior surface formed entirely by the right ventricle; apex hidden; heart's area large. Right ventricle much larger than the left, and its walls equal in thickness to those of the left. Right auricle also dilated and thickened. Tricuspid orifice much dilated, admitting five fingers; the other valves healthy. Foramen ovale perfectly closed, the inter-auricular septum being unusually perfect; there was no interventricular communication. Pulmonary artery was of normal calibre, and its valves perfect. Lungs congested and œdematous. There were patches of emphysema along the anterior margins. The lobes were arranged in the normal manner. Numerous enlarged bronchial glands occupied the root of both lungs. Liver, spleen, and kidneys were healthy.

Remarks.—This case appeared during life to be a typical one of cyanosis, dependent on intermixture of blood through a patent foramen ovale. It seemed probable, too, that the pulmonary artery was small in size, and that this condition had given rise to hypertrophy of the right ventricle, tricuspid regurgitation, and general venous engorgement. The apparent malposition of the heart supported the idea that this organ must be imperfectly or abnormally developed. It was, however, noticed as a remarkable fact that although the heart seemed to be located entirely to the right of the median line, there was no evidence of transposition of any other viscus. After death it was found that no communication existed

between either the two auricles or the two ventricles; there was no contraction of the pulmonary artery; but the whole of the right side had been developed to an unusual extent, and to this chiefly was due the apparent malposition of the heart. There was no abnormality in the lungs to account for the hypertrophy of the right ventricle, as the existence of a few enlarged bronchial glands in the root of the lungs could scarcely be a sufficient cause. The inference was accordingly adopted that the great development of the right side of the heart must be considered as the primary morbid element; and the history of the patient warrants the conclusion that this abnormal development was congenital in its origin. The very great dilatation of the tricuspid orifice, the marked venous pulsation in the neck, and the very loud bruit heard over the heart's area, which was probably caused by tricuspid regurgitation, indicate the mechanical difficulties in the circulation, which became at last altogether insurmountable. The condition of the finger-tips and nails bears out the view that the difficulties in circulation dated from or before birth; a very marked condition of clubbing, combined with incurvation, and an extremely cyanotic condition were observed during life, but were much less distinct after death.

CROUP AND DIPHTHERIA:

A CONTRAST.

By RICHARD B. SEARLE, L.R.C.P., Lond. M.R.C.S., etc.

As a general practitioner of twenty-three years' standing in West Cornwall, I have had opportunities of becoming acquainted with a large number of cases of croup—simple and malignant,—and have arrived at the conclusion that the latter is an asthenic form of the former, and that they bear a similar relationship to each other that typhoid or congestive fever does to typhus or nervous and ataxic; requiring, consequently, the most opposite treatment. On my first coming into Cornwall I found simple or tracheal croup, like typhoid fever, *endemic* to the district, as indeed the latter still is—the one due to the great humidity of the atmosphere, the other to impure water from faulty drainage. Cases of diphtheria, like typhus, were exceedingly rare; but for years past simple croup has nearly disappeared from the district, as far as my experience goes, and diphtheria as an *epidemic* seems to have taken its place. Having changed its type, the disease has shifted its locality. Both commence with catarrhal symptoms—the former bronchial, invariably attended with hoarseness of the voice from the onset, and with a peculiar bark-like cough; the latter of the naso-pharyngeal tract, attended with coryza of an ichorous, sanious character, accompanied with difficulty in swallowing. It is due to this last symptom that parents apply at an early stage to the doctor; whereas in croup, from the child not refusing its food, but continuing cheerful until symptoms of impending suffocation ensue in due course, when they apply the period for successful antiphlogistic treatment has slipped by, and the services of the medical attendant are chiefly available in order to furnish a certificate, and thereby avoid the necessity of a coroner's inquest.

Owing to the neglect of primary symptoms, the mortality from croup is greatly in excess of diphtheria—the latter in my experience being barely 10 per cent., whereas the former is full 25 per cent.,—though more amenable to treatment, as I do not recollect ever failing to cut short an impending attack of croup by a liberal administration of tartar emetic, followed, it may be, with leeches and a warm bath: whereas the mortality from diphtheria cannot be calculated as capable of further diminution than one-half; a large proportion of cases from this disease having been of some days' duration before one is summoned. As an example, eighteen years since I was called to a case where there was laryngeal symptoms and great dyspnœa, and, on inspection, the palate and fauces were covered with false membrane, the uvula (elongated one inch and a half) presented the appearance of the finger of a soiled white kid glove, of a yellowish-white colour.

During the past year I have had six cases of diphtheria, the two earliest being the only children in the same family; they recovered under my usual plan of treatment—liq. ferri perchloridi fort. to the throat and tonsils, and a diluted solution of the same injected into the nostrils. Six years previously the parents lost a child from simple croup, the disease being limited to the larynx, trachea, and bronchial tubes, there being no false membrane appreciable on ocular inspection, no swelling of neighbouring glands, nor any hæmorrhage, which is of such frequent occurrence from the mucous membrane affected in diphtheria. The third case of diphtheria occurred in a child four years of age, and proved fatal on the fifteenth day of my attendance, from general exhaustion, attended with paralysis of the muscles of deglutition, all trace of false membrane having disappeared for some days previously. The father stated that he had previously lost two other children from a throat affection of a similar character, but which were more rapid in their course, being of a few days' duration. Two other cases in another family came under my care three months since. The first, a child twenty months of age, having become attacked with catarrh of an influenza character, together with conjunctivitis of both eyes, symptoms of diphtheria soon developed themselves, the disease extending to the inflamed eyes, which rapidly became distended with false membrane, and the sight of one eye was lost from sloughing of the cornea; the second child, four years of age, soon also became affected with diphtheria, and had hardly recovered from the exhaustion due to the disease, and from the aphonia which so frequently ensues, when scarlet fever set in, which also attacked the youngest child. Both are now recovering.

I have had of late about thirty cases of scarlet fever, some mild, many of the anginosa variety, attended with inflammation of the throat of a bright red colour, and enlarged tonsils, followed by ulceration, in one so severe as to penetrate the soft palate. The topical treatment has been a strong solution of argenti nitras, which I found very efficacious applied with a camel-hair brush to the soft pultaceous tonsils, but which has no effect upon the membrane of diphtheria when it has become tough and leathery, which it speedily does. I have had no death as yet from the present epidemic of scarlet fever. The sixth case of diphtheria has recovered perfectly under my usual treatment.

Both croup and diphtheria are probably infectious diseases, but the intensity of infection varies considerably, that of simple croup not exceeding that of phthisis, which is generally considered non-infectious, but is not absolutely so, though such has been by some denied; whereas diphtheria, in my past experience, has attacked several members of the same family in such rapid succession, that, like typhus—which I have known prostrate a whole family—its power of infection must be admitted; and both alike do not limit themselves to age, attacking principally the poor and ill-nourished, requiring consequently from the onset a nourishing and stimulant plan of treatment. Croup, like typhoid fever, on the contrary, is more restricted in its ravages, the former attacking the robust and well-nourished child, the latter the plethoric and the well-to-do adult; and should it casually attack any of a weak constitution or suffering from organic disease, it is an exceedingly rare case that such die from the visitation. The latter fever, as a rule, consequently requires an unstimulant plan of treatment; and, whilst combating local congestions by leeching and counter-irritants, a milk diet has insured the most satisfactory termination.

Viewing the state of ataxia now so prevalent, especially among the labouring portion of the community, typhus may be expected ere long to resume its former sway.

CASE OF STRANGULATED UMBILICAL HERNIA—RECOVERY.

By J. HOYSTED COURTENAY, L.K.Q.C.P., L.R.C.S.I.,
Government Medical Officer, Jamaica.

Reading in your journal of October 14, 1876, of two cases of strangulated femoral hernia successfully operated upon by Dr. Savage, of Birmingham, both cases occurring in persons of advanced years, it struck me that the following case might present some interesting features, being, as it is, a further corroboration of Dr. Savage's opinion that age should not have too great an influence in deterring one from operating in cases of strangulated hernia.

Ann W., a negro woman, aged sixty-eight, was admitted to the Lucea Parochial Hospital, on December 18, 1875, suffering from a strangulated umbilical hernia. She was in a very weak condition when admitted, her face having the characteristic anxious expression and sunken appearance of the eyes so indicative of prostration in cases of this kind. Stercoraceous

vomiting came on immediately after her admission, so no time was lost in putting the patient under chloroform, trying to reduce the hernia by the taxis. Having failed to reduce it by that means, I made an incision about two inches in length over the neck of the tumour, and by breaking down the adhesions, which were very dense, succeeded in reducing the hernia without opening the sac. I may mention that my patient's strength was so much reduced that forty minims of chloroform were sufficient to keep her under the influence of that anæsthetic during the time I was employing the taxis and performing the operation—about twenty minutes altogether. Immediately after the operation the pulse improved. I then ordered one-grain doses of opium and quinine, together with half an ounce of brandy, to be given every four hours, and beef-tea every two hours. The following day, although very weak, there was considerable improvement in my patient, and on the evening of that day the bowels acted of themselves. On the evening of the 20th (two days after the operation), a slight rigor having come on, I removed all the sutures, and a small quantity of pus exuded from the lips of the wound. I immediately ordered linseed-meal poultices to be applied at intervals. Under this treatment the wound became perfectly healthy and healed completely, and in a month from the date of her admission, being provided with a suitable truss, my patient was discharged from hospital. In conclusion, I may confess that, taking into consideration the advanced years of my patient (for sixty-eight is considered extremely old in the West Indies), at first I felt extremely reluctant to operate; but the thought of being a passive spectator of what must be the inevitable result of such a case, if left to itself, determined me in operating, and, I am happy to add, with a successful result.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

LONDON HOSPITAL.

ON THE MODE IN WHICH LUPUS SPREADS.(a)

(By Mr. JONATHAN HUTCHINSON.)

The mode in which lupus extends itself, and more especially the manner in which multiple patches are developed, is well worthy of investigation. My impression is that the processes are by cell-infection, and very closely similar to what we observe in cancer. When we see a patch of lupus spreading at the edge by the production of fresh tubercles in continuity with the original ones, we can have little doubt that the process is one of contagion by continuity. The diseased structures grow into the adjacent healthy skin. This is exactly what we observe in cancer of the skin, and more especially in that form of it which is known as rodent ulcer. In some forms of rodent ulcer we even observe a tendency to heal in the parts where the skin has been destroyed, closely similar to the process which is so constant in lupus. The two differ in this: that whilst the lupus cell-growth appears unable to maintain itself excepting in the skin-tissues, the cancerous growth, although it may have originated in skin, can grow deeply into the fascia, muscle, bone, etc. Yet let us note that although cancer can do this, it often manifests a remarkable tendency to restrict itself to the skin in which it was first developed.

The cases of multiple lupus, or what we have sometimes called "psoriasis-lupus," may be explained either on the hypothesis that nuclei or cells have been transferred from the original patch of disease through the lymphatic system or the bloodvessels, or by mere cell-travelling, to the parts secondarily affected; or, secondly, that some altered condition of the blood generally is the cause of the more or less simultaneous outbreak at different parts of similar processes of diseased action. The facts seem to me very strongly in favour of the first of these suggestions. If lupus were originally a blood-disease, it ought, like common psoriasis, to arrange itself symmetrically. Now, I believe that, with the exception of the rare and peculiar form known as erythema-lupus (*L. erythematosus*), it never does so. I have seen many cases of multiple or psoriasis-lupus, but scarcely any in which the similarity to psoriasis was maintained in this particular. On the contrary, the deviations from symmetry are often very great. Thus, you may find one limb severely affected, and its fellow exempt; one cheek covered with lupus patches, and none at all on the other. Psoriasis never does this. Again, we see the resemblance to cancer in the way in which the secondary deposits of lupus are often seen in close proximity, although not absolutely continuous with the original ones. I have often asked your attention to this fact in cases of cancer, and appealed to it as evidence that cancer is in the first instance a local disease. The secondary manifestations do not occur at random, and are not manifested with equal profusion at a distance and near to the original growth. Thus, in the case of cancer of the breast, we often find a number of little glossy nodules developed in the skin overlying the tumour. It is impossible to explain why they should be here, and not on the opposite side, on any theory of blood-origin, or, I think, upon any hypothesis whatever, other than that which teaches that they are due to the direct travelling of germs derived from the original infective source. It is precisely so with lupus: we constantly see a number of tubercles produced at a little distance from the border of the original patch, and it is comparatively exceptional to find them spread irregularly over the surface of the body. To these exceptional cases of multiple lupus we may suitably compare the rare examples of multiple cancer, usually the melanotic form, in which the new growth shows itself by a copious development of perfectly distinct tumours. I have seen cases of melanosis in which the patient was spotted over like a leopard with these growths; and in all such I believe they are secondary to an original one.

If we accept this theory of the mode of spread of lupus, we shall have to admit that facts favour the belief, either that individuals differ very much in their liability to permit such spread, or that the nature of the disease-product varies much in its capacity for migration. But neither of these involves any improbability, and they are both of them facts to which we are obliged to make frequent reference in explaining the phenomena of cancer.

You will see that the correctness or incorrectness of this theory is of considerable importance, as indeed all theories are, in its bearing upon practice. If lupus be, as I hold that it is, an infective tissue-malady rather than a blood-disease, we have a strong additional reason for vigour in the use of those methods of treatment which are likely to eradicate its first local manifestations. We apply to it the same rule that we so constantly reiterate in reference to cancer—"Stamp out the very first indications of flame, in order to prevent the spread of the fire."

(a) Part of a clinical lecture delivered in November, 1874.

HÔPITAL ST. LOUIS, PARIS.

CASES ILLUSTRATING THE TRANSMISSION OF SYPHILIS.

(In the Service of M. FOURNIER.)

[Reported by Dr. ALLEN STURGE.]

Case 1.—A. M., aged thirty-two, was admitted May 19, 1877. Patient has been married ten years, and is the mother of a family. Her last child was born March 8, 1876, and died on February 2, 1877, in a convulsion. There is no history of syphilis of any kind in the family. The patient after the death of her child, having a good breast of milk, gave suck to the child of a neighbour. This neighbour was a woman who had formerly been a sufferer from syphilis, and had been a patient at the Lourcine Hospital under the care of M. Fournier. She noticed that the child always had a cold in its head, that there was a good deal of discharge from the nose, and that it had upon its lower lip some hollow round holes. When spoken to about this the mother of the child said that it often scratched itself. About three weeks after beginning to suckle the child, the patient presented upon her right breast, on the outer side of the nipple, a small superficial and indolent erosion, which soon increased in size until it presented the appearance of a syphilitic chancre. Indeed, its induration did not escape the notice of the patient herself, and a sympathetic enlargement of glands occurred in the axilla, which can still be felt. About nine weeks after the first appearance of the chancre, and about a fortnight before admission into the hospital, she began to complain of feverishness and of headache coming on in the evening, and since then she has gradually passed into the condition which she presented on admission. There

was seen at the spot where the chancre had been situated a moderately large hypertrophied syphilide—the chancre itself being almost healed. There was an eruption over the whole body, consisting of large papules of a coppery-brown colour, and there were numerous large hypertrophied papules round the vulva. There were hard swellings of the lymphatic glands to be felt at the back of the neck, in the axilla, and in the inguinal regions.

History of the Mother of the Child nursed by the above Patient.—She is twenty-two years old, and the child in question is the only one she has had. Five years ago she was admitted into the Lourcine Hospital (a hospital set apart for prostitutes suffering from specific disease), under the care of M. Fournier. She was then suffering from a severe specific sore throat, and presented an indolent bubo in the left inguinal region. She was treated with protiodide of mercury for five or six months. Four months after leaving Lourcine she suffered from an eruption on the neck, which gave rise to large crusts. Since then had a miscarriage at an early stage of pregnancy. Her present child was born in May, 1876, and was nursed by its mother, who at the same time nursed another child, which died in a cachectic state aged four months, after having been nursed by her for three weeks. Three months ago she began to have violent pains in the head, much worse in the evening; and at the same time she had a scaly eruption of the back and front of the right forearm, slightly of the left forearm, and on both thighs. This eruption persists. It consists of serpiginous patches elevated above the surrounding skin, dull red in colour, dry and scaly. The child was presented at the consultation. It was cachectic, and was suffering from a nasal discharge, the bridge of the nose being flattened. It presented an erosion, evidently specific in character, on the upper lip. There were enlarged and hard glands in the occipital region and in the groins.

Case 2.—E. C. B., aged thirty-four. The patient has always enjoyed good health. She was married eight years ago, and has had six children, three of whom are dead. One died aged six months, of bronchitis; one aged eight months, of measles; and the last child was born in July last, and died in February, of small-pox. After the death of her child she became wet-nurse to the child of a neighbour. This infant was premature, having been born at the end of eight months, and it was three weeks old when the patient took charge of it. It was very small, and suffered from constant running at the nose, and its lips and tongue were inflamed and covered with yellow patches. While patient was nursing the infant it became very yellow, and grew thinner and thinner, until at last it appeared to be nothing but skin and bone. Patient nursed it for six weeks, when it died, having had frequent convulsions for three weeks before its death. Fifteen days after beginning to nurse the child she noticed a little pimple on the left breast at the areola surrounding the nipple. This grew bigger, until it was about the size of a half-franc piece. It then ulcerated, and a little crust formed on its surface, which dropped off, being replaced by a fresh scab. Three weeks after the first appearance of the sore place on the left breast, a similar one appeared on the right breast, in the same position as that on the left—viz., on the areola just above and outside the nipple. She presented herself at St. Louis on April 4, and the sores on both breasts were well marked. They were indolent, slightly ulcerated patches, presenting the characteristic induration of a syphilitic chancre; and M. Fournier had not the slightest hesitation in pronouncing both of them to be primary syphilitic sores. There was indolent enlargement of the glands in both axillæ. She has had an eruption on the skin, presenting the characters of a secondary syphilitic eruption. She says this first came out a fortnight after the appearance of her first chancre. She attended at St. Louis till April 28, when she was discharged, the chancres being cured, and there being no trace of rash at that time.

Case 3.—A. B., female, aged about twenty-eight, had been nursing a child of her own for thirteen months, which was then weaned. Mother and child in perfect health. Having still a great deal of milk, she offered to nurse the child of a neighbour which was sickly and weak. This child had some patches in the mouth, which its mother said were due to thrush. A. B. nursed the child for a month, when it died, as is allowed, of syphilis. Eleven days after the death of the child, two pimples came out on the nurse's right breast close to the nipple, and five on the left breast. These enlarged and became hard. She was treated by a chemist with strong mercurial ointment applied to the breasts. The result was that the sores took on a phagedænic form in both breasts, and when she presented herself at St. Louis there were deeply excavated sores surrounding about two-thirds of the nipple of each breast, with hard, slightly elevated margins, and unhealthy, sloughy-looking floor. The neighbouring parts of the mammæ were red, swollen, and very tender. The patient was treated in a purely emollient manner, so as to allow the inflammation to subside. At the end of ten days the sores were reduced to about half the original size, and were filling up from the bottom; the neighbouring inflammation, moreover, was entirely subdued. There has been throughout indolent enlargement of the glands in both axillæ.

A patient recently at the Hôpital St. Louis was an example of the converse of the above cases—viz., of the transmission of syphilis from an infected nurse to a healthy child. The patient, who was an ordinary wet-nurse, was suffering from secondary syphilis, one of the manifestations being mucous tubercles on the lips and tongue. The child of whom she had charge had the habit of putting its fingers into the mouth of anyone who was nursing it, and afterwards into its own mouth, and *viee versâ*. M. Fournier was called to attend this child for a sore on the tongue, and on investigation he found this to be a primary syphilitic sore. The child had been continuing its practice of inserting its finger alternately into its own and into other people's mouths, and in this way it had infected several persons, including both its father and mother and grandmother, all of whom presented, after a short time, syphilitic chancres of the lips or tongue.

Remarks.—These cases, though presenting considerable clinical interest, are of even greater importance from a social point of view. Their importance socially will at once become evident when we state that all these three cases have occurred at the St. Louis Hospital in the short space of six weeks; and in speaking of them M. Fournier was able to refer to a large number of similar cases he had seen both in hospital and private practice. The relations between the child and nurse give rise to a means of transmission, insidious and quite unlooked-for, of this horrible disease into respectablo and well-conducted households; and when once introduced, there are unusual facilities for the spread of the infection, because the sores occur on parts which may be brought so easily and frequently into contact with other people. In this way may occur what M. Fournier terms "epidemics of syphilis." In the third case referred to above, several other members of the family were infected before they could be warned of their danger. In another case which came under the notice of M. Fournier, a nurse who had become infected by one child went to her own village and nursed other children, and from herself, or from the children who had contracted the disease from her, no less than twenty-four persons became infected. When, moreover, a wet-nurse has been employed for one child who has died, she frequently engages herself to nurse another child almost immediately. Now, if the first child has died of congenital syphilis, the nurse may be in the period of incubation of syphilis, and after nursing the second child for a few days a chancre may appear on the breast, and by this means she will transmit syphilis to the second child. M. Fournier has seen a certain number of cases of this description, and he lays it down as a rule that whenever a child nursed by a wet-nurse has died, unless its antecedents and cause of death can be accurately ascertained, the nurse should not be allowed to take another baby for at least a month. Where it is known that the father of a child has had syphilis, or where a child has presented the slightest sign of hereditary syphilis, it is of the utmost importance that only the mother shall suckle the child. It was pointed out by Colles, and the observation has been repeatedly confirmed since, that the mother of a syphilitic child, even though she may never herself have had syphilis, does not contract the disease from the child during lactation, whereas an uninfected wet-nurse will do so at once. If the mother has no milk, the child must be brought up by hand, or, what is better, as such children rarely survive if nourished simply by the bottle, with goat's milk, the child being trained to suck the milk directly from the goat. This is a plan that M. Fournier has repeatedly tried with good success, and he affirms that there is no difficulty whatever in the matter. Should a wet-nurse have become infected from the child, M. Fournier lays down that it is the imperative duty of the doctor to do all he can to retain her in the family, both for the sake of the child and to avoid the chance of her spreading infection elsewhere. This is often a difficult and delicate task, and he will in many cases fail in his attempt.

THE FORMATION OF FAT IN THE ANIMAL BODY.

There have been few more interesting chapters on the history of physiology than that which deals with the development of force within the human frame. Since Mayer first enunciated the proposition *Ex nihilo nihil fit* as applicable to the animal as well as the purely physical world, much has been done. But nothiug has been more clearly made out than this: that, on the whole, albuminous substances are applied to the repair of waste; whilst hydrocarbons are either directly burnt up and appear as force, or are laid up as a reserve in a new and modified form. The form in which they are thus laid up in plants is starch; in animals, fat. Here, however, as far as animals are concerned, we enter ou the borders of a most difficult question—that is, the relations of the substance called glycogen produced in the liver; but this, in the meanwhile, we must put on one side. No men have done more in their own peculiar way thau Messrs. Lawes and Gilbert to elucidate practically the applications of abstract physiology to overyday life, or perhaps we might put it *vice versâ*. To those acquainted with scientific farming little has to be said —to them the names of Lawes and Gilbert are familiar; but to our professional brethren they are not perhaps so well known as they might be. Be that as it may, these two gentlemen have for many years devoted their attention to applied physiology, especially as regards farming operations, and in the last number of the *Journal of Anatomy and Physiology* they supply a kind of *résumé* of their results with respect to the formation of fat in the animal body.

It was first advanced by Liebig that a great part of the fat of the animal body was derived from hydrocarbons other than fat. This view was strenuously combated by none more than by the two distinguished Munich Professors—Pettenkofer and Voit. As every physiologist knows, Pettenkofer had a large air-tight chamber constructed, in which a man might live, and by means of which the various gases excreted by the human body might be collected for analysis. As regards the formation of fat, the experiments made by these gentlemen were on a dog—rather, we should think, an unfortunate selection. In the result they found, as they thought, that the fat deposited in the animal resulted—first, from fatty substances contained in the food; secondly, from the decomposition of albumen; that starch or sugar only saved the alb uminous materials of the body from being partially converted into fat.

The experiments long ago undertaken by Mcssrs. Lawes and Gilbert led to a totally different belief. They were partly made with regard to the feeding of ruminants, and partly with regard to the feeding of pigs. In 1866 they announced their results in a short paper published in the *Philosophical Magazine*, which we noticed at the time; but these results have been called in question, as above indicated. The authors have since reviewed their investigations, and the result is to be found in the article just referred to. They find that, as far as ruminants go, the results are not decisive, these animals having no special predisposition to the formation of fat; but in pigs it is otherwisc. In dcaling with pigs, the proportion of nitrogenous to non-uitrogenous substance in the food used was cousiderably higher thau is recognised by experience as the most suitable in the fattening food of the animals. More nitrogenous substance was available for fat-formation than was necessary to supply the estimated amount of produced fat. In the cases in which the nitrogenous substance was not so excessive, but still more than is the most appropriate, there was a considerable proportion of the total produced fat which could not possibly have been derived from the nitrogenous substance of the food. Lastly, when the proportion of the nitrogenous to the non-nitrogenous substance in the food was the most appropriate for fattening, there was a much larger proportion (about 40 per cent.) of the total produced fat which could not possibly have had its source in the nitrogenous substance consumed. Striking as are these results, it is obvious that a still larger proportion of the produced fat would appear to be formed from the carbo-hydrates, if it were assumed, with Henneberg and Voit, and as is doubtless nearer the truth, that 100 parts of albumen will not yield more than 51·4 parts of fat, instead of about 61 parts.

As the outcome of all these experiments, the authors say:—

"It is, then, perfectly clear that neither the amount of food consumed in relation to a given live-weight within a given time (which of course covered the requirements for increase as well as sustenance), nor the amouut taken to yield a given amount of increase in live-weight (which in its turn covered the requirements for sustenance also), was at all in proportion to the amount of the nitrogenous constituents it supplied. It is quite obvious that the consumption, both for sustenance and for increase, was much more nearly in proportion to the amount of digestible non-nitrogenous constituents supplied; but it was more nearly still guided by the amount of the total digestible organic substance—nitrogenous and non-nitrogenous together—which the foods contained.

"That the great variation in the amount of nitrogenous substance consumed was not due to a deficiency of it in most of the foods employed, is shown by the fact that it was in the experiment in which the food contained the lowest proportion of it that the smallest amount of nitrogenous matter was not only consumed in relation to a given live-weight within a given time, but was required to produce a given amount of increase. It is obvious that where two or three times as much nitrogenous substance was consumed it was much in excess of the normal requirement. In fact, the animals consumed, almost regardless of the amount of nitrogenous substance supplied, until they had obtained a sufficiency of non-nitrogenous, or of total organic substance. It is further obvious

that the range of variation in the amounts of non-nitrogenous constituents consumed would have been very much less but for the very variable amount of nitrogenous substance necessarily taken with it, the variable amounts of fat in the foods, and the greater amount of indigestible matter in some of them than in others. The indication is, indeed, that the excess of nitrogenous substance consumed substituted a certain amount of non-nitrogenous constituents; that, in fact, within certain limits the two classes of constituents may, for the purposes of respiration and fat-formation, mutually replace each other.

"Lastly on this point, not only did neither the amount of food consumed, nor the amount of increase in live-weight yielded, bear any relation to the amount of nitrogenous substance supplied, but the more excessive the supply of it the greater was the tendency to grow, and the less the tendency to fatten. There is, of course, a point below which the proportion of nitrogenous substance in the food should not be reduced, but if this be much exceeded, the proportion of the increase, and especially of tho fat increase, to the nitrogenous substance consumed, rapidly decreases; and it may be stated generally, that, taking our current fattening food-stuffs as they are, it is their supply of digestible non-nitrogenous, rather than of nitrogenous constituents, which guides the amount, both of the food consumed, and of the increase produced, by the fattening animal."

Finally, they conclude that, as far as pigs are concerned, more fat was produced by various feeding than could possibly be derived from the albumen of their food, and that both experiment and experience in feeding point to the fact that carbo-hydrates must be of essential service in the production of animal fat.

Of course these results are not new—they are only advanced by the authors as confirmatory; but it is none the less useful to recall them to the minds of our readers. They have here in a concrete and practical form the knowledge acquired in very different ways. We are sure we need not point out its practical application.

THE DISPUTE IN THE UNIVERSITY OF LONDON.

When we wrote last week upon this subject, Convocation of the University of London was on the eve of one of the most eventful days in its history. That day has passed, and will be remembered with satisfaction by the independent members of the University, and by every lover of constitutional freedom. During the agitation (which, we trust, has now been brought to a close) we have had frequent occasion to express our opinion upon the points at issue. While the question of the admission of women to degrees in medicine occupied the attention of the University, we urged that the women should be treated with all fairness, and that no obstruction should be placed, or even left, in their way towards the attainment of perfect equality with men. But, as we pointed out last week, the question at issue in the University of London lately has become, not one of sex, but a question of the rights and privileges of Convocation; and in this the graduates have had our cordial sympathy and support; and now, in addition to these, we have, we rejoice to say, to offer them our congratulations. On Friday, the 27th ult., by a majority of 114 to 71, Convocation passed a resolution expressing its regret at its recent treatment by the Senate; and, by a majority of 88 votes to 52, a second resolution, empowering the Annual Committee to confer with the Senate on the subject, and to request them to take no further action on the admission of women to degrees in medicine. We recommend to our readers the perusal of the report (which will be found elsewhere in our pages) of the proceedings of the meeting, furnishing as it does the leading arguments by which the result was secured. The speeches of Dr. Tilbury Fox and Dr. Curnow, while powerfully vindicating the rights of Convocation, and protesting earnestly against the conduct of the Senate, were delivered in a calm and friendly spirit, which gave the best possible tone to the whole proceedings.

Dr. Fox stated the charges against the Senate with remarkable clearness, force, and eloquence. Admitting that the Senate had a legal right to compel the University to accept the provisions of an Act of Parliament, he showed how the spirit of the Charter and the privileges of Convocation had on this occasion been violated. Russell Gurney's Act was a purely permissive Act; Convocation had specially requested the Senate not to proceed under it for the present; and only three years before, the Senate had apologised to Convocation for similar treatment of its privileges, and had promised amendment. For each of these reasons, and inasmuch as they were aware that by their action they were doing for the Faculty of Medicine what they could not do in the other faculties without a new Charter,—or, in other words, inasmuch as they were superseding the powers of Convocation by means of a *quasi*-new Charter,—the Senate might have paused instead of proceeding. Morally and equitably they were wrong. Having proved this point, Dr. Fox proceeded to read two letters from Mr. Farrer Herschell, whose opinion was received with the greatest attention, and produced a very marked effect upon the meeting. Mr. Herschell's opinion was distinctly adverse to the Senate, and that for reasons identical with those just stated. But Mr. Herschell drew special attention to another point with respect to Russell Gurney's Act, which we mentioned last week, and which proved to be of such serious importance that alone it would probably have determined the vote of Convocation, and cannot fail to arrest the further action of the Senate in this matter. We refer to the proviso contained in the Act against the admission of future women-graduates to Convocation. By this clause women-graduates are not to be entitled to take part in the government of the University by reason of "registration" (!)—a provision which is in the first place absurd, and secondly perfectly invalid, inasmuch as it does not enact that the same privilege shall not be conferred on women by their "degree." Far as the Senate may strain their powers, they surely would not attempt to force upon Convocation a new set of members of the opposite sex! The meeting was manifestly greatly relieved by the statement of Mr. Herschell's opinion: its anxiety gave place to amusement when Dr. Fox read the confession of the law officers that there was "a slip in the words" of the proviso; and amusement found vent in something like ironical applause when Mr. Russell Gurney's opinion of his own Act was heard. The two last points in Dr. Fox's speech were very happily introduced together. On the one hand, he reminded Convocation of the number and status of its members, and of their ever-increasing interest and importance in the University. On the other hand, he drew a picture of the Senate attempting to work a constitutional change because a single woman had requested them to exercise the powers of a permissive Act of Parliament. Truly the affair in this light is "too monstrous to be discussed for a moment."

In their speeches in defence of the Senate, Mr. Hensman, Mr. Shaen, Mr. Fitch, and Mr. Osler dwelt upon the perfect legality of the step that had been taken; on the "responsibility" that rested upon the Senate to adopt an Act that was believed to be for the best interests of the University; and on the recent resolution of the Senate to obtain a Charter which should enable them to admit women to degrees in all faculties. Mr. Shaen charged the minority in the Senate, who were opposed to the adoption of the Act, with having been silent on the rights of Convocation during the early part of the discussion in the Upper House. To this charge Dr. Quain replied. As one of the members referred to, he said tha

they had not failed to inquire into the subject fully, but not until the Senate had deliberately disregarded the wish of Convocation: and that the medical graduates had naturally expected their legal friends to take care that the constitutional rights of Convocation were respected. Dr. Quain repudiated the idea of the present resolution being a vote of censure; it was an expression of regret. He urged that the Senate should cease to act on the permissive legislation, which cast no responsibility upon them, and should raise the question of the admission of women to degrees in all the faculties by asking Convocation to assist in obtaining a supplementary Charter giving them power to do so.

The second amendment, which was defeated like the first, was hardly stronger than the resolution sent up from Convocation in May, which the Senate treated so cavalierly. The second resolution was the natural practical application of the first. The first expressed an opinion, the second determined action. The Annual Committee of Convocation will confer with the Senate, and request them to take no further action under Russell Gurney's Act. And it seems to us that there is no other course left open for the Senate to pursue. The serious and altogether unexpected position in which they have found themselves, in resolving to adopt an Act of which neither they nor its promoter himself knew the significance until now, furnishes a sufficient reason why they should withdraw with perfect consistency and dignity from the course that they have hitherto pursued. But, while this is so, the Senate of the University of London cannot afford to forget their recent experience. They have learned that the Convocation of a great University is able to know its affairs, to express its opinion upon them, and successfully to assert its rights in spite of every opposition. The Senate of the University of London contains at least four members of the last Liberal Government, and yet it defied the spirit of independence, which is flourishing with so much promise amongst the graduates of every university in the land. We congratulate Convocation of the University of London on the success that has attended its efforts. The medical members who have devoted so much time and trouble to this struggle have been well rewarded by the brilliant victory that they have gained, and the thanks of the profession will surely be gratefully accorded to them.

THE THERAPEUTIC ACTION OF SALICIN.

In a lecture lately delivered before the Berlin Medical Society, Professor H. Senator summed up his experience of the use of salicin in more than seventy cases of different kinds, in which the aggregate number of individual observations amounted to at least 500. The following abstract of the lecture, which is published in full in the *Berliner Klin. Wochenschrift*, No. 14, 1877, contains the most important conclusions at which he arrived. The quantity of salicin necessary to produce a definite effect on an adult ranges, on the average, between eight and ten grammes, but even larger doses may be taken without any injurious result. The drug is best given in powder enclosed in wafers (*Oblaten*), each containing from 1 to 1·5 gramme. Solutions, each tablespoonful of which contains from 0·8 to 1 gramme, are also convenient, but require a large admixture of sugar to cover their strong bitter taste. Senator's observations deal with (1) the antipyretic, (2) the antiseptic, (3) the specific, and (4) the sedative action of salicin. Its antipyretic action was tested in typhoid fever and phthisis pulmonum, the temperatures being taken in the morning between 7.30 and 8.30, and in the afternoon between 4.30 and 5.30, the thermometer being usually placed in the axilla. Comparisons were made from time to time between the effects of salicin and those of salicylate of soda and salicylate of quinine. The latter drug, which Dr. Senator has constantly used for nearly a year and a half, almost always exerts a decided action on the temperature when given in doses of 1 to 1·5 grammes at a suitable time. Nine cases of typhoid were treated with salicin, in all seventeen times, and with one exception with decided reduction of the temperature. The greatest fall observed was 2° Cent.; in other cases all that was noticed was, that when the salicin was given in the forenoon, the expected evening elevation of temperature either did not occur, or was relatively very slight. The largest reductions of temperature appeared to follow the administration of the drug in the evening. The reduction was not always proportionate to the dose, perhaps owing to individual peculiarities, and to the varying severity of the cases. The action of salicin was often prolonged for twenty-four to thirty-six hours, whereas that of quinine is ordinarily over in ten, or at latest twenty hours, and that of salicylic acid still earlier. Salicin never reduces the temperature so powerfully as quinine or salicylic acid. Its use is never followed by copious perspiration.

In phthisis the action of salicin (administered once or more in fifteen cases) is much more variable than in typhoid fever, and is sometimes scarcely at all appreciable. The greatest reduction observed was 3° Cent., in a patient who previously had only had morning remissions of 1·5° to 1·8°. The chief advantage which salicin possesses over quinine and salicylate of soda in phthisis is the absence of the unpleasant after-effects, such as nausea, vomiting, and a feeling of persistent weakness, which not unfrequently follow the use of the latter remedies, and cause phthisical patients to object to their further trial. Salicin can also be given for a long time without affecting the digestive powers; nor does it, either in typhoid fever or phthisis, intensify diarrhœa if present, or increase the night perspirations in phthisis, as do salicylic acid and salicylate of soda. In pleurisy, parametritis, and other febrile diseases, the antipyretic action of salicin is similar to that in typhoid fever and phthisis. In some cases the first effect of its administration is to *raise* the temperature.

The antiseptic action of salicin internally administered was tested in one recent and two chronic cases of cystitis, but the ammoniacal condition of the urine was unaffected by its use. Senator's own experience is in favour of the treatment of vesical catarrh by the balsams, and especially by *balsam of Peru*, which seems to be better tolerated than copaiba and turpentine, and which can be readily taken dissolved in ether, spirit, or wine. With regard to the *specific* action of salicin in acute rheumatism, Senator entirely agrees with Maclagan and the other English writers who have published their experience of its value. In one point only he differs from Maclagan, for he denies that it entirely prevents cardiac complications. He gives details of a very interesting case in which endocarditis developed while the patient was under observation, and after he had taken large doses of salicin and salicylate of soda. Senator recommends medical men not to give large doses of salicin in rheumatic fever, but rather to let the patient take 0·5 to 1·5 gramme at intervals of one to three hours. In several cases of chronic rheumatic joint-inflammations following rheumatic fever, as well as in two cases of rheumatoid arthritis, and in two cases of true gout, salicin rendered decided service, not only in reducing the pain (sedative action), but also in reducing the swelling of the parts. In fifteen recent cases of intermittent fever treated with salicin, eight were cured, or exactly the same proportion as have been benefited by salicylic acid. In two cases of diabetes—a slight and a severe case—seven to twelve grammes of salicin per diem were absolutely without effect.

In concluding his lecture, Prof. Senator stated that at present there was very little chance of salicin being widely used, at any rate in Berlin, owing to the exhaustion of the supply by the great run that had been lately made upon it. The

price of salicin in Berlin is as high as, or higher than, that of quinine.

THE WEEK.

TOPICS OF THE DAY.

Last week a very scantily attended meeting took place at St. James's Hall, to celebrate the anniversary of the Society for the Total Abolition and Utter Suppression of Vivisection. The chairman, the Rev. Charles Grove, having expressed his entire approval of the object of the Society, called upon the Honorary Secretary and Treasurer, Mr. G. R. Jesse, to read the report. The latter gentleman proceeded to deliver a lengthy address on the history and aim of the present organisation. It was established, he said, to make clear to the world the uselessness for any scientific purpose, and the unphilosophical nature, of the practice of vivisection. As a rather singular proof of the "success" of the movement, it was stated that the Society had already enrolled 600 subscribers—not a very large number when the energetic efforts of the agitators is taken into consideration. Mr. Jesse proceeded to offer an opinion that the Government Vivisection Act was a virtual, if not an intentional, surrender to the advocates of vivisection, and that, in point of fact, it for the first time legalised this inhuman practice. He denounced in very strong terms the report of the Royal Commission on the subject, and criticised very severely the statement relative to vivisection said to have been made by Mr. W. E. Forster, M.P., at the meeting of the Medical College connected with the London Hospital, held on the 18th ult. Judged by the small amount of interest which this meeting seemed to excite, the anti-vivisection outcry would almost appear to be dying out; and in such case no one would grudge any official or supporter of this Society the empty pleasure of an indulgence in denunciatory language, "severe" criticism, or self-laudation.

The annual anniversary dinner in connexion with St. Bartholomew's Hospital took place on the 25th ult., in the Great Hall of the institution, Sir Sydney Waterlow, M.P., the Treasurer, presiding. A large number of the governors attended upon the occasion, and speeches were made by Mr. Walter, M.P., Sir James Paget, and Sir Sydney Waterlow, the latter of whom gave a short retrospect of the work done by the Hospital during the past year, concluding with an appeal on behalf of a Convalescent Home for Women, the Hospital already possessing a Convalescent Home for Men.

The proprietors of the Widcombe-bridge, at Bath, by the fall of which ten persons were killed and fifty injured, appear to have taken a sensible view of their liabilities. In order to save the important item of law costs, they have invited those who contemplate seeking compensation to submit their claims to a committee, to be mutually appointed by the proprietors and the sufferers, whose decision is to be final, all actions in the meantime to be stayed.

A meeting was held last week at the Society of Arts, for the purpose of organising a body of volunteer sick-bearers; Colonel Loyd-Lindsay presiding. The proposal was to obtain a number of gentlemen, medical officers of volunteer corps, who were ready to undergo the course of field surgery as practised in the Army Hospital Corps at Aldershot, and thus qualify themselves to instruct a certain proportion of men in each regiment in the important duty of attending to sick and wounded in the field. The chairman observed that the object under consideration was desirable, and as his Royal Highness the Commander-in-Chief was favourable to the scheme, and the funds could not be expected from the Government, it was for them to see that these were not wanting. It was important that at the least they should have a school in London, and then they could apply to the Government for a capitation grant. In reply to a question as to how much time it would take the instructor to teach the members of the corps, the chairman said that it would be like musketry instruction. Dr. Platt remarked that, speaking of his own corps, the commanding officer threw cold water on the scheme; in his own case he had been refused the use even of a "medical field companion," which would cost only about seven guineas. The following resolution was then proposed by Major Duncan, R.A., and adopted:—"That in the event of the Volunteer Sick-Bearers' Association finding an average nightly attendance of twelve medical officers, non-commissioned officers, or privates, the Secretary of State for War be requested to detail a competent medical officer and sergeant to be quartered in London for the purpose of superintending the drills. In return for this indulgence, the Association would be glad to place any means at their disposal, or to arrange their hours of attendance, so as to admit of the regular troops sharing in the drill. No expense save the pay of the instructors to be caused to the Government, while it is hoped that the efficiency of so many drilled men will more than compensate for the expenditure. A sub-committee was then appointed to carry out the objects of the meeting.

At the meeting of the Barnet Rural Sanitary Authority held last week, a letter was read from Dr. Saunders, Medical Officer of Health, who said he had investigated the case of three deaths which occurred in one house at Kenwood's Farm, Finchley. One child was attacked with erysipelas, another with inflammation of the umbilical cord (a newly-born infant), and a third with diphtheria. The house in which these cases occurred was a farmhouse, occupied by a labourer employed on a farm rented from Lord Mansfield. There was nothing in the sanitary condition of the dwelling to account for the disease, but the water-supply, which was pumped from a well in Lord Mansfield's park, was polluted. This well also supplied Lord Mansfield's dairy and house adjoining it, and he had obtained some evidence from the occupiers that they had suffered from diarrhœa at different times, and notably at the time the labourer's children were suffering. The Board ordered a copy of the report to be sent to Lord Mansfield.

A correspondent of the *Times* recently pointed out that the patients in Charing-cross Hospital suffered greatly from the noise made by the market-carts proceeding in early morning to Covent-garden Market, and suggested that, as the Strand and King William-street had recently been paved with wood, some exertion should be made to obtain the paving of the other streets round it with the same material. The Treasurers of the Hospital now report that they have arranged with the Board of Works of the Strand District to have a noiseless pavement laid down at a cost of about £500; but the condition is that the Hospital authorities shall find the half of such amount. In the interests of the patients this latter condition has been agreed to, but the Governors frankly admit that the sum cannot be provided out of the funds set aside for the maintenance of the Hospital during the current year, and they rely for special aid on the charitable support of the public. Mr. Charles Soames has already offered to give £100 towards the required sum, provided the remaining £150 be raised by September 1.

The Archbishop of Canterbury, it will be remembered, officiated at the ceremony of laying the first stone of the Hospital for Sick Children in Great Ormond-street, in 1872; and recently, accompanied by Mrs. Tait, he paid a long visit of inspection to the institution. Nearly all the 100 beds were occupied; and his Grace remarked upon the contrast between the present admirable arrangements and the former inconvenient adaptation of an old mansion to the purposes of a hospital. It was explained to the Archbishop that twenty-

five years ago a children's hospital was a novelty in London, and its twenty beds sufficed to meet all demands; but the 104 beds now available are always occupied, and a new wing to receive sixteen additional children is to be opened in a few weeks.

An extraordinary case of poisoning at sea has just been made public. It is alleged that while the ship *Crown Prince*, of New Brunswick, was on a voyage in November last from the Peruvian coast to Falmouth, a new cask of pork was taken out, and the crew, numbering twenty-one, partook of it. On the following day they all became ill, with vomiting and other symptoms of poisoning. The captain, against whom there appears to be no complaint, steered for Port Stanley, the principal harbour in the Falkland Islands, but on reaching there one man died in horrible agony, another the day after, and a third two days later. The crew were sent into hospital at Port Stanley, and eventually three more succumbed, the doctor stating that they had all been poisoned by putrid pork. Three of the survivors have recently reached this country, and when they left Port Stanley four of the crew were still in hospital there. The *Crown Prince* arrived in the Clyde a few days ago with a fresh crew, and, after communication with the marine authorities, the captain has been committed pending further inquiry.

Last Saturday the meeting to consider the best means of bringing into general and practical use in the metropolis the Provident Dispensary system now adopted in many large towns, was held at the rooms of the Medical Society, Chandos-street, Cavendish-square, under the presidency of Mr. Timothy Holmes. There were also present Sir Charles Trevelyan, Dr. Ford Anderson, Mr. Jabez Hogg, Dr. J. Rogers, Dr. Nankivell, etc. The chairman said the meeting had assembled to confer upon three points especially, these being—1. What steps should be taken to increase the number of provident dispensaries in London? 2. What should be the relations of the provident dispensaries to the hospitals? 3. Is it possible to secure a correspondence between the different provident dispensaries in London, so that a member of a provident dispensary, when he removes to another district, can, without delay and without entrance fee, immediately obtain medical relief in the provident dispensary nearest his new residence? As the result of this conference, a resolution was agreed to that a committee should be appointed to report upon the best means of giving effect to the views expressed, and that this committee should be composed of representatives of free hospitals and dispensaries, and other cognate institutions in the metropolis, of representatives of the metropolitan provident dispensaries, and of the members of the Medical Committee of the Charity Organisation Society. Mr. T. Holmes was solicited to become the Chairman of the Committee to be thus composed.

THE TREATMENT OF NON-PAUPER PATIENTS IN EPIDEMICS.

In his annual report on the sanitary condition of Birkenhead and Cloughton-cum-Grange for the year 1876, Mr. Francis Vacher, the Medical Officer of Health, makes some very pertinent and able remarks on the truth that the officers of the Sanitary Authority are still without the sense of security and confidence which would follow consciousness of powers to *fulfil all* their obligations. The Fever Hospital, he observes, is of great service in providing the means of isolating a few specially circumstanced infected subjects, whose friends can afford to pay small maintenance charges; but this is the utmost it can, or was ever intended to, accomplish. In the presence of an epidemic the proportion of destitute and indigent who suffer is always much in excess of all others; yet these are the very cases which the Sanitary Authority's officers have no power to deal with. The removal of such patients, even when their consent and the consent of their friends has been obtained, depends wholly upon another authority; and whether this authority takes action, or not, depends upon the answer that may be given to the question, Is the sufferer a fit subject for relief? If the answer is in the negative, nothing is done. The Sanitary Authority has no accommodation for those who cannot pay for their maintenance, and the parish authorities only provide for those they regard as fit subjects for relief. It not unfrequently happens that those affected with infectious disease cannot pay a charge of fourteen shillings a week, and are yet not so destitute as to bring them within the operation of the Poor-law; and such cases may be the initial cases of an epidemic. Success in checking infectious epidemic disease, Mr. Vacher goes on to remark, is only to be achieved by prompt isolation of early cases in an outbreak; and powers and means to effect this must be placed in the hands of *one* authority, or the work will be but partially and imperfectly done. "At such times it is useless to ask if the patient is a fit subject for relief, the solution of which involves delay. A person suffering from infectious disease belongs to the local community, and it is for the relief of the community, quite as much as for the relief of the sick person, that his removal is desirable." There is no doubt that Mr. Vacher's view of the case is a perfectly correct one, and in times of epidemic the first object should be to isolate the patient as quickly as possible, without waiting to inquire into his ability to pay a few shillings a week.

THE HOSPITAL SUNDAY FUND COLLECTION.

The remarks which we recently published on the result of the Sunday Hospital Fund collection have proved substantially correct; the total amount received at the beginning of the present week is only about £26,000. Some amounts have not yet been received, but these will scarcely have any material effect upon the total sum subscribed. Some of the amounts received show a decrease, others an increase, as compared with last year; thus, the receipts at Quebec Chapel were £321, as compared with £356 last year; Union Chapel, Islington, £78, as compared with £96 at the previous collection; St. Andrew's, Wells-street, £133, as compared with £175; All Souls, Langham-place, £62, against £91; St. James's, Piccadilly, £151, against £183; Paddington Parish Church, £175, against £242; the Oratory, Brompton, £30, against £48; St. Jude's, South Kensington, £132, against £236; St. Paul's, Onslow-square, £177, against £101; Kensington Parish Church, £312, against £241; St. Margaret's, Westminster, £145, against £50; St. George's, Hanover-square, £151, against £98. The largest collection of the year was that previously recorded by us, at St. Peter's, Eaton-square,—viz., £425, against £420 last year; and the next to this was the amount collected at St. Stephen's, Westbourne-park, which realised £420. It must, moreover, be borne in mind that the anniversary day this year was unexceptionable as to weather, whereas in 1876 it was rainy and generally unfavourable.

CLAPTON ASYLUM FOR IMBECILE CHILDREN.

The second annual report of this Asylum bears out the hopes and anticipations of those who were instrumental in carrying out a separation of the children idiots from the adults, with whom in the past they used to be mixed up. Indeed, the report of Dr. Fletcher Beach, to whose untiring exertions so much of the success is due, shows the almost unexpected results of the industrial training which the children are subjected to under his immediate superintendence. We find that one boy in the shoemakers' shop rivets sixteen pairs of boots per week, and five boys in the tailors' shop are able to use the sewing-machine. When we consider that these boys, under the old system, would never have been trained at all, and, worse still, would have been doomed to pass their time with adults hopelessly imbecile, we can form some idea of the good

which the managers of this Asylum, under the able leadership of Sir Edmund Currie, are carrying out. We congratulate all the officers of the institution on the success of their efforts, we wish them all the prosperity which their cause so thoroughly deserves, and we trust that they will long continue to be presided over by so able and so enthusiastic a chairman.

HOSPITAL FEES IN DUBLIN.

At a very numerously attended adjourned meeting of the physicians and surgeons of the clinical hospitals of Dublin, held at the College of Physicians on the afternoon of Monday, July 30, Dr. Gordon, President of the College, in the chair, the following resolutions were unanimously agreed to:—"1. That the first portion of the report of the secretaries (viz., the increase of the hospital fees, as follows:—Winter six months, eight guineas; summer three months, five guineas; nine months, twelve guineas) be adopted." "2. That the practice of taking perpetual pupils at the Dublin hospitals be abolished." It was also agreed that the scale of fees as arranged be signed by the physicians and surgeons of the several hospitals, and that the document so signed be placed in the charge of the Registrar of the College of Physicians, copies being forwarded to the hospitals. The question of raising the hospital fees in Dublin has thus been definitely settled. It is satisfactory to find that in the end complete unanimity prevailed, the Adelaide Hospital having withdrawn its opposition to the proposed arrangements.

MEDICAL RESEARCH.

The Scientific Grants Committee of the British Medical Association has recommended to the Committee of Council that the following new grants be made towards the expenses in aid of researches in medicine and allied sciences for the year 1877-78—viz., to Mr. W. H. Gaskell, Cambridge, a grant of £30 in aid of a research upon the nature of the reflex action of the vascular system and muscles, and reflex vaso-motor action generally; Mr. Longley, M.B., St. John's College, Cambridge, £25, for research upon the changes produced in the salivary glands by nerve influence; Professor Rutherford, F.R.S., £50, on the action of cholagogues; Dr. Braidwood (Birkenhead), £40, for engravings to illustrate the third report upon the life-history of contagium; Dr. Pye, £8 15s., for continued research upon the investigation of the relation that the retinal circulation bears to that of the brain; Mr. Bruce Clarke, for continued research upon syncope and shock, £10. The Scientific Grants Committee will meet again to consider further applications for grants in aid of research, at Manchester, on Thursday, the 9th inst., before which date communications should be addressed to the General Secretary of the Association, at the office of the Association, 36, Great Queen-street, London, W.C.

ROYAL COLLEGE OF PHYSICIANS, LONDON.

At a meeting of the Royal College of Physicians, held on the 26th of last month, the thanks of the College were specially voted to Dr. Arthur Farre for his munificent and valuable present of the whole of his medical library and some physiological preparations: also for the gift of his own portrait. The library thus presented to the College by Dr. Farre consists of more than 1300 volumes, more than half of which were not previously in the Library of the College, and some of them are works of much rarity. The books have been placed in one of the glazed cases in the south gallery of the Library. The drawings, diagrams, preparations, and pamphlets of the late Dr. Sibson were also presented to the College by his widow, and a special vote of thanks was passed for her valuable gift. A communication was received from the General Medical Council, approving the proposed formation of a Conjoint Examining Board for England, and was referred to the Council of the College. The list of College officers—Censor, Treasurer, Registrar, Librarian, Examiners, and Curators of the Museum—nominated by the President and Council, was elected, and some other formal business was transacted.

PREVALENCE OF SYPHILIS AMONG MERCHANT SEAMEN.

Mr. Frederick Lowndes intends to bring forward, at the approaching meeting of the British Medical Association, the subject of the prevalence and severity of syphilitic disease among merchant seamen; and in the hope of enlisting the aid of the Association to induce Government to institute preventive measures, he will at the annual meeting propose the following resolution:—"That the British Medical Association nominate a deputation to Mr. Secretary Cross, to request that a Government inquiry be made into the state of our large mercantile seaports (especially Liverpool, Bristol, Hull, and Cardiff) with reference to the subjects of prostitution and venereal diseases; and also to suggest means for diminishing the prevalence of prostitution and venereal diseases."

HEALTH OF H.R.H. PRINCE ALBERT VICTOR.

The course of the fever in H.R.H. Prince Albert Victor's case has up to the present time been satisfactory. An abatement of the temperature took place on the twenty-second day, and has continued. The fever process may be expected to end by Saturday next.

The disease has been said to have been contracted at Sandringham, and to have been caused by contamination of the water-supply there; but if that is true, it is not a little remarkable that the Prince should, so far as is known, be the only sufferer.

THE VACANCY AT THE LONDON HOSPITAL.

We find that there will be three candidates for the post now vacant of Assistant-Physician to this Hospital—Dr. Gilbart Smith, Dr. Warner, and Dr. Thomas Barlow. The last-named gentleman has, we believe, the support of the medical staff of the Hospital, and will be recommended as the most eligible candidate to the Managing Committee, with whom the election virtually rests.

MEDICAL PARLIAMENTARY AFFAIRS.

Lunatic Asylums.—As it is proposed to reduce the number of county prisons by the Act just passed, the Earl of Sandwich proposed that disused prisons should be converted into lunatic asylums. The Duke of Richmond admitted that disused prisons might be put to any profitable use by the county authorities when they became the property of the county, but the Government were not prepared to take steps to effect the conversion of prisons into lunatic asylums. Earl Cowper hoped the Government would take over the central and general management of lunatic asylums, to insure regularity of treatment all over the country, and to relieve the local authorities, as they had now been relieved of the management of prisons.

Adulteration.—The Sale of Food and Drugs Act Amendment Bill has passed the third reading in the House of Commons.

The French Association for the Advancement of Science.—This learned body will hold its annual session at Havre from August 23 to 30, with Prof. Broca as President.

The Nubians in Paris.—The Société d'Anthropologie has had a true "god-send" by the arrival at Paris, in charge of some animals sent to the Jardin d'Acclimatation, of a number of Nubian Amrans. They are of a bronze colour, and of tall and slender form, with their hair arranged in a tuft at the top of the head. The Society has formed a committee, consisting of MM. Broca, Girard, Dally, Bordier, and Mazard, to examine into their peculiarities. They have arrived in a very favourable condition for such examination, having their arms and trophies with them, their lances, long swords, instruments of music, etc.—*Union Méd.*, July 26.

UNIVERSITY OF LONDON.

MEETING OF CONVOCATION.

An extraordinary meeting of Convocation of the University of London was held on July 27. It was summoned for the purpose of considering the constitutional privileges of Convocation in connexion with the recent action of the Senate in adopting Russell Gurney's Act for the admission of women to degrees in medicine, contrary to the express desire of Convocation. The meeting was very large; and throughout the whole of the proceedings, which occupied four hours, the greatest calmness, earnestness, and good feeling were displayed by the members. Dr. F. J. Wood was called to the chair, in the unfortunate absence of Dr. Storrar through indisposition. The preliminary formalities having been completed, the Registrar read a second opinion of the law officers of the Crown upon the subject before the meeting, which was as follows:—"We do not find in Clause 21 of the Charter any power given to Convocation to interfere in any way with the powers given to the Senate of conferring degrees in medicine, and we therefore think that it will be competent to the Senate to grant degrees to women without the concurrence of Convocation.—JOHN HOLKER; HARDINGE GIFFARD.—6, Crown-office-row, Temple, July 16."

The first resolution was proposed by Dr. Tilbury Fox in the following terms:—"That this House regrets that the Senate has, by adopting a *permissive* Act of Parliament (Act 39 and 40 Vict., cap. 41), without reference to, or consultation with, Convocation, materially altered the constitution of the University, and has thus practically superseded the privileges of Convocation." He said that while no one would attempt to question the purely legal right of the Senate to admit women to medical degrees under the Act of last session without the consent of Convocation, the action of the Senate assumed a very unfair character when the nature of the Russell Gurney Act and the circumstances under which it had been adopted were considered; and when it could be shown that by its adoption violence was done to the spirit of the Charter and the privileges of Convocation. It had been said that the Act was in reality compulsory; but it was strictly permissive, applying to some twenty licensing bodies, not one of whom apart from the University, except one Irish body, had taken any notice of it. To make the matter worse, the Senate put the Act in force after Convocation had deliberately asked it to defer action in the matter. On a former occasion, when the Senate promoted a private Act of Parliament to enable the University to join in the Conjoint Scheme (thereby effecting a decided change in the University), it had been requested by Convocation not to ignore the privileges of the latter in any similar action thereafter. But again the Senate had effected a fundamental change; and the mere chance (the passing of the Act of last year) had given the Senate the opportunity and power to do in the Medical Faculty what it desired to do, but could not, in the other faculties, without the consent of Convocation. Was it fair that one particular faculty should be dealt with in this exceptional way? It was therefore evident that although the Senate had been legally right, it had done that which was equitably and morally wrong. Surely the fact of an Act of Parliament being permissive implied that it was to be used with some limitation, and not as a compulsory Act—in other words, fairly. The equitable view of the matter had been well put to the Master of the Rolls for his opinion by the Registrar of the University, as follows:—"While giving to the Senate the uncontrolled power (subject only to the veto of the Home Secretary) of treating the affairs of the University within the limits prescribed by its Charter, that Charter explicitly provides that no new Charter shall take effect, nor any old one be surrendered, without the *joint assent* of the Senate and Convocation. And it is contended that this is morally tantamount to providing that no fundamental change in the constitution of the University, such as it would (unless made by Act of Parliament) require a new Charter to effect, should be made without such joint assent. This provision would, of course, be overridden by any positive enactment of Parliament. But, it is urged, a merely permissive Act ought not to be applied by the Senate without the concurrence of Convocation in any way which fundamentally changes the constitution of the University; the spirit, if not the letter of the Charter, requiring that in such a matter the University should *act as a whole*." The opinion of the Master of the Rolls, in reply, was based upon the fact that the powers of the Senate had been enlarged by the Permissive Act. But such a *legal* opinion was unnecessary. Dr. Fox had put the case to a very distinguished graduate of the University, Mr. Farrer Herschell, Q.C.; and Mr. Herschell had replied as follows:—" . . . I should certainly support the view that the Senate ought not to have adopted the Act of last session without communication with Convocation. There can, of course, be no question that they had a *legal* right to do so. As the executive body, it lay with them to exercise the power given by the Act or not. But there is no doubt that the intention in depriving the Senate of the power of accepting a new charter without the consent of Convocation was to prevent any fundamental change in the nature of the University or in its operation being made without the concurrence of the latter body. And no one can deny that a change of considerable importance has been made by the adoption of the Act of last session. Because its effect, coupled with the Medical Act of 1858, is, I suppose, to give the University power to grant degrees of M.B., M.D., or M.S. to women. . . . It may, indeed, be said that although degrees may, by the adoption of the Act of last session, be granted to women, yet the proviso to Section 1 of that Act would prevent the women obtaining such degrees from taking any part in the government of the University, and would therefore exclude them from Convocation. Even assuming this to be the case, I think the change is none the less fundamental. It is wholly beyond the powers of the existing Charter; but for the Act could only have been done by virtue of a new Charter; and I think the Act, being permissive only, should only have been adopted by the same authority which would accept a new Charter—viz., the Senate and Convocation combined. But I would call your attention to the very singular wording of the proviso. I cannot doubt that its intention was what I have stated above. But it is so worded as certainly to leave open the contention that women receiving degrees would become members of Convocation. The proviso says that 'No person who but for this Act would not have been entitled to be registered, shall, *by reason of such registration*, be entitled to take part in the government of the Universities mentioned in the Medical Act' (including the University of London). Now, the membership of Convocation results from the degree, not from registration under the Medical Act, which has nothing to do with it. It may be said, therefore, that it is nowhere provided that the 'qualification'—that is, the 'degree'—which the University is empowered to give to women, shall not have all its natural consequences, and, *inter alia*, the right to a part in the government of the University, it being provided only that such persons shall not, by reason of *registration* (which the section itself distinguishes from the qualification), have any such right. I think it very likely that this wording is a piece of blundering; but if there is anything in the point I have suggested, the constitution of Convocation itself may be fundamentally affected." Mr. Herschell wrote a second letter on July 23, in which he said:—"On considering further the legal point to which I alluded, I am more and more convinced that there is a great deal in it. It is, to say the least, *very doubtful* whether the Courts would not hold that the female graduates become members of Convocation. It is possible that they might hold otherwise, to carry out the apparent intention of the clause; but it is, to say the least, *very possible* that they might hold themselves unable to do so. It would depend a good deal on the constitution of the Court before whom the question came. If this be so, surely in such uncertainty on this point the Act ought not to be adopted. . . . Don't be led away by the statement, if it be made, that the law officers have advised the contrary. It is worth little unless you see the exact terms of the opinion." The law officers of the Crown (continued Dr. Fox) had, in giving their opinion on the proviso, concluded with a most important paragraph, which appeared to have been suppressed in the discussions on the subject. Speaking of the proviso, they said, that it was obvious "that there was a slip in the words." "It ought," they thought, "to be construed as if the words *qualification for such registration* had been used instead of the words

such registration." The Attorney and Solicitor-General therefore "hedged" with the concluding paragraph. But Dr. Fox said he would now show that there had been no "slip in the words of the proviso." Mr. Russell Gurney, to whom he wrote on the subject, replied that "lawyers differed as to the clause. The proviso had been given to him as the condition on which the Bill would be allowed to pass, and he consented to it; and," he added, "he wished it had been worded differently." If there was no slip in the proviso, Mr. Herschell was wholly right. The House would therefore feel convinced that by the adoption of the Russell Gurney Act the constitution of Convocation would be fundamentally changed. Dr. Fox concluded by saying that he had surely proved that the Senate was straining its power to an unconstitutional degree, and that, if Convocation permitted it, it virtually deprived itself of all its privileges but one, and that was the occasional nomination of a senator. He trusted the House would consider the time chosen for the institution of this new *régime* of Cæsarism by the Senate—the time when the constituency of the University, by virtue of its increasing numbers and the status of its members, ought to have its privileges increased, and not curtailed or annihilated. He would point out, in the last place, that upon a request made to the Senate by a mere outsider to alter the constitution of the University for his or her benefit, the Senate had felt itself justified in ignoring the rights and privileges of the whole constituency of the University for the sake of one of the public. The thing was too monstrous to be discussed for a moment. Dr. Fox hoped that that House would be true to itself, and that it would show by its vote that it was tenacious of its just rights and worthy of their exercise; otherwise the result could only be disastrous for the University.

Professor Curnow seconded the motion, pointing out that the Senate had superseded the powers of Convocation in adopting an Act of Parliament instead of obtaining a supplementary charter.

Mr. A. P. Hensman moved as an amendment—"That the Senate, by adopting the Act which permits it to grant degrees in medicine to women, has promoted the best interests of the University." He said the medical graduates had abandoned the question of legal right, and taken high moral ground. But the Charter did not, even in spirit, support the view that a constitutional change could not be made without the consent of Convocation. Acts of Parliament overrode a charter, and the Senate were bound to adopt an Act if they considered that it would further the interests of the University.

Dr. T. de Courcy Atkins seconded the amendment.

Sir William Jenner and Mr. T. Lister Godlee spoke strongly in favour of the resolution.

Mr. Shaen said that Russell Gurney's Act having thrown a great responsibility on the Senate, the Senate (which for the application of the Act were the "University") were bound to adopt it.

Several other members, including Mr. Goldsmid, M.P., Mr. W. Fowler, Mr. Fitch, Dr. Quain, Mr. Osler, and Mr. H. Payne, having expressed their opinion, the House divided, when it was found that 143 had voted for the resolution and 82 for the amendment, which was accordingly lost.

Mr. E. H. Busk then moved, and Mr. W. Fowler seconded, the following amendment:—"That this House having learned that doubts have been expressed whether degrees granted to women by virtue of the power conferred on the University by the Act of 39 and 40 Vict., chap. 41, will not constitute the holders thereof members of Convocation, and having learned that the Senate is about to apply for a new Charter, empowering them to grant to women degrees in all faculties, by which the rights of women holding degrees will be fully determined, requests the Senate to refrain from availing itself of the powers conferred by the Act until after an opportunity shall have been afforded to consider the terms of the proposed Charter."

The House again divided, after a short debate, when 77 voted for the amendment and 113 for the original motion. Finally the original resolution was substantively carried by 114 to 71. Loud cheers greeted the announcement of the division.

Professor Curnow then moved, Mr. Rickman J. Godlee seconded, and it was carried by 88 votes to 52—"That it be referred to the Annual Committee to confer with the Senate in reference to the foregoing resolution, and to ask them not to take any further action under the Act of 39 and 40 Vict., chap. 41."

The proceedings terminated with a vote of thanks to the chairman.

THE SULPHUROUS WATERS OF ALLEVARD-LES-BAINS.

We are indebted for the following interesting account of Allevard-les-Bains, its waters, and "the treatment" adopted there, to a lay friend, who has been greatly benefited by his stay there. Some of our readers may be able to turn a knowledge of the place to good account in their practice:—

Hôtel du Parc, Allevard-les-Bains, Isère, France,
July 18, 1877.

Without wishing in any way to favour one place on the Continent at the expense of another, or to disparage the natural beauties of the Pyrénées and the curative virtues of the waters of Cauterets, Eaux Bonnes, etc., I am yet constrained to ask why so few English people come to this place. It must, surely, be because it is unknown to them: for in every respect it is a worthy rival of those other baths. There are very many invalids who, having passed the winter at some one of the many health-resorts on the Riviera, would derive immense advantage from a short sojourn here before returning to England. Driven by the heat from Cannes or Mentone towards the middle or end of April, they could not do better than spend the month of May on the lakes—Baveno on Lago Maggiore, if Church privileges be an additional attraction—and come on to Allevard for June. The season begins about May 20; before that they would scarcely find hotels or the different parts of "the treatment" in working order.

Allevard is a small town of about 3000 souls, situated at the eastern extremity of the department of the Isère, in a lovely valley of the Alps of Dauphiné, at an elevation of about 1500 feet above the sea, and is surrounded by natural beauties of all sorts—glaciers, mountains, waterfalls, gorges, woods, etc. It has the great advantage for delicate people of being on the road home, if the Mont Cenis route be selected, as it is only about two hours and a half distant from Chambéry, on the line of railway between that place and Grenoble It is well supplied with hotels, while the cost of living is extremely moderate. Here, *e.g.*, the *pension*, that is, *déjeûner à la fourchette* at 10.30, dinner at 5.30, bedroom (candles and attendance), varies from eight francs to eleven francs a day, according to the position of the bedroom. An additional franc is charged if one has coffee in the early morning; and in case the hours should be inconvenient, or from any other cause visitors prefer to have their meals separately, a franc a day is added to the *pension*.

The generality of cases under treatment here are diseases connected with what the French call "Les voies respiratoires." Consumption, bronchitis, and clergyman's throat are especially benefited by these waters. Taking an ordinary case of this latter, the course would probably be similar to that prescribed for us by Dr. Chataing, the able Assistant Medical Inspector—viz., Four times a day gargle with a tumblerful of water (lukewarm). Every other day, unless it rained, a bath 95° Fahr. for half an hour. Three sittings of ten minutes each, separated by an interval of five or six minutes, morning and evening, in the "salle d'inhalation." The length of these sittings is gradually increased as the system is able to bear them. "To drink half a glass of the water one hour before lunch, and again one hour before dinner. The quantity to be taken is increased or diminished as the stomach is disturbed or not by it. Between 3 and 4 p.m. a 'douche pharyngienne' for twenty minutes or half an hour." A word or two may be added on these "douches" and the "salle d'inhalation." In order to thoroughly restore health to the pharynx, the manager and medical men have arranged that the water may be brought to bear especially on that organ. The patient is seated with a waterproof apron round his neck, in front of a sort of fountain, with a tap by which he can regulate the force of the jet and stop it from time to time. The water when turned on is directed on to the part affected. In cases where it is needed, this "douche" is converted into a spray-producer. The "salles d'inhalation" are rooms with a fountain in the middle, so constructed that by falling from basin to basin the gases contained in the water are detached and fill the room. It is believed that the air of the room is so saturated with the sulphurous properties of the water that a piece of silver would, if exposed, become black in less than ten minutes; and it is certain that any silver carried in the pocket quickly becomes tarnished.

A model of this apparatus is to be exhibited in Paris next year.

To those who carry out the treatment with any degree of strictness, it will not be easy to find time for many excursions. Of these, however, there are plenty in the neighbourhood, and of exceeding beauty. Not to speak of the Château and Park of Allevard, there is a very pretty walk of about twenty minutes to "La Tour du Treuil," a square building about eighty feet in height, with a kind of platform at the top, from which there is a very lovely view. Of course, it is said to be haunted, and has all sorts of romantic stories attached to it. Its name, however, would seem to point to something much more matter of fact, for a local word, "trouiller," means "to make wine"; and "trouil," or "treuil," a cottage in a vineyard in which the press, etc., is kept. Another short and beautiful walk is to the waterfall above the Foundry, called "La Cascade du bout du Monde." Then there is the walk of one hour and a half or two hours to the top of the "Brâme Farine." From this elevation is a magnificent view of the rich plain of Chambéry, and a great part of the valley of the "Graisivandan." To the left, all the country watered by the Isère, as far as Grenoble; facing, Les Bauges; and in the distance, the capital of Savoy, the town of Aix-les-Bains, and the Lake "du Bourget"—altogether a most lovely panorama. More extended excursions (available, however, solely for those who are not undergoing, or who have finished, the treatment) may just be mentioned. They are "Les Grottes de la Jeannotte," Valley of Saint Hugo, with the "Devil's Bridge" over the torrent of Beus, formed by the neighbouring glaciers, and which on this side was the frontier between France and Savoy. The bridge made for the use of La Chartreuse is of a single arch, at the height of 300 feet, thrown across the precipice, and is the only access to the ruins of La Chartreuse. To Ponthaut is a walk of about two hours. To mention but one more, there is the excursion to the Mountain of the Seven Lakes; but this requires seven hours, at least, to get there.

Allevard can, I believe, boast of no greater antiquity, as the known possessor of an invaluable spring, than the present century; and at first was visited solely by the people of the immediate vicinity. But within the last thirty or forty years the curative properties of the waters have been thoroughly investigated, and year by year sufferers arrive from all parts of the Continent to find, if not a cure, a certain alleviation of disease and prolongation of life. For my own part, I most strongly advise any who are suffering from asthma, bronchitis, incipient or threatening consumption, or clergyman's throat, to select Allevard as the place for their summer holiday. Let them remain there under treatment for about three weeks or a month,(a) and on their return to England they will acknowledge that they owe a lasting debt of gratitude to the writer of these lines for bringing the place to their notice.

Several books or pamphlets have been written on the local and medical history of Allevard and its waters. The very interesting work of Dr. Dupasquier is unfortunately out of print. But there are still to be had on the spot "Eau Sulfureuse d'Allevard," by Dr. Laure; "L'Inhalation d'Allevard," by Dr. Baron; "Eau Sulfureuse et Iodée d'Allevard," by Dr. B. Niepce, one of the medical inspectors. From these may be gathered everything that is necessary both as to the chemical analysis of the water, and the course to be followed by those who place themselves under treatment. Any additional information which may be desired will, I am sure, be gladly given by Monsieur Marius Porte, the courteous and obliging Director of the Etablissement des Bains, Allevard, Isère.

The best route from Paris (if the journey be done without a break) is to take the 8.40 p.m. train to Macon and Chambéry, which is due at this latter at 10.8 the next morning. At 12.25 a train starts for Goncelin, whence the omnibus of the Hôtel will take travellers up to Allevard. But to persons for whom this would be too fatiguing a journey I should recommend a train which leaves Paris at 11 a.m., and reaches Lyon Perrache about 10 p.m. There they may stay the night, and by taking the train departing at 11.55 next morning they will arrive at Goncelin by 8 p.m. I should add that no English is spoken at Allevard—only French.

P. M. S.

Professor Lister.—The Cothenius Medal of the Leopold-Carolinian Academy has been awarded to Prof. Lister on the recommendation of Profs. Rokitansky, Virchow, and Leyden.

(a) The season closes at the end of September.

FROM ABROAD.

Opening an Abscess of the Brain.

A case that has occurred under the care of Dr. Proust at the Lariboisière has recently made a considerable stir in Paris, and although the "success" at first reported has turned out to be no success at all, we may give the chief particulars. As a consequence of an attack of typhoid fever, a man aged fifty-five (*Gaz. des Hôp.*, July 21 and 28) was attacked with inflammation of the posterior and superior part of the left parietal bone, which was followed by a fistula giving issue to a small quantity of pus. His health was otherwise satisfactory, and he was remaining in the hospital as a convalescent, when on July 10, while quietly talking, he suddenly fell down insensible. The loss of consciousness did not long continue, but he was found to have become hemiplegic on the right side, while he could only stammer out some words with great difficulty. On the 12th he fell into the comatose state again, and Dr. Proust now began to connect this condition with the lesion of the parietal bone. The symptoms might, indeed, be explained by a cerebral hæmorrhage or an embolus; but, on the other hand, the seat of the lesion opposite the motor regions of the cerebral surface, to which so much attention has of late been called, seemed to point to a not less probable explanation. The necrosis of the parietal bone was of considerable extent, and corresponded over a pretty large surface to the motor zone of the encephalon. Might not a spiculum of bone be compressing the nervous substance at this point? So, also, a collection of pus may have formed under the bone which produced the compression. In fact, the irregularity of the symptoms as regards their intensity, and the rapid and temporary amelioration which ensued, little favoured the supposition of the existence of an effusion of blood. Under these circumstances, Dr. Proust sought the opinion of Dr. Tillaux as to how far surgical intervention was desirable. In M. Tillaux's opinion, the symptoms observed were most probably due to the compression produced by a fragment of necrosed bone, while the hypothesis of the existence of an abscess beneath the dura mater, or formed at a distance in the cerebral substance (such as is often observed as a consequence of lesions of the cranium, and especially in caries of the petrous bone), might be very reasonably entertained. He therefore made a crucial incision into the scalp, and removed the sequestra, the dura mater beneath being found thickened and covered with fungosities. It was now determined to wait awhile before incising the dura mater, to see the effect of the removal of the pressure caused by the spicula. On the 13th the patient seemed a little better, his speech being somewhat more easy; but next day the signs of cerebral compression returned more markedly than before. Some variation was observed in the condition of the patient during the following days, but upon the whole he continued to get worse, and surgical intervention seemed called for. Accordingly, on the 17th, M. Tillaux laid bare the cranium around the loss of its substance which already existed, and having removed the necrosed portions of bone, found himself in close vicinity to the mesial line. By careful manipulation with a small chisel and mallet, the bone being very thin, he laid bare the dura mater over a space about four or five centimetres in length and three or four in breadth. All the part of the dura mater corresponding to the necrosed bone was covered with fungosities, but beyond this it appeared healthy. A crucial incision was made into it, and beneath its fungous part the brain was obviously softened. After some hesitation, seeing the man's desperate state, it was resolved to penetrate the brain itself in search of a deep-seated abscess. A puncture extending at least to two centimetres and a half was made, and some thick, creamy, "laudable" pus escaped by the side of the bistoury. This came out much more abundantly when a grooved director was passed in to the distance of four centimetres, so that at least three spoonfuls were discharged. The patient did not seem to suffer during the operation, and on interrogating him some tolerably just replies were elicited, but the paralysis persisted; his speech continued embarrassed, and his intellect was evidently obtuse. On the 18th the man seemed better, and

there seemed less "intellectual oppression." A considerable quantity of pus was discharged. On the 19th fever was set up, and the condition seemed very unfavourable. No pus was discharged, softened, tumefied, and diffluent cerebral substance seeming to have filled up what was the cavity of the abscess. The man died shortly after, and at the autopsy there were found three other abscesses within the substance of the brain, two of which were much nearer the region which has been termed the motor zone—*i.e.*, the region in the vicinity of the fissure of Rolando. Moreover, the cerebral substance itself had undergone great alterations in the centrum ovale, behind this fissure.

Dr. Revillout, in giving an account of the case, considers that the operation, in the desperate state of the man, was quite justifiable. When, on the discharge of the pus, the hemiplegia still persisted, other abscesses or lesions were to be expected, which would probably be found, as they were found, nearer to the fissure of Rolando than the abscess which was opened; for otherwise, a greater effect would have been produced in the hemiplegia by the issue of so large a quantity of pus. "The case was the more valuable as it has given a double confirmation of the conclusions drawn from the experiments on animals regarding the motor zone. It is a confirmation in the living subject, for an abscess was suspected, and has been found where it was sought for; and a confirmation at the autopsy, as the negative results which followed the operation, as regards the symptomatology, led to the very probable supposition that alterations could be found closer to the vicinity of the fissure of Rolando, where, in fact, there existed two abscesses and softening of the white substance of the centrum ovale."

Suicides in France in 1876.

By a return published in the *Révue Méd.*, July 9, it appears that the suicides in 1876 were 5467, of which 4435 occurred in men and 1032 in women. As is always the case, the Department of the Seine furnished by far the largest number, viz., 915; while no other department, even the most populous, hardly attained 100. Of the 5467 deaths, 2472 took place by hanging; 1514 by drowning; 895 (14 in women) by fire-arms; 407 (216 being women) by charcoal fumes; 154 by precipitation; and 109 by poison, which was usually laudanum; 31 persons killed themselves by lying on railway lines, 1 man jumped into a furnace, and another inflicted castration on himself. Among the suicides 1946 were celibates, 151 widowed without children, and 801 married with children. The ages were as follows:—Under 16, 29; from 16 to 21, 195; from 21 to 30, 648; from 30 to 40, 829; from 40 to 50, 1053; from 50 to 60, 1161; from 60 to 70, 993; from 70 to 80, 528; and above 80, 98. As to occupation, 1828 are returned as peasants, 1038 as workmen, 228 as servants, 987 as of liberal professions, and 241 as engaged in commerce. Among the most frequent causes, there are returned 1433 from drunkenness, 320 fear of destitution, 633 domestic sorrows, and 798 (277 being women) supposed to be suffering from incurable disease.

Inutility of Blistering in Acute Diseases.

Dr. Alix, Principal Medical Officer to the Lyons Military Hospital, in a paper read at one of the medical societies (*Lyon Méd.*, No. 19), explains that his object is not to suggest any new remedy, but the elimination of an old one. During the last four years he has discarded the employment of blisters in acute affections; and for that period the results have been as follows:—In 819 cases of simple *bronchitis*, unaccompanied by any tubercular complication, but 100 of the number being examples of capillary bronchitis, he has only had one death. When the case is quite simple, he confines himself to dietetic regulation, rest, some agreeable drink, and sometimes a little opium. When he has to do with capillary bronchitis with mucous râles spreading all over the lung, he gives ipecacuanha, and soon passes on to alcohol and other tonics, favouring expectoration by every possible means, and abstaining from any use of opiates. Of 146 cases of *pneumonia*, only three proved fatal; in none were any tubercular complications present. When the disease is simple, limited, and regular in its course, and under suitable diet, rest, and emollient drinks, the patient gets well in a few days. When the temperature rises to 41° C. or more, and the course of the disease is irregular, he gives digitalis two or three days in succession. When there is anxiety and sharp pain, so as to be an obstacle to respiration, he employs some subcutaneous injections of morphia, after which the pain is relieved and the course of the disease becomes regular. When, however, the constitution is bad, and the slow evolution of the disease leads to the fear of hepatisation, he does not hesitate to employ alcohol, tonics in general, quinine, coffee, together with a substantial diet; the object being to stimulate the economy, rendering the local circulation active by developing the general circulation. Among 155 cases of *pleurisy* without tubercular complication, he had four deaths. He gives digitalis at first whenever the temperature is somewhat high, whatever may be the amount of effusion, while absolute rest and a moderate diet are insisted on. The digitalis is continued in lesser doses for a longer time than in pneumonia, in consequence of the diuretic action attributed to it. When the temperature, which is never very high in pleurisy, has fallen, repose still being insisted on, he orders opium, and, if the pains are sharp, hypodermic injections, to secure sleep. When the effusion is only slight, the effects of the opium and warm bed are assisted by the application of large diachylon or pitch plasters to the thorax. It must never be forgotten, in treating pleurisy, that even in the most simple cases it is a disease of long duration; and it is forgetting this fact that has led to the hasty application of blisters and other painful means. Sometimes Dover's powder or diuretics may be prescribed; and in cases in which there is only a medium amount of effusion, absorption will take place just as quickly as under the use of revulsives. When the effusion, on the contrary, increases and becomes dangerous, paracentesis should be performed, the patient being placed in the recumbent posture, and the liquid only being slowly and partly withdrawn, when absorption will remove the rest. The operation should not be performed during the process of the formation of the fluid, as by disturbing this it may induce suppuration. It is, in fact, but rarely required. *Articular rheumatism* occurring in the young subjects with which Dr. Alix had to do, always terminates favourably, as it did in the 244 cases which he reports. He always envelopes the joint or joints in a thick layer of wadding, after smearing them with an opium or belladonna liniment. If the pains are very intense, he either gives opiates or employs hypodermic injection. After a very variable number of days, the patients are cured. Complications of heart affections are very rare in first attacks, but are frequent in succeeding ones.

Dr. Alix is the more satisfied with the results of his present simple mode of practice in the above cases by contrasting them with those which he obtained during his nine years' residence in Algeria, during which time he treated 505 cases of bronchitis, 110 of pneumonia, and 39 of pleurisy. Of the 505 cases of bronchitis, he lost 4 out of 318 patients among the military population, 15 out of 109 of the civil population, and 5 of 78 of the indigenous population, and that although the climate is far more favourable to these cases than is that of Lyons. Of the 110 cases of pneumonia, 32 proved fatal. For these cases blistering was largely employed.

Caution to Experimenters.—Another "martyr to science" has occurred in the person of M. Alfred Deshaies, aged thirty-six, chemical *préparateur* in the Collége du France, who was found lying on the ground in the laboratory at his residence, death having taken place two days before. It is supposed that he was engaged in trying upon himself the effects of some chemical products that he had been examining for a long time past, and specimens of which were lying around him.—*Union Méd.*, July 26.

Movement of the Population in the Chief European States.—The *Gazette Médicale* (No. 38) extracts the following figures from a table recently published by the *Journal Officiel* relating to the period 1872-75:—1. *Births:* These were 26·27 per 1000 inhabitants in France; 34·23 in Great Britain; 36·65 in Italy; 39·71 in Germany; 40 in Austro-Hungary; and 47·20 in Russia. 2. *Mortality:* There were 21·35 deaths per 1000 in Great Britain; 22·46 in France; 27·72 in Germany; 30·40 in Italy; 34 in Russia; and 38·96 in Austro-Hungary. 3. Proportion of *Excess of Births:* By the two tables given above, we find that the excess of births over deaths per 1000 is 13·20 in Russia; 12·88 in Great Britain; 11·90 in Germany; 6·25 in Italy; 3·81 in France; and 1·04 in Austro-Hungary. Thus, although France occupies the second rank with respect to her slight mortality, she is last but one among the great Powers as regards the excess of births over deaths.

REVIEWS.

Transactions of the American Gynecological Society. Vol. I. for the year 1876. Boston, 1877. London: Trübner and Co. Pp. 387.

As an indication of combined harmonious action on the part of our American brethren, we are glad to receive this volume. We in England have long recognised the value of the incentive of appreciation and the corrective of criticism which societies like this afford; and we therefore like to see our example followed in this respect. The most noteworthy articles in the volume are one by Dr. Battey, on extirpation of the functionally active ovaries for the remedy of otherwise incurable diseases; a case of abdominal pregnancy treated by laparotomy, which Dr. Gaillard Thomas contributes; a paper on the spontaneous and artificial destruction and expulsion of fibroid tumours of the uterus, by Dr. Byford; and a case by Dr. Peaslee, in which both ovaries were removed for the relief of epileptic seizures ascribed to ovarian irritation; and last, but not least, a paper on the relations of pregnancy to general pathology, by our eminent specialist, Dr. Barnes, who during the year visited America in the capacity of representative of the Obstetrical Society of London, and as such was invited by the President to address the Society. The volume contains also articles by other English writers, the publication of which we can only regard as a proof of the good nature of our American *confrères* and their love for the old country. We hope our English gynæcologists, seeing thus the extent of the kindness of our Transatlantic friends, will be careful not to impose upon it, but will only send contributions when they have something to say that the profession in America is not acquainted with.

A Practical Treatise on Operative Dentistry. By J. Taft, Professor of Operative Dentistry in the Ohio College of Dental Surgery, U.S.A. Third edition. London: J. and A. Churchil. 1877. Pp. 521.

The book before us is one of much value. It is a thorough and complete treatise on the art of practical dentistry. "Only those affections which pertain to the teeth directly and the contiguous parts will here be considered; and the latter only so far, in the main, as surgical treatment is concerned. Nor will the pathology of contiguous parts be introduced, for the treatment of these, being therapeutic rather than surgical, would involve a discussion of questions not within the scope of the present volume. Indeed, it is proposed merely to speak of those affections of the teeth which generally suggest surgical remedies." This quotation will give a fairly good idea of the scope of the work. Nevertheless, the author does now and then enter into pathological details. In the first chapter, for instance, he discusses, among other things, the origin of deposits, the causes of exostosis and of necrosis; and in the second chapter, on caries of the teeth, the whole subject is treated,—the predisposing causes, the exciting causes, comparative liability to caries, and its consequences, are each in turn discussed. This deviation from the line laid down, however, adds much useful matter to the book; the knowledge of cause greatly facilitating the sound treatment of disease. The chapter on filling is very practical, and deserves special attention. Those who have any personal experience well know the frequency with which the dentist is called on to fill and stop teeth, and therefore the subject is one of great importance. Here the student will find an exhaustive *résumé* of what is known. The relative value of every kind of stopping is well discussed. Nor is the subject of instruments for filling less well handled; and this chapter is copiously illustrated with well-drawn woodcuts. The mechanical genius of the author's nationality is here clearly manifest.

The chapter on extraction of teeth is also good. The author in his last chapter considers the subject of anæsthetics. He says—"During the administration of ether or chloroform the pulse usually becomes more frequent; but it should not be accelerated, nor its strength and fulness be much diminished. Enfeebled or irregular pulse should in all cases be regarded as a warning, and if the feebleness and irregularity be very marked, the operator should desist. . . . The degree to which anæsthesia should be carried is a matter on which there is much diversity of opinion. Every condition of it, from that of simple allayed irritability to that of complete insensibility and unconsciousness, has its advocates. . . . The fingers of the person administering the chloroform should be kept on the carotid, since the state of the circulation will be better recognised by this than by the radial artery, and it is a more convenient point for observation. In favourable cases it is preferable to continue the inhalation till there is free muscular relaxation."

The book strikes us as a decidedly good one, and we have much pleasure in drawing the attention of English readers to it.

Examination Papers for the use of Medical Students. Compiled by W. J. H. Lush, M.R.C.P., M.R.C.S. London: J. and A. Churchill. 1877. Pp. 112.

This neat little compilation will be found exceedingly useful by students at all stages of their curriculum. As the author points out in his preface, "the habit of *writing* down answers to a set of questions on any subject not only tends to fix the information thoroughly in the mind, but also helps the student to accustom himself to be precise and accurate in his answers." In this we fully agree. It is within our knowledge that many a valuable scholarship and prize have been lost for want of the power of condensing and accurately expressing the answer to an examination question. Few men are born writers, and this exercise in answering questions is just as necessary to aspirant prize-takers, if they would succeed, as public speaking is to a man who would become a great orator.

We cordially recommend both the subject and the book to the attention of medical students.

NEW INVENTIONS AND IMPROVEMENTS.

BIRRESBORN MINERAL WATER.

There has undoubtedly been of late a yearly increasing demand for natural mineral waters, and, as an inevitable consequence, an equal, if not still greater, growth in the supply. The demand is probably in part a consequence of the lessened consumption of wines in the undiluted form, and of other alcoholic drinks, but it is in larger part, probably, the outcome of the increased appreciation of the greater value and pleasantness of natural over artificial aërated waters. Whatever the causes may be, however, there can be no doubt that there are being constantly offered to the British public new mineral waters, both medicinal and dietetic. To the latter class belongs the Birresborn Natural Mineral Water, of which Messrs. Robinson and Macnicoll, 81, Gracechurch-street, are the sole importers. It flows, we are informed, from the Birresborn Spring, of old local fame, in the Eifel Mountains in Rhenish Prussia. The published analysis of it by Professor Fresenius, of Wiesbaden, which is corroborated by Heisch and other analysts in England, shows that it is rich in bicarbonate of soda, besides containing lithia and other alkalies, and a minute proportion of iron. It is clear and bright, and is charged with a sufficient quantity of free carbonic acid gas to make it very sparkling; and though more decidedly alkaline than many other well-known mineral waters, it is very agreeable and palatable. From our experience of it we can confidently recommend it as a pleasant and wholesome beverage, either alone or mingled with a light wine; and we doubt not that it will be found very useful and valuable as an agreeable alkaline and slightly chalybeate table-water.

Fetid Feet.—In an article in the *Révue de Thérapeutique* it is stated that an immediate remedy for this noisome affection is found in washing the feet with a solution (1 in 100) of chloral, and keeping them enveloped in compresses wetted with the same solution. Results as satisfactory have long since been obtained by Dr. Bourdon by the employment of a solution (commencing with 3 in 1000) of the permanganate of potash. Dr. Berthold also indicates an efficacious method which is less troublesome than that of bathing with solutions. It consists in powdering the interior of the patient's socks with a powder composed of one part of salicylic acid and five of starch. This is, too, an excellent mode of treating the local sweating which in fat persons often takes place between the scrotum and the thighs, and if not arrested leads to a troublesome eczema, and its accompanying pruritus.—*Gazette Méd.*, No. 38.

MEDICAL NEWS.

UNIVERSITY OF LONDON.—The following are lists of candidates who have passed the recent examinations :—

PRELIMINARY SCIENTIFIC (M.B.) EXAMINATION.

First Division.—Edwin Leonard Adeney, Guy's Hospital; Charles Alfred Ballance, St. Thomas's Hospital; Alexander Barron, Owens College; John Williams Batterham, Westminster Hospital; Harry Poole Berry, Guy's Hospital; Isaac Blore, The Leys, Cambridge; Charles Edward Cassal, University College; Joseph Clegg, Owens College; Henry Francis Corbould, Charing-cross Hospital; Edgar March Crookshank, University College; Robert Ernest Gillhurst Cuffe, St. Mary's Hospital; Oswald James Currie, Guy's Hospital; William Radford Dakin, Owens College; Donald Douglas Day, St. Bartholomew's Hospital; George Parsons Naylor Dixon, St. Bartholomew's Hospital; Lewis Humfrey Edmunds, University College; Arthur Grayling, St. George's Hospital and Epsom College; Philip Rhys Griffiths, University College; Charles Gross, Guy's Hospital; Henry Louis Preston Hardy, London Hospital and private study; Charles Skinner Harper, Guy's Hospital; Thomas Harris, Owens College; George William Hill, King's College and private study; Frederick Matthew Holman, University College; Henry Hoole, Charing-cross Hospital; William Heaton Horrocks, Owens College; William Henry Horrocks, Owens College; John Hughes-Jones, St. Bartholomew's Hospital; Jonathan Hutchinson, London Hospital; Leonard Frank I'Anson, Epsom College; Arthur John Jefferson, St. Thomas's Hospital; Robert Jones, St. Bartholomew's Hospital; Frederick Herbert Lane, Epsom College; William Lane, Guy's Hospital; Arthur Hamilton Nicholson Lewers, University College; William Thomas Maddison, King's College; Hyde Marriott, Owens College; Sidney Harris Cox Martin, University College; Herbert Percy Miller, University College; Paul Frank Moline, University College; Desmond Ernest John Mortimer, Westminster Hospital; Michael O'Kane, Guy's Hospital; Richard Prothero, Liverpool Medical School and St. Bartholomew's Hospital; Lionel Philip Purton, University College; Bernard Rice, St. Bartholomew's Hospital; Edward Rice, St. Bartholomew's Hospital; Richard Pritchard Roberts, University College; John Thomas Rogerson, Owens College; David John Rygate, London Hospital; William Sellers, University of Edinburgh; Harold Bailey Shaw, Epsom College; John Smith, Guy's Hospital; Lockhart Edward Walker Stephens, Epsom College; Frederick Wallis Stoddart, University College, Bristol; St. Clair Thomson, private tuition and study; Francis Harper Treherne, St. Bartholomew's Hospital; Joseph James Udale, Guy's Hospital; Malcolm Webb, Owens College; George Henry Whitelegge, University College; John Whiting, St. Bartholomew's Hospital.

Second Division.—Alfred James Glanville Barker, University College; Pramatha Nath Bose, University College; William Job Collins, St. Bartholomew's Hospital; John Roberson Day, University College; Edmund Jesse Dobell, University College; Joseph Dobson, private study; Charles Downing, University College; John Fletcher, Owens College; John Alfred Gray, St. Bartholomew's Hospital; Francis Hickman, University of Edinburgh; Sydney John Hickson, University College; William Havelock Hill, University College; James Atkinson Hosker, private study: Eugene Arthur Laurent, University College; Joseph Herbert Lister, Guy's Hospital; James Samuel McDonagh, University College; Alfred Derwent Maitland, University College; Frederic Maude, St. Bartholomew's Hospital; Richard Basil Morley, Leeds School of Medicine; Henry Wilkinson Newsholme, University College; Thomas Pemberton Pemberton, Queen's College, Birmingham; Samuel Rabbeth, King's College; John Richmond, Guy's Hospital; Arthur Guy Salmon, St. Bartholomew's Hospital; Charles Sanders, St. Bartholomew's Hospital; Isaac Scarth, Owens College; John Alexander Shaw, University College and private study; Lauriston Elgie Shaw, University College; Arthur Thomas Wills, Owens College.

FIRST B.SC. EXAMINATION.

First Division.—Alfred Hodgetts Atkins, private study; Herbert Irving Bell, private study; Charles Frederick Cross, King's and Owens Colleges; Samuel Dixon, Owens College and private study; Henry Edmonds, private study; Lewis Humfrey Edmunds, University College; Walter Fowler, Caius College, Cambridge; Ernest Compton Gill, private study; Wintour Frederick Gwinnell, Royal School of Mines; Edward Harlock, Owens College; Hugh Erat Harrison, University College; William Havelock Hill, University College; William Heaton Horrocks, Owens College; Moses John Jackson, University College; Alfred John King, Owens College; Frederick Herbert Lane, Epsom College; Joseph Larmor, St. John's College, Cambridge; Hyde Marriott, Owens College; Sidney Harris Cox Martin, University College; Samuel Sheppard Oakley Morris, private study; Thomas Jeffery Parker, Royal School of Mines; Herbert Pearce, University College; George Henry Spencer Pearson, private study; Richard Charles Rowe, M.A., Trinity College, Cambridge; Frederick Wallis Stoddart, University College, Bristol; Duncan Taylor, private study; William Henry Thomas, Royal College of Chemistry; Daniel Walker, Owens College and private study; Malcolm Webb, Owens College.

Second Division.—Isaac Blore, The Leys, Cambridge; Pramatha Nath Bose, University College; Edwin Drew, private study; Sydney John Hickson, University College; Henry Robert Hind, private study; Isaac Patchett, private study; Arthur Lee Sparkes, B.A., private tuition; Peter Thom, University of Aberdeen.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The following gentleman was admitted a Fellow on July 26 :—

Jelly, William, Madrid.

The following gentlemen were admitted Members on the same day :—

Thomas, William Robert, M.D. Queen's Univ. Ire., Sheffield.
Savage, Thomas, M.D. St. And., Birmingham.
Longstaff, George Blundell, M.B. Oxford, Wandsworth, S.W.
Wybrants, Jonathan, M.D. Aber., Shepton Mallet.
Houghton, Walter Benoni, M.D. Lond., 114, Tottenham-court-road, W.
West, Samuel Hatch, M.B. Oxford, 6, Colville-terrace West, W.
Phillips, Charles Douglas Ferguson, M.D. Aber., 107, Lancaster-gate, W.
O'Neill, William, M.D. Aber., Lincoln.
Sullivan, John, 28, Keppel-street, W.C

The following gentlemen were admitted Licentiates on the same day :—

Aplin, Alfred, 8, Harrington-street, N.W.
Arnott, Sandford, 24, New Ormond-street, W.C.
Bennett, Arthur, London Hospital, E.
Beresford, William Hugh, 4, Gloucester-crescent, W.
Biale, John Seton, St. George's Hospital, S.W.
Brett, John, 49, Ladbroke-grove-road, W.
Brock, Alexander Cameron, Dorking.
Collet, Golding Bird, 155, Marylebone-road, N.W.
Evans, William Morgan, Guy's Hospital, S.E.
Frankish, William John, University Hospital, W.C.
Friend, Herbert Edward, St. George's Hospital, S.W.
Galloway, Arthur Wilton, 54, Fitzroy-road, N.W.
Gaisford, Martin, King's College Hospital, W.C.
Gomes, Dominic Anthony, 18, Tavistock-street, W.C.
Ground, Edward, King's College Hospital, W.C.
Hemsted, Arthur, Wellingborough.
Heinemann, William, 36, Hilldrop-crescent, N.W.
Langdon, John Sydney, University Hospital, W.C.
Lacey, Charles William, Guy's Hospital, S.E.
Mackay, James Jerome, King's College Hospital, W.C.
Mackern, John, 4, Park-place, Blackheath, S.E.
Pickford, John Kemble, Maiden Newton.
Reporter, Maneckjee Eduljee, 1, Gower-place, W.C.
Stewart, Howard Douglas, King's College Hospital, W.C.
Vasey, James Adams, 5, Cavendish-place, W.
Wiglesworth, Joseph, Liverpool.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College at a meeting of the Court of Examiners on the 26th ult., viz. :—

Cripps, Charles Couper, Bristol, student of University College.
Davies, Louis Walter, Carmarthen, of Liverpool and Guy's Hospitals.
Golland, Alfred, Oxford, of Royal Infirmary 4, Manchester.
Hadden, Walter Baugh, Liverpool, of St. Thomas's Hospital and Liverpool Royal Infirmary.
Hammond, Thomas, Whitehaven, of Guy's Hospital.
Jaynes, Victor Alexander, L.S.A., Gloucester.
Neale, John Edward, St. John's-wood, of University College.
Norman, Reginald, Manton, Rutland, of St. George's Hospital.
Stock, Gregory, of the Bristol Infirmary.
Vachell, Edward Shearman, Bath, of the London Hospital.
Woods, Arthur Appleton, M.D., Q.U.I., of Belfast.

Three candidates who passed in Surgery at previous meetings of the Court, having subsequently obtained medical qualifications, were admitted Members of the College, viz. :—

Mackern, John, L.R.C.P. Lond., Blackheath, student of Guy's Hospital.
Proctor, Samuel Fitzgerald, L.R.C.P. Ed., Trinidad, of St. Thomas's Hospital.
Weekes, Francis Henry, L.S.A., Auckland, New Zealand, of St. Thomas's Hospital.

Six candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College. The other nine candidates were referred to their professional studies for a period of not less than six months.

The following gentlemen were admitted Members of the College on the 27th ult., viz. :—

Arthur, Walter, L.S.A., Oakley-street, S.W., student of Westminster Hospital.
Bathe, Anthony John, Purton, Wilts, of St. Bartholomew's Hospital.
Bennett, Arthur, L.R.C.P. Lond., L.S.A., M.B. Aber., Stawell, Victoria, of the London Hospital.
Bigg, George Kilworth Sherman, L.S.A., Wimpole-street, of Middlesex Hospital.
Budler, Charles Ferdinand, Cape of Good Hope, of University College.
Coffin, Thomas Walker, Earl's Court-road, of King's College.
Collier, Herbert, L.S.A. and L.R.C.P. Edin., Turnham-green, of St. George's Hospital.
Dalton, Charles Gerald, L.S.A., Lincoln, of the London Hospital.
Fulford, John, Melbourne, of Melbourne University and University College.
Gimlette, George Start Desmond, Southsea, of St. Thomas's Hospital.
Gipps, Alexander George Pemberton, Lonsdale-square, of St. Bartholomew's Hospital.
Harle, William John Vincent, L.S.A., Hackney, of Cambridge University and the London Hospital.
Hyde, Samuel, Buxton, of King's College.
Inman, Robert Edward, L.S.A., Hackney-road, of London Hospital.
Norton, Ritchie Robinson, Carmarthen, of University College Hospital.
Maberly, William Henry, M.B. Edin., Leamington, of Edinburgh University and St. Bartholomew's Hospital.
Milles, Walter Jennings, Staplehurst, Kent, of King's College Hospital.
Pain, Alfred, Bridgwater, of Guy's Hospital.
Sutton, Thomas Seagrave, L.S.A., Thame, Oxfordshire, of Middlesex Hospital.
Quicke, William Jenkins, L.S.A., Exeter, of Westminster Hospital.
Wallis, Percy Evershed, Hartfield, of Guy's Hospital.
Yoshida, Kenzo Hidenari, Japan, of University College Hospital.

One candidate who passed in Surgery at a previous meeting of the Court, having subsequently obtained a medical qualification, was admitted a Member of the College, viz. :—

Instone, Samuel Vaughan, L.S.A., Addison-road, Kensington, of Guy's Hospital.

Two candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College. One candidate was referred to his professional studies for a period of not less than six months.

The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College at a meeting of the Court of Examiners on the 30th ult., viz.:—

Atkey, William T., Chichester, of University College Hospital.
Berdoe, Edward, L.S.A., L.R.C.P. Edin., Victoria-park-road, of the London Hospital.
Beverhoudt, William Trend Hamlyn von, Plymouth, of King's College Hospital.
Blackman, Josiah George, L.S.A., Southampton, of Charing-cross Hospital.
Clark, John George, L.S.A., West Hartlepool, of the London Hospital.
Coumbe, John Batten, L.R.C.P. Edin., Plymouth, of St. Mary's Hospital.
Duncan, John Thornton, Tunbridge Wells, of St. Bartholomew's Hospital.
Harding, Arthur, Warminster, Wilts, of King's College Hospital.
Heath, William Lenton, Totnes, of St. Bartholomew's Hospital.
Hodgson, George Goodfellow, Liverpool, of University College and the Royal Infirmary. Liverpool.
Holland, Philip Alexander, M.A. Oxon., Oxford, of the University of Aberdeen and St. Bartholomew's Hospital.
Latour, Bertrand Edgar de, Hammersmith, of King's College Hospital.
Lowdell, Charles John Walton, Wadhurst, of Guy's Hospital.
Verdon, Michael John, Craven-street, of King's College Hospital.
Wagstaff, John Philip, L.S.A., Dalston, of the London Hospital.
Weller, John, L.S.A., Amersham, of the London Hospital.

Three candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College. The other five candidates were referred to their professional studies for a period of not less than six months.

The following gentlemen were admitted Members of the College on the 31st ult., viz.:—

Battle, William Henry, Lincoln, student of St. Thomas's Hospital.
Dale, Henry Ridley, St. George's-square, N.W., of University College.
Fraser, Græme Bisdee, Weston-super-Mare, of St. Mary's Hospital.
Hawkins, Cæsar Frederick, L.S.A., Bristol, of the London Hospital.
Hinton, James Thomas, Croydon, of Guy's Hospital.
Maybury, Lysander, Frimley, of Galway and St. Thomas's Hospital.
Neylan, John, L.S.A., Ennis, of the London Hospital.
Nickoll, John Sayer, L.S.A., Milton-next-Gravesend, of the London Hospital.
Pemberton, Robert, Madras, of Guy's Hospital.
Pinder, John William, Cleethorps, Leeds, of the Middlesex and Charing-cross Hospitals.
Sheppard, Charles Edward, Addison-gardens, Kensington, of St. Thomas's Hospital.
Tritton, William Parsons, L.S.A., Kilburn-park, of King's College.
Wishart, John, M.B., Toronto, of the University of Toronto and St. Thomas's Hospital.

One candidate who had previously qualified in Surgery, having passed in Medicine, was also admitted a Member.

Three candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College. The other eight candidates were referred to their professional studies for a period of not less than six months.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, July 26:—

Brown, Alexander Stewart, Leamington.
Collet, Golding Bird, Western Ophthalmic Hospital.
Devis, Charles James, King's-heath, Birmingham.
Harran, James, 14, Nelson-street, Leicester.
Instone, Samuel Vaughan, Addison-road, Kensington.
Stewart, Howard Douglas, St. James-garden-square-crescent.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Cuthbert, Charles Firmin, St. Bartholomew's Hospital.
Robins, Harvey, St. Mary's Hospital.
Sutton, Leonard W., St. Thomas's Hospital.
Haslam, William F., St. Thomas's Hospital.
Rusher, James B., St. Bartholomew's Hospital.

BIRTHS.

FRANKLIN.—On July 28, at Leicester, the wife of George C. Franklin, F.R.C.S., of a son.

RAYNER.—On July 23, at Teviot Dale, Stockport, the wife of Edward Rayner, M.D., of a daughter.

SEAMAN.—On July 23, at Ramsgate, the wife of W. C. Seaman, M.D., Deputy Inspector-General of Hospitals, of a daughter.

TEALE.—On July 26, at 2, Belvoir-terrace, Scarborough, the wife of John W. Teale, M.A., F.R.C.S., of a daughter.

WILKINSON.—On July 24, at Silver-street, Lincoln, the wife of T. M. Wilkinson, L.R.C.P. Edin., L.R.C.S., L.S.A., of a son.

MARRIAGES.

ANDERSON—DUNLOP.—On July 25, at St. Paul's Church, Edinburgh, John Anderson, Surgeon-Major A.M.D., to Jessie Usher, second daughter of the late James Usher Dunlop.

ANDERSON—UDALL.—On July 26, at St. James's, Birch, Charles Marmaduke, only son of Arthur Anderson, M.D., C.B., Inspector-General of Hospitals, Pitlochrie, N.B., to Marianne Charlotte, daughter of Robert Udall, of Kent House, Victoria-park, Manchester.

BARNES—MARTEN.—On July 31, at St. George's Church, Canterbury, Arthur Richard Barnes, M.B., of West Bromwich, Staffordshire, fifth son of the late Henry Barnes, Esq., of Faversham, to Mary Elizabeth, youngest daughter of Peter Marten, Esq., J.P. and D.L., of Canterbury, and Beach House, Deal.

BOURCHIER—MERRIMAN.—On July 25, at St. Nicholas Church, Blundellsands, near Liverpool, Seton Longuet, only son of Captain Bourchier, R.N., late of Liverpool, to Georgiana Marian, younger daughter of the late James N. Merriman, M.D., of Kensington.

DARNELL—RICHMOND.—On July 26, at St. Mary Magdalene, Bermondsey, John Monk, third son of William Darnell, of Bermondsey, to Helen Sophia Richmond, of Camden-square, N.W., youngest daughter of the late Robert Knewstub Richmond, M.R.C.S.E., of Bermondsey.

FORSTER—BENZON.—On July 24, at St. James's, Paddington, Stuart Forster, Trin. Coll., Camb., eldest and only surviving son of J. Cooper Forster, F.R.C.S., of Upper Grosvenor-street, to Elizabeth Marie Rudolpha, adopted daughter of the late Ernst Benzon, of Kensington Palace-gardens.

HARTLEY—THOMAS.—On July 26, at St. Gabriel's, Warwick-square, Francis Hartley, jun., of Gloucester, second son of Edmund Hartley, L.Q.C.P.I., of Warwick-square, London, to Maude Stanley, elder daughter of the late B. Minshull Thomas, of Twyning-park, Gloucestershire.

LANGDALE—TRIST.—On July 25, at St. Bartholomew's Church, Sydenham, Henry Marmaduke Langdale, M.R.C.S., L.S.A., of Uckfield, third son of the Rev. Edward Langdale, Rector of East Hothly, Sussex, to Rose Ellen, elder daughter of George Trist, of Eliot Lodge, Sydenham.

MCLEOD—AITKEN.—On July 26, at St. John's Church, Edinburgh, Surgeon-Major Kenneth McLeod, M.D., Indian Medical Service, to Jane Christie, eldest daughter of the late John Christie Aitken, Esq., of Christchurch, New Zealand.

SHERROTT—FARNHAM.—On July 28, at St. Joseph's Retreat, Highgate, Augustus John Sherrott, M.R.C.V.S., of Winchester, to Mary Anne Agnes Farnham (widow), only child of Albert Paterson, Esq., of Finchley, Middlesex.

TAIT—HARRIS.—On July 28, at St. Peter's, Regent-square, G. D. Tait, Esq., B.A., to Annie Gertrude, third daughter of Richard Harris, Esq., M.D., of Brunswick-square.

DEATHS.

BELLAMY, GEORGE EDWARD, only son of Edward Bellamy, F.R.C.S., of 59, Margaret-street, Cavendish-square, W., of typhoid fever, on July 27, aged 2½ years.

DALGAIRNS, CHARLES ANDERSON, M.D., M.R.C.S., youngest son of the late William Dalgairns, of The Rosaire, Guernsey, at his residence, St. Mildred's, Westgate-on-Sea, on July 28, aged 52.

NICHOLSON, the Hon. THOS., M.D., for many years member of the Executive Council of that island, at Antigua, W.I., on July 8, in his 78th year.

NOAD, HENRY M., Ph.D., F.R.S., for nearly thirty years Professor of Chemistry at the Medical School of St. George's Hospital, at Lower Norwood, in his 63rd year.

PICKFORD, EMILY JOSEPHINE, younger daughter of the late James H. Pickford, M.D., Justice of the Peace and Deputy-Lieutenant for the county of Sussex, at 1, Cavendish-place, Brighton, on July 28.

REDFERN-VANCOUVERS, T., M.D., Surgeon to H.M.S. *Rocket*, at Esquimalt, on July 1, aged 37.

REEVE, J. FOSTER, M.R.C.S., formerly of Lamb's Conduit-place, at Upper Norwood, on July 24, aged 87.

WILLIAMS, MARY, widow of the late William Rice Williams, M.R.C.S., L.S.A., at 117, Finchley-road, N.W., on July 25.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

NORTH WITCHFORD UNION, CAMBRIDGESHIRE.—Medical Officer. Salary £50. Will be appointed Public Vaccinator. Fees, together with fees for surgical operations and midwifery cases, £10 to £15. Every probability of a good private practice being acquired, there being no medical man resident within eight miles. Applications, with testimonials, on or before August 7, to Thomas Tusting, Clerk to the Guardians, March, Cambridgeshire.

TAMWORTH UNION RURAL SANITARY AUTHORITY.—Medical Officer. Appointment will be made subject to approval of the Local Government Board, and will be from date of appointment until March 25, 1878. Salary after the rate of £120, including travelling and other expenses. Must be legally qualified medical practitioners, registered under the Medical Act of 1858, and must produce diplomas, etc. Applications, with testimonials, in own handwriting, before 10 a.m. on August 11, to John Shaw, Clerk, Tamworth.

TAMWORTH UNION.—Medical Officer. Salary for Workhouse £30, and District £75, which includes all extra fees, except vaccination. Would be appointed Public Vaccinator. Fees 1s. 6d., 2s. 6d., and 3s. 6d. Must be legally qualified. Sealed applications before 10 a.m. on August 11, to John Shaw, Clerk, Tamworth.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Farnham and Hartley Wintney School District.—Mr. Clarke has resigned the School; salary £40 per annum.

Gateshead Union.—The Whickham is vacant; area 5302; population 483; salary £35 per annum.

Grantham Union.—The Ancaster District is vacant; area 17,832; population 2887; salary £39 per annum.

Guiltcross Union.—Mr. E. G. Archer has resigned the Fifth District; area 6578; population 1903; salary £37 10s. per annum.

Wisbech Union.—Mr. A. B. Ewen has resigned the Second B District; area 4837; population 1065; salary £15 per annum.

Woburn Union.—Mr. H. Veasey has resigned the Workhouse; salary £45 per annum.

APPOINTMENTS.

Ashby-de-la-Zouch Union.—Wm. Donovan, L.R.C.P. and L.R.C.S. Edin., to the Fourth District.

Bath Union.—Caleb Barrett, F.R.C.S., L.S.A., to the Eighth District.

Carmarthenshire.—Wm. Morgan, F.C.S., as Analyst for the County.

Crickhowell Union.—Philip E. Hill, M.R.C.S. Eng., L.S.A., to the Workhouse.

Norwich Union.—F. C. Bailey, M.R.C.S. Eng., L.S.A., to the Workhouse.

Westbourne Union.—George H. Elliott, M.R.C.S., L.S.A., to the Third District.

Wigan Union.—Nathan Hannah, L.R.C.P. Edin., L.F.P. and S. Glasg., to the Ashton-in-Makerfield District.

THE library of the Medical Society of London will be closed from August 6 to September 5.

MAGISTERIAL APPOINTMENT.—Dr. George Hare Philipson, M.A., F.R.C.P., of Newcastle-upon-Tyne, has been placed upon the Commission of the Peace for the town and county of Newcastle-upon-Tyne.

ANODYNE ENEMA.—Chloroform one to two grammes (a quarter to half a drachm), powdered gum acacia eight grammes, the yelk of one egg, and water 125 grammes. This is Dr. Aran's *lavement calmant*, intended to be used whenever pain has to be subdued, and especially in hepatic or nephritic colic, cystitis, etc. Camomile tea or decoction of poppy-heads may be used in place of the water.—*Union Méd.*, July 26.

POPULATION OF THE BRITISH EMPIRE.—M. Marcel Lemercier thus concludes an able article in the *Journal de la Société de Statitisque de Paris* for July, "On the English Empire of the Indies," with the following summary:—"Putting aside China, the figures concerning which are at least doubtful, we may class as follows, in relation to population, the principal States of the world:—1. The British Empire—viz., the United Kingdom, 31,628,338; the Indian Empire, 239,000,000; the other colonies, 11,710,111; total, 282,338,449. 2. Russia, 82,172,022. 3. Germany, 42,723,242. 4. United States, 38,558,371. 5. France, 36,469,875. 6. Austro-Hungary, 35,904,435. 7. Turkey, 35,350,000. In the year 14 A.C., Augustus, master of the world, delivered with pride to the Roman Senate the census of his 85,000,000 subjects dispersed over all parts of the globe. What would the great Emperor now say in the presence of the colossal power which has been attained by that British nation, the name of which he scarcely knew, and which has actually under its domination a number of subjects three times as great as that which the Roman Empire could claim during the days of its greatest prosperity?"

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—Bacon.

H. Stokes.—Received, with thanks.

Inquirer.—1. We are not aware that zinc ever gives rise to any symptoms that can well be mistaken for those of lead-poisoning. 2. The only source of lead that we can suggest is that possibly some solder may have been employed in the manufacture of the buckets; but buckets made of galvanised zinc ought to be absolutely safe.

A Widow.—The first cottage hospital was established at Cranleigh about twenty-two years ago, by Sir Albert Napper. It was a cottage made into a small hospital for six patients, at an expense of £50.

Testimonial.—Mr. James Neighbour, the Sanitary Officer of St. Luke's, has been presented by the Vestry with twenty guineas, in recognition of his valuable services during the small-pox epidemic; when, thanks to the prompt means he adopted to prevent the disease spreading, a second case occurred in only a small number of houses.

W. C. N.—It was about 1630, we believe, that the idea was conceived by a Frenchman that leeches might be kept in regular farms and bred just like any other animal. Leech-breeding had come to be regarded as a distinct industry, and was successfully carried on to a considerable extent in different parts of the Continent. Paris alone, it was estimated, "consumed" some 12,000,000 leeches annually.

Douglas.—In the early part of the present century, persons pitted with marks of small-pox were quite common. The disease was at its worst 150 years ago. The *first* thing that gave it a check was inoculation. Jenner died in 1823.

Invalid.—The leading features of the climate of Ajaccio, Corsica, are "great atmospheric purity and uniformity, regularity in seasonal changes, slight barometric oscillation, mean annual temperature 63·6°, mean winter temperature 63·2°."

M. P. P.—Of the deterioration of the Dutch seamen, and the conditions of a sea life, Dr. Roe, Physician to the Seamen's Hospital at Callao, writes—"He (the sailor) generally works all day, and at night he is four hours on the watch and four hours below alternately, but his rest is often broken. Crowded with others into a small place; restricted to a monotonous, unwholesome diet; undergoing great variations of temperature with inadequate clothing; going for days, sometimes in bad weather, without a cooked meal; without the means of being cleanly or even decent; add to these the mental worry of often impending shipwreck, and the hard and unremitting discipline necessary to drag both ship and men through the manifold dangers of the sea,—and it is not strange that the sailor arriving in port is debilitated and exhausted. Possessed of an uncontrollable desire for change, for freedom, for stimulants, for food, he deserts, and plunges into all kinds of debauchery."

Charlie.—The Copley Medal was presented to Claude Bernard, the famous French physiologist, by the Royal Society for his discovery of the sugar-making function of the liver.

W. B., Sussex.—The remarks of the President of the Epidemiological Society on the use of the word "epidemic" were—"The use of the word epidemic itself was probably a necessity of medicine, but it should be used only in its common and natural sense, to signify common to or affecting a whole people, or a great number in a community, and all mystical notions with regard to it should be wholly laid aside. It is the disease that constitutes the epidemic, and not the epidemic the disease."

Dispenser.—Yes; at the beginning of the past year the druggists of Austria were ordered by the Government to adopt the decimal system in their weights and measures. To facilitate the change, a table of equivalents on the old and the new system has been published, with special instructions for the prevention of mistakes. The gramme is the unit of weight.

Vigo.—The Select Committee of the House of Commons have just concluded their inquiries on the Lunacy Laws. The evidence will be laid before Parliament, and permission asked to sit again next year to consider their recommendations and draw up their report.

A Guardian, Lancashire.—The last report of the Irish Local Government Board shows for last year the smallest number of paupers ever known in Irish workhouses, namely, 43,000; also that a fewer number died in the workhouse hospitals than in any previous year.

Good Templar.—As to the right of a publican to be drunk in his own house, Mr. Justice Mellor and Mr. Justice Lush have cleared up any doubt. A publican at Salford was recently convicted under the Act of 1872, which says that "every person found drunk on licensed premises" shall be liable to be convicted. The publican closed his house at 11.30 p.m., and his wife went for a policeman, who found him drunk, and took him into custody for an offence under the Act. He was convicted, and appealed, and was successful. The judges held that the offence, if any, is against the public, and cannot be committed in the private house of a defendant, where his bad example is limited to his own family. The Legislature never intended to place publicans under particular obligations as to personal sobriety, and when their houses were closed to the public they were private. The conviction was consequently quashed.

Malcolm.—The late Mr. Edward Blyth, the creator of the Natural History Museum, Calcutta, eventually got a pension of £150 a year, owing, it is stated, to the untiring efforts made in London on his behalf by the late Sir P. Cautley and Dr. Falconer. It was Gould who described Blyth "as one of the first zoologists of his time, and the founder of the study of that science in India." Blyth died of heart disease on December 27, 1874, within a day or two of his sixty-third birthday.

DE LISLE ALLEN FUND.

The Hon. Treasurer begs to announce the following subscriptions to the above-named fund in response to the appeal in this journal on July 20:—

	£	s.	d.
Barker, A. E., Esq., London	1	1	0
Bury, G., Esq., Whetstone	1	1	0
Bull, G., Esq., M.D., Hereford	2	2	0
Fowler, O. H., Esq., Cirencester	5	0	0
Fox, Tilbury, Esq., M.D., London	2	2	0
Jackson, Hughlings, Esq., M.D., London	3	3	0
Jackson, Carr, Esq., London	2	2	0
Jenner, Sir W., M.D., Bart., London	2	2	0
L. T. C., Esq., Berkhampstead	1	1	0
Reynolds, Russell, Esq., M.D., London	3	3	0
Stear, H. Esq., Saffron Walden	2	0	0

Further subscriptions to the Fund sent to the Hon. Treasurer, Dr. Benjamin W. Richardson, F.R.S., 12, Hinde-street, London, W., or to the "De Lisle Allen" Fund, Union Bank of London, Argyll-place, Regent-street, W., will be thankfully received.

COMMUNICATIONS have been received from—

University of London; Mrs. D. de Lisle Allen; Royal College of Physicians, London; Apothecaries' Hall, London; Mr. F. W. Lowndes, Liverpool; Mr. W. E. Porter, Lindfield; Mr. Lawson Tait, Birmingham; Mr. G. Street, London; Mr. H. W. Bellew, Punjaub; Brit., Con., and General Federation; English Anti-Tobacco Society; Dr. Bruce, London; Messrs. Auld, Burton, and Co., London; Dr. G. H. Philipson, Newcastle-on Tyne; Dr. Henry Thompson, London; Mr. A. B. Carter, London; General Secretary of the British Medical Association, London; Sir William Gull, London; Mr. R. Brudenell Carter, London; Dr. Barlow, London; Mr. Jonathan Hutchinson, London; Dr. Sparks, Crewkerne, Somerset; Mr. John Chatto, London; Mr. W. E. Poole, London; Dr. H. K. Hitchcock, Lewisham; Dr. Alexander Wallace, Colchester.

BOOKS AND PAMPHLETS RECEIVED—

Dr. H. von Ziemssen, Cyclopædia of the Practice of Medicine, vol. xv.—Ackers, B. St. J., Vocal Speech for the Dumb—Dr. Tatham's Report on the Health of Salford—Report of the British Lying-in Hospital, Endell-street, W.C.—Prospectus of Queen's College, Galway—Cooper, R. T., M.D., Removal of Foreign Bodies from the Ear—Cooper, R. T., M.D., A New Uterine Repositor and Retracting Speculum—Galloway, Robert, F.C.S., A Plan for rendering Salted Meat more Nutritious, thereby preventing Scurvy—Tripe, John W., M.D., etc., Report on the Sanitary Condition of the Hackney District—Annual Announcement of the Medical Department of the University of Pennsylvania—Croskery, Hugh, The Gospel of the Kingdom—Rapport de la Commission spéciale du Traitement des Plaies à la Société de Chirurgie de Moscou, 10 Janvier, 1877—Folsom, C. F., M.D., Disease of the Mind—Lund, Edward, F.R.C.S., Internal Urethrotomy—St. Thomas's Hospital Reports, vol. vii.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—Medical Examiner—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Iron—Home Chronicler—La Province Médicale—Science-Gossip—Cassell's History of India, part xx.—Supplement to the Queensland Government Gazette—Sunday at Home—Leisure Hour—New York Druggists' Advertiser—L'Echo—Liverpool Daily Courier—Veterinarian—National Anti-Compulsory Vaccination Reporter—Paper-Printing Trades' Journal—Monthly Homœopathic Review—Edinburgh Medical Journal—Bentley and Trimen's Medicinal Plants, part xxiii.—Archives Générales de Médecine—Einladung.

APPOINTMENTS FOR THE WEEK.

August 4. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

6. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

7. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

8. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (hy Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

9. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

10. *Friday*.

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, July 28, 1877.

BIRTHS.

Births of Boys, 1239; Girls, 1199; Total, 2429.
Average of 10 corresponding years 1867-76, 2178·6.

DEATHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·72 in. The lowest reading was 29·36 in. on Monday, and the highest 29·99 in. on Saturday.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

LECTURE IV.—HYPERMETROPIA AND MYOPIA.

Mr. PRESIDENT,—The definition already given of hypermetropia, as a state in which the length of the eyeball is less than the focal length of the refracting media, so that parallel rays, if they could pass through the ocular tunics, would be united in a focus behind them, implies, of course, that such an eye, when in a state of rest, can only obtain clear images from convergent rays. Such rays, however, do not exist in nature—that is, they are not reflected from any natural objects; and hence the passive hypermetropic eye can only see clearly when convergent rays are supplied to it by art. The simplest way of supplying them is by refraction through a convex lens; and we have seen already that the degree of hypermetropia is to be measured and expressed by the power of the lens which, in each case, will render parallel rays so far convergent, before they enter the eye, that the refracting media will unite them in a focus upon the retina. We have seen also, that the act of accommodation is precisely analogous to the addition of a convex lens to the passive eye; and, for the relief of hypermetropia, it is a matter of indifference, optically speaking, whether the required lens is added within the eye by accommodation, or externally to it by art. A person who has hypermetropia of five dioptrics, and who has also five dioptrics of accommodation, will be able to overcome the defect by the exercise of the faculty. It is obvious, however, since he thus uses all his accommodation in order to obtain clear images from the parallel rays which come from distant objects, that he will have no accommodation available for the ordinary purpose of obtaining clear images from the divergent rays which come from near objects; and hence, to use a happy phrase taken from Donders, a patient, who is compelled by his hypermetropia to use some of his accommodation for distant objects, starts with a deficit for all the other requirements of life. The amount of this deficit will depend upon two factors—the degree of the hypermetropia, and the range of the accommodation.

The degree of hypermetropia varies from those slight forms of the affection which are only discoverable by very careful examination, up to conditions which may fairly be described as microphthalmos. I have already assigned reasons for my belief that a small degree of hypermetropia may be regarded as almost the normal formation of the eye; but the higher grades are comparatively seldom met with. Among the 239 hypermetropes found by Cohn in his examination of 10,060 school-children, none were included in whom the defect was less than 0·75, or three-quarters of a dioptric; and the highest grade found was 4·50 dioptrics. Between this highest grade and 3·0 dioptrics, there were only seven cases in all; and many more than half the cases (168 out of the 239) were between 1·0 and 1·75. Donders has recorded a case, observed by Mr. Bowman, in which the hypermetropia amounted to twenty dioptrics; but such an eye as this is quite exceptional; and I should say that six dioptrics would be the highest grade which would be passed by in practice without exciting attention as a matter of singularity; while the great majority of patients support Cohn's figures, and present grades of about two dioptrics or even less. Of course it must be remembered that nearly all instances of the higher grades are forced to seek optical assistance; while many persons with the lower grades contrive to carry on their work unaided; and, in this way, surgeons may often obtain erroneous ideas of the relative prevalence of the slighter and of the more pronounced degrees of the affection.

If we refer again to the diagram of the range and the region of accommodation, given at Fig. 16 in the second lecture, we shall see the amount of deficit which hypermetropia would produce in every case. Assuming the patient to be twenty-two years of age, and to be in possession of the nine dioptrics of accommodation which are to be expected at that period of life, the second line of the diagram shows the precise effect of a hypermetropia of four dioptrics. Four of the nine dioptrics of accommodation are required for parallel rays—that is, for seeing the horizon clearly; and only five dioptrics remain for divergent rays—that is, for seeing near objects clearly. These remaining five dioptrics will bring the near-point no nearer than to eight English inches from the eye; and, as few can continuously exert more than half of the entire range of accommodation, which half, in the case supposed, would be four and a half dioptrics, the actual and practical near-point for sustained vision would be at eighty inches away. If two-thirds of the accommodation could be continuously employed this amount would bring the near-point to twenty inches; but even this distance is too great to allow very small print to be read without assistance. Other grades are not laid down on the diagram, but their construction upon the same lines is simple and easy. The average hypermetropia of two dioptrics leaves seven dioptrics of accommodation at liberty for brief efforts; and the 4·50 dioptrics which can be employed habitually or constantly would afford only 2·50 for divergent rays, so as to bring the near-point for sustained vision to sixteen inches from the eye. If the hypermetropia exceeds 4·50 dioptrics, no sustained effort will be possible for any point nearer than the horizon; although for a short time such an effort could be made successfully. If the hypermetropia exceeds nine dioptrics, the near-point will be always beyond infinite distance; or, in other words, no exertion of accommodation will suffice to unite parallel rays upon the retina, and vision of all distant objects will be indistinct, unless aided by a convex lens.

As stated in the first lecture, the measure of the degree of hypermetropia is given by the strongest convex lens through which the eye obtains clear images of distant objects; but, in order to apply this test correctly, the accommodation must first be rendered passive. In all hypermetropic eyes the habitual state of the muscle of accommodation is one of contraction, rendered necessary by the instinctive craving for clear images—a craving which cannot be gratified in any other manner without optical assistance. In the case already supposed, where there is hypermetropia of four dioptrics and accommodation of nine dioptrics, four of the dioptrics of accommodation would always be in use. If this amount of effort were laid aside, all distant objects would appear dim and undefined; and such a condition of vision is not only unsatisfying, but it would in many people give rise to vertigo. Hence, the eye never fully relaxes its accommodation; and the muscle is so habituated to a certain amount of effort that this amount becomes its nearest approach to relaxation during waking hours. The eye is always enough accommodated to see distant objects clearly; and hence, if we place before it a convex lens, say of four dioptrics, the power thus given would be an unnecessary addition to its own accommodation, and would render distant objects dim until the accommodation effort was laid aside. Even the weakest convex lens might act in a similar manner; the eye not recognising the presence of the lens as a reason for relaxing its accommodation, or perhaps not having the power of relaxing it. In other cases, again, the eye constantly exerts some accommodation, but not enough to give the best distant vision which is attainable; and then it derives aid from a weak convex lens, but rejects the stronger one which would fully compensate for its defect. The hypermetropia which at once declares itself, the patient saying that a convex lens of given power improves distant vision, is said to be *Manifest;* and its amount is expressed in the ordinary way, by the power of the strongest lens which can be thus employed. In most cases, however, at least in young people, the accommodation is still at work together with the lens; and then, when the accommodation has been paralysed by atropine, a still stronger lens is accepted as the best. The additional hypermetropia thus revealed is said to have been *Latent;* and the manifest and the latent together make up the *Total.* Thus, in the assumed standard case, if only three dioptrics of accommodation were constantly employed, a convex lens of one dioptric would improve distant vision, and there would be manifest hypermetropia to this extent. When the accommodation was fully paralysed, a lens of four dioptrics would be required; and the three dioptrics of defect which had been

previously latent, or concealed by the accommodation, would become apparent and serve to make up the total.

The proportion which the latent bears to the manifest or to the total hypermetropia must evidently be constantly changing, as the power of accommodation diminishes with advancing life. According to Donders, we may often have as much as six dioptrics of hypermetropia latent in childhood. By the age of twenty, as much as half of this, and by the age of forty more than three-fourths of it, will have become manifest. By the age of seventy, the whole of the hypermetropia will be manifest; and even a higher grade may be found than that which was at first supposed to be the total. Donders regards this apparent higher total of old age as being partly made up of what he calls *hypermetropia acquisita;* but, as I have already set forth, I think there is much reason to regard it as the real total, part of which had been concealed, in earlier life, by the resistance of the ciliary muscle to any single application of atropia.

From considerations which have been already urged, it is manifest that the effort of accommodation, which is required in order to overcome hypermetropia, will be most easily made in conjunction with effort of the convergence. We have seen, in Fig. 18, that the emmetropic eyes of the subject from whom the diagram was taken, with their visual lines parallel, could exert only three dioptrics of accommodation; but that, when the visual lines were convergent to twelve inches (11° 21′), the same eyes could exert more than seven dioptrics of accommodation. In hypermetropia, the conditions, although not exactly parallel, are strictly analogous; and hence cases of hypermetropia were divided by Donders into three classes, with reference to the relation of the defect to the convergence function. He calls the hypermetropia *Absolute*, when accommodation for parallel rays is unattainable, even with the strongest convergence of the visual lines; *Relative*, when there is accommodation for a near-point, but only during convergence to a point still nearer (*e.g.*, when it is possible to accommodate for a point sixteen inches away by convergence to a point twelve inches away); and *Facultative*, when objects can be correctly seen with parallel visual lines, and either with or without convex glasses. Another definition is that hypermetropia is absolute, when the focus of parallel rays remains behind the retina, even with the strongest possible tension of accommodation and of convergence; relative, when the focus of parallel rays can be brought to the retina by accommodation and convergence; facultative, when the focus of parallel rays can be brought to the retina by accommodation alone, the visual lines remaining parallel. These distinctions are met with in books, and it is necessary to be acquainted with their meanings; but they are of little practical value, if only for the reason that in every case the conditions are constantly being changed by time, as the power of accommodation becomes confined within narrower and narrower limits. The facultative hypermetropia of childhood becomes relative in adult age, and absolute in the decline of life.

Another result of the connexion between accommodation and convergence is that a pair of hypermetropic eyes, in order to accommodate to the extent rendered necessary by the requirements of vision, keep their muscles of convergence in a state of constant tension. As shown by Dr. Loring's experiments, already quoted, this tension of the interni may be overcome by similar tension of the externi, exerted in the interests of single vision; but, in a large proportion of cases, the interni preponderate, and the eyes are brought into a state of habitual convergence, as a consequence of the habitual exercise of their accommodation. The convergence thus produced is at first equal on both sides, and it generally commences during the third or fourth year of life. After a time, in consequence of the double vision caused by the faulty position of the eyes which is thus produced, it becomes necessary for the child to correct this position by voluntary effort; and this is accomplished, when both externi are unequal to the task, by associating one externus with the internus of the other eye. Both eyes being convergent when at rest, and parallelism being unattainable, the patient sometimes brings the right eye into the middle of its palpebral fissure by looking to the right, sometimes the left eye by looking to the left. It is plain that the effort which, in the natural state, would roll the right eye outwards, will stop short of this by precisely the degree in which the eye was previously rolled inwards by its habitual convergence; and, thus stopping short, will direct its visual line straight forwards. While the action of one of the externi, starting from a position of convergence, produces only the middle position for the eye on which it acts, the associated effort of the opposite internus, also starting from a position of convergence, rolls its eye completely inwards. It would do this, even if the natural relations of the two muscles remained unchanged; but, as a matter of fact, the internus which thus acts is one which is in a state of exaggerated development from constant work. The externus and the internus receive the same motor stimulus from the centre; but the stronger muscle responds to this stimulus more powerfully than the weaker one. The result is, that the eye on which the internus acts is turned inwards in a greater degree than its fellow is turned outwards by the externus; and in this way the common concomitant convergent squint is produced. As long as the subject uses one or the other eye indifferently, this form of squint is only objectionable because it is unsightly, and because it prevents binocular vision. In most cases, however, either because one externus is stronger than its fellow, or because one eye has better vision than its fellow, one is after a time always directed forward, and the other always directed inward. As soon as this happens —as soon as one is always the working eye, and the other always the squinting eye—the vision of the latter begins to suffer; and it is then generally desirable to operate for the cure of the squint without delay, in order to prevent the deterioration of vision from attaining any considerable degree. It follows, from the account thus given of the mechanism of squint, that the affection is really binocular; and that both interni should be divided in nearly all cases. It is often possible to produce parallel visual lines for distance by dividing one tendon only; but such an operation, although it may be coarsely successful, leaves one eye with a weak and the other with a strong internus, and the two cannot respond in equal degrees to the convergence stimulus. The result is that they are never found to act comfortably together when directed to near objects; and the operated eye, under such circumstances, is apt apparently to squint outwards, its real position being not one of divergence, but one of imperfect convergence only. When the total squint is of small magnitude, it is desirable to divide the tendon of the squinting eye first, and to let this regain a firm attachment before dividing the other. In many instances, the neglect of this precaution has led to too extensive an operation, and hence to a divergent squint which would be permanent unless removed by another operation of a contrary tendency to the first. When the effect of the first operation is fully declared, that of the second may generally be precisely calculated.

Although hypermetropia is the cause of nearly all the cases of convergent squint, and although perhaps 90 per cent. of all who squint convergently are hypermetropic, the reverse of this proportion does not hold good. Cohn, in his already quoted statistics, found 239 cases of declared hypermetropia. Of these, 158, or almost precisely two-thirds, were the subjects of convergent squint. The reasons why some hypermetropes squint, and others do not, require further investigation. It would seem, at first sight, as if the difference must depend upon difference in the equilibrium, or proportionate strength, of the externi and the interni; that is, as if squinting would be obviated in those eyes in which the externi were able, on Loring's principle, to resist, for the sake of fusion, the heightened tension of the interni incidental to constant strain of the accommodation. It is also possible that the desire for fusion may be stronger in some persons than in others; and again, that in some the heightened tension of the interni produced by accommodation may be less considerable than in others. It is certain that many hypermetropes may be withheld from squinting by the habitual use of convex glasses, which diminish or remove the demand for accommodation; but this element in the question would not have any appreciable influence upon Cohn's figures, because only nine of the scholars included in his tables were so provided. If we remove these altogether, the proportion of squinting to non-squinting hypermetropes is practically unchanged.

The diagnosis of hypermetropia rests upon the appearance of the eye, upon the conditions of vision, and upon the relief afforded by suitable convex glasses.

The appearance of the eye, at least in pronounced cases, is such as to show that the affection is due to arrested or imperfect development. The eye is smaller than natural in all its dimensions, and its small size is generally most manifest when it is adducted to the fullest possible extent. The orbits also are in most cases small; and these peculiarities of formation are often hereditary, and are often shared by other members

of the family. The popular belief about squint arising from imitations seems to have no better foundation than its frequent occurrence, as a result of similar physical formation, in several brothers and sisters. Not long ago, I operated for squint, at St. George's Hospital, upon six sisters and their mother; and it is the exception, rather than the rule, for only one child in a family to be affected.

The conditions of vision depend entirely upon the degree of the hypermetropia, checked by the power of accommodation. If the hypermetropia is of small degree, as of one dioptric, and the range of accommodation normal, no inconvenience will be experienced until the time comes when the power of accommodation is curtailed by the advance of years, and then the only symptom will be the early on-coming of presbyopia. Such a patient will require reading-spectacles by the age of forty, and always thereafter will require for all purposes glasses a dioptric stronger than his period of life would indicate. When his power of accommodation is lost, he will require glasses of one dioptric for clear distant vision.

When the hypermetropia is originally of such a degree as to consume for its correction nearly half the power of accommodation, so that the use of the eyes upon near objects can only be accomplished by means of the remaining half, or whenever this state of things is brought about later in life by decline of the accommodation, any attempt at sustained effort of the eyes is soon rendered impossible by muscular fatigue. The symptoms of this fatigue have been known for many years as constituting one of the forms of the malady called asthenopia; but it was reserved for Donders to trace this form of asthenopia to its origin, and to show that it is neither more nor less than a result of overstrain of the accommodation. Until this discovery was made, the asthenopia was incurable, and the unfortunate sufferers from it were advised to relinquish all pursuits in which employment of the eyes upon near objects was required. Not an uncommon prescription was to go to Australia and to turn sheep farmer; and this, when it was followed, had the twofold advantage of diminishing the discomfort of the asthenopia, and of getting rid of a patient who did little credit to any of his generally numerous advisers. The discovery of the nature of the affection disclosed the means of curing it by substituting for the accommodation effort the employment of convex glasses; and the form of asthenopia which depends upon hypermetropia alone is now no longer a source of trouble either to patient or doctor. The hypermetropia must be corrected, either wholly or partially, by suitable lenses, and the fatigue in which the asthenopia had its origin will be at once relieved. The principles on which the lenses must be chosen are very simple, but I must reserve certain matters of detail which bear upon this point until the last lecture of the course, in which the treatment of all the forms of asthenopia will be discussed after their several causes have been described.

In very high degrees of hypermetropia, the diagnosis of the affection is sometimes less easy than in the lower grades, and the symptoms may even simulate those of myopia. The patient (necessarily a child, because these high degrees always interfere with education, and call for relief long before adult age is attained) is said by parents and friends to be "short-sighted." We find, on examination, that he cannot see distant objects distinctly, and that he brings a book very close to the eyes. We sometimes find that he declares distant vision to be improved by a weak concave lens. The explanation of these conditions is as follows:—The patient cannot see distant objects clearly, either because his accommodation is insufficient to neutralise his defect, or because the muscle of accommodation, always contracted, passes into a state of spasm and over-corrects the defect. The book is brought near to the eyes, because the larger visual angle subtended by the near object gives a correspondingly larger image on the retina, and thus facilitates recognition. The diffusion of light due to the hypermetropia is at the same time increased; but Donders has shown that the magnitude of the retinal image increases more rapidly than the magnitude of the diffusion circle, so that the balance of advantage remains on the side of approximation of the object. The balance is the more decided, because the highly hypermetropic eye is not accustomed to perfectly defined images, and therefore appreciates magnitude more highly than clearness. The preference for a weak concave glass, when it occurs, is a result of over-correction of the hypermetropia by spasm of accommodation. Such cases as those now described present little difficulty to any who have been warned of them; for the eyes have always the hypermetropic formation in a marked degree, and the thorough application of atropine at once clears up any doubt which may be felt. It is in such cases that we find the necessity of repeated and systematic atropinisation, and discover the error of trusting to one application alone. I have seen instances in which there was apparent myopia to the extent of a dioptric, and in which, after the use of atropine twice or thrice daily for three or four days, as much as six dioptrics of total hypermetropia became revealed.

The principle on which hypermetropia should be treated is manifestly by the use of spectacles with convex lenses, such that they, as nearly as possible, correct the faulty shape of the eye, by rendering the rays which reach the cornea so convergent that they may be brought to a focus on the retina with little or no effort of accommodation. In a hypermetropia of four dioptrics, lenses of four dioptrics might not unreasonably be supposed to enable the eyes to be passive, as if they were emmetropic, during vision of distant objects, and to release all their accommodation for employment upon near objects. We find, however, that this expectation is not entirely fulfilled. The muscles of accommodation have usually been brought, by constant exercise, into a state of tonic spasm; and they show little inclination to become relaxed. If we correct the total hypermetropia, we render the patient short-sighted, because he has correction and accommodation too. It is therefore generally necessary to feel our way, and to accustom the eyes to partial correction, and to the abandonment of some of their customary effort, before they are called upon to abandon the whole of it. Donders laid down the good practical rule that we should correct the whole of the manifest hypermetropia and about one-fourth of the latent. The glasses which do this will usually relieve any discomfort which had been produced by accommodation strain; and the patient will for a time be delighted with them. After a while, the amount of accommodation effort which is still required becomes irksome; and the old symptoms show signs of returning. The patient may again be relieved by strengthening his glasses to the extent of perhaps half of the still uncorrected defect; and then, if after another interval he is again distressed, he may receive full correction, and may go away freed from the consequences of his defect, and able, for ever afterwards, "to forget that he has eyes." But, in order that such a result may be obtained, the patient must wear the glasses constantly. If they are sometimes off and sometimes on, the eye will never learn to lay aside its accommodation effort for distance; and consequently will always be fatigued, and will always see the horizon indistinctly.

By way of illustration, let us suppose the case of a patient who has one dioptric of manifest hypermetropia, and whose eyes, when thoroughly under atropine, show five dioptries, four of which were previously latent, or concealed by the accommodation. In order to correct all the manifest and one-fourth of the latent, we give spectacles of two dioptrics, directing them to be worn constantly. In a few months, when the old symptoms return, we correct half of the remaining defect—that is, we increase the power of the glasses by a dioptric and a half, which raises them to three and a half dioptrics. If the symptoms return again, we give five dioptrics; and then the patient will require nothing more until he reaches the time of life at which presbyopia commences. His spectacles for near work must then receive an addition of as much power as an emmetropic person would use for the same purposes at the same period of life.

(To be continued.)

A Grateful Pupil of the Abbé de l'Epée.—M. Martin, formerly a pupil of the National Institution for the Deaf and Dumb, and of the Ecole des Beaux Arts, has just executed in marble a group consisting of the Abbé de l'Epée instructing a young deaf-and-dumb. The group received an honourable mention at the last Exposition, and M. Martin, in token of his gratitude to the Abbé for his services to his brothers in misfortune, has just presented it to the Institution, which has been the parent of all other existing establishments. The Minister has consented that the statue shall be placed in the courtyard of the Institution, where it will be at once a testimony of gratitude and a motive for emulation of future students, showing them what labour and perseverance may accomplish for the development of their faculties.—*Union Méd.*, July 31.

FORTY-FIFTH MEETING

OF THE

BRITISH MEDICAL ASSOCIATION,

HELD IN MANCHESTER, AUGUST 7, 8, 9, AND 10, 1877.

PRESIDENT'S ADDRESS.

By M. A. EASON WILKINSON, M.D., F.R.C.P.,
Senior Physician to the Manchester Royal Infirmary.

MY first duty, gentlemen, is to thank you for the honour you have conferred upon me in electing me President of this Association; my next is to give you now a hearty welcome to Manchester.

It is twenty-three years since we met here under the presidency of Mr. Wilson. Many important changes have taken place in our city since then, the effect of which, I trust, will be to make this meeting second to none, whether in local interest or in general scientific information. If we have seemed tardy in showing our desire to receive you here, it has been due to untoward causes which have been rather our misfortune than our fault. It is only after several years of negotiating that the desirable union of the Manchester Royal School of Medicine with the Owens College has at last been effected. It is, therefore, only lately that, through the liberality of the Council and Senate of that institution, we have been able to provide suitable accommodation for the reception of such a large and influential meeting as was sure to assemble from our Association, which now numbers seven thousand members, and these from the four quarters of the globe, and embracing the most distinguished men in our profession.

Before proceeding to the subject of my Address, I must make a few personal references, which I know will receive your sympathy. First, of Mr. Southam, whose untimely death we much deplore. He always stood in the van of those who strove to advance the interests of his profession, and his loss will be especially felt by the younger members, for whom his advice and help were ever ready. He was beloved by the students of the School of Medicine, of which he was the first dean, and was honoured in being made President of the Council of the British Medical Association. We have next to lament the loss of one who took a deep and active interest in all that concerned the Association, and whose energy and perseverance, combined with great foresight, materially tended to create its present high position. You know that I refer to Dr. Sibson, whose cultivated mind, amiability of character, conscientious and unflagging devotion to his profession, with unimpeachable honour and integrity, have endeared him to us all, and have rendered his name a beacon-light for the guidance of the rising generation.

Another name must be added to the list of those who have passed away since the Association last met. Sir William Fergusson, under whose presidency we assembled at our last meeting in London, has been taken from us, but not till he had obtained the highest honours open to our profession in this country. As a student in Knox's dissecting-rooms when Mr. Fergusson was demonstrator, I learned to admire the beauty of his dissections and the brilliancy of his demonstrations, which were only surpassed by his future career as an operator.

There is still another name to be added to the list of those who have been called from our ranks: Mr. Whipple, who was President of the Association at Plymouth in 1871, and one of our Vice-Presidents at the time of his death. He distinguished himself as an operator, and practised for more than forty years in Plymouth and the surrounding country, beloved and respected.

I refrain from further details respecting the careers of these several eminent men, as their connexion with medicine and surgery, and their achievements in their several walks, will be brought before you in the different sections.

The loss to medical education and to science experienced through the retirement of Sir Robert Christison from the Chair of Materia Medica in the University of Edinburgh, where he has laboured so long and done so much to advance our knowledge on this subject, ought not to be passed over. The success of the meeting in Edinburgh was, for the most part, due to the share he took as your President. Looked upon as one of the first, if not the first, authority on poisons in Europe, Sir Robert's advice has been sought in numerous ca involving most difficult and delicate points, and his judgme has always been valued as of the highest importance. H career as a teacher, extending as it has done over a period more than fifty years, the never-failing regularity with whi he attended to his duties, and the clearness and originality his lectures, are themes deserving more praise than I am co petent to bestow. We can only join in the hope that he w long be spared to give us the benefit of his great and vari experience.

In *our* profession no one need be at a loss to find a subje for the Annual Presidential Address to the Association. happens that, in this town especially, the question of hospi defects and their remedies is greatly engaging the attention the local medical men.

Reports recently presented to the trustees of the Manches Royal Infirmary by Mr. Netten Radcliffe, of the Local Gover ment Board, and by Mr. Field, an engineer of eminence sanitary matters, have condemned the buildings as defecti in construction and drainage, and inadequate in accommod tion. I have, therefore, thought the subject a suitable one be brought before the Association, seeing that everything whi applies to our special case has a general bearing upon hospi construction everywhere.

Our Infirmary owes its origin to several public-spirited me who, in the year 1752, chose Mr. Joseph Bancroft, a mercha of Manchester, as the first treasurer, he having offered, if one would join him, to defray the expenses of a hospital for o year, provided Charles White, then practising here as a surgeo would give his professional assistance. Mr. White at on fell in with this proposal, and a house in Garden-street, Shud hill, was engaged. This was opened for the relief of ou patients in June, 1752, and in the following month f in-patients. During the first year, seventy-five of the latt and 249 of the former were admitted.

In 1753 the good arising from this institution became manifest that the trustees determined to erect a more suitab building, and land was purchased from Sir Oswald Mosle situated on the south-west outskirts of the town, removed fro all noise and bustle of the business then carried on, with unimpeded view of the country to a distance of eight or t miles. This situation became surrounded in the course of tir by dwelling-houses, then by mills, around which cottag sprang up in badly drained streets. The rapid growth of t population, and the extension of manufacturing interests, soo placed the Infirmary in the centre, instead of on the outskir of the town. It has, indeed, been alleged that the origin site of our Hospital was surrounded by mills and warehouse but this is a mistake.

The original building was of red brick, and was a mode unpretending structure; it was one of the first provinci hospitals built in England. It was constructed with a centr corridor, there being small wards of low elevation on eac side, and was at first intended to accommodate forty patient but, on further consideration, the place was extended receive eighty. This was opened in 1755; and ten years lat the Lunatic Hospital and Asylum was founded and erecte The benevolent-minded were as liberal in their subscriptio to this part of the charity as they had been to the Infirmar and, to all intents and purposes, the two charities were co sidered one.

In 1781 the plan of having patients attended at their ow homes was introduced. At the same time, public baths we erected in connexion with the Infirmary. The north or "di pensary wing" was added in 1792. The expense was, to great extent, defrayed by special collections in churches an in chapels of every denomination throughout the town an surrounding country. The idea of Hospital Sunday w evidently derived from this circumstance. The sum of near £4300 thus obtained stands in remarkable contrast to th sums now collected, if we consider the enormous increase wealth and population.

In the year 1825 it was proposed to embellish the exteri of this modest brick building by encasing it in stone. Fro want of funds, this could not be accomplished till, in 1831, portion of a bequest from the late Mrs. Hall was devoted the purpose. By way of further embellishment, four massi pillars were placed in the centre of the building facin Piccadilly, giving an almost palatial aspect outside, whi alas! darkening the wards and preventing a proper circul tion of air, so as to render the Hospital decidedly unhealthy

No attention seems at this time to have been paid to the ainage either of the building itself or of the grounds sur-unding it, there being then no corporate body in existence ith power to compel attention to these matters. The pond in ont of the Infirmary was in such a state that, according to e reports of the Weekly Board, it had frequently to be mented to prevent the exudation of water into the cellars of e building. The consequence of all this was, that the round under and around the Infirmary became saturated with wage and other drainage; the stone encasement of the walls turally prevented the escape of the effluvia, which were thus nfined within the building itself. We now know it as an evitable consequence of this condition of things that erysi-las and other diseases of blood-poisoning should recur. deed, to such an extent was this the case, that during the ring and autumn months no capital operations were per-rmed unless absolutely necessary.

In 1847 the attention of the Weekly Board was directed to e unhealthy and overcrowded state of the Hospital, and it as determined that a south wing should be erected, the rner-stone of which was laid in that year, and the building as completed in 1848.

In 1851, mainly through the liberality of Madame Gold-hmidt, then "Jenny Lind," the north wing, which bears her me, was erected; and in 1854 this aggregation of upwards a century was crowned with a dome, which is, in truth, chitecturally, the best part of the Manchester Royal In-mary.

It must be remembered that hospital construction was at is time in its infancy. Considering the rapid strides made ring the last few years in the treatment of disease, we may k whether, in the construction of our hospitals, all has been ne that can be done to obtain the best results; in other ords, to put our patients under the best possible conditions r the successful application of our improved treatment. In-much as the advantages of medical skill, good diet, and reful nursing more than counterbalance any disadvantage of ing removed from home and friends, the applicants for the nefit of our hospitals increase year by year; and the question nes to be considered, Have we yet, in the construction of our spitals, succeeded in obtaining the hygienic conditions best culated to benefit those under our care, and on a sufficient le to accommodate all who apply for relief?

Now, the sanitary state of a hospital may be taken as the st criterion of its fitness for the end. Build a hospital on a an which all are agreed is the best, give the requisite amount cubic space to each bed, provide everything necessary for e comfort of the patients, in the shape of skilled medical at-dance and nurses; but, at the same time, place it in the dst of a crowded manufacturing city, over immense drains m which mephitic gases are constantly escaping into the ilding, and where the external circulation cannot be properly veloped, and you ought not to be surprised at finding the mber of deaths from blood-poisoning excessive.

We all remember the discussion excited by the essay on Hospitalism" of the distinguished professor Sir James apson. So impressed was he with the high mortality, ributable, in a great degree, to preventable causes, that he nt the length of declaring that, "If our present medical, gical, and obstetric hospitals, instead of being crowded aces with a layer of sick to each flat, were villages or groups cottages with one or, at most, two patients in each room, a eat saving of human life would be effected." In fact, the tage hospitals in various parts of the country showed ults that were most gratifying, and seemed to confirm the th of this dictum. Nevertheless, in a large manufacturing y like ours, drawing patients from all parts of a densely pulated district, such a plan would be wholly impracticable.

In providing hospital accommodation, we have to consider site, the value of ground, the number of sick to be accom-dated, the amount of space to be allowed to each bed, the ount of fresh air and light at our disposal, the possibility conveying thither the sick and wounded, the convenience the administrative body, and the accessibility for medical cers, students, and patients' friends.

As regards the site of our present Infirmary, I think it is erally agreed by the medical staff that we could not be re unfortunate. No legitimate excuse can be urged for aining it in the midst of the foul air, smoke, and bustle of densely crowded city. The convenience of the consulting ff and of the Medical School would be as well consulted in a purer atmosphere, and, if recovery of the sick be the object aimed at, this would be greatly facilitated.

I think we must all agree with Miss Nightingale when she says, "Fresh country air is better for the sick than impure town air, and hence the question narrows itself within the compass of accessibility; any site which can be obtained with pure air and sufficiently convenient means of access will fulfil the required conditions."

The question of removing the Manchester Infirmary has been long under consideration, but has never taken definite shape until within the last year, when the continued complaints of the acting medical staff regarding the unhealthiness of the present building have awakened public attention to its importance.

Miss Nightingale has said, and I think wisely, that if a new hospital be wanted, the true way to proceed is—first, to determine in what district it should be; next, to look out the possible sites; and lastly, to have each site examined by competent men, with a view to select the best. She goes on to say that the evil consequence arising out of any other course is, that party spirit becomes the leading motive, especially among those who are not sufficiently acquainted with the subject, whereby the cause that we all have at heart suffers. Such has to some extent been the case here.

When removal was first suggested, several sites were proposed; but conflicting interests brought out such strong feelings that the hope of removal has for a time been checked, while means are being taken to patch up still further the building already patched to death.

Now, apart from the defects in regard to position and drainage, the building itself is constructed on a plan which is faulty. The porticos and their columns deprive a number of the wards of the amount of light requisite for ordinary convenience; the partial Block System prevents that free circulation of external air which is absolutely necessary for avoiding stagnation within. The central corridors, besides acting as shafts for the conveyance of poisonous particles from one extremity of the building to the other, necessitate the placing of beds along dead walls, thus interfering still further with the supply of light and air to the patients.

I have thus endeavoured to give you some idea of the imperfections of our Infirmary as to site and construction, and of the means which should be taken to remedy them. I have discussed the matter in no factious spirit, but have endeavoured to put plainly before you a question which, although local in character, yet brings us face to face with some of the most important questions connected with modern hospital hygiene.

Originally, hospitals were built for the helpless, the infirm, the sick, and the aged; many such may be seen in different parts of this country and on the Continent. These houses were generally attached to some monastic or other religious foundation. The medical treatment was probably, in a great many respects, faulty, as compared with our own times. It is only of late years that architects, and those interested in the subject of building, have been convinced that, in constructing a hospital, something more is required than room for beds and a tolerable amount of light.

Only a few years ago it was not at all uncommon, in passing through some of the Continental hospitals, to find the wards dark and heated by stoves, with no attempt at ventilation; the windows had double sashes, and during the winter these were never opened, but were plugged so as to prevent the slightest admission of air. The floors were covered with beds, and it was impossible to make your way through the wards without disturbing the patients. Indeed, it is not long since the Local Government Board in this country condemned the plans of a hospital on the Pavilion system, with water-closets and bath-rooms at the end of the ward; and they compelled the authorities to place the water-closets in the middle of the building and in immediate proximity to the kitchen, leading, of course, to the presence of noxious odours there. All this has been changed of late; and the same department insists now upon having temporary hospitals, with the most perfect arrangements for isolation, drainage, and ventilation. In such a case, one would have thought that, with the scientific medical skill at their disposal, there could have been no hesitation.

To cure the sick as rapidly and effectually as possible should be the object of every medical man; and, consequently, we should endeavour to aim at a consensus of opinion as regards hospital construction. Every town in the kingdom of any size has its hospital, and medical men are absolutely required

both to know what is best in hospital construction, and to rest their opinion upon such solid grounds as shall be convincing against opponents.

There is no doubt that a very large majority of those who have studied the question earnestly and practically give their decided voice in favour of the Pavilion System. When the Infirmary here was in process of rearrangement thirty years ago, I strongly urged the adoption of this plan, but I was defeated. Time has shown that a mistake was made in the matter, and means have lately been suggested to rectify this.

I need not tell you that all the proposed improvements have been made with reference to the Pavilion plan. There are a number of modifications of the system which it would be a waste of time to enumerate; but the first principle is, to have each ward completely open to the air on each side, with drains running outside, and ventilated, with bath-rooms and other conveniences projecting from the building at one end, and nurses' rooms and administration at the other. These could be multiplied indefinitely, and, provided land was cheap, would require to be only of one storey; there would be no objection, however, to two or even more.

In connexion with the subject of hospital construction, it may not be amiss briefly to touch upon the scheme, lately agitated in London, for providing hospital accommodation for the well-to-do classes. This proposal has received the support of some of the leading medical men in the metropolis, and has been favourably noticed by many important journals.

Considering the size of some of our existing hopitals, and the conveniences already established in them, would it not be better to add wards to them for the reception of paying patients who should be attended by their own medical men? Some objections which are now put forward in regard to management, etc., might thus be got over, and all the advantages of hospital treatment might be obtained with a minimum of expenditure. The Hopkins Hospital in Baltimore, United States, recently endowed through the munificence of a gentleman of that city, and in process of erection, is arranged upon this basis; and other hospitals on the continent of Europe carry out the same idea. I do not see why, with special arrangements, the same ends might not be attained as are now being striven for by the promotion of the "home hospitals."

A city approaching in size to ours needs a general hospital of at least 500 beds, in order to accommodate all classes of disease. Without this you cannot meet the various requirements of a large community, nor can you have a perfect school of medicine and surgery.

It must not be forgotten that Manchester is the seat of the largest English School of Medicine out of London. Inaugurated in the early part of this century by the energy of Mr. Jordan, who was the first provincial lecturer recognised by the medical corporations as qualifying for examination, it became expanded into a school by the late Mr. Turner. The love of teaching, and the desire to advance the profession by thoroughly educating the candidates for admission into it, alone actuated those men who were associated with the illustrious Dalton, Sir James Bardsley, and others; and, through their united endeavours, the Pine-street School became the educational centre for the North of England.

Friendly rivalry was at that time strong among the medical men; and encouraged, I believe, by the success of the above-mentioned school, another was established in 1850 in Chatham-street, under the direction of the late Mr. Southam, the late Mr. Dumville, and Dr. Watts. This latter also prospered, and, in 1853, it was thought advisable to unite the two. From that date to the present we have had but one medical school in Manchester. To the pioneers in this work we owe a deep debt of gratitude.

Now we come to an important period, as I believe, in the history of Manchester and of Medicine. The promoters of the united school being anxious to place themselves under the best conditions for the education of the students under their charge, took steps in 1872 to bring their institution more closely into connexion with the Owens College, which was then becoming celebrated as a school of scientific education. The Owens College owes its existence to the liberality of John Owens, a prosperous Manchester merchant, who left his property to the late Mr. George Faulkner and other trustees, for the purpose of founding a college after the models of the older English universities. Mr. Faulkner accepted the trust, and, having purchased some property in Quay-street, he presented it with the buildings thereon to the College. The lectures of the Owens College were here begun in 1851, and were carried on until the class-rooms were found to be inadequate to accommodate the number of students who assembled to avail themselves of the advantages offered by the institution. About this time, her Majesty, by Royal Warrant, affiliated the College to the London University. Great interest was taken in the young College, and benefactions flowed in from all sides, providing a number of valuable scholarships. Its progress was not rapid, but sure; and in 186 a movement was inaugurated for extending the then limited accommodation. Land was bought in Oxford-road, and, to b brief, on October 7, 1873, the present buildings were opened by the Duke of Devonshire, President of the College. M Waterhouse, with his skill and anxious desire to carry ou the wishes of the staff of professors, has given them a commodation which has no rival, I believe, in its suitability for their various requirements. The laboratories ar second to none in Europe—it has even been said that they ar the first, having been specially planned under the supervisio of the distinguished professors in these departments; the possess all the most recent and perfect apparatus for th purposes of scientific research.

Under such circumstances, we cannot wonder that th governing body should have been desirous of adding anothe Faculty to those already in existence. A large bequest b the late Miss Brackenbury, for the purpose of founding medical school in connexion with the College, gave an impetu to negotiations which had been begun between the authoriti of the College and the Manchester Royal School of Medicin tending to this object. These efforts were successful. A appeal to the public soon brought the additional necessar funds; and in October, 1874, the best appointed medical scho in the provinces was opened. The advantages of the unio have not only accrued to the Medical School, by providin increased accommodation and greater facilities for experi mental medicine, but also to the College, in thus rapidl increasing its numbers, and adding to its area of usefulness.

The Infirmary authorities are now invited to take their sha in furthering the cause of Scientific Medical Education; to this effectively, the disadvantages under which we have so lo laboured from having a defective hospital must be remedied

It is unnecessary that I should occupy more of your tim when there is so much that is interesting to be brought befo you during the meeting of our Association.

I have dwelt at length on the subject of hospitals and th connexion with medical education, holding, as I do and ha long done, the deep conviction that it is a question of t highest importance in all its bearings, and this not only medical men, but to every member of the community. believe I shall have the sympathy of this great and influent meeting in the views I have expressed and in the statemen I have made.

Allow me in conclusion, gentlemen, to offer you once m our sincere welcome to Manchester.

ADDRESS IN MEDICINE.

By WILLIAM ROBERTS, M.D., F.R.S.,
Physician to the Manchester Royal Infirmary; Professor of Clinical Medicine in Owens College; etc.

THE DOCTRINE OF CONTAGIUM VIVUM AND I APPLICATIONS TO MEDICINE.

Gentlemen,—The notion that contagious diseases are p duced by minute organisms has prevailed in a vague way fr a remote age; but it is only within the last twenty year since the publication of Pasteur's researches on fermentat and putrefaction—that it has assumed the position of a seri pathological doctrine. In the last decade, startling d coveries of organisms in the blood have given this doctrine support of actual observation; and its application as a gu in the treatment of wounds by Professor Lister has made subject of universal interest to medical practitioners.

The resemblance between a contagious fever and the ac of yeast in fermentation—or the action of bacteria in dec position—is in many points so striking that it is difficult avoid the impression that there is some real analogy betw them. If, for example, we compare the action of yeast v small-pox, this resemblance comes out very distinctly, as following experiment will show. I filled two pint bottle

and B, with fresh saccharine urine, and inserted a delicate thermometer in each. A was inoculated with a minute quantity of yeast, but nothing was added to B. Both bottles were then placed in a warm place in my room, at a temperature of about 70° Fahr. In order to get a correct standard of temperature for comparison, I placed beside these a third bottle (C) filled with water, and inserted a delicate thermometer in it. All these bottles were carefully swathed in cotton-wadding, for the purpose of isolating their individual temperatures, and to obviate, as much as possible, the disturbing effects of the varying temperature of the room. For twelve hours no change took place; but, at the end of this time, A began to ferment, and the thermometer marked a distinct elevation of temperature. On the second day, A was in full fermentation, and its temperature was 2·7° above B and C. This disturbance continued for five days, the temperature ranging from two to three degrees above the companion bottles. The disturbance then subsided, and the temperature fell to an equality with B and C, and a considerable sediment, composed of yeast, settled at the bottom. In the meanwhile, B showed little alteration; but on the sixth day it began to ferment, the temperature went up, and for more than a week its thermometer stood about two degrees above A and C. Finally, the temperature in B declined, the disturbance subsided, and the newly formed yeast settled to the bottom of the vessel.

This fever in a bottle resembled small-pox in the following points. A period of incubation intervened between inoculation and the commencement of disturbance; then followed a period of disturbance accompanied by elevation of temperature; this was succeeded by a subsidence of the disturbance and a return to the normal state. Great multiplication of the infective material (or yeast) took place during the process, and, after its conclusion, the liquid was protected from further infection with the same contagium. We likewise notice that the contagium of fermentation, like that of small-pox, may take effect either by direct purposive inoculation or by fortuitous infection through the atmosphere. In both cases the infective material has the power of preserving its activity for an indefinite period. The comparison fails in at least one important point—in the fermented urine, sugar is replaced by alcohol and carbonic acid; but we are not aware that any pronounced chemical changes occur in the blood or tissues during an attack of small-pox. I would, moreover, carefully guard myself against being supposed to suggest that the enhanced temperature in the fermenting urine is a real analogue of the preternatural heat of fever.

Let me direct your attention to another example—a kind of partial decomposition or fermentation which takes place in boiled hay-infusion when it is inoculated with the *Bacillus subtilis*. The *Bacillus subtilis* is a very common bacterium found in vegetable infusions and in curdling milk. I hope you will take note of this little organism; for I shall have to refer to it more than once in the course of this Address. I took a flask containing hay-infusion, which had been sterilised by boiling, and inoculated it with a drop of fluid swarming with *Bacillus subtilis*. After the lapse of twenty-four hours the previously transparent infusion became turbid. This turbidity increased, and on the second day a film or crust formed on the surface of the infusion. On the third and subsequent days the crust broke up and fell in pieces to the bottom of the vessel. In about a fortnight the turbidity passed away, and the original transparency of the infusion was perfectly restored, so that it looked exactly as it did before the process began, except that there was now a sediment consisting of the spores of the little organism at the bottom of the flask. In this case, again, there was the same succession of events: a period of incubation, followed by a period of disturbance, succeeded by a period of subsidence, and, finally, restoration to the normal state. There was also great increase of the infective material and immunity from further attack by the same contagium.

The yeast-plant and the *Bacillus subtilis* may be taken as representatives of a large class of organisms in regard to which we are only beginning to realise their vast importance in the economy of Nature and in the life of man. They are, as I shall presently show, the essential agents in all fermentations, decompositions, and putrefactions. We may group them together, for the convenience of description, under the general designation of *saprophytes*, a term intended to include under one heading all the organisms associated with the decomposition and decay of organic matter. The yeast-plant and its allies, and all the numerous species and varieties of bacteria, belong to this group. In size and form they are among the smallest and simplest of living things, but their vital endowments are wonderful.

All the organisms hitherto found associated with infective inflammations and contagious fevers belong to the tribe of bacteria, and we cannot advantageously enter on a study of that association without a knowledge of the origin and attributes of these organisms. This brings us into a field of active controversy. It has been alleged, as you know, on high authority, that these organisms, under certain conditions, depart entirely from the universal law of generation which is expressed in the aphorism *omne vivum è vivo*, and that they may arise spontaneously by a process of abiogenesis. It is also alleged that these organisms are not the actual agents of decomposition, but are merely associated with that process as secondary or accidental accompaniments. I propose to lay before you evidence that both these allegations are unsustainable, and to prove that bacteria, like other organisms, arise from pre-existing parent germs, and in no other way, and that they are the actual agents in all decomposition and putrefaction.

The first proposition I shall endeavour to establish is this: that organic matter has no inherent power of generating bacteria, and no inherent power of passing into decomposition.

I have here placed before you samples of three sets of preparations, out of a large number in my possession, which serve to substantiate this proposition.

The first set consists of organic liquids and mixtures which have been rendered sterile by a sufficiently prolonged application of the heat of boiling water. They are composed of infusions of vegetable and animal substances, fragments of meat, fish, albumen, and vegetables, floating in water. They are contained in oblong glass bulbs, and are protected from the dust of the air by a plug of cotton-wool inserted into the necks of the bulbs, but freely open to its gaseous elements, which pass in and out through the cotton-wool. They are all, as you see, perfectly transparent and unchanged, though most of them have been in my possession for several years.

The second set consists of organic liquids which have been simply filtered under pressure through unglazed earthenware into sterilised flasks. They include acid and neutralised urine, albuminous urine, diluted blood, infusions of meat and of hay. As these preparations were obtained by a method which is in some respects new, I will describe it to you. A piece of common tobacco-pipe, about six inches long, served as the filter. This was secured by indiarubber piping to the exit-tube of one of the little flasks used by chemists for fractional distillation. The flask is first charged with distilled water, and then a tight plug of cotton-wool is inserted into its neck. The flask is next set a-boiling briskly over a lamp. The steam rushes through the cotton-wool plug and through the tobacco-pipe, clearing both these passages of any germs they might contain. When the water has nearly boiled away, the end of the tobacco-pipe is hermetically sealed with melted sealing-wax. After a little more boiling, the flame is withdrawn and the neck of the flask is instantly closed with a tight vulcanite cork. The apparatus is now ready for action, and the tobacco-pipe is immersed in the liquid to be filtered. When the flask cools, a vacuum is created within it, and this serves as a soliciting force to draw the liquid through the earthenware into the flask. The process of filtration is very slow; it takes two or three days to charge the flask. When a sufficiency has come over, the apparatus is removed and placed on a shelf for a few days until the pressure inside and outside the flask is equalised. The vulcanite cork is then withdrawn, and the exit-tube is separated and sealed in the flame of a lamp. In this way you obtain a sterilised flask charged with the filtered organic liquid, and protected from outside contamination by a plug of cotton-wool. Preparations obtained in this way, if due precaution have been used in the manipulation, remain permanently unchanged; organisms do not appear in them, and decomposition does not ensue.

The third set of preparations are, in some respects, the most significant of the three. They consist of organic liquids which have been simply removed from the interior of the living body, and transferred, without extraneous contamination, into purified glass vessels. I will not detain you with the methods employed to obtain them; it is sufficient to say that, by the use of proper precautions, it is possible to convey blood, pus, urine, ascitic fluid, pleuritic effusion, blister serum, or the contents of an egg, into sterilised glass vessels without contact with any infecting agency. Preparations thus obtained are exhibited in these flasks; they are protected from air-dust by

a simple covering of cotton-wool. All of them are absolutely free from organisms and from any signs of decomposition.

What meaning can we attach to these preparations? You all know that liquids and mixtures such as these speedily decompose and swarm with organisms when left to themselves exposed to the air. They are of most varied composition, and the most apt of all known substances to breed bacteria and to become decomposed. They have been exposed to the most favourable conditions in regard to warmth, moisture, and air. Many of them have been in my possession several years, and all of them for several months, yet they are wholly barren and without sign of decomposition. I venture to say that these preparations substantiate in a positive manner the proposition with which we started—namely, *that organic matter has no inherent power of generating bacteria, and no inherent power of passing into decomposition.*

A second proposition is likewise established by these preparations—namely, *that bacteria are the actual agents of decomposition.*

In all the preparations, the absence of bacteria coincides with the absence of decomposition. If I were to cause bacteria to appear in them, either by purposive infection or by exposing them to the unfiltered air, decomposition would infallibly follow. The filtration experiments supply a new and telling argument on this point. Some of the liquids became decomposed and full of bacteria while the filtration was going on, but the part which came over into the flasks remained without further change, showing that decomposition cannot go on without the actual contact of the living organisms.

We have next to ask ourselves, What are the sources and what is the nature of the fecundating influence which causes organic liquids, when abandoned to themselves without protection, to become peopled with organisms? In regard to their source, the answer is not doubtful. If I remove the covering of cotton-wool from any of these preparations, and admit unfiltered air, or a few drops of any ordinary water, however pure, or anything that has been in contact with air or water, organisms make their appearance infallibly in a few hours. As to the nature of the infective agents, we can say positively that they must consist of solid particles, otherwise they could not be separated by filtration through cotton-wool and porous earthenware. Is it not a most natural inference that they are the parent germs of the brood which springs up at their impact? They are, however, so minute that we cannot identify them as such under the microscope; but Professor Tyndall has demonstrated that air which is optically pure—that is, air which is free from particles—has no fecundating power.

It is contended in some quarters that these particles are not living germs of any sort, but simply particles of albuminoid matter in a state of change which, when they fall into an organic liquid, communicate to it their own molecular movement, like particles of a soluble ferment, and so produce decomposition, which, in its turn, provides the conditions necessary for the abiogenic generation of bacteria. Filtration through porous earthenware furnishes a complete answer to this theory, for I found on trial that the soluble ferments passed with ease through the porous earthenware. If, therefore, this theory were true, the filtered liquids, if already commencing to be decomposed, would go on decomposing, and would develope bacteria after filtration; but instead of that they remain unchanged and barren. We are absolutely driven to the conclusion that these particles are living germs; no other hypothesis squares in the least degree with the facts of the case.

We may formulate this conclusion in a third proposition as follows:—*The organisms which appear as if spontaneously in decomposing fluids owe their origin exclusively to parent germs derived from the surrounding media.*

But how, you will ask, has it been possible, in the face of this evidence, to maintain, with a show of success, the contrary opinion that bacteria can and do, exceptionally at least, and in certain media, arise spontaneously? This opinion is based on two undoubted facts, which, taken together, seem at first sight to stand in direct contradiction with the propositions I have enunciated. The first fact is that bacteria are invariably killed when exposed to a temperature of about 140° Fahr., or any higher temperature. The other fact is that certain liquids, such as neutralised hay-infusion and milk, often produce bacteria after having been boiled—sometimes after having been boiled for two or three hours—and when there was no possibility of subsequent infection. It seemed at first sight a fair inference from these two facts that the apparition of organisms in boiled liquids was due to spontaneous generation, or abiogenesis. It does seem difficult to believe that any living thing can survive a boiling heat for several hours—and yet such is undoubtedly the truth. When I published on this question in 1874, I advanced more than one line of proof which appeared conclusive that germinal particles of some sort did, under certain circumstances, survive a boiling heat; and that the instances referred to were examples of such survival, and not of a *de novo* generation. But I was not then able to explain the apparent contradiction involved in these experiments.

Since then, a new and surprising light has been thrown on this subject by the researches of Professor Cohn, of Breslau, and we are now in a position to offer a complete solution of the riddle. All the confusion has arisen from our having failed to distinguish between the growing organism and its seed or spore. You are all familiar with the immense difference in vital endurance between the seed and the growing plant. The same difference exists between a spore and its offspring. Some spores have an extraordinary power of resisting heat. Mr. Dallinger and Dr. Drysdale, in the course of their inquiries into the life-history of septic monads, demonstrated that while the living monads are killed by a heat of 140° Fahr., the spores of one variety, which are so minute that they cannot be seen, except in mass, by the highest powers of the microscope, are capable of germinating after being subjected to a heat of 300° Fahr. for ten minutes! If the spores of monads can resist this tremendous heat, there is no reason why the spores of bacteria should not be able to survive the feebler heat of boiling water. The development of bacteria in hay-infusion, after having been boiled continuously for several hours in hermetically sealed vessels, seemed to furnish the very strongest attainable evidence in favour of the abiogenic origin of these organisms; and yet, by a singular fatality, the investigations of Cohn have shown that this evidence, rightly interpreted, supplies a crowning argument against that view.

Cohn had the curiosity to examine the organisms which arose under these extraordinary circumstances. Did he find a new birth? On the contrary, he recognised a familiar form: none other than our old acquaintance the *Bacillus subtilis*. He followed it through all the stages of its development. It first appeared some twenty-four hours after the boiling, in the form of innumerable short moving rods. On the second day these rods shot out into long threads; on the third day there appeared on the threads, at perfectly regular intervals, strongly refractive oval bodies, which he identified as spores. Finally, the threads broke down and the spores were set free. In many hundred observations he saw this one organism and no other, and witnessed the successive stages of its development occurring with the constancy of a physical experiment.

Now, let me ask if this looks like an act of abiogenesis. The evolutionist demands, for the transformation of one organic type into its next descendant, myriads of generations, and I know not what lapse of ages. But here, if this be a case of abiogenesis, we see accomplished at one leap, in a single generation, and in seventy hours, not merely the bridging over of the gulf between the dead and the living, but the development of a specifically distinct organism, with definite form, dimensions, and mode of growth, and furnished with a complete provision for the reproduction of the species! I need scarcely say that such a feat would be, not only without parallel in the history of evolution, but would be wholly contradictory to that theory.

The only group of bacteria, so far as is known, which form spores are the *Bacilli;* and Cohn remarks that in all the various cases in which he had observed organisms to arise in boiled liquids, they belonged in every instance to the *Bacilli*.

Before leaving this part of my subject, I wish to suggest certain considerations in regard to the nutrition and function of saprophytes, which appear to me to render it in the highest degree improbable that spontaneous generation should ever be discovered in this quarter. If it be assumed that the occurrence of abiogenesis, at some time in the past history of the globe, is a necessary postulate in science, then I see nothing unscientific—looking to the law of continuity in the operations of nature—in the supposition that it is occurring at the present day somewhere or other on the earth's surface, but certainly not in decomposing liquids.

Saprophytes are, as is well known, destitute of chlorophyll, and, like all such plants, they are unable to assimilate carbonic acid. They obtain their carbon exclusively from more complex compounds which have been prepared for them by pre-

existing living beings. It is, therefore, manifestly impossible that the primordial forms of life could have belonged to this group; for if we throw ourselves back in imagination to that remote era when life first appeared on the globe, we should find ourselves in a purely inorganic world—amid conditions in which saprophytes could not possibly life nor obtain nourishment. The special function of saprophytes in the order of nature is to destroy, not to create, organic matter; and they constitute the last, not the first, link in the biological chain. For if we regard the order of life as it now proceeds on the earth's surface, we may describe it as beginning with the chlorophyll body, and ending with the saprophyte. The chlorophyll body is the only known form of protoplasm which obtains all its nutriment from inorganic sources: here integration is at its maximum, and disintegration at its minimum, and the resultant of the nutritive operations is increase of organic matter. The saprophyte, on the contrary, feeds on nutriment prepared for it by other beings: here integration is at its minimum, and disintegration at its maximum, and the resultant of the nutritive process is decrease of organic matter. What takes place in a decomposing liquid, under the action of saprophytes, is progressive disintegration, and finally a breaking-up of all the organic compounds it contains into carbonic acid and ammonia; and the process ends with the mutual destruction of the organisms themselves. Organisms could not, therefore, begin in this way. The primordial protoplasm must have been either the chlorophyll body itself, or a body having a similar mode of nutrition.

If the search for contemporary abiogenesis is to be continued—as doubtless it must be, for science is insatiable,—it appears to me that the inquirer should endeavour to realise the conditions under which abiogenesis must have occurred in the first instance. For, if the process be going on amongst us at this day, it may be assumed as probable that it still proceeds on the original lines laid down at the dawn of life. If ever I should be privileged to witness an abiogenic birth, I should certainly not expect to see a saprophyte: I should rather expect to see a speck of protoplasm slowly formed, without definite shape or dimensions, and nourishing itself, like the chlorophyll body, on a purely mineral diet. The more one reflects on this subject, the more clearly does it appear that the spontaneous origin of saprophytes is logically impossible. Speaking as an evolutionist, I should rather infer that saprophytes were a late development—probably a degradation from some algal forms which had found their profit in feeding on waste organic matter, and which gradually lost their chlorophyll through want of use, and with it their power of feeding on an exclusively mineral diet.

We now approach the more practical side of our subject—that which concerns us as practitioners of medicine and students of pathology. I have already directed your attention to the analogy between the action of an organised ferment and a contagious fever. The analogy is probably real, in so far at least that it leads us to the inference that contagium, like a ferment, is something that is alive. We know of nothing in all our experience that exhibits the phenomena of growth and self-propagation except a thing possessed of life.

This living something can only be one of two things: either it is an independent organism (a parasite) multiplying within the body or on its surface, or it is a morbid cell or mass of protoplasm detached from the diseased body and engrafted on the healthy body. Possibly, both these conceptions may have their application in the explanation of different types of infective diseases. In regard to the latter conception, however (the graft theory), which has been so ably developed by my friend Dr. Ross, I will only say that it has not, as yet, emerged from the region of pure speculation. It lacks an established instance or prototype, and it fails to account for the long-enduring dormant vitality so characteristic of many contagia, which conforms so exactly with the persistent latent vitality of seeds or spores, but which contrasts strongly with the fugitive vitality of detached protoplasm.

If, then, the doctrine of a contagium vivum be true, we are almost forced to the conclusion that a contagium consists (at least, in the immense majority of cases) of an independent organism or parasite; and it is in this sense alone that I shall consider the doctrine.

It is no part of my purpose, even if I had the time, to give an account of the present state of knowledge on this question in regard to every contagious disease. My object is to establish the doctrine as a true doctrine; to produce evidence that it is undoubtedly true in regard to some infective inflammations and some contagious fevers. In an argument of this kind, it is of capital importance to get hold of an authentic instance; because it is more than probable—looking to the general analogy between them—that all infective diseases conform in some fashion to one fundamental type. If septic bacteria are the cause of septicæmia—if the spirilla are the cause of relapsing fever—if the *Bacillus anthracis* is the cause of splenic fever—the inference is almost irresistible that other analogous organisms are the cause of other infective inflammations and of other specific fevers.

I shall confine my observations to the three diseases just named—septicæmia, relapsing fever, and splenic fever; merely remarking that, in regard to vaccinia, small-pox, sheep-pox, diphtheria, erysipelas, and glanders, the virus of these has been proved to consist of minute particles having the character of micrococci; and that, in regard to typhus, scarlet fever, measles, and the rest of the contagious fevers, their connexion with pathogenic organisms is as yet a matter of pure inference. For further details I must refer you to the able reports of Dr. Braidwood and Mr. Vacher on the Life-History of Contagium, made on behalf of this Association, and published in the *Journal* in the course of the past and present years.

Septicæmia.—We will first inquire how it stands with this doctrine in regard to traumatic septicæmia and pyæmia. You are all aware that foul, ill-conditioned wounds are attended with severe, often fatal, symptoms, consisting essentially of fever of a remittent type, tending to run on to the formation of embolic inflammations and secondary abscesses.

The notion that septicæmia is produced by bacteria, and the *rationale* of the antiseptic treatment which is based thereupon, is founded on the following series of considerations:—

1. It is known that decomposing animal substances—blood, muscle, and pus—develope, at an early stage of the process, a virulent poison, which, when injected into the body of an animal, produces symptoms similar to those of clinical septicæmia. This poison is evidently not itself an organism; it is soluble, or at least diffusible, in water, and it is capable by appropriate means of being separated from the decomposing liquid and its contained organisms. When thus isolated, it behaves like any other chemical poison; its effects are proportionate to the dose, and it has not the least power of self-multiplication in the body. To this substance Dr. Burdon-Sanderson has given the appropriate name of pyrogen. It is the only known substance which produces a simple uncomplicated paroxysm of fever—begining with a rigor, followed by a rise of temperature, and ending (if the dose be not too large) in defervescence and recovery.

2. We know further, from the evidence I have laid before you, that decomposition cannot take place without bacteria, and that bacteria are never produced spontaneously, but originate invariably from germs derived from the surrounding media. We are warranted by analogy in regarding pyrogen as the product of a special fermentation taking place in decomposing albuminoid mixtures, but we cannot name the particular organism nor the particular albuminoid compound which are mutually engaged in the process.

3. In the third place, we know that when a wound becomes unhealthy, as surgeons term it, the discharges become offensive—in other words, decomposed,—and when examined under the microscope they are found to swarm with organisms resembling those found in all decomposing fluids. Meanwhile the patient becomes feverish, and suffers from the train of symptoms which we call septicæmia.

It is a natural inference that what takes place in decomposing blood or muscle in the laboratory, takes place also in the serous discharges and dead tissues of the wound. These become infected from the surrounding air, or from the water used in the dressings, with septic organisms; on that follows decomposition and the production of the septic poison, or pyrogen; the poison is absorbed into the blood, and septicæmia ensues.

It was the distinguished merit of Lister to perceive that these considerations pointed to a means of preventing septicæmia. He argued that if you could prevent the access of septic organisms to the wound, or destroy them there, you would prevent decomposition, prevent the production of the septic poison, and thus obviate the danger of septicæmia. It is not within the scope of this Address to describe the means by which Lister attained this object, still less to pass

judgment on his practice, but I may be permitted to express my belief that the principle on which the treatment is founded is unassailable.

We should probably differ less about the antiseptic treatment if we took a broader view of its principle. We are apt to confound the principle of the treatment with Lister's method of carrying it out. The essence of the principle, it appears to me, is not exactly to protect the wound from the septic organisms, but *to defend the patient against the septic poison*. Defined in this way, I believe that every successful method of treating wounds will be found to conform to the antiseptic principle, and that herein lies the secret of the favourable results of modes of treatment which at first sight appear to be in contradiction to the antiseptic principle. Take, for example, the open method of treating wounds, which is sometimes compared in its results with Lister's method. What is this treatment but another way (only less ideally perfect than Lister's) of defending the patient against the septic poison? Because, if the surgeon succeeds in providing such free exit for the discharges that there is no lodgment of them in the wound, either they pass out of it before there is time for the production of the septic poison, or, if any be produced, it escapes so quickly that there is not enough absorbed to provoke an appreciable toxic effect.

Before we can understand the pathology of septicæmia, we must have clear ideas on the relation of septic bacteria to our bodies. We see in our laboratories that dead animal tissues, when exposed to ordinary air or ordinary water, invariably breed septic organisms; in other words, contact of the septic germs with the dead tissues never fails to produce successful septic inoculation. But it is quite otherwise with the same tissues when alive and forming part of our bodies. You cannot successfully inoculate the healthy tissues with septic bacteria. It has been proved over and over again that these organisms, when separated from the decomposing medium in which they grow, can be injected in quantity into the blood or tissues of a healthy animal, or applied to a sore on its skin, without producing the least effect. The healthy living tissues are an unsuitable soil for them; they cannot grow in it; or, to put it in another way, ordinary septic bacteria are not parasitic on the living tissues.

This fact is of fundamental importance in the discussion of the pathology of septicæmia. We have a familiar illustration of its truth in the now common practice of subcutaneous injection. Every time you make a subcutaneous injection you inject septic germs into the tissues. I had the curiosity to test this point with the morphia solution used for this purpose in the Manchester Infirmary. I injected five drops of this solution into four flasks of sterilised beef-tea, which had remained unchanged in my room for several months, taking care to avoid any other source of contamination. In forty-eight hours they were all in full putrefaction. But we know that no such effect follows when similar injections are made into the bodies of our patients.

It seems also probable that septic organisms enter constantly into our bodies with the air we breathe and the food we take; they pass, presumably, like any other minute particles, through the open mouths of the lymphatics and lacteals, and penetrate some distance into these channels; they certainly come in contact with the accidental cuts, sores, and scratches which so often bedeck our skins. Notwithstanding all this, our bodies do not decompose; indeed, if ordinary septic organisms could breed in the living tissues as they do in the same tissues when dead, animal life would be impossible—every living creature would infallibly perish. How these organisms are disposed of when they do enter our bodies accidentally, as it were, in the various ways I have suggested, we cannot say; we can only suppose that they must speedily perish, for we find no traces of them in the healthy blood and healthy tissues.(a)

Bearing in mind, then, that ordinary septic organisms cannot breed in the living tissues, unless, at least, they are reduced to near the moribund state; bearing also in mind that there is a sharp distinction to be drawn between the septic poison and the organisms which generate it, we are in a better position to consider the course of events in a wound which leads on to septicæmia and pyæmia. What probably takes place is this. An unprotected wound receives infection from the septic organisms of the surrounding media. If the discharges are retained in the sinuosities of the wound, decomposition of them sets in with production of the septic poison. This is absorbed into the blood, a toxic effect follows, and septicæmia is established. As this effect increases with the continuous absorption of the poison, the vitality of the system is progressively lowered, and especially the vitality of the tissues bordering the wound, which may be topically affected by the poison which percolates through them. These tissues at length become moribund or die outright; the septic organisms then invade and breed in them, more septic poison is produced and absorbed; the toxæmia becomes intense, embolic centres of inflammation and suppuration are formed, and the end comes. In all this history there is no necessity to assume, nor even a probability, that septic organisms invade, or at least multiply in, the blood. They may do so at the near approach of death, but scarcely before that period.

In the course of traumatic septicæmia there sometimes occurs an event of great importance which imparts a new feature to the disease: I mean *infectiveness*. How this arises is a matter of speculation. To me it appears probable that, under a certain concurrence of conditions in and about the wound, a modification takes place in the vital endowments of the septic organism, whereby it acquires a parasitic habit, which enables it to breed in tissues of degraded vitality, or even in the healthy tissues, and in this way to produce the infective endemic pyæmia which we sometimes witness in the wards of our large hospitals.(b) I shall develope this idea more fully by-and-by.

Before leaving the subject of septicæmia, I may allude to the possibility of wounds being infected with septic organisms from within. As a rare occurrence, I am inclined to think that this is possible, and that it may account for the occasional alleged infection of protected wounds. From an observation by Chauveau, it may be inferred that septic organisms, when injected directly into the blood, are able to survive for two or three days, although unable to breed there.(c) It is conceivable that occasionally a septic germ, entering the body in some of the ways which have been suggested, may escape destruction and pass into the blood, and lurk there awhile, and finding by chance some dead tissue or liquid within its reach, may multiply therein and produce septic effects. Such a contingency, if it ever occur, must be very rare, and would not appreciably detract from the value of the antiseptic mode of dressing wounds.

Relapsing Fever.—In 1872, Dr. Obermeier, of Berlin, discovered minute spiral organisms (spirilla) in the blood of patients suffering from relapsing fever. This discovery has been fully confirmed by subsequent observations. The organisms are found during the paroxysms; they disappear at the crisis; and are absent during the apyrexial periods.

The drawings represent the various appearances presented by these little parasites. They consist of spiral fibrils of the most extreme tenuity, varying in length from two to six times the breadth of a blood corpuscle. In the fresh state they move about actively in the blood. They have not been detected in any of the fluids or secretions of the body except the blood, nor in any other disease than relapsing fever. In form and botanical characters they are almost identical with the *Spirochaete plicatilis*, of Ehrenberg (*Spirillum* of Dujardin), a species of bacteria found in dirty water, and occasionally in the mucus of the mouth. Cohn designated the variety found in the blood *S. Obermeieri*, in honour of its discoverer.

In the beginning of the current year, Dr. Heydenreich,(d) of St. Petersburg, published an elaborate monograph on this subject, which, I think, goes far to reconcile the conflicting statements and opinions put forth by previous writers in regard to the connexion of the spirilla with relapsing fever. It is based on forty-six cases; these cases were studied with the most minute care; the blood was examined, and the temperature observed from two to six times each day. Altogether, over a thousand examinations of the blood were made.

Relapsing fever still prevails extensively in certain districts of Germany and Russia, but it is almost a forgotten disease

(a) Exception must apparently be made in regard to the tissues and organs in the immediate vicinity of the absorbent surfaces. Both Klebs and Burdon-Sanderson found that portions of the liver and kidneys removed from the body without extraneous contamination produced bacteria, contrasting in this respect with the blood and muscles.—*British Medical Journal*, February 13, 1875.

(b) Such a modification or "variation" might be correlated with a modification of the ferment action, whereby a more virulent septic poison is produced. Would not such a view explain the sudden intensification of the infecting virus which was found by Chauveau and Dr. Sanderson in their experiments on infective inflammations?

(c) *Comptes-Rendus*, 1873, page 1092.

(d) L. Heydenreich, "Ueber den Parasiten des Rückfallstyphus." Berlin, 1877. He gives a good *résumé* of the literature of the subject.

in this country; and probably the majority of those in this room have never seen a case. It will, therefore, not be amiss if I remind my hearers, and myself, of its principal features. It is a contagious epidemic fever, characterised by a sharp paroxysm of pyrexia, which lasts about a week, and ends with a severe critical sweating. This is succeeded by an intermission, also of about a week, during which the patient is apyrexial; then follows a second paroxysm, or relapse, which lasts four or five days, and ends, as before, in a critical sweating. Recovery usually follows the second paroxysm, but not unfrequently a third paroxysm occurs, and sometimes a fourth.

The paroxysms are occasionally broken by remissions or pseudo-crises; and the apyrexial periods are sometimes interrupted by slight temporary rises of temperature.

Bearing these characteristics in mind, we shall be able to understand the significance of Heydenreich's observations. He found that every rise of temperature, whether that of the true paroxysm, or that following a pseudo-crisis, or those occurring during the intermissions, was invariably preceded by the appearance of spirilla in the blood. They disappeared entirely shortly before the crisis, and remained absent during defervescence and the subsequent apyrexial periods. During the whole of the main paroxysms spirilla were usually to be found in the blood, but their number varied in the most puzzling manner from day to day. One day they were abundant, the next day they were scanty, and the day after again abundant; they even varied at different hours of the same day; sometimes they vanished altogether for a time, and then reappeared in vast numbers a few hours later. Throughout these variations the temperature remained steadily high, or with only slight or moderate oscillations.

These discrepancies had been observed by previous inquirers, and had led some to doubt whether the spirilla had anything to do with the virus of relapsing fever; but a happy idea suggested itself to Heydenreich which seems capable of explaining them.

He found that when a little blood containing spirilla was abstracted from the patient and kept at the ordinary temperature of the room, the organisms lived in it for several days; but if the blood was placed in an incubator and maintained at the normal temperature of the body, they died in from twelve to twenty hours; and if the temperature was kept up to feverheat (104° Fahr.) their life was still shorter—they only survived from four to twelve hours. This led him to the conjecture that, during the main paroxysm, not one, but several successive generations of spirilla were born and died before their final disappearance at the crisis. He surmised that, in the usual course, the broods would overlap each other more or less, the new brood making its appearance before the last survivors of the old brood had passed away. This explained the variable number of spirilla found on different days and different hours of the same day. Sometimes the old brood would have altogether perished before the new brood reached maturity; this explained the occasional temporary absence of spirilla from the blood; it also explained the remissions, or pseudo-crises, sometimes observed in the course of the paroxysms. So precise was the correspondence found to be between the appearance of the spirilla and a subsequent rise of temperature, that Heydenreich was able to predict with certainty, during the apyrexial periods, the approaching advent of a transient rise of temperature from the re-appearance of spirilla in the blood, although at the time the patient presented no other indication of what was about to happen.

If these observations are to be relied on—and they appear to have been made with the most scrupulous care—we are led to the conclusion that the spirilla are the actual virus of relapsing fever.

The same conclusion is also strongly indicated by the results of inoculation experiments. Relapsing fever is easily communicated to a healthy person by inoculation with the blood of a patient suffering from the disease. Experiments made in Russia on individuals who voluntarily submitted themselves to this practice, show that the blood is only infective during the paroxysms, but not at the crises nor during the apyrexial periods. None of the fluids or secretions of the body except the blood are infective. All this shows that the virus is intimately associated with the spirilla, and is absent or present in exactly the same circumstances as the latter.(e)

(e) See a paper by Motschutoffsky, in the *Centralblatt für die Medicinischen Wissenschaften*, 1876, p. 193. During the paroxysm the blood was infective, whether spirilla were detected in it or not. This agrees with Heydenreich's theory, that their occasional apparent absence during the paroxysm is due to their being incompletely developed, or immature, and therefore unrecognisable under the microscope.

The occasionally observed vanishing and reappearance of the spirilla during the paroxysm, without a possibility of new infection, seems to indicate that when the spirilla disappear they leave behind them something in the nature of seed or spores, from which the new brood springs forth. Ocular evidence of such germs is, however, still wanting. Several observers have noticed minute particles in the blood of relapsing fever which might pass for spores, and Heydenreich observed that some of the spirilla had a dotted appearance. But hitherto all efforts to cultivate the spores out of the body have failed, and their power of developing spores is more an inference than a demonstration.

Splenic Fever.—The first trustworthy observation of the presence of organic forms in an infective disease was made in splenic fever. This formidable disorder attacks sheep, cows, and horses, and is not unfrequently fatal to man. In 1855, Pollender discovered minute staff-shaped bacteria in the blood of splenic fever. This discovery was confirmed in a very extensive series of researches by Brauell, and has been corroborated by Davaine and other inquirers in France.

The bacterium of splenic fever is a short, straight, motionless rod, about as long as the breadth of a blood corpuscle, and, so far as is known, it exists in no other form in the living body. It is found, besides the blood, in the spleen, in the lymphatic glands, and in some other tissues. That this organism is the true virus of splenic fever has long been probable; and the labours of Davaine, Bollinger, Tiegel, Klebs, and, most of all, of Koch, have removed the last doubts on the subject. The work done by Koch is not only valuable as a triumphant demonstration of a disputed pathological question, but is noteworthy as a model of patient, ingenious, and exact pathological research.

We here come across an example of scientific prescience on the part of two distinguished men which is worth notice. It had been remarked by several observers that the contagium of splenic fever, as it existed in the blood, was comparatively short-lived and fugitive, but that, under some unexplained circumstances, the contagium was very persistent, and lurked for years in stables and other places where cattle were kept. Dr. Burdon-Sanderson, writing in 1874, inferred from this circumstance that the organisms of splenic fever must have two states of existence; namely, that of the perishable bacteria found in the blood, and some other more permanent form, like seeds or spores, in which they were capable of surviving for an indefinite period. In like manner, Professor Cohn, guided by the botanical characters of the rods found in the blood, classed them in that group of bacteria named by him *Bacillus;* and, as he had observed that all the *Bacilli* produced spores, he inferred that the *Bacillus anthracis*—for so he named the bacterium of splenic fever—would also be found to produce spores. These previsions were proved by the researches of Koch to be perfectly exact.

The following is a brief abstract of those points in these researches which chiefly concern us:—

Koch found that mice were peculiarly susceptible to the virus of splenic fever. The minutest particle of the fresh blood or spleen of an infected animal infallibly produced the disease when brought into contact with the living tissue of the mouse. He found further that he could cultivate the organism artificially outside the body. He proceeded in the following manner. He placed a speck of the spleen containing the rods on a glass slide in a drop of the blood-serum of the ox, or a drop of the aqueous humour of the eye of the same animal, and covered it with a piece of thin glass. He then placed the slide in an incubator maintained constantly at the temperature of the body, and examined the preparation from time to time under the microscope. In a couple of hours he observed that the rods began to lengthen, and in a few hours to grow into long threads. These threads, after growing to twenty or a hundred times the length of the original rods, began by-and-by to assume a dotted appearance. The dots gradually increased in size and distinctness, until, after the lapse of fifteen or twenty hours from the beginning of the experiment, they acquired the appearance of strongly refractive oval bodies, which were placed at regular intervals along the threads. Finally, the threads broke down, and the oval bodies, which could be nothing else than spores, were set free and sank to the more depending parts of the drop. If the supply of nutriment were then exhausted, the process ended here, and the spores remained permanently unchanged; but, if additional nourishment were provided, the new spores were seen presently to elongate into rods, exactly resembling those originally existing in the blood or spleen. If

the conditions were favourable, the new rods, after a period of rapid multiplication, in their turn entered on the formation of a new generation of threads and a new generation of spores. The figure shown represents the successive phases of this short and simple, but perfectly definite, life-history as they were actually seen to occur under the lens of the microscope.

The next point was to test the pathogenic activity of the rods and spores cultivated in this artificial manner. This was done by introducing minute quantities of the rods, or of the spores alone, into a small incision made in the skin of a mouse. Speedy death from splenic fever occurred in every instance. Koch found, without exception, that, if the tested material produced threads and spores in the incubator, it also produced splenic fever when inoculated into the mouse; and, on the contrary, if no such growth and development took place in the incubator, the tested material produced no effect when inoculated into the mouse. Proof could go no further: the infection absolutely followed the specific organism; it came with it, it went with it. These observations were repeated with the strictest precautions at the Physiological Institute at Breslau, under the eyes of Professor Cohn and other competent observers, who fully corroborated their exactness.

The variable duration of the activity of the contagium of splenic fever was now explained. Koch found that the rods had only a comparatively fugitive vitality; they lost their infective power generally in a few days; at the most, in about five weeks. But the spores retained their infective activity for an indefinite period, in spite of all kinds of maltreatment. They could be reduced to dust, wetted and dried repeatedly, kept in putrefying liquids for weeks, and yet, at the end of four years, they still displayed an undiminished virulence.

Cohn calls attention to the fact that the organism of splenic fever is identical in form and development with the *B. subtilis*. The only difference he could detect between them was, that the rods of *B. anthracis* are motionless, while those of *B. subtilis* exhibit movements. The figures you see before you might be indifferently labelled *B. subtilis* or *B. anthracis*, and yet one of these organisms is a harmless saprophyte, and the other a deadly contagium. We have likewise seen that the spirilla of splenic fever are morphologically similar with the *Spirochaete plicatilis*. We have further seen that there is ground for the assumption that the infective agent in contagious septicæmia is the common bacterium of putrefaction, but modified in such a way as to have become endowed with a heightened capacity for growing in the healthy tissues. Do not these remarkable coincidences point to a natural explanation of the origin of contagia? If contagia are organisms, they must necessarily possess the fundamental tendencies and attributes of all organised beings. Among the most important of these attributes is the capacity for "variation" or "sporting." This capacity is an essential link in the theory of evolution; and Darwin brings forward strong grounds for the belief that variation in plants and animals is not the result of chance or caprice, but is the definite effect of definite (though often quite obscure) causes. I see no more difficulty in believing that the *B. anthracis* is a sport from the *B. subtilis* than in believing, as all botanists tells us, that the bitter almond is a sport from the sweet almond—the one a bland, innocuous fruit, and the other containing the elements of a deadly poison.

The laws of variation seem to apply in a curiously exact manner to many of the phenomena of contagious diseases. One of these laws is the tendency of a variation, once produced, to become permanent and to be transmitted ever after with perfect exactness from parent to offspring; another and controlling law is the tendency of a variation, after persisting a certain time, to revert once more (under altered conditions) to the original type. The sporting of the nectarine from the peach is known to many horticulturists. A peach-tree, after producing thousands and thousands of peach-buds, will, as a rare event and at rare intervals, produce a bud and branch which ever after bear only nectarines; and, conversely, a nectarine at long intervals, and as a rare event, will produce a branch which bears only peaches ever after. Does not this remind us of the occasional apparent sporting of diphtheria from scarlet fever? My friend Dr. Ransome, who has paid so much attention to the laws governing the spread of epidemics, relates the following instance:—A general outbreak of scarlet fever occurred at a large public school. One of the masters who took the infection exhibited diphtheritic patches on the throat. This patient was sent to his own home in Bowdon. Six days after his arrival, his mother was attacked, not with scarlet fever, but with diphtheria; though there were no cases of diphtheria at the time, neither at the school nor in Bowdon.(f)

Take another illustration. Cholera suddenly breaks out in some remote district in India, and spreads from that centre over half the globe. In three or four seasons the epidemic dies away, and ceases altogether from among men. A few years later it reappears and spreads again, and disappears as before. Does not this look as if the cholera virus were an occasional sport from some Indian saprophyte, which by variation has acquired a parasitic habit, and, having run through countless generations, either dies out or reverts again to its original type? Similarly, typhoid fever might be explained as due to a variation from some common saprophyte of our stagnant pools or sewers, which, under certain conditions of its own surroundings, or certain conditions within the human body, acquires a parasitic habit. Having acquired this habit, it becomes a contagious virus, which is transmitted with its new habit through a certain number of generations; but finally, these conditions ceasing, it reverts again to its original non-parasitic type.

In regard to some contagia, such as small-pox and scarlet fever, it might be said that the variation was a very rare one, but also a very permanent one, with little or no tendency to reversion; while others, like erysipelas and typhoid fever, were frequent sports, with a more decided tendency to reversion to the original type. In regard to some pathogenic organisms, it might be assumed that the parent type had disappeared, and the parasitic variety only remained—just as the wild parents of many of our cultivated flowers and vegetables have disappeared, leaving behind them only their altered descendants.

How aptly, too, this view explains what used to be called the "epidemic constitution," and the hybrid forms and sub-varieties of eruptive and other fevers.

I must not pursue this vein further. I have said enough to indicate that this conception enables us—if it does nothing else—to have coherent ideas about the origin and the spread of zymotic diseases.

In applying the doctrine of pathogenic organisms—or *pathophytes*, as they might be termed—to the explanation of the phenomena of infective diseases, we must be on our guard against hard-and-fast lines of interpretation. So far as our very limited knowledge now extends, the pathophytes hitherto discovered all belong to that group of the fungi which are called bacteria. Now, fungi have two marked characteristics—namely, the tendency to assume the parasitic habit, and the possession by some of them of a special ferment action. Both these characteristics may bear a part in the action of pathogenic organisms. In the complex phenomena of septicæmia such would appear to be the case—a poisonous ferment-product first intoxicates the system, and then the organisms themselves prey upon the dead or moribund tissues.

There is, as Dr. B. Sanderson has pointed out, a marked distinction to be drawn between those common processes of infective inflammation which are shared in by animals generally—such as septo-pyæmia, erysipelas, and the diphtheritic process—and those specific contagia which are strictly confined, like ordinary parasites, to particular species. There is nothing in all nature more wonderful than the intimate and subtle nexus which unites a parasite to its host. A hundred examples might be given. Even different varieties or races of the same species have different and exclusive parasites. It would seem as if this nexus depended on some delicate shade—a *nuance*—something like an odour, or a savour, or a colour, rather than on differences of structure or chemical composition. The same minute correlation is seen in specific contagia—all are strictly confined to one or a few species. Vaccinia is confined to man, the horse, and the cow; scarlet fever is confined to man, and perhaps the swine; most of our specific diseases are absolutely confined to man. The human and ovine small-pox, although so wonderfully similar, are not intercommunicable. I am, therefore, inclined to believe that, in regard to specific contagia, we shall find more guiding analogies in parasitism than in fermentation. Our information at present is, however, so defective that it is not wise to enter into further speculations on this subject.

Gentlemen, I have brought my task to a conclusion. I believe that the doctrine of a contagium vivum is established on a solid foundation; and that the principle it involves, if

(f) Complex cases of mingled scarlet fever and diphtheria are sometimes seen. Similarly, the peach-tree will occasionally, among a multitude of ordinary fruit, produce one fruit of which one half has the peach character, and the other half the nectarine character.—*Darwin.*

firmly grasped in capable hands, will prove a powerful instrument of future discoveries. And let no man doubt that such discoveries will lead to incalculable benefits to the human race: our business in life is to do battle with disease, and we may rest assured that the more we know of our enemy the more successfully we shall be able to combat him.

ADDRESS IN SURGERY.

By T. SPENCER WELLS, F.R.C.S.,
Surgeon to the Queen's Household, etc.

Mr. President and Gentlemen,—When I received from the President of the Council of this great Association the unanimous request of the Committee of Council that I would deliver this Address, and was further assured that I was thus invited at the suggestion of a deputation from Manchester, I felt that any hesitation on my part might appear ungrateful, or as if I did not appreciate a great honour. So, without wasting your time by apologies, and simply thanking you for the exceeding kindness of your greeting to-day, I will ask you to consider with me how as an Association, how in each of our branches, how, individually as well as collectively, every one of us may assist in the advancement of the

Surgery of the Future;

how the art and science of the present, which we have received from our forefathers and our teachers, and as far as we could have improved, may be so handed down that our followers, taught by our success, warned by our failures, knowing where our knowledge is defective, our methods faulty, may so work and so observe that in each succeeding year surgery may become more perfect as an art, more exact as a science, and more honourable as a profession.

It is almost impossible to estimate the state of surgery of the present day, still more so to look forward to what surgery may become, without some review of its condition long ago and of the progress made during the existence of this Association.

It is one of the remarkable coincidences of English history that the reigns, nearly equal in duration, of the two Queens, Elizabeth and Victoria, have been the two ages most distinguished by the rapidity and extent of national development. Elizabeth mounted the throne after the death of her sister Mary, accelerated by disappointment at the termination of supposed pregnancy in dropsy, which was no doubt ovarian, and treated according to ignorant routine by successive bleedings. Treated with the knowledge now at command, the destinies of England might have been strangely altered. Elizabeth reigned forty-five years, and in her time, surgery, though already chartered as a profession, was neither an art nor a science. For the most part it was carried on as a trade, after the fashion of the country farriers of our day. Indeed, it was unanimously agreed by the Queen's Commissioners that it was unlawful for surgeons to administer internal remedies even in cases of wounds. "Bookes of Chirurgerie" were collections of sayings and nostrums. Life was rude, living was unwholesome, and death came early. The people perished by scurvy and sweating sickness; they were killed or scarred by small-pox; their blood was poor, and the barbers bled them. Fighting-men began to suffer from gunshot wounds, and their blood, gushing from arteries cut in hacking amputations, was staunched by "chokebands," by boiling pitch, or by hot irons. The first impulse towards improvement came from Ambrose Paré. But men long looked suspiciously on his new practice of tying blood-vessels in amputations. And so as an art, surgery—an exception to the general progress—stood almost still, even long after Harvey's great discovery, and scarcely any important advance, beyond such manual dexterity as that of Cheselden, was made until the time of Hunter. His noble work is thus epigrammatically acknowledged by the philosophical Malgaigne:—"Surgery, which in the middle ages scarcely ranked above a common trade, and grew to be honoured as an art in the hands of Paré and Petit, was raised by Hunter to the dignity of a science." What it has become since, and is now, we may perhaps best see by rapidly tracing its development parallel with the history of our Association, which may almost be said to be the offspring of the age of Victoria.

Before this Association was founded, the daily practice of surgery was guided by a knowledge of what Hunter and Scarpa had done as to the ligature of arterial trunks. Resection of joints had been frequently, though not commonly, performed. Bell's teachings of the different nerve-functions had been universally accepted. Auscultation and percussion had been gradually perfecting diagnosis among those who were then about entering into practice. The vegetable alkaloids were beginning to take the place of the coarser materials previously used as remedies. Almost coincidently with the formation of this Society, in 1832, there began to be spoken about vaguely, and as curiosities, things which are now so universally practised that probably very few of those who listen to me recollect how very recently they have been accepted as part and parcel of surgical practice. I am not one of the oldest here, but I can well remember when lithotrity was a novelty, when the subcutaneous section of tendons was absolutely new, when orthopædic surgery was unknown, when the torsion of arteries was spoken of as a barely possible substitute for the ligature, when the radical cure of hernia was scoffed at as a French delusion, when the treatment of aneurism by compression had hardly even entered into the professional imagination, and the study of uterine pathology was only just opened up by the introduction of the speculum as a means of investigating the condition of the mouth and neck of the uterus.

In 1832, when it was resolved to form this Association, and at the succeeding meetings in 1833 and 1834, all these things were new, and almost untried. In 1835, at Oxford, Costello publicly demonstrated lithotrity as a novelty before the assembled members; and I think we may fairly date the establishment of that operation, now so carefully and generally practised by so many of our associates, from that meeting.

In 1836 the Association met for the first time at Manchester. Crosse, of Norwich, was the first surgeon to give a retrospective address. In it he mentions as a recent discovery that of the trichina spiralis by Owen. He makes the first notice of the chloride of zinc in cancer, and doubtingly hopes that the use of the speculum even in this country may become general. He states that in this year there is the first known example in Great Britain in which both mother and child were saved by the Cæsarian operation, done by Knowles of Birmingham.

And here for a moment let me ask you to recall to mind the man who forty years ago was speaking to the Association as I now speak, not with his power, but to an audience enormously increased in numbers and influence. Crosse lived till 1850. I did not know him personally, but friends of mine who did speak of him as a man upright in character, earnest, natural, joyous, communicative, a fellow-worker with his pupils, of intense and untiring energy, priding himself upon gaining a most exact information of the progress of surgery, self-reliant, rapid in judgment, ready in action, calm and dexterous as an operator, yet with a strong conservative tendency as regards the knife, and most scrupulous in his attention to even the minutest details in the management of his cases. A clear and accurate writer, an industrious contributor to periodical literature, the good he did lives after him, especially in the impetus which he gave to the study of the direction, sanitary condition, and improvement of hospitals.

After Crosse, the next retrospective Surgical Address was by James, of Exeter, in 1839. In this he alludes, as a great novelty, to the fact that a member of our Association, Jeaffreson, of Framlingham, had successfully extirpated an ovarian cyst through a small incision; and also mentions that King, of Saxmundham, had repeated the operation on another patient with an equally good result. In 1840, at Southampton, Dodd, of Chichester, in the Address on Surgery, gives an account of the recent experience of Dieffenbach and Liston in operating for strabismus as something new, and reports that lithotrity does not seem to make any great advance in the favour of the profession in this country; and in 1843, at Leeds, William Hey said that "the rage for dividing muscles and tendons is somewhat moderated." In his own words, "the past year has been signalised by the successful performance of several operations for the removal of ovarian tumours from the abdomen. Dr. Clay, of Manchester, has recorded five cases, of which three were successful, and Mr. Walne, of London, one successful case." The William Hey who gave this Address on Surgery was the third in the line of the great family, the head of whom was president of the meeting. Owing to his advanced age, the general address was read for him, and he died in the course of the following year. As a pupil of the Leeds Infirmary forty years ago, I well remember the careful teaching and painstaking kindness of William Hey, jun., as he was then called. The name of Hey stood almost as high in Yorkshire

as those of Abernethy and Cooper in London, and one of the family, Richard, grandson of the president, and for many years Surgeon to the York County Hospital, almost simultaneously with Abernethy tied with success the common iliac artery for external iliac aneurism. The surgeoncy of the Leeds Infirmary has been held in the same name for 106 years, and descendants of the third and fourth generation are members of the present staff. Worthy representatives of the great family to which they belong, they still maintain the high reputation of the surgery of the North. Another well-known member of a noted family of Yorkshire surgeons, Thomas Pridgin Teale, read the Address at Sheffield in 1845. He alludes to the treatment of aneurism by compression, as indicating a great advance in the science of surgery. He notices Key's modification of herniotomy by dividing the stricture outside the sac as gradually assuming the position in the estimation of the profession to which it is entitled.

We now come to what will ever be looked on in future time as the commencement of a new era in surgery. In 1847, at Derby, Walshe, of Worcester, introduces for the first time the subject of anæsthesia, Crosse remarking that the inhalation of sulphuric ether was a subject of deep importance and great novelty. Your hourly familiarity with the use of anæsthetics of various kinds will make it difficult for you to realise the fact that it is only thirty years since Crosse spoke before this Association of the inhalation of ether chiefly as a means of disarming *a patient of his antagonism*. The first considerable essay on anæsthesia, and anæsthetic substances generally, was published in our transactions in the following year by Nunneley of Leeds. That was in 1848, and in the same year, at Bath, chloroform was for the first time publicly mentioned before this Association. In a review of the history of surgery in the reigns of Elizabeth and Victoria, there is no brighter page than that which records the discovery of anæsthetics, and not one in which the contrast is more strikingly in favour of the practice of our day. Anæsthesia in midwifery met with more opposition than in surgery, and there must be many here who know well how much was done by the personal example of our own Queen towards allaying groundless fears and disarming irrational prejudice. National vanity may be more flattered by some public deeds of Royal devotion; but I cannot call to mind a stronger proof of moral courage, of wiser consideration for the interests of her subjects, nor any act which, in the personal relations of the Queen to her people, demands more respectful recognition from the profession, or has a stronger claim on national gratitude.

In 1854 the Association met for the second time at Manchester—its twenty-second anniversary meeting. Instead of 7000 members as now, there were but little more than 2000. Instead of the large attendance so hospitably welcomed this week, only 202 members attended.

The Surgical Address in 1856 at Birmingham, by Langston Parker, should be remembered as a judicial summary of what was known of the treatment of cancer by caustics.

In 1857, at Nottingham, your Manchester Southam read the Address on Surgery, limiting himself to the subject of cancer and its treatment. Many of you knew Southam better than I did, but sitting with him in the Council of the College of Surgeons, and joining in the friendly gatherings which follow some of those meetings, I learnt to appreciate his sterling straightforward honesty, his kind genial character, and his ardent love for our profession and its work. And I can fully endorse all that was said of him by Sir James Paget in his obituary notice of the deceased Fellows of the Medico-Chirurgical Society, and acknowledge with extreme interest all that Sir James said as to Southam's services in the early days of ovariotomy in England.

Passing on to the Edinburgh meeting in 1858, it was then that we heard for the first time of local anæsthesia. Here also the subcutaneous injection of narcotics was brought under notice by Alexander Wood, who stated that even then the practice, although but lately introduced, was becoming general in Edinburgh. And recent improvements in the treatment of vesico-vaginal fistula were described to the Association by Mr. Baker Brown. Sims's speculum and wire sutures were then unfamiliar: though they are now acknowledged to rank among the chief of the improvements for which we are indebted to our American brethren. Baker Brown was one of the first to adopt, and afterwards to modify, the proceedings of Sims. Brown had previously done good service by demonstrating the mode of curing old ruptures of the perineum, and his example undoubtedly assisted in the improvement of this department of surgery. As an operator he was almost perfect, and he was one of the earliest London surgeons to practise ovariotomy. Many years afterwards he extended the use of the cautery-clamp (employed by Clay, of Birmingham, to divide adhesions and stop bleeding from omental vessels) as a mode of separating and securing the pedicle. May I be excused if I venture to remind you that in 1861, at the Canterbury meeting, I brought before the Association a paper on the treatment of ovarian cysts which others have said had some influence in directing professional attention to an improved method of performing ovariotomy, and to the selection of cases for the operation, and other modes of treatment?

The first meeting of the Association in London—1862, its thirtieth anniversary—was rendered memorable by the Surgical Address of Paget. He spoke of the management of patients after surgical operations, and urged upon us all the study of the large group of diseases classed under the name of pyæmia, their origin, multiform nature, and mode of prevention. Read the lecture; it is a surgical classic, an eloquent but despairing cry from a great surgeon who feels the "deep regrets, the bitter disappointments from which we might be saved if there were less risk" after many of the operations done to save life, and who shudders at the "tolerated barbarisms of practice," only justified by the belief that the risk of "a cutting operation is so great that there is nothing too bad to be substituted for it," and who can find but one thing that he can call remedial for the whole disease pyæmia, and that is, a profuse supply of fresh air—"wind blowing all about the rooms." In his concluding remarks the orator impressed us all by his appeal to lessen the number of preventable deaths after great operations, insisting that the mortality "will be reduced if the members of this Association will decide that it shall be, and will act vigorously on their decision."

Deeply sympathising with this desire to remove all possible sources of excessive mortality after surgical operations, I brought the subject again before the Association at the Cambridge meeting in 1864. Feeling that something more than an abundant supply of fresh air was wanted, and knowing that with the air might enter unsuspected sources of danger to the patient through his wound, I directed attention to the researches of Pasteur upon the presence of infectious germs or organisms in the atmosphere, and to the demonstrations of Charcot and others of the impure particles in hospital wards, and showed how the development of low forms of animal and vegetable life was checked by the use of sulphur and the sulphites, as taught by Polli.

The Leamington meeting, in 1865, was distinguished by the Address of Syme, in which he reviews the progress of surgery during the previous forty years, alluding, among many other matters of interest, to the *new position* which the operations of Thomas Keith, and my own, had given to an operation previously regarded as remarkable for uncertainty of prognosis, difficulty of diagnosis, and danger of execution. Coming from such a man at that time, and on such an occasion, this judgment must have had considerable weight on professional opinion; and more than one writer has expressed his belief that by actually performing the operation on two patients in the following year, before the assembled Association at Chester, showing that it could be done and how it was done to a large number of practical surgeons, another step was gained in securing a more general admission of ovariotomy among the legitimate proceedings of surgery.

By this time the numbers of the members of the Association had greatly increased, the meetings were more numerously attended, and that at Dublin, in 1867, was reported as the largest known by several hundreds. There, as at Oxford in 1868, distinguished foreigners arrived among the visitors, surgical papers became more abundant, and the application of general science to surgery is more noticeable. Electricity, optics, acoustics, chemistry, had all contributed to the perfection of instruments facilitating more exact diagnosis. The ophthalmoscope, the otoscope, the laryngoscope, and the endoscope, all appear as familiar aids for exploration. The thermometer was in almost universal use, the sphygmograph still confined to the select few; the splanchnoscope or diaphanoscope then, as now, a curiosity. Microscopic parasites, animal and vegetable, were recognised in greater number, and were divided into orders, genera, and species. The infectious influence of hospital atmosphere was being more feared and more carefully guarded against; drainage was coming more into practice in the treatment of wounds, and as a preventive of local inflammation

and general fever after surgical operations. At the Leeds meeting, in 1869, the antiseptic treatment was brought before the Association by Nunneley, who ridiculed it as a professional error, and said that he believed "if stumps heal under such treatment they do so in spite of it." Remember, this was only eight years ago! Two years later, at Plymouth, in 1871, the Surgical Address was given by Lister mainly on this one subject, and exclusively as the result of his own observation and experience, but with the effect of giving an immediate stimulus to the spread of the antiseptic system at home and abroad.

The meetings in 1872 at Birmingham, and in 1873 in London, with the attendance largely increased, the work methodically arranged in sections, the papers more varied, the discussions more animated, the presence of the Prime Minister at the dinner, the more complete amalgamation of the metropolitan and the provincial members, had both their share in assisting in the advancement of the social position of the profession and the progress of surgery. At Norwich, in 1874, Mr. Cadge noted as recent improvements Esmarch's bloodless operations and the use of Dittel's elastic ligature. The germ theory of putrefaction and antiseptic surgery he looked at as subjects still waiting for solution.

At Edinburgh, in 1875, Lister's demonstrations and Spence's criticisms fairly brought all sides of the question under intelligent observation. Lister showed before large bodies of skilled and discriminating witnesses exactly what he did and how he did it, and with what results; while Spence, before the same assemblies, sharply criticised the work of his colleagues, and contended that as much could be done under similar conditions without antiseptic precautions. It is impossible to conceive a more satisfactory mode of completely discussing the principles of a new system of treatment than such a public trial before able and impartial judges, with the advocacy of an earnest, enthusiastic, scientific investigator and worker on the one hand, and on the other with the opposition of a cool and sceptical rival minutely criticising the accuracy of every assertion and the logical value of each inference. And here, in passing, let me beg you not to forget one chief, if not the chief, advantage of these meetings. The most animated controversy may be carried on in the warmest manner, the most opposite opinions may be entertained and supported, the keenest rivalry for the honours awaiting him who first seizes upon a new truth may be exercised in the arena of discussion without the slightest personal animosity, but rather with an increase of the feeling of good-fellowship and mutual respect brought about at the social gatherings, where men are either thrown together for the first time or ripen old acquaintance.

It is impossible to review

The Surgery of the Present Day

without observing the result upon it of the work of Simpson, Syme, and Fergusson, whose deaths followed each other in such rapid succession.

The association of Simpson's name with chloroform and the lessening of hospital mortality, with the attempt to "stamp out" infectious disease, with acupressure, with the uterine sound, and generally with the recently improved diagnosis and treatment of the diseases of women, need only be mentioned to be felt and acknowledged.

Syme's influence was rather that of a great teacher of clinical surgery, sending forth every year a large addition to the number of our profession, well grounded in the well-established principles of practice.

Fergusson, in the words of Paget, "the greatest master of the art, the greatest practical surgeon of our time," was the founder of the school which he, twenty-five years ago, first characterised by the happy term of Conservative Surgery—a term since become so familiar and so suggestive to the operating surgeon of care not to sacrifice limbs or parts which can possibly be saved, and never to risk life unnecessarily, that it has gradually developed a race of modern surgeons who, not content with performing operations in the best possible manner, pride themselves far more on the number of lives and limbs that they have preserved. Fergusson said, "No one can more thoroughly appreciate a well-performed amputation than I do, but I certainly appreciate more highly the operation which sets aside the necessity for that mutilation." Teaching all this as he did by example and precept for many years to large classes of young men, and to their seniors by his published writings and by lectures at the College of Surgeons, he has in a marked degree modified the character of the surgery of our age. The improvements which he introduced in lithotrity and in the cure of cleft-palate may be almost considered as typical of the school of modern conservative surgery, and will long be acknowledged as triumphs of British Surgery in the reign of Victoria. Of the man himself, so lately presiding at our meetings, so kind and friendly, the skilful surgeon, the beloved teacher, the wise and prudent counsellor, so lately lost to us almost everyone here still retains a vivid recollection; and his death is mourned as a loss to the Association which he adorned, and by a large number of our members as that of a dear friend.

And here, before quitting the progress of surgery in connexion with the growth of the Association, let me ask if anyone can doubt that the art and science of surgery have not advanced as much since the Elizabethan age as any other art or any other science, great as those advances may have been.

And in considering how that advance, as recent as it has been rapid, may be carried further on, let me first draw your attention for a moment to the subject of

Anæsthesia and Anæsthetics.

In 1872 I made known my opinion that all the advantages of complete anæsthesia, with fewer drawbacks, could be obtained by the use of bichloride of methyline or chloromethyl than by any other known anæsthetic. That was the result of an experience of five years, and of 350 serious operations. The experience of the five succeeding years, up to the present time, with more than 600 additional cases of ovariotomy, and many other cases of surgical operations, has fully confirmed me in this belief. Given properly diluted with air, the vapour of chloromethyl has, in my experience of ten years, with more than 1000 operations, of a nature unusually severe as tests of an anæsthetic, proved to be without a single exception applicable to every patient, perfectly certain to produce complete anæsthesia, relieving the surgeon from all alarm or even anxiety; and its use has never been followed by any dangerous symptom which could be fairly attributed to it. I wish I could speak as confidently of the chemical composition of the fluid sold as bichloride of methyline as I can of its anæsthetic properties. But whatever may be its chemical composition—whether it is or is not chloroform mixed with some spirit or ether, or whether it really is bichloride of methyline,—I am still content with the effects of the liquid sold under that name, when properly administered. The only deaths ever attributed to it were, I believe, rather due to asphyxia. No air was given with the methyline. By Junker's apparatus, air charged with methyline vapour is given—not the vapour itself,—and, so employed, it has always been, in my experience, both efficient and safe. I am sorry that some of the analytical chemists whom I have asked to clear up the question of its composition have not done so. It ought to be done, it can be done, and it must be done.

The Committee appointed in Edinburgh two years ago, reappointed last year in Sheffield, but which has never met until this morning, might very well undertake this task. Perhaps, as the Committee is a very large one, and is made up of members from Aberdeen, from Edinburgh, from Dublin, as well as from London, it is almost impossible for them to do what is required in the words of the resolution, namely, "to inquire into and report upon the use in surgery of various anæsthetic agents and mixtures of such agents, and to collect and summarise the evidence of British practitioners in surgery and medicine as to the relative advantages of chloroform, ether, nitrous oxide gas, and other agents, and to carry on suitable experimental investigations." It would appear to me far better to expend any sum devoted to this purpose by the Scientific Grants Committee—and this sum ought to be a sufficient one,—so as to encourage one really competent investigator to do the work thoroughly well, bearing the full responsibility, and taking the credit which is due to work well done. The valuable reports on the life-history of contagium, on the electric currents of the brain, and on the biliary secretion of the dog—which have already appeared in the *Journal*, and others of equal importance waiting for publication—are quite sufficient encouragement for us to extend the practice of entrusting original investigations to individuals, who should be as liberally remunerated as the funds of the Association will permit, rather than trusting to the uncertain or impossible conjoint action of honorary committees. Perhaps we are hardly aware how much the public expect from us in this matter. Deaths from chloroform are alarmingly frequent, yet no substitute for it has found universal or even general acceptance in this country; and I am not speaking too

strongly if I say it is the duty of the Association at once, without any unnecessary delay, to satisfy the public that all that is possible is being done to discover the means by which anæsthesia, effectual now, may be rendered safe for the future.

It is more than twenty years since I brought Wutzer's operation for the

Radical Cure of Reducible Hernia

to the notice of English surgeons. Wutzer's practice, afterwards modified by Rothmund, and the much more important change introduced and so successfully practised by Mr. Wood, of drawing firmly together the hernial apertures, so as to establish again the valve-like action of the inguinal canal, have hardly had the effect of generalising any of these procedures. For reducible hernia a truss, for strangulated hernia operation, are still the rule. I believe the time is coming when most cases of reducible hernia, at any rate those not completely secured by a truss, will be radically cured by the surgeons, if not of this generation, certainly of the next. In many cases of inguinal hernia in young persons, Wood's operation under antiseptics will become more general. But we have reason to hope that we may obliterate the hernial sac, close its abdominal orifice, and strengthen the abdominal wall by the use of insulated needles connected with the positive pole of the galvanic battery, causing shrinking and occlusion of the sac, while the alternate use externally of galvanisation and faradisation may assist in restoring tone to the weakened muscles. This is by no means the least of the many applications which may probably be made hereafter of

Electricity as a Therapeutic Agent

in surgical treatment.

In 1848 I directed attention to the use of a weak continuous electric current in the treatment of ulcers. Dr. Golding Bird presented the results of my experience to the readers of his well-known work. Although the results were striking, Mr. Nunn is almost the only surgeon who seems to have made much use of the information. But recently a son of Dr. Golding Bird has published some very important additions to our knowledge of this subject, and has most advantageously treated scrofulous lymphatic glands by a painless electrolytic caustic. When chloride of zinc is employed as an arrow or paste, or in any other way, the pain is very severe. But if formed electrically in the tissues of the living body, it acts in the nascent state as a caustic or destructive agent almost without pain. The albuminate of soda formed at the silver or electro-negative plate is probably inert, but the electric current certainly exerts some stimulating action, affects the capillary circulation, and so modifies reparative force as to quicken cicatrisation. In the electrolytic dispersion of tumours, caustic or destructive action at the positive pole, and the influence of the negative pole upon the vaso-motor nerves of the part, are both brought to bear. The more rapid action of the galvanic cautery upon nævus, or as a substitute for the knife, is already sufficiently appreciated; but the slower electrolytic action upon bronchocele, upon fibroid tumours, upon cancer in any of its forms, has yet to be worked out, and I hope that some of you who are now present will not fail to take advantage of so fair an opportunity of doing good and distinguishing yourselves.

You start under immense advantages. When I began to practise surgery, the only test of normal or fever heat was the sensation conveyed to the surgeon's hand. It is hardly more than twenty years since the coincidence of a rigor and high temperature was first satisfactorily proved. Now the most delicate self-registering thermometers are not only carried by every careful surgeon, but every well-trained nurse is taught to make and record as many daily observations as the nature of the case may require. The various forms of surgical fever, pyæmia, septicæmia, erysipelas, are in consequence far better known and more perfectly guarded against, while the ground is cleared for the study of their more successful treatment.

So with the pulse: everyone could count it, anyone could soon learn to distinguish a strong from a feeble pulse, a hard from a soft pulse, a pulse easily compressed from one that was incompressible, a regular from an intermitting beat; but to obtain a trustworthy and exact measure of arterial tension and the influence of treatment upon it, we must have the tracings of the sphygmograph. We are learning from its use after operations that the sthenic pulse with high arterial tension is an important guide for treatment, while the dicrotic pulse of low tension will warn us that septicæmia threatens, if it has not already attacked, the patient. As an aid in detecting the effects of alcoholism, the earlier stages of the disease recently described as capillary fibrosis, and of kidney disease, the sphygmograph may prove of great service to the surgeon who is considering the fitness of a patient for operation. Dr. Mahomed's valuable observations on the exact localisation of an aneurism about the arch of the aorta, and the question of operation for its cure by distal ligature of one or more of the large vessels, are certain to lead to more accurate diagnosis and successful treatment.

In 1853 I introduced the ophthalmoscope of Coccius to the profession in England. One distinguished ophthalmologist still living ridiculed it in print as a toy. Another, also happily among us, wrote that in cases of blindness it must be useless; and in all other cases where the retina was sensitive it was too dangerous ever to be employed. This was only twenty-four years ago, and I ask you what would be thought of an ophthalmic surgeon now who attempted to practise without an ophthalmoscope? I need not weary you by more than the barest allusion to what has been done by the aid of the laryngoscope and the otoscope, or what may be expected from the endoscope or the diaphanoscope, when the instruments are perfected and their use has become general.

Till quite lately the tourniquet or compression of the main artery was relied upon as the chief means of checking the loss of blood in amputations and other operations. Esmarch's system of

Bloodless Surgery

not only prevents the loss of blood much more completely, but, as the parts operated upon are not bathed in blood, the surgeon can better recognise the nature and extent of disease, and perform many operations more easily with a smaller number of assistants, while the process appears to exercise a favourable influence upon the healing of the wound. The elastic constrictor will take an important place in the armamentarium of the surgery of the future, and no doubt many of the inconveniences ascribed to its use will be avoided when it comes to be more generally practised. So also with transfusion of blood. Dr. Roussel's apparatus for the transfusion of pure blood, and the subject generally, are to be specially discussed at this meeting. I need only, therefore, express my hope that everyone who practises surgery hereafter will make himself competent to transfuse safely, not only when a patient is bleeding to death after childbirth, or some accident or operation, but in other cases where the blood is insufficient in quantity or deteriorated in its composition.

A certain section of the community, well-meaning it may be, but led astray by thoughtless enthusiasts or self-interested itinerant lecturers, vehemently asserts that if we are to perfect ourselves in these or in other modes of saving human life, or lessening human suffering, we must only do so by practice upon the human subject; we must not, as a surgeon or a physiologist, take the life of a dog or a cat, a rabbit or a sheep, a pigeon or a frog, for any scientific purpose, or with the object of benefiting the human race. Anybody may slaughter oxen and sheep by thousands for human food, in any way he pleases; oysters may be eaten alive; the pheasant or the partridge, the fox or the deer, may be expressly reared to supply the sportsman with exercise or the amusement of killing,—in a word, the lower animals may be devoted to the use of man for any purpose that is not scientific. But if a surgeon experimentally sacrifices half a dozen dogs or rabbits in the hope of improving some operation which may prevent the loss of human life or lessen human suffering, he is branded as inhuman, and barely escapes the supervision of the police. Possibly some of these benevolent individuals will voluntarily offer up themselves to our Committee on Transfusion, in the hope of perfecting the practice. Until they do so, they will perhaps be a little less clamorous if a few sheep or rabbits are used in the cause of humanity. With regard to splenotomy, pancreotomy, and nephrotomy, accident has proved that the spleen, or the pancreas, or a kidney, may be lost without great injury to the human being. Surgeons have removed a wounded pancreas and enlarged spleens, and a diseased kidney has been extirpated on two occasions at least; but the operative proceedings are still imperfect. Are surgeons to be allowed to excise the spleen or a kidney of a dog or a rat, or will zealous members of some Anti-Vivisection Society enroll themselves as candidates for that immortality which is gained by anyone who immolates himself upon the altar of science?

What is to be the future of nerve-stretching in neuralgia, or of skin-grafting as an aid in cicatrisation or the replacing of lost tissue, it will be for you to say when sufficient observations

have been gathered together. And I pass on to speak of some undoubted triumphs of British surgery in our own time. The cure of vaginal fistula was scarcely ever attempted thirty years ago, and the operation was seldom successful when attempted long after that time. It now, even in very unpromising cases, almost certainly ends well in the hands of many operators in many countries.

It would be false modesty if I were not to say boldly before this Association that I am proud of the share which British surgeons have had, and of the share which I myself have had, in placing

OVARIOTOMY

upon the roll of successful surgical operations. Great leaders among us—Simpson and Syme, Stromeyer and Billroth, Velpeau and Nélaton—have shown a generous appreciation of our work. And can you imagine a greater pleasure to a surgeon than to hear the President of the Medical and Chirurgical Society speak last year of his improvements in the operation of ovariotomy as "one of the greatest achievements of surgery in this century, and that the influence for good extended through every department of operative surgery?" while at the same Society in 1850 Lawrence had asked whether this operation "can be encouraged and continued without danger to the character of the profession."

Less than a quarter of a century after this denunciation, Lord Selborne, one of the most distinguished of our Chancellors, publicly stated the result of a calculation, that by my first 500 operations I had added something like 10,000 years to the lives of European women.

What number of operations has been done by other surgeons I know not, but supposing that the same probability of the duration of life applies to the women who have recovered from operations I have done since the results of my first 500 cases were published in 1872, the gain would be about 18,000 years,—and this by one surgeon alone, and by an operation which only thirty years ago was denounced as so "fearful in its nature, often so immediately fatal in its results," that, whenever performed, "a fundamental principle of medical morality is outraged."

I should not venture to say all this if it were not by way of encouragement to everyone who hears me to do the work which comes before him, whatever it may be. Nothing could be more unlikely than that I, up till 1855 a naval surgeon, serving in 1855 and 1856 with the army in the Crimea, never having till that time treated a single case of ovarian disease, removing an ovarian tumour for the first time in 1858, and waiting three years before I had done ten cases, should now be able to say that I have completed the operation on 870 women.

And, what is still more gratifying, that I should be able, among the performances of the many surgeons who have been running the race with me, striving with generous rivalry to obtain the reward of those who do good in their day and generation, to refer to the brilliant results obtained by my dear friend Thomas Keith, who, out of 241 operations, has saved 206 lives—a success hitherto unequalled in the history of any capital operation. How ovariotomy, since it has become so generally accepted here, has spread in America, in France, and Germany—indeed, all over the world,—I have tried to tell elsewhere, and I will not weary you by telling the story again; but I cannot pass from this part of my subject without expressing my confident assurance that what the surgery of the present age has done for the treatment of ovarian tumours, the surgery of the future will do for that of uterine tumours. Already large fibroid and fibro-cystic tumours of the uterus have been removed in America by Atlee, Kimball, and others; in this country by Clay, Keith, Bryant, Thornton, Routh, and myself; in France by Kœberlé and Péan—quite in sufficient number, and with results sufficiently satisfactory, to prove that we only require a better knowledge of the details of the operative procedure, and greater experience in meeting the various difficulties which may arise, to place the removal of uterine tumours by gastrotomy amongst the most hopeful of the many lines of thought and action open to the operating surgeon of the future.

But I think those who study and are to become the

CONSERVATIVE SURGEONS OF THE FUTURE

must not be content with saving limbs only. It is life that must be saved. And the great lesson taught by the success of ovariotomy and of operations for the removal of uterine tumours is, that they must not be done except under the most favourable possible conditions, whether in private houses or in hospitals. We are only just beginning to reap the benefit of the results of the labours of the Health of Towns Commission, and of the work done by medical officers of health all over the country; and a great deal more must be effected before we can insure even to the most wealthy of our patients a plentiful supply of pure water, a room well warmed, well aired, and free from the presence of sewer gases, and security from the entrance of infectious disease.

In hospitals the problem is still more difficult, whether the hospital be large or small, old or new. But we do know that overcrowding of any building is of more importance than its size. A large crowded hospital must be a more dangerous place for operations than a small one equally crowded; but a large hospital, where each patient has plenty of space and fresh air, would certainly be a safer place for an operation than a crowded hospital, even though much smaller. In the hospitals of the future, whatever their size may be, the patients must not be allowed to poison each other. And for my own part I would rather operate in a clean, quiet, well-warmed, and well-ventilated building, be it large or small, without any antiseptic precautions, than run the risk of trusting to the neutralising or destructive power of chlorine or iodine, sulphur or tar, borax or the permanganates, salicylic or any other acid, in a place tainted by the presence of sewer gas or the seeds of some infectious or contagious disease.

I should have said more on this important subject of antiseptic surgery if the bearing of the germ theory on infectious disease had not been so ably and exhaustively treated by Dr. Roberts in the Address on Medicine, and if in the Surgical Section a special discussion had not been arranged. But as both these things have been planned as distinct parts of the meeting, I leave what would otherwise have occupied nearly the whole of this Address, to ask you for a moment to consider what must be the

EDUCATION

of the men who are to advance the science and practise the art of surgery in the future; how some of the best of the men of the coming generation are to be induced to adopt this career.

I need not speak to such an assembly as this in Manchester, where all the essentials of a chartered university already exist, of the importance, or rather of the absolute necessity, that the surgeons of the future must be educated gentlemen; that we should so order our schemes of education, whether conjoint or not, as to bring into the profession, as far as possible, young men who have had the advantage of the highest general culture to be obtained by an English education. Until this is secured, the flower of our university youth will still choose the Church or the Bar, the Army or the Navy, or some branch of the Civil Service of the State, where they at once take an enviable social position as members of an honourable profession, and where a successful career may lead to a seat in the House of Lords, to the pensions and titles freely granted to the fortunate soldier or sailor, and, more sparingly, to the meritorious Civil Servant of the Crown.

It is rather surprising that without any of these inducements, and in spite of the taint of trade forced upon the profession by the powers of the Apothecaries' Company, and its continued alliance with our Colleges and Universities, we still have abundant evidence of a rapid rise of the profession in the social scale. Apart from examples at home familiar to us all, the marriage of the German surgeon, Esmarch, to a princess of his own country, is even a less striking indication of a change for the better in the social standing of our profession abroad, than the fact, much less generally known, that a royal prince by birth, Prince Charles Theodore of Bavaria, is a doctor of medicine, is known to be a clever operating ophthalmic surgeon, and has written a very able article, published in a late number of *Virchow's Archives*, on leucocytes in the substance of the brain in various diseases.

When German princes practise surgery, and a brother of an English earl, a Cabinet Minister, is met with as a practising physician, we may think less of the admission of members of our profession into royal and noble families, and look with more hope for recognition by the Government of services rendered by medicine and surgery to the nation. We shall not then have to notice anything so disheartening to a learned profession as the fact, that while for the affair of Magdala Lord Napier was honoured by a title and rewarded with a pension, the extended average duration of life of the whole population and its actual increase, due to sanitary and medical

science—far exceeding in importance the annexation of a province, or even of a kingdom,—has earned for Simon the barren right, shared by many less honourably known men, of putting the magic letters C.B. after his name, and William Farr still remains without any mark of national gratitude.

Why should a baronetcy be the highest titular distinction conferred upon members of our profession? Is Jenner or Paget less worthy of a life-peerage than any one of the eminent men who now sit on the bench of bishops, or any of the lawyers, soldiers, or sailors who have been rewarded by hereditary peerage? Can any member of the House of Lords do greater service to his country in that assembly than would such a wise and learned physician as Watson, who so very lately has proved himself capable of the highest efforts of statesmanship by his remarkable essay on the abolition of zymotic disease?

Since the health of the people is, or should be, one of the first objects of legislation and administration, the help of acknowledged masters of sanitary science is indispensable. That want now manifest in the recent ill-devised Acts of Parliament, and the imperfect machinery put in action for their execution, must force upon the nation the conviction that medical science ought to be properly represented in Parliament, and especially in the House of Lords. None of our leaders have time for electioneering or the turmoil of party struggles in the House of Commons; whereas many of them are well fitted for the more dignified position, and would be quite able to devote their time and energy to sanitary legislation in the Senate.

And what a task lies before the medical statesman! Never in the whole history of our profession have we had so much work to do, such problems to solve, so many human beings dependent for their health on our knowledge and our care. The Roman Empire in its greatest power sinks into insignificance in comparison with the dominions now under the sway of Queen Victoria, Empress of India. Two hundred millions of human beings in India, other millions in Africa, Australia, New Zealand, the islands of the Pacific, in Canada, and the West Indies, are affected for good or for evil by the action of the sanitary advisers of our Government. At home, until we can disband the great army of paupers, we must at least save them from preventable disease, and the multitudes of our neglected children must be taught some elementary facts necessary for the preservation of their health and the prolongation of life. The day cannot be far distant when this will be done by Parliament under medical guidance.

But until that day comes, it is for this great Association, for every member of it, to strive to secure for our countrymen and our dependants protection from the effects of incomplete and neglectful legislation. And there is ample encouragement to set to work at once, earnestly and with set purpose, acting in the spirit of the noble motto of the French Society of Surgery:—

"Verité dans la Science,
Moralité dans l'Art."

If, in the forty years since this Association was founded, the great progress which I have so hastily and imperfectly endeavoured to review has been made, what may we not augur for it in years to come? The Association had its early struggles, and has passed through them. It is now powerful and vigorous; its organisation is almost complete, its resources are yearly increasing, and its influence, through its annual meetings, its branch operations, and the wide circulation of its invaluable journal, is universally felt. The history of the past and the study of the present, alike help us to look forward with hope and trust to the future.

"Look not mournfully into the past. It comes not back again. Wisely improve the present. It is thine. Go forth to meet the shadowy future without fear, and with a manly heart."

Cyanide of Zinc in Facial Neuralgia.—Dr. Luton, of Rheims, states that he has obtained excellent results from the cyanide of zinc in rheumatic facial neuralgia simulating cerebral rheumatism. He relates two cases in which, with intense facial neuralgia, there was continued and ardent fever, cephalalgia, and tenderness on pressure at the points where the nerves emerged. The symptoms rapidly abated under the use of the following mixture:—Cyanide of zinc one-fifth of a part, distilled cherry-laurel water twenty-five parts, and tragacanth mucilage mixture 100 parts. A tablespoonful from hour to hour.—*Rév. Méd.*, July 16.

ORIGINAL COMMUNICATIONS.

A THERAPEUTIC PROPOSITION.

By ALEXANDER WALLACE, M.D., M.R.C.P.L.,
Physician to the Essex and Colchester Hospital.

1. Evidence in plenty exists to warrant the view that various diseases, such as diphtheritic and other sore-throats, erysipelas, the exanthemata, typhoid and probably typhus fever, etc., are the outcome of changes in the blood induced by a ζύμη, or fermentative organic element, introduced from without, so minute as in our present state of knowledge to defy isolation or demonstration; yet capable of an intensely rapid self-multiplication in the fluids of the body, at the expense probably of some portion (or pabulum) of the same, effecting thereby an alteration in the character and constitution of the blood: destroying life, sometimes with great rapidity, by its poisonous effect on the nervous centres; or less quickly by a rapid oxidation of tissue; or more slowly by local disorganisation.

2. It is possible that the varying virulence of an attack may depend (α) on the varying amount of suitable pabulum existing in individuals, and the sudden change of this from an innocent to a poisonous compound; or (β) on the elimination of the individual being at the time in a defective condition.

3. If it be conceded that rapid changes in the blood, dangerous to life, are thus effected, then our aim, therapeutically speaking, must be rapidly and without endangering life to neutralise the morbid elements, to restore the vital fluids to their normal state, and thus place our patient in the best possible condition to attain convalescence.

4. That it is possible to counteract dangerous morbific changes set up in the blood, is evidenced by the well-known fact, that if an individual receive the contagium of variola, and be at once vaccinated, the incubation of vaccinia—*i.e.*, the change taking place in the blood under the influence of that organic element—not only runs its course in a shorter time than those changes which are effected under the influence of the variolous element, but also so modifies the nature of the blood that the further changes effected in it by variola are of a modified and insignificant nature, and the result, as is well-known, is an aborted or modified attack of small-pox, not dangerous to life; or, as it might be put, the pabulum in the blood, which, if acted upon by small-pox, would result in a product highly morbific and poisonous to life, is under the impress of vaccinia changed into a comparatively innocuous product, and, being once changed, is not susceptible of further change by variola.

5. If a preservative change can be effected in the blood, so as to neutralise the force of one of the most formidable maladies that afflict mankind, not merely antecedent to, but even after its impress, we may fairly hope to find other influences modifying diseases of a like nature—nay, more, it is our duty to look for them.

6. Surgery, our sister science, reads us a lesson in this direction by her antiseptic treatment of wounds. She has demonstrated how the healing processes are promoted—(1) by the exclusion of poisonous germs floating in the atmosphere from contact with wounded surfaces; (2) by processes by which, if not excluded, these may be devitalised and rendered innocuous, through the interposition of certain fluids destructive of microzootic organisms between them and the cells of the wounded surfaces.

7. Could we apply to the internal fluids of the body the principles which the surgeon applies to the external surface—viz., the destruction or neutralisation of morbific germs by antiseptic remedies not injurious to life—we should obtain a vantage-ground to operate successfully against blood-diseases, as powerful as that which we already have in vaccination.

8. The exhibition of the hyposulphites of Polli is a move in this direction; and the saturation of the system with salicylic acid in cases of rheumatic fever, and with iodide of potassium in certain forms of syphilis, all point the same way.

9. But whereas the continued ingestion of such remedies by the stomach is apt to upset the digestion and interfere with the alimentation of the patient; and inasmuch as hypodermic injection, powerful and all-pervading though its effect be, is negatived in the case of remedies of an irritant nature likely to produce local ulceration and sloughing: some other mode must be sought for, whereby the blood may be rapidly

influenced, and the internal fluids saturated, so to speak, with an antiseptic remedy innocuous to life.

10. Now, we know that the whole volume of blood passes through the lungs in a brief period, is there exposed to the action of the air, and undergoes a great change—oxygen is absorbed, carbonic acid given off,—and that this change is necessary to life. We have, then, in the lungs a natural apparatus specially framed for the purpose of climinating from the blood a poisonous element, and introducing from without in its place a life-giving element.

11. Here, then, we have an organ of the body specially constructed, as it were, for the purpose—the very means by which volatile antiseptic remedies in a minute state of subdivision can be rapidly and effectually introduced into the blood in an amount easily controllable till saturation is effected, and their physiological effects be produced.

12. Of these volatile antiseptic remedies, iodine, creasote, carbolic acid, sulphurous acid, and chlorine, are the most familiar to us; but it is more than probable that when the attention of the profession has been drawn to the requirements indicated, other more suitable agents may be brought into notice by the chemistry of the age.

13. It was once the fashion to attribute to inhalants a very low place in therapeutic treatment, but when we reflect for a moment on the great benefits resulting from the inhalation of ether, chloroform, and nitrite of amyl, it is quite clear that inhalants must be raised to a very high rank in practical utility; and it is also most probable that as yet we have advanced but a very little way in the knowledge of the uses to which such remedies may be applied.

14. I propose, therefore, to the profession, to make a trial, in diseases which have the characters of blood-poisoning, of the exhibition of volatile antiseptic agents by means of inhalation; and I ask our chemists specially to call attention to those volatile agents which have an antiseptic value, that experiments may be made.

Believing as I do that the propositions I have put forward contain a germ of truth powerful for good to mankind, and not knowing that they have elsewhere been urged, I venture to offer them to my brethren, feeling sure that whatever good may be underlying, it will more speedily be brought to light by general professional examination, than were I alone to undertake to disentangle it.

Trinity House, Colchester.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

MIDDLESEX HOSPITAL.

CASE OF ASYNERGIA WITH ARTHROPATHY.

(Under the care of Dr. HENRY THOMPSON.)

[The following record is in the main an abridgment of the notes taken by Mr. E. A. Fardon.]

Emily W., aged fifty-three, the wife of a labourer, was admitted May 11, 1877. There is no history of any neurosis in the family. Two of her brothers died of phthisis. She herself enjoyed good general health until four years ago. She has been married twice, and has given birth to ten children, six of whom died of diseases incidental to childhood. Her climacteric period arrived two years ago, and to this date she refers the full development of her malady. For two years, however, prior to this time she had suffered from severe menorrhagia, accompanied by pain across the loins; the pain was confined to this region, and disappeared when menstruation ceased. Two months before the cessation of the menses, without any preceding pain, she noticed a numbness in both lower limbs. This feeling persisted, and grew upon her gradually. She then lost command over the movements of her legs, and began to walk in an awkward, ungainly fashion. On the occurrence of the menopause the unsteadiness in walking increased, and now arose a new assemblage of symptoms —derangements of vision and hearing, with pain and swelling in the lower extremities. All these symptoms seem to have made their appearance about the same time, and to have rapidly reached their present climax, but the patient is unable to assign exact dates, and can give no more than a general account of their sequence. They have all been more or less persistent during the last two years. The pains she describes as often occurring two or three times in twenty-four hours; they were always worse at night; they were either lancinating in character, shooting sometimes from the hips to the ankles, at others from the ankles to the hips, or they were constrictive, and then limited to the neighbourhood of the knees and ankles. The affections of the eye seem to have been purely nervous; her sight, she says, became "all dazzling." There is no history of strabismus, ptosis, or muscular paralysis in any form. In the ears she heard singing and roaring noises. A slight degree of deafness supervened. The increased difficulty in walking was well marked. At first it did not interfere much with the distance she could go; it was more in the manner of doing it that she broke down. At dusk she could hardly walk at all. Soon her movements became so disorderly that her husband often took her to task for her awkwardness, and even her friends complained of the noisy way in which she stamped about. Her excuse was, "she could not help it; she could not feel the ground." The swelling in the joints began first in the left knee. It was attended with a constrictive pain. The swelling and the pain lasted about two or three months, and then disappeared, their disappearance being immediately followed by a similar attack upon both ankles simultaneously. On this occasion the legs were swollen over a space of four or five inches above the ankles. The swelling in the ankle-joints subsided in the course of a month, when the disease reappeared in the left knee, where it has remained ever since. Even the ankle-joints never entirely cast off the lesion; they have been weak, loose, and at times painful. She has often distinctly heard crackling in all the afore-mentioned joints when she has put them in motion. The upper extremities have escaped scot-free in every sense save one; they are liable to occasional tremors.

State on Admission.—Patient is a fairly nourished woman, singularly intelligent and well-spoken for her condition in life. The left knee is swollen, but not tender; it is one inch in circumference larger than the right. There is a feeling of fluctuation on each side of the patella. The ligaments and parts around are relaxed—so much so that the joint admits of considerable deflexion laterally. The head of the tibia is enlarged, the margins of its condyles projecting beyond those of the femur, especially on the inner side, where also may be perceived what are apparently new outgrowths of bone springing from the natural bony prominences. On flexing and extending the joint, distinct roughness and grating may be felt, and with the aid of the stethoscope crackling may be heard. The right ankle-joint is slightly swollen, and presents the same grating and crackling on movement. The girth around the thigh and the calf is exactly equal in both limbs. The patient offers strong resistance to flexion and extension—stronger by far, however, in the right knee than in the left. There appears to be little or no difference between the two limbs in their degree of electro-contractility, which is exceedingly slight in both. Electro-sensibility is less impaired, but it differs on the two sides; it is more acute in the left limb than in the right. When she is told to shut her eyes, and the legs are crossed one over the other, she never gives a wrong answer respecting their relative position. There is no strabismus, no apparent over-action or inactivity in any of the muscles of the orbit, no oscillation of the eyeballs; the discs are well defined, and the vessels large; the pupils are contracted, and respond imperfectly to light. There is nothing abnormal in the behaviour of the arms, hands, and fingers, except that they show a marked tremor and unsteadiness whenever she assumes the standing posture. She can manage to maintain this posture fairly well when the feet are apart, but the moment she puts them together there is obvious instability, and if she closes the eyes she instantly loses her balance altogether. When she walks, her whole mind seems to be engrossed in the operation. She raises her feet abruptly, and brings them down with a stamp, staggering forward to the place she has fixed upon for the end of her journey. If she is tired with any unwonted exertion, this manner of walking becomes exaggerated; she can hardly feel the ground, and it seems to her as though she were walking upon springs. The pulse, the temperature, and the characters of the urine were normal, or nearly so, throughout the whole career of the case.

May 24.—To-day there is much tremor of the hands, and a shooting pain across the forehead and temples, with photophobia. She is liable to similar attacks. A decided but short systolic murmur may be heard at the heart's apex, where the first sound is briefly though roughly prefaced.

30th.—Pupils still contracted. Shooting pains in both legs.

She stands well with the feet asunder, or even in apposition, when her eyes are open, although she is not looking at her limbs, and although the sight of the limbs is shut off by the interposition of the medicine-card; but in the same attitudes she at once loses her equilibrium the moment her eyes are closed.

31st.—Suffered from flashes of pain in the night, and now suffers from headache and præcordial distress.

June 11.—Pupils inordinately contracted, almost to the size of a pin's head.

17th.—Severe frontal headache, relieved in two hours by twenty-five grains of guarana.

21st.—Great improvement in her power of walking, standing, and resisting flexion and extension. Left knee markedly diminished in bulk. She is perfectly and instantaneously conscious of degrees of temperature. On the application of a pair of compasses there was no constancy in her replies as to whether she was touched in one, two, or three points; nor did the distance they were apart appear to make much difference. In the evening she complained of tingling in the knees and legs, and of darting pains in the *right* knee, which, she said, kept her from sleeping.

22nd.—Went to sleep after chloral, but the right knee is still painful, though not apparently tender. It hurts her, however, when moved, and yields a distinct crepitus, which may be felt by the hand, or heard with the stethoscope.

July 6.—Electro-sensibility remains as before, more acute in the left leg than in the right. Sensibility to ordinary stimuli is peculiar. She invariably calls pinches "pricks," but is generally correct in other matters, such as rubbing, pricking, pressure, and the application of heat and cold. She never fails to name the seat of irritation.

From this date until the day of discharge nothing material occurred to break the monotony of the case. She only varied with the vicissitudes of the weather; damp and gloom were sure to call forth a visitation of pain, and clear sunshine was sure to dispel it. After many advances and backslidings, due to this cause, on the whole she gained ground, and took her departure July 31, greatly improved in all respects.

As for treatment, nitro-hydrochloric acid was given in the first instance, and at a later period iodide of potassium, in deference to Fournier, who holds that a large proportion of cases may be traced to syphilis. For the alleviation of pain, opium was freely exhibited, and belladonna liniment rubbed over the parts involved. Electrisation in all its ordinary modes and degrees of power was fairly tried and found wanting. Unfortunately, nothing would avail to excite muscular contraction save a faradic current too strong to be borne with impunity.

Remarks by Dr. Thompson.—The foregoing case, in spite of a few shortcomings and anomalies, offers a fair presentation of asynergia in its average form. The following points are noteworthy:—1. It is usual, and even convenient, to draw a line of distinction between the premonitory symptoms—or, more correctly speaking, the inaugural symptoms—and the proper phenomena of the declared disease. The order, however, is not invariable, and may be reversed. It has been reversed in our case. The malady *began* with incoördination and loss or perversion of sensibility, and the so-called prodromata ran last in the race. 2. The joint-disease (the arthropathy) is not in accord with the classical description of Charcot. In the first place, there was no general turgescence of the limb when the original attack was made upon the left knee-joint, although there seems to have been a circumscribed swelling of the tissues around when the ankle-joints were secondarily invaded. Again, Charcot makes no mention of bony protuberances; in fact, on his showing, the whole process is one of dwindling and decay. In our case overgrowth of bone stands conspicuously in the foreground. From the cases recorded in the *Medical Times and Gazette* for June 16, 1877, it appears that the bones are open to attack apart from the articulations. Arthropathy, then, after all, is only a species of osteopathy as a genus. The bone-change may occur anywhere in the osseous system, but by preference it assails the articular extremities, where the movements of bone are freest and the exposure to injury is greatest. 3. Much stress has been laid on the value of seeing the limbs as a guide and support to the asynergic in steadying the acts of locomotion and equilibration. The experiment recorded in the note to May 30 plainly shows that this cannot be all that is lost on closing the eyes. Dr. Bazire suggests in a general way the loss of the confidence inspired by light. Surely there must be something more particular in operation. The main disadvantage of darkness would seem to be the loss of the sight of surrounding objects, which, in their ever-changing relations to the percipient, help to maintain the movements and the equilibrium of all men alike, whether they be ataxic or eutaxic.

SATURDAY, AUGUST 11, 1877.

THE PRESIDENTIAL ADDRESS TO THE BRITISH MEDICAL ASSOCIATION.

We have on more than one occasion remarked on the difficulty that the President of the British Medical Association must often feel in the selection of the subject of the Address with which it is his duty to open the Annual Meeting. He has to avoid—or, at any rate, it is desirable that he should avoid—trenching on the ground occupied by the orators in the various principal departments of Medicine; and no man will in these days be ambitious enough to attempt a review, or *résumé*, of the progress made in the whole field of the art and science of Medicine. The difficulty becomes greater each year as the growing strength and importance of the Association enables them to command more and more fully the services of the most eminent men in all the branches of the profession; and hence, as the President at the Sheffield meeting last year remarked, it has of late become almost the rule that the President shall, in his Address, "descant upon the merits of the town wherein the Association was actually assembled; should sing the praises of some of its notable citizens, past or present; or should describe in full detail its industries, its position, or its character"; and the President of that year gave a very instructive address on those lines. This year the President, Dr. Eason Wilkinson, might well have felt justified in taking the same line, for besides the addresses-in-chief,—in Medicine, Surgery, and Obstetric Medicine, and addresses that might be looked for from the Presidents of the six sections—viz., Medicine, Surgery, Obstetric Medicine, Public Medicine, Physiology, and Psychology—a special subject had been selected for discussion in every section, except that of Physiology; and in some of the sections more than one subject. Thus in the Medical

Section, Aortic Aneurism, and the Treatment of Pleuritic Effusion, had been chosen; in the Surgical Section, Excision of the Knee, the Treatment of Stricture of the Urethra, and Antiseptic Surgery; in the Section of Obstetric Medicine, Transfusion of Blood; Hospital Out-Patient Reform and the Contagious Diseases Act, in the Section of Public Health; and in the Psychological Section, the Best Method of Treating Habitual Drunkards. What subject, then, the ground being so well covered, was left for the President except the greatness and some of the medical specialities of Manchester? A subject large enough, truly, to satisfy any orator—its very largeness being, however, almost a fault; but Dr. Wilkinson found a more manageable topic in the question of hospital defects and their remedies, which, as is well known, has of late largely occupied the attention of medical and other authorities in that city.

The President prefaced his remarks on this topic by a few words as to the growth of the Association since they last met, twenty-three years ago, in Manchester; and then spoke briefly of the loss the Association and the profession had sustained by the deaths of Mr. Southam, Dr. Sibson, and Sir William Fergusson; and to the loss to medical education and to science experienced through the retirement of Sir Robert Christison from the chair of Materia Medica in the University of Edinburgh. And then entering on the special subject of his Address, he gave an interesting sketch of the rise and growth of the Infirmary—a history which might, in all probability, serve for that of the rise and growth of the hospitals and infirmaries in many of our prosperous and rapidly increasing cities. One of the first provincial hospitals in England, it was erected in 1753 on land situated on the south-west outskirts of the town, well remote from the noise and bustle of business, and with a clear unimpeded view of the country for a distance of eight or ten miles; but by the great extension of manufacturing interests, and the rapid growth of the population, the Infirmary now, instead of being in an admirably quiet and healthy situation on the outskirts, is in the very centre of the busy, noisy, smoky, crowded town. No special or scientific attention was bestowed on the drainage of either the Infirmary itself or the grounds in which it stood; and gradually, as the institution grew in importance and extent, and Manchester grew in population and wealth, the modest red-brick building was embellished, and made to look more worthy of the town: that is, the brick walls were encased in stone, a grand portico and four massive pillars were added to the centre of the building, "giving an almost palatial aspect outside, while, alas! darkening the wards, and preventing a proper circulation of air, so as to render the building decidedly unhealthy," and additional wings were, one after another, added, so as to gradually fill up the site, and further interfere with light and ventilation. The ground under and around the Infirmary also became by degrees saturated with sewage and other drainage; the stone encasement of the walls hindered the escape of the effluvia, which were therefore confined within the building; and "the central corridors, besides acting as shafts for the conveyance of poisonous particles from one extremity of the building to the other, necessitated the placing of beds along dead walls," and so further lessened the supply of air to the patients. Of course erysipelas and other diseases of blood-poisoning became rife in spite of skilled medical attendance and nursing, and of the full supply of everything necessary to the comfort of the patients. As an inevitable result a new hospital must be built, and a much larger one; one more suitable to the size of Manchester and to the growing importance of the Manchester School of Medicine. But in connexion with that there has arisen the question of a change of site for the Hospital. Dr. Wilkinson observed that, in providing hospital accommodation, "we have to consider the site, the value of the ground, the number of sick to be accommodated, the amount of space to be allowed to each bed, the amount of fresh air and light at our disposal, the possibility of conveying thither the sick and wounded, the convenience of the administrative body, and the accessibility for medical officers, students, and patients' friends"; and he adds that, as regards the site of the present Infirmary, he thinks it is generally agreed by the medical staff that it could not be more unfortunate; while "the convenience of the consulting staff and of the Medical School would be as well consulted in a purer atmosphere, and, if the recovery of the sick be the object aimed at, this would be greatly facilitated." As our readers are well aware, the question of removal of the Infirmary has lately been repeatedly discussed, and several new sites have been proposed and considered; but "conflicting interests," to quote again from the President's Address, "brought out such strong feelings that the hope of removal has for a time been checked, while means are being taken to patch up still further the building already patched to death." Dr. Wilkinson added some excellent remarks on hospital construction; alluded briefly to the question of "home hospitals"; and concluded his Address with a short sketch of the rise and progress of the Manchester School of Medicine, now the most important and best appointed Medical School in the provinces. The School needs a much larger and better hospital than the present Manchester Infirmary; and the Manchester of to-day needs a general hospital containing at least 500 beds. There can be no doubt about the thorough unhealthiness and general unfitness of the present hospital-buildings; they have been condemned as defective in construction and drainage, and inadequate in accommodation, by Mr. Netten Radcliffe, and Mr. Field, the sanitary engineer, and their verdict has received general acquiescence. There may, however, be differences of opinion about the advisability of a change of site, as that question has to be considered from many points of view; but such differences certainly ought not to be allowed to delay for any length of time the rebuilding of the Hospital. Everyone must hope that some means may be found shortly of reconciling "conflicting interests," and of removing all difficulties, so that no long time may be suffered to elapse before Manchester is provided with a new Hospital worthy in every way of a city of such wealth and size, and equal to all the needs and requirements of the Medical School.

THE ADDRESS IN MEDICINE.

All those who know Dr. William Roberts, of Manchester, who this year gave the Address in Medicine at the meeting of the British Medical Association, directly, or indirectly through his writings, will have looked to an Address of more than ordinary excellence and finish, as respects both matter and style; and certainly that expectation has not been disappointed. Dr. Roberts took for his subject one of the questions of the day, viz., "The Doctrine of Contagium Vivum, and its Applications to Medicine," and his Address is a lucid and forcible exposition and justification of his own beliefs and theories on his chosen topics. It is simply impossible in the time and space at our command to notice such an Address critically, and we do not mean to attempt to do so. We shall content ourselves with giving some idea of its character and scope, and commending it to the attention and study of our readers.

Dr. Roberts first directs attention to the resemblance between a contagious fever and the action of yeast in fermentation, or the action of bacteria in decomposition. A bottle of fresh saccharine urine is inoculated with a minute quantity of yeast, and kept in a moderately warm place; and "a fever in a bottle" results. After inoculation there is a period of incubation, then a period of disturbance accompanied by elevation of temperature; and to this succeeds a subsidence of the disturbance, and a return to the normal state. Again, if some boiled

hay-infusion is inoculated with the *Bacillus subtilis*, the same succession of events may be observed—a period of incubation, followed by a period of disturbance, succeeded by a period of subsidence, and, finally, restoration to the normal state. In each instance there is a great increase of the infective material, and, finally, immunity from further attack by the same contagium. Dr. Roberts, however, is careful to point out where the comparison with infective fever fails, and to guard himself against being supposed to suggest that the enhanced temperature in the fermenting urine is a real analogue of the preternatural heat of fever. He then observes that the yeast-plant and the *Bacillus subtilis* may be taken as representatives of a large class of organisms which in size and form are among the smallest and simplest of living things, but possess wonderful vital endowments. They are the essential ageuts in all fermentatious, decompositions, and putrefactions, and he proposes to group them together under the general designation of *saprophytes*—"a term intended to include under one heading all the organisms associated with the decomposition and decay of organic matter." The *Bacillus subtilis* is a very common bacterium, and all the organisms as yet found in association with infective inflammations and contagious fevers belong to the tribe of bacteria. Before that association can be properly studied, however, it is necessary to have a knowledge of the origin and attributes of bacteria; and this leads Dr. Roberts to the spontaneous generation controversy, and to the question whether these organisms are the actual agents of decomposition, or are merely associated with that process as secondary or accidental accompaniments. He himself holds most positively that bacteria, like other organisms, arise from pre-existent parent germs, and in no other way, and that they are the actual agents in all decomposition and putrefaction. He brings forward experiments and arguments by which he substantiates, he believes, in a positive manner, the proposition "that organic matter has no inherent power of generating bacteria, and no inherent power of passing into decomposition"; "that bacteria are the actual agents of decomposition"; and that "the organisms which appear as if spontaneously in decomposing fluids owe their origin exclusively to parent germs derived from the surrounding media." We do not doubt that to those who already hold, or are inclined to hold, that the doctrine of spontaneous generation is wrong, Dr. Roberts' argument and demonstrations will appear as conclusive as they are ingenious and clear in expression; but others, among whom we class ourselves as regards the second proposition, will be content to withhold assent till his experiments have been tried by other skilled workers in the same field of inquiry. Following Mr. Gladstone's example, they "keep their minds open." Dr. Roberts of course refers to, and lays stress on, the experiments of Cohn and others, showing the great difference in vitality between the growing organism and the seed or spore—the first is killed by a heat of 140° Fahr., whilst the spores are capable of germinating after being subjected to a heat of 300° Fahr. for ten minutes. "The only group of bacteria, so far as is known," he states, "which form spores, are the *Bacilli;* and Cohn remarks that in all the various cases in which he had observed organisms to arise in boiled liquids, they belonged in every instance to the *Bacilli*." In connexion with this part of his subject, Dr. Roberts adduces an argument that to us is new. Saprophytes are, he says, destitute of chlorophyll; and, like all such plants, they are unable to assimilate carbonic acid. They obtain their carbon exclusively from more complex compounds, which have been prepared for them by pre-existing living beings. Their special function in the order of nature is to destroy, not to create, organic matter; and they constitute the last, not the first, link in the biological chain. The chlorophyll body is the only known form of protoplasm which obtains all its nutriment from inorganic sources. The saprophyte, on the contrary, feeds on nutriment prepared for it by other beings. Consequently, he says, "if ever I should be privileged to witness an abiogenic birth, I should certainly not expect to see a saprophyte: I should rather expect to see a speck of protoplasm slowly formed, without definite shape or dimensions, and nourishing itself, like the chlorophyll body, on a purely mineral diet. The more one reflects on this subject, the more clearly does it appear that the spontaneous origin of saprophytes is logically impossible. Speaking as an evolutionist, I should rather iufer that saprophytes were a late development; probably a degradation from some algal forms which had found their profit in feeding on waste organic matter, and which gradually lost their chlorophyll through want of use, and with it their power of feeding on an exclusively mineral diet." Dr. Roberts then addresses himself to the more practical side of his subject, and to the proof that contagium, like a ferment, is something that is alive: and, further, that if the doctrine of a contagium vivum be true, we are almost forced to the conclusion that a contagium consists (at least in the immense majority of cases) of an independent organism or parasite; and he seeks to produce evidence that this doctrine is undoubtedly true in regard to three infectious diseases—viz., septicæmia, relapsing fever, and splenic fever.

He contends that septic bacteria arc the cause of septicæmia, that the spirilla are the cause of relapsing fever, and that the *Bacillus anthracis* is the cause of splenic fever; but we must refer our readers to the Address for the most skilful and interesting statement of the arguments and observations by which he supports his contention. They will not bear condensing, and we cannot here attempt to examine into or criticise them. We will, however, draw attention to the warning that he gives, that "in applying the doctrine of pathogenic organisms—or *pathophytes*, as they might be termed—to the explanation of the phenomena of infective diseases, we must be on our guard against hard-and-fast lines of interpretation." He says, "So far as our very limited knowledge now extends, the pathophytes hitherto discovered all belong to that group of the fungi which are called bacteria. Now, fungi have two marked characteristics—namely, the tendency to assume the parasitic habit, and the possession by some of them of a special ferment action. Both these characteristics may bear a part in the action of pathogenic organisms. In the complex phenomena of septicæmia such would appear to be the case—a poisonous ferment-product first intoxicates the system, and then the organisms themselves prey upon the dead or moribund tissues."

Dr. Roberts does not take much, if any, note of the arguments of those who have opposed this, which we may perhaps be allowed to call the bacterian, germ theory of the infective diseases. Thus, he does not allude, so far as we see, to Dr. Lionel Beale's statement in his Lumleian Lectures, which are to be found in our volume for 1876, regarding bacteria. Dr. Beale says—"The very last conclusion, it seems to me, that would be adopted by anyone who thoroughly thought over the matter would be, that these low organisms are the *causes* of the changes in the fluids by which their growth was favoured, much less that they were the cause of the diseases which had existed some time before they began to multiply. One might, I think, with as much show of reason, advocate the doctrine that bacteria were invariably the cause of death, since after every form of death they grow and multiply in the tissues and fluids of the body." And in another place he points out that the germs of bacteria are to be found in every tissue and fluid of the healthy body, ready to develope under favourable circumstances into countless numbers of bacteria. But this is perhaps met, indirectly, by Dr. Roberts' statement that septic bacteria cannot live and grow in healthy living tissues. "The healthy living tissues," he says, "are an unsuitable soil for them—they cannot grow there; or,

to put it in another way, ordinary septic bacteria are not parasitic on the living tissues." And, further, he remarks, "It seems also probable that septic organisms enter constantly into our bodies with the air we breathe and the food we take; they pass, presumably, like any other minute particles, through the open mouths of the lymphatics and lacteals, and penetrate some distance into these channels; they certainly come in contact with the accidental cuts, sores, and scratches which so often bedeck our skins. Notwithstanding all this, our bodies do not decompose; indeed, if ordinary septic organisms could breed in the living tissues as they do in the same tissues when dead, animal life would be impossible—every living creature would infallibly perish. How these organisms are disposed of when they do enter our bodies accidentally, as it were, in the various ways I have suggested, we cannot say; we can only suppose that they must speedily perish, for we find no traces of them in the healthy blood and healthy tissues." Are there, then, perfectly innocent bacteria, which cannot be distinguished from septic bacteria save by the mischief the latter cause? or must some unacknowledged state of ill-health or commencing disease prepare the body for the fever-producing septic bacteria? and what is the "cause" of such necessary initial condition?

Dr. Roberts concludes his most able address by saying, "I believe that the doctrine of a contagium vivum is established on a solid foundation; and that the principle it involves, if firmly grasped in capable hands, will prove a powerful instrument of future discoveries. And let no man doubt that such discoveries will lead to incalculable benefits to the human race. Our business is to do battle with disease, and we may rest assured that the more we know of our enemy, the more successfully we shall be able to combat him." The truth of the last clause of this sentence certainly no one will dispute or deny.

WATERING-PLACES AND SUMMER RESORTS.

We more than suspect that the vast majority of English would deem anyone a foolish alarmist who would advise them to consult the Registrar-General's return for the quarter ending in June before deciding to which inland or seaside health-resort they would go, or send their families, during the summer and autumn. Yet, as in England we can learn pretty accurately whether the mortality of any given place is below or above the average, and whether or not zymotic disease has prevailed there of late, it would surely be wise to avail ourselves to some extent of such information. The Registrar-General's quarterly return, just published, gives, as usual, the health-report, or, to speak with exactness, the death-rate, of forty-six English watering-places during the three months ending June last. The mortality returns of the registration districts and sub-districts comprising these holiday and health resorts are altogether very satisfactory. The estimated population of the whole forty-six watering-places, in the middle of 1877, somewhat exceeds one million, and the average annual rate of mortality of the whole during the months of April, May, and June was 18 per 1000. In the thirty-seven seaside districts the rate was 17·8, while in the nine inland places, which are on the whole the densest, it was 18·6—not a great difference; but the death-rate of both classes combined, viz., 18, was 3·5 below the death-rate, 21·5 per 1000, of the kingdom, and 4·7 below that of the town districts. The seaside towns are situated round England and Wales, from Whitby on the north-east coast, to Blackpool and Fleetwood on the north-west, and have a wide range of population, from Brighton, which has over 100,000, to Bognor and Lyme-Regis, each of which has but a few over 4000. The whole mortality was much below the average in some; thus in Margate it was only 13, in Ramsgate and Broadstairs 16, in Eastbourne and Seaford 13, in Worthing 16, in Lyme-Regis 11, and in Lowestoft 14; while in several it was above the average. It may be said, however, that it would be foolish to pay much regard to the whole mortality returns of these places, especially of the small ones, for any one quarter; but it would certainly be unwise not to pay attention to the mortality from the seven principal zymotic diseases during the last quarter; and in this much difference will be found. The annual rate of mortality per 1000 living from these diseases averaged 1·5 in the forty-six watering-places, and was higher in the inland than in the seaside towns. In Bath, with a total mortality of 21·7 per 1000, the zymotic mortality was 3·8; and in Harrogate, with a total mortality rate of 22·8, the death-rate from the zymotic diseases was 3·2. Clifton was, on the whole, the healthiest of the inland towns, its total mortality-rate being 14·3, and its zymotic death-rate 0·7. In Buxton and Malvern the zymotic mortality was slightly lower, but the general death-rate higher than that of Clifton. Among the seaside towns the zymotic death-rate was *nil* in Lyme-Regis, Beaumaris, and Dartmouth; less than 0·5 in Margate, Teignmouth, and Bangor; and below 1 in Yarmouth, Deal, Folkestone, Eastbourne, Worthing, Littlehampton, Ottery St. Mary, and Ilfracombe; while it equalled or exceeded 2 per 1000 in Whitby, Lowestoft, Dover, Weymouth, Penzance, Tenby, Llandudno, New Brighton, Blackpool, and Bognor; and in two last-named districts it reached 3·6 and 6·6 respectively. Of course it should not be forgotten that in places with a small population, a few deaths from zymotic disease greatly raise the mortality rate; and the prevalence of zymotic disease may ere this have quite ceased; and both sets of statistics should be looked at in choosing a place. Thus Bognor, with its high zymotic mortality, had a death-rate of 18·7, while Bangor, with a zymotic rate of only 0·3, had a death-rate of 21·8; and in some places both the rates were high, as Harrogate, the rates of which we have already given; Tenby, which had a death-rate of 20·5 and a zymotic rate of 3·2; Whitby, 23·7 and 2·0; and Llandudno, a death-rate of 26·5 and a zymotic rate of 2·1. A consideration of the two rates together may surely be allowed to have some weight in the choice of a place as a holiday resort; and it will be allowed that, as the Registrar-General observes, the returns show the general character of a district, and will, or should be, of some use to the public, and to medical men in advising their patients. Especially will families with young children do well to take the returns into account.

THE WEEK.

TOPICS OF THE DAY.

At the meeting of the Hospital Sunday Fund, which took place at the Mansion House last week, under the presidency of Sir Sydney Waterlow, a report was read, stating that the total amount now recommended to be distributed on account of the present year's collection was £24,960, to be divided as follows:—£22,747 to seventy-six hospitals, including four institutions which might be classed as hospitals; and £2223 to forty-three dispensaries. Nearly all the present awards were slightly below those of 1876, in consequence of an increasing number of applications to participate, and a slight decrease in the amount to be administered by the Council. It was proposed that any additional payment to the Fund after the present date be allowed to accumulate in aid of next year's Fund. The chairman alluded to some circumstances of a grave character affecting the management of, and the treatment of patients in, the Hospital for Diseases of the Throat, touching which an investigation had been instituted at the instance of the Prince of Wales, the Patron of the Hospital. The Distribution Committee had received a report upon this inquiry, but it was marked confidential, and accordingly could not be read to the meeting. The Committee, however, recommended that any award should be withheld from this Hospital for the

present, and he moved a resolution to that effect, which was unanimously carried. The proposed scheme of distribution was then put and carried, as were several votes of thanks to the Committee of Distribution, the Chairman, and others.

In the reports recently issued by the Inspectors of Factories is a letter from a certifying surgeon in Dublin, which exhibits a want of supervision in preventing the spread of disease, calling for prompt attention. The letter in question says:—"Many rooms and workshops are, to the great danger of the public, in a most unhealthy condition, without medical inspection or certifying. I have met with cases of itch, syphilis, and other contagious diseases among those employed in confectionery and biscuit making. In one of these works close on 200 hands are employed, without any medical inspection or certifying, as I am informed. I have pressed on employers the necessity of letting me know before taking on any hands who may have recently had infectious diseases, with a view to prevent their introduction into factories."

It is stated, apparently with good foundation, that the proposed vote on account of a College for Naval Cadets at Dartmouth will not be brought forward during the present session. Pending the decision of the Admiralty upon the question of establishing a naval college ashore at any of the southern ports, the *Britannia* will be retained as a training-ship; and meanwhile the contemplated purchase of the Mount Boone site at Dartmouth will lapse, although it was favourably reported upon by a committee, including the Director-General of the Naval Medical Department, as it cannot be completed within the period prescribed by the vendors.

It will be a matter of some interest to the public to ascertain who is responsible for the slippery and dangerous condition of the flights of stone steps leading from the Victoria Embankment to Waterloo-bridge. Last week Mr. Langham, the coroner, held an inquiry at Charing-cross Hospital touching the death of Mr. Henry James Potter, a gentleman connected with the London press, who died in that institution on the 28th ult., from fracture of the skull. Mr. Edwards, a witness, was called, who deposed that on the afternoon of the 28th ult., about one o'clock, he saw the deceased ascending the second flight of steps we have referred to. The steps were, as usual, in a most dangerous condition, and on Mr. Potter reaching the fifteenth he slipped, and slid down to the bottom. Witness assisted in removing him to Charing-cross Hospital, where he died in two hours without having recovered consciousness. The jury returned a verdict of "Accidental death," and expressed their opinion that the steps should be at once repaired by the Metropolitan Board of Works. If such work comes within their province, it is to be hoped this suggestion will be adopted without delay.

The scheme for drawing the water-supply for the town of Manchester from the Thirlmere Lake, which we recently noticed, was last week approved at a special meeting of the Town Council, and a resolution was unanimously passed authorising the promotion of a Bill for carrying out the object.

Mr. Hawkesley, C.E., who has been appointed to remodel the drainage of Windsor, reports that the new works are nearly completed. The cost of the undertaking is estimated at £42,500. A new brick sewer from the lowest part of the existing system has been constructed to the Ham at Old Windsor, adjoining the Windsor Castle Sewage Farm, crossing the navigable cut of the Thames at Old Windsor, the distance being about two miles. Tanks have been constructed at the Ham, where it is intended to treat the sewage by precipitation, the effluent water to be disposed of by filtration. At the meeting held last week, the Committee under whose direction the work has proceeded presented their final report, which stated that negotiations had been entered into with M. Hillé, and the Town Council decided to adopt his system for the treatment of the sewage, subject to the preparation of the necessary contracts. It was stated that M. Hillé's system was the cheapest to work which the Committee had investigated. It is expected that, in the course of a very short time, the further purification of the Thames will be effected by the entire diversion of the Windsor sewage. At a recent meeting of the Town Council it transpired that the costs of the prosecution of the Windsor Town Council by the Thames Conservators had amounted to £137.

The scheme for the establishment of home hospitals is now definitely before the public. The Duke of Northumberland has promised to subscribe £1000 to the Association if the whole of the £20,000 named in the prospectus is raised by January 1, 1879. About £4000 has up to the present time been promised, and contributions are requested to be sent to the Honorary Treasurer at the Mansion House.

Perhaps it is as well that some of the dwellers in the metropolis are happily ignorant of what lies beneath the houses they inhabit, but such oblivion has been denied to the dwellers in New Bunhill-fields, at the south side of Church-street, Upper-street, Islington. The owner of the property appealed last week against an order of the parish to demolish these buildings, and in support of the order a Mr. Jones was called, who said he had known the ground for forty-three years, and had been proprietor of it. It was closed as a burying-ground in 1853, but there had been thousands of burials there to his knowledge. On the particular spot where the houses were built there was room for ninety graves, and on an average they put nine coffins in each grave; there would, therefore, be about 600 or 700 bodies in that part of the ground. A great number of burials used to take place there from the Fever Hospital, and the particular spot on which these houses had been erected was not drained at all; the whole of the ground was made up of bones, rubbish, wood, and remains of bodies. Joseph Fursman gave corroborative evidence; he said that when some coffins were dragged out the men employed were up to their knees in black slush, and stimulants had to be given to them in consequence of the stench. Dr. Thomas Stevenson said he had examined the houses, and had come to the conclusion that if there was leakage through the concrete floorings they would be unfit for human habitations. Nothing but entire impermeability would render such houses fit for habitation. Most remarkable to state, however, the Assistant Judge held that this was not a case that came under the provisions of the Artisans' Dwellings' Improvement Act, and quashed the order with costs.

On Monday last the Local Government Board issued a circular bringing under the notice of all sanitary authorities the provisions of the Rivers' Pollution Prevention Act of 1876, and pointing out that after the 15th inst. the proceedings authorised by the Act in respect of offences arising from sewage, manufacturing, or mining pollutions, may be taken. The sanitary authorities are also reminded that they have the power to enforce the prohibition against putting solid matter into streams from the date of the passing of the Act.

During the first six months of 1877 the butchers in Paris who deal in horse-flesh have delivered for consumption 5283 horses, donkeys, and mules. During the corresponding period of 1876 the number of these animals slaughtered for food was 4422. The increase is therefore of a marked character. The persons who endeavour to popularise the use of horse-flesh affirm that it is more wholesome and more nourishing than beef, although not always so agreeable. Paris contains more than fifty butchers' shops specially devoted to the sale of this article. A very good *pot-au-feu*, it is stated, may be made with the inferior parts, at the insignificant price of 25c. and

30c. the pound. The choicest pieces—fillet, undercut, etc.—command a much higher price.

The office of Master in Lunacy, vacant by the death of Mr. Samuel Warren, Q.C., has been filled up by the appointment of Mr. W. Norris Nicholson, who has for the last sixteen years been the Lord Chancellor's legal Visitor of Lunatics, and Chairman of the Board of Visitors. Mr. Nicholson is to be succeeded by Mr. Edward Ross, Secretary of Commissioners.

CONVICTION FOR FORGING DEATH-CERTIFICATES.

At the Leeds Assizes, on the 30th ult., William M'Irvine, an unqualified practitioner, aged twenty-five, residing at Stockbridge, was found guilty of having wilfully made and forged a false certificate, contrary to the Births and Deaths Registration Act, relative to the death of a person at Stockbridge. The prisoner had at one time been acting, at Stockbridge, as the unqualified assistant of Dr. Mason, of Sheffield, and after leaving that gentleman's service had continued to practise on his own account. In the case above mentioned he had attended professionally, and had signed the death-certificate with the name of Dr. J. S. Roberts, of Sheffield, who had refused Mr. M'Irvine leave to act in any way for him or in his name. It appeared that the prisoner had systematically given such certificates when his patients died. The case is of special importance, the prosecution having been instituted by the Treasury, under the Act for the Registration of Births and Deaths. In sentencing the prisoner to one year's imprisonment with hard labour, the judge addressed him as follows:—"The offence is a most serious one. You have acted as though you were a properly qualified practitioner, in open violation of the law of which I am unable to believe you can be ignorant. Your crime is that of forging the name of another person in order to conceal the fact of your want of qualification. This is an offence which, perhaps, is hardly likely to be repeated, still it is necessary to pass upon you a sentence which will mark the character of the offence, and operate, as I hope, as a warning to others."

THE MEDICAL REGISTER AND NEW QUALIFICATIONS.

We understand that, at a meeting of the Irish Branch of the General Medical Council, held in July, the Registrar for the Branch submitted an application from Mr. Arthur Vernon Macan to have tho degree of Master of the Obstetric Art, conferred upon him by the University of Dublin, entered in the Medical Register as an additional qualification; and a letter was read from the Rev. S. Haughton, M.D., claiming on the part of the authorities of Trinity College to have the degree registered, and submitting a certified copy of the decree of the Senate of the University of Dublin, instituting the degree in question. The Council came to the resolution that it does not appear from the wording of the Medical Act that they have any power to interfere, in the first instance, with the registration of any licence or degree, "Section 26 vesting the power of dealing with any application for registration in the discretion of the Registrar of this Council; and that it is only as a case of appeal that the question can come before this Branch Council." The new degree has, we believe, been registered with the Branch Council for Ireland, and will, by transmission thence, come in due course before the Registrar of the General Council.

THE PUBLIC HEALTH (IRELAND) BILL, 1877.

We are happy to say that some most important amendments have been introduced into this measure by the Select Committee of the House of Commons—to which this Bill was referred some three weeks ago—in deference to the representations made by the Irish Medical Association and other public bodies in Ireland. These amendments we hope to specify in detail next week. Suffice it to state at present that Sir Michael Hicks Beach has conceded the necessity of the principle of supervision, the title of "medical officer of health," the amendment of the scale of salaries of the medical officers of health, and other equally important points. To Dr. Grimshaw, the deputed representative and chairman of Council of the Irish Medical Association, the credit belongs of having so well and successfully fought the battle of his professional brethren while the Select Committee were considering the Bill. We understand that Mr. Charles Meldon, M.P., also rendered valuable service in introducing several of the necessary amendments.

ARMY MEDICAL DEPARTMENT.

The following is a list of candidates who were successful at both the London and Netley examinations, having passed through a course of instruction at the Army Medical School, Netley. Tho first-named gentleman gained the Herbert Prize:—

	Marks.		Marks.
1. Mullen, J. J.	5718	9. Armstrong, J.	3970
2. Murphy, F. H. S.	5098	10. Kenny, W. W.	3895
3. Johnston, W. T.	4656	11. Ellis, P. M.	3772
4. De Caux, F.	4595	12. O'Sullivan, P. J.	3758
5. Browne, A. W.	4193	13. Hogan, E. M. A.	3671
6. Hodson, R. D.	4138	14. Irwin, A.	3310
7. Powell, C. K.	4075	15. Kearney, T.	3193
8. Kirkpatrick, H. C.	4038	16. McCarthy, W.	2831

17. Brodie, J. F. . . 2773 marks.

APOTHECARIES' HALL OF IRELAND.

At the annual meeting of the General Council of the Apothecaries' Hall of Ireland, convened, in pursuance of the statute of incorporation, on August 1, 1877, the following members were elected as the office-bearers for the ensuing year:—*Governor:* James Shaw, L.R.C.S.I. *Deputy-Governor:* Henry Palmer Nolan, M.D. *Court of Directors and Examiners:* Edward Howard Bolland, M.D., M.R.C.S.E.; Thomas Collins, M.R.C.S.E.; John Evans, Esq.; Arthur Harvey, Esq.; Charles Holmes, M.D.; Charles H. Leet, M.D., M.C.; Charles F. Moore, M.D., F.R.C.S.I.; Robert Montgomery, M.R.C.S.E.; Jerome O'Flaherty, L.R.C.S.I.; Edward J. O'Neil, M.D., L.R.C.S.I.; Sir George B. Owens, M.D.; John Ryan, M.D., M.R.C.S.E.; John Wyse, M.D. *Examiners in Arts:* John William Moore, M.D., University of Dublin; Edward W. Collins, M.D., Univ. of Dublin. *Representative on the General Medical Council:* Dr. Charles Henry Leet.

MEDICO-PSYCHOLOGICAL ASSOCIATION.

The annual meeting of the Medico-Psychological Association was held on Thursday, August 2, at the Royal College of Physicians, London, and was very numerously attended. Dr. Fielding Blandford, the President, in his address gave an interesting historical sketch of the progress of lunacy legislation during the last hundred years. Dr. Crichton Browne, Lord Chancellor's Visitor in Lunacy, was unanimously chosen President-elect of the Association. In the evening the members and their friends dined together at the "Ship," Greenwich.

HEALTH OF H.R.H. PRINCE ALBERT VICTOR.

The course of the fever in the case of H.R.H. Prince Albert Victor has been as anticipated in our last report. On Saturday last, the twenty-ninth day, the temperature fell to 98° Fahr., together with an abatement of all the symptoms. The convalescence is now satisfactorily established.

MEDICAL PARLIAMENTARY AFFAIRS.

In the House of Commons, on Friday, August 3, the Sale of Food and Drugs Act Amendment Bill was read a third time and passed to the Upper House.

The Committee sat on the Public Health Bill for Ireland and the Local Government Board's Bill for the Improvement of Artisans' and Labourers' Dwellings.

On Tuesday, August 7, the Canal Boats Bill was read a

second time in the House of Lords. The Duke of Richmond roughly estimated the amount of this floating population at from 30,000 to 80,000, whose condition generally was very deplorable. The education of the children was neglected, and the men and women were grossly ignorant. The families all lived and slept in small, ill-ventilated cabins a few feet square, so that infectious diseases spread with very great rapidity. The Royal Commission which had carefully inquired into the condition of this floating population had recommended the adoption of very stringent measures, but the Government did not think it desirable to go to the extent of their recommendations. The Bill which had been prepared would fairly meet the requirements of the case. The Earl of Shaftesbury expressed his thanks to the Government for pushing on this measure during the present session. No doubt they would ultimately carry out the whole of the recommendations of the Royal Commissioners.

THE BRITISH MEDICAL ASSOCIATION.

MANCHESTER.

On Tuesday, the 7th inst., the proceedings in connexion with the forty-fifth annual meeting of the British Medical Association, held this year in Manchester, began, as usual, with a special religious service. This was held in the Cathedral. In the course of it the Bishop delivered a sermon which has been universally praised, not only for its earnestness, but for its sound practical views, strongly and sensibly enforced. The Bishop of Manchester is not so renowned as some of his brother-preachers for eloquence, but he yields to none of them in that sound common sense which is perhaps even a more useful quality in this workaday world.

According to statutory arrangements, the meeting of the British Medical Association begins on the first Tuesday of August; but as this year the month began on a Wednesday, the meeting is a week later than it was last year. A good many men, on leaving off work, begin their holidays by attending this annual meeting, but from its being thus a week later than usual, some may possibly have left town before its commencement. Nevertheless, though the number of London men present may be fewer than we have seen, those who are here are highly representative, including many well-known names, as Sir William Jenner, Drs. Russell Reynolds, Andrew Clark, Priestley, Graily Hewitt, Barnes, Braxton Hicks, A. P. Stewart, Broadbent, Langdon Down, and many others. London surgeons seem to be less numerous; but among them we have seen Messrs. Spencer Wells, Cooper Forster, and W. Adams. Practitioners from other parts of the country we cannot enumerate; for the meeting bids fair to be one of the largest and most popular of recent years. It is curious to a regular attendant of these meetings to note how year by year the physiognomy of the frequenters of it varies. Each district brings out its own contingent of the profession, and though we invariably see some well-known faces, yet year by year there is a change in the great body of members attending. Certainly the profession in and around Manchester have spared no pains and no money to make the meeting a success, and in this they are greatly aided by the facilities offered by the possession of the Owens College, in which most of the meetings are held. This building, which is of quite a recent date, is situated at some distance from the heart of the town, and from the various railway-stations. To remedy the inconveniences arising from this fact, the authorities secured the large Concert Hall in the centre of the town, and converted it into a reception-room. Here, too, the first general meeting was held, and the President's Address delivered, and here tickets are issued and all necessary information given. Access from this central spot to Owens College is easy by 'bus or by cab, or, to those who prefer going on foot, by a twenty minutes' walk. The building now devoted to educational purposes under the name of Owens College stands within its own grounds where town is beginning to merge into country, and the houses are surrounded by greater breathing space than is possible in the centre of the city. The structure itself has, comparatively speaking, a mean and unimposing elevation, and the stranger is surprised on entering it to find how commodious in every respect it is. Corridors seem to run everywhere, but abundance of space is left for class-rooms and laboratories of every description. These are certainly the best we have seen, and contrast strongly with the miserable school accommodation with which we are familiar in London. Apparatus, too, is abundant; in short, the teaching appliances are of the best, and it is not for lack of these that Manchester can fail as a school of science or of medicine. The connexion of the Medical Faculty with Owens College only dates from 1874. Previous to that there was a School (indeed, at one time two) of Medicine in Manchester, but it was only at the period mentioned that medicine was combined with other teaching at Owens College. No doubt this amalgamation is a great and distinct gain to all concerned, but we are so accustomed to look upon a close and intimate alliance between the instruction given in the science of medicine and its practical application in the hospital, that we must look with regret on the distance which separates the Infirmary from the Medical School. This is a great drawback, and may lead, should the Infirmary be still retained on its old site, to the institution of something like a clinical hospital not far from the College—as has been done in Glasgow, for instance.

But to revert to the actual proceedings of the Association. It has during a good many years been the custom for the President to deliver his Inaugural Address in the evening, when the first general meeting was held, but this year it was decided to begin the work in the afternoon. On the afternoon of Tuesday, then, Dr. Eason Wilkinson, the Senior Physician to the Royal Infirmary here, took the chair vacated by Dr. Bartolomé, of Sheffield, and delivered the plain and sensible address elsewhere reported. Somehow or other a kind of fashion has crept in for presidents to found their observations on the medical history of the town where the meeting may be held; and Dr. Wilkinson's address was no exception to the rule. Suffice it to say that it was well delivered, though in a weak tone of voice, and cordially received by the assembly. At the general meeting which followed this address the annual report of the Association was read and passed; whereupon two motions should have come up for discussion. One of them was proposed by Mr. Lowndes, of Liverpool, regarding the extension of the Contagious Diseases Acts to certain seaport towns. This was relegated to the Health Section. The other was one of the usual nonsensical propositions with regard to the editing of the *British Medical Journal*. It is plain that some people do not know when they are well off; but this year's motion was more than usually absurd. It was neither more nor less than to edit the journal by a committee! They might quite as sensibly propose to do away with an editor altogether,—it would be a distinct saving, which is much in the eyes of some. And then—which again would be a great comfort—every member of the Association could edit himself.

In the evening a *soirée* was given by the President and the Senate and Council of the Owens College, in that building. This was most numerously attended by ladies and gentlemen, and was in every way worthy of the character and position of those who gave it. We have seldom seen better or more complete arrangements. Of course, the ample space available aided greatly in this. Lectures were delivered by Dr. Ransome on "The Present Position of State Medicine in England," and by Dr. Boyd Dawkins on "The Antiquity of Man"; and demonstrations were given in Physics and Physiology. The whole was thoroughly successful, and people left in a drizzling rain, well pleased with themselves and with their entertainment.

Wednesday morning opened showery, and towards midday there was a very sharp thunderstorm, with a tremendous downpour of rain. In connexion with this a somewhat absurd incident occurred. About twelve o'clock, whilst Dr. Roberts was delivering the admirable Address elsewhere published, the storm burst. The Address was being listened to by an audience filling to overflowing the large chemistry-lecture theatre, and the windows were open for the purpose of ventilation. Through these the rain poured. First hats went on; next umbrellas went up, until the orator seemed to be addressing an audience, part of which, at least, might as well have been in the open air. Proceedings had to be stopped, until the man could be found who understood how to work the apparatus necessary to close the windows. At one o'clock a demonstration was given by Professor Charcot, of Paris, of certain specimens illustrative of his views as to the pathology of certain diseases of the spinal cord, liver, and lungs. The diseases of the spinal cord were those already identified with his name, and with regard to which his views have been recently

published in his lectures; cirrhosis of the liver, and the tubercular nature of broncho-pneumonia or caseous pneumonia, were also illustrated. This demonstration lasting somewhat longer than was expected, the work of the sections did not begin, as it should have done, exactly at two o'clock, but was postponed for a short space. When, however, the sections were about to be opened there was a great rush to hear Sir William Jenner, the President of the Medical Section. His address was short and pithy in the extreme, but was admirably adapted to its purposes, dealing mainly with the good done by such meetings and by such discussions as those likely to follow in his section and in others. The special subject of the day in this section was the treatment of internal aneurism. This was not, however, reached until a somewhat late period in the afternoon. The other subjects for discussion in the various sections were—in Psychology, the treatment of habitual drunkards; and in State Medicine, the whole question of infection.

The morning was devoted by many to an inspection of the treasures in the Museum. These might be divided into three sections—drugs, surgical appliances, and pathological specimens. We have seen museums richer in pathology, but seldom, if ever, such a collection of drugs and surgical appliances. It would be so unfair to mention any one exhibitor specially that we will name none. There was, however, one feature which forcibly struck us. A few years ago an attempt was made to familiarise the ordinary practitioner with the applications of electricity to medicine. Then it was hardly possible to procure sufficient batteries so as to form a fair show; to-day they were to be seen by the score. And it may be a fact worthy of attention that there seemed to be a constant tendency to fall back on some form of the Leclanché cell as the primary element. This will probably in a few years supersede almost every other form of medical battery. The absurd little electro-magnetic apparatus was conspicuous by its absence.

There was also a good display of microscopes, of various degrees of complexity and price, a good many of them brought forward as competitors with the now well-known and justly esteemed Hartnack. By the way, there was a large number of these Hartnacks exhibited by Messrs. Ferris and Co., of Bristol, from whom they might, in all probability, be more easily procured than from abroad. The price is, we think, seven guineas. In the Pathological Section not very much was displayed which was of real interest. There was, however, a unique collection of distorted pelves exhibited by Dr. Radford, such as is seldom seen, and the same gentleman also showed a most interesting collection of obstetrical instruments of all ages. It might be well, also, to mention a fine collection of photographs of the insane. In the Physiological Laboratory were to be seen some excellent specimens of physiological apparatus, some belonging to the College, some to a Parisian exhibitor. To the Sanitary Museum, established in the grounds, we cannot now do more than refer.

In the evening a reception was given by the Mayor and Corporation of Manchester in the new and magnificent Town Hall, thus for the first time, though informally, thrown open to the public; but details must be reserved for another occasion.

Small-Pox and the Port Sanitary Committee.—The Port Sanitary Committee of the Corporation of London have recently issued an additional notice recommending "as a precautionary measure" that as long as the epidemic exists all seamen should be medically examined in accordance with the provisions of sec. 10, Merchant Shipping Act, 1867. This section is permissive only. It is believed, however, that if some of the cases found afloat affected with small-pox had been examined at the time of signing articles the disease would have been discovered. At the last meeting of the Court of Common Council the Port Sanitary Committee were authorised to prepare estimates and invite tenders for the building of a new steam launch. This launch is to be used by the officers, chiefly in the Pool, to board all such kinds of craft as have their crews always on board; and hence require much more supervision than the large ocean-going ships, which haul into dock and pay off immediately. The ordinary visitation of ships on the river keeps a steam launch very fully employed, and it is calculated that the Corporation's little vessel employed for this purpose is under steam for more hours during the working days of the week than any other craft of her class in the port of London.

REVIEWS.

Smellie's Treatise on the Theory and Practice of Midwifery. Edited with Annotations by Alfred H. McClintock, M.D., etc. Vol. II. London: The New Sydenham Society. 1877.

We are glad to be able to say that we have received the second volume of this work more punctually than the first. The book is one the merit of which is that of a pioneer. We fully recognise its great, its matchless worth. It cannot be surpassed, because no one can ever again write a book under circumstances like Smellie's. But we cannot but remember that *now* any fairly educated physician, even though without a tithe of Smellie's genius, could yet compile a book which should tell more about natural processes, and be a better guide in practice. For we, at the present day, receive, as it were, with compound interest, the treasure which Smellie bequeathed. Therefore we look upon this book as one interesting rather than useful; a staff to be admired rather than leaned on. To the obstetric specialist working at a particular subject, this volume, containing as it does a collection of cases of undoubted veracity, with thoughts thereon by a great and original mind, is, we might almost say, indispensable; but for the hard-working general practitioner, who reads to keep himself abreast of the science of to-day, more useful books might be found.

In making these remarks we refer to the text of the book, not to Dr. McClintock's annotations. He, as editor, has done his part very well. He has numbered the cases, and enriched them with many clear and practical notes and helpful references. The reader will find the notes suggestive as well as the text; and he who consults the book for help in practice may perhaps find some of them (without disparagement of Smellie) more useful.

GENERAL CORRESPONDENCE.

VIN DE BAUDON.

Letter from Dr. Andrew Clark.

[To the Editor of the Medical Times and Gazette.]

Sir,—My attention having been called to an advertisement of the Vin de Baudon in which my name is mentioned in such a manner as to beget the idea that I had employed this compound, that to its employment I had ascribed the recovery of a patient from empyema, and that I recommended its use, perhaps you will kindly permit me to state, in answer to many communications on the subject, that the wine was prescribed by the resident medical officer of the London Hospital; that in my opinion its use exerted no favourable influence upon the patient's recovery; that I have never prescribed the preparation; that the garbled extracts from the reports of the case, neither written nor revised by me, used by the advertisers to promote the sale of their commodity, have been published without my knowledge; and that the continued use of the advertisement as it now runs is contrary to my judgment of what is right. I am, &c., Andrew Clark, M.D.,

August 4. Physician to the London Hospital.

The Library of the Royal Medical and Chirurgical Society will be closed for one month from Monday, August 13, to Wednesday, September 12 (both days inclusive).

Royal College of Surgeons in Ireland.—A special meeting of the Fellows of the College was held on Monday, August 2, for the purpose of electing Professors to fill the chairs in the School of Surgery, vacated by the recent deaths of Mr. Henry Wilson and Dr. John Cronyn. Mr. H. Rosborough Swanzy was elected Professor of Ophthalmic Surgery; and Dr. William Roe, Professor of Midwifery.

The New Hôtel-Dieu.—This Hospital was opened a few days since, with an imposing ceremony, by M. Isnard, Inspector-General of the Assistance Publique, the transference of the patients commencing after each ward had been blessed. Already, however, complaints are commencing, that important body, the *internes*, having addressed a memorial to the Director complaining of the utter unsuitability of the dark and damp condition of the locality assigned to them, and where they have to pass so large a portion of their time, while the bureaux and apartments of the administrative *employés* are luxuriously and sumptuously fitted up.—*Gaz. Méd.*, August 3.

MEDICAL NEWS.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College at a meeting of the Court of Examiners on the 1st inst., viz. :—

Dunstan, William, L.S.A., Brixton, student of Guy's Hospital.
Keer, John Cordy, L.S.A., Wickham Market, of Guy's Hospital.
Miller, Richard Shalders, L.S.A., Lowestoft, of University College.
Potts, Laurence, L.S.A., Beckenham, Kent, Charing-cross Hospital.
Prideaux, Thomas Engledue Pegamus, L.S.A., L.R.C.P. Lond., Scarborough, of St. Bartholomew's Hospital.
Ross, Richard Alexander, Brighton, of Guy's Hospital.
Sheldon, Thomas Steele, Congleton, Cheshire, of Guy's Hospital.
Shipton, Arthur, L.S.A., Buxton, of King's College Hospital.
Smith, Hugh, L.S.A., Wimpole-street, of King's College Hospital.
Taylor, Harold Gilbertson, L.S.A., Queen's-road, W., of King's College Hospital.
Wilmot, Thomas, L.S.A., L.R.C.P. Lond., Fenton, Lincoln, of St. Bartholomew's Hospital.
Vachell, Herbert Redwood, L.S.A., Llandaff, of King's College Hospital.

Six candidates passed the examination in Surgery and when qualified in Medicine will be admitted Members of the College. The other six candidates were referred to their professional studies for a period of not less than six months.

The following gentlemen were admitted Members of the College on the 2nd inst., viz. :—

Birdwood, Roger Alan, B.A. Cant., Bombay, student of the University of Cambridge and Guy's Hospital.
Burgess, William Milner, L.S.A., Harlesden, N.W., of St. Bartholomew's Hospital.
Cardew, George Arthur, L.S.A., Cheltenham, of the General Hospital, Birmingham, and University College.
Chubb, William Lindsay, Torpoint, Cornwall, of Guy's Hospital.
Davy, Henry, Ottery St. Mary, of Guy's Hospital.
Langdon, John Winkly, L.S.A., Chester, of St. Bartholomew's Hospital.
Paddison, Edmund Howard, Denbigh-road, Bayswater, of Guy's Hospital.
Poland, James Harry, L.S.A., Blackheath, of Guy's Hospital.
Pope, Charles Ernest, Chilfrome, of King's College Hospital.
Prosser, Thomas Gilbert, L.S.A., Monmouth, of St. Bartholomew's Hospital.
Smyth, Albert Charles Butler, L.S.A., L.R.C.P. Edin., Dublin, of St. Bartholomew's Hospital.
White, Robert Godfrey, L.S.A., Chinkiang, China, of the London Hospital.

One candidate, who passed in Surgery at a previous meeting of the Court, having subsequently obtained medical qualifications, was admitted a Member of the College, viz. :—

Hall, C. C. R., L.R.C.P. Edin., Tottenham, student of St. Bartholomew's Hospital.

Two candidates, who had previously qualified in Surgery, having passed in Medicine, were also admitted Members, viz. :

Cobbin, Wm. I., Torrington-square, student of University College Hospital.
Gardiner, John Twiname, Ilfracombe, of Guy's Hospital.

Five candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College. The other seven candidates were referred to their professional studies for a period of not less than six months.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—At the examination for the Licence to practise Surgery, held on July 23 and following days, the undermentioned candidates, having passed the required tests for the diploma, and having made and subscribed the necessary declaration, were admitted Licentiates of the College :—

Arthur, Thomas F.
Bagnell, William H.
Beattie, Joseph J.
Bell, Thomas V.
Blacker, Edward J. L.
Bothwell, James.
Carmody, Patrick J.
Charlton, Henry A. H.
Collins, Patrick J.
Cooper, William R.
Curran, Thomas.
Delmege, Louis.
Evans, William G.
Finlay, David A. M.
Hamilton, John R.
Hoctor, Wm. H. de Burgh.
Kehoe, Matthew
Kerrigan, Laurence.
Leary, Edward G.
Mackey, Wm. B.
Madigan, Bartholomew.
M'Cann, Joseph.
M'Donnell, Edward P.
Mullen, John W.
O'Callaghan, Robert.
Orr, David W.
O'Sullivan, Daniel.
Poirotte, Benjamin.
Russell, Samuel.
Sherrard, Henry R.
Sillard, Thomas P.
Thompson, Andrew C.
Thunder, Edmund J.
White, Thomas G.
Yourell, John B.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, August 2 :—

Eastwood, Lewis, North-road, Darlington.
Temple, Thomas Cameron, Doddington-grove, Kennington.
Young, Alexander Stewart Ward Young, Chandos Villas, Clifton.

The following gentlemen also on the same day passed their Primary Professional Examination :—

Alban, Evan, St. Bartholomew's Hospital.
Blackburn, Herbert B., Guy's Hospital.
Dykes, John Swindells, Queen's College, Birmingham.
Farmer, Ernest W. W., University College.
Nance, Henry Chester, St. Bartholomew's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

ROE, WILLIAM, M.D., F.R.C.S.I., Professor of Midwifery to the Royal College of Surgeons in Ireland.

NAVAL, MILITARY, &c., APPOINTMENTS.

WAR OFFICE.—YEOMANRY CAVALRY.—Staffordshire: Henry Palmer Welshman, gentleman, to be surgeon.

BIRTHS.

ANNANDALE.—On August 2, at Salisbury-green, Edinburgh, the wife of Thomas Annandale, F.R.C.S., of a daughter.

BROWN.—On August 4, at 1, Bartholomew's-road, Kentish Town, the wife of Andrew Brown, L.R.C.P.E., L.R.C.S.E., of a daughter.

DALY.—On August 7, at 101, Queen's-road, Dalston, the wife of Frederick H. Daly, M.D., of a son.

FINNY.—On July 30, at 19, Lower Baggot-street, Dublin, the wife of J. Magee Finny, M.D., of a son.

GUINNESS.—On June 16, at Tonghoo, the wife of H. C. Guinness, L.K.Q.C.P., Surgeon-Major 89th Regiment, of a son.

HOPWOOD.—On August 2, at Warley, Essex, the wife of Surgeon-Major E. J. Hopwood, M.R.C.S. Eng., of a son.

LONGHURST.—On August 2, at 22, Wilton-street, S.W., the wife of Dr. Arthur E. T. Longhurst, of a daughter.

NASH.—On August 4, at Westgate-on-Sea, the wife of Edmund Nash, M.D., of a son.

RATTRAY.—On August 2, at 31, Lauder-road, Edinburgh, the wife of James C. Rattray, M.D., of Coral Bank, Blairgowrie, of a son.

SMITH.—On August 1, at 2, Eastbourne-terrace, Hyde-park, the wife of W. Wilberforce Smith, M.D., M.R.C.S., L.R.C.P., of a son.

SMITH.—On August 3, at London-road, Croydon, the wife of W. H. M. Smith, L.R.C.P., of a son.

WINKFIELD.—On August 1, at Shirley, Southampton, the wife of W. B. Winkfield, L.R.C.P. Edin., of a daughter.

MARRIAGES.

CROCKFORD—KEY.—On August 2, at the Chapel Royal, Savoy, George Thomas Crockford, of the precinct of the Savoy, to Ann Key, daughter of the late David Key, surgeon, of Brixton.

GREIG—BAYLIS.—On August 2, at Westbury-upon-Frome, Gloucestershire, Charles Greig, F.R.C.S., of Clifton, to Nelly, fourth daughter of the late Captain Edward Bayliss, 9th Lancers, of Knuthurst, Staffordshire.

HARRIS—NOTT.—On August 7, at St. Margaret's, Westminster, Henry Graham, only son of Captain Harris, of Alverstoke, Hants, to Frances Isabel, youngest daughter of W. F. Nott, M.R.C.S., of Kennington, Surrey.

HOLLAND—LOMAX.—On August 1, at Cheadle, Cheshire, Robert Holland, of Norton-hill, Cheshire, to Hannah Martha, eldest daughter of the late Henry J. Lomax, M.D.

HUMPHREYS—MCWILLIAM.—On August 2, at St. Michael's, East Teignmouth, Frederick William Humphreys, F.R.C.S., to Catherine, sixth daughter of the late James Ormiston McWilliam, C.B., F.R.S., M.D.

LAYMAN—PAPINEAU.—On August 2, at St. Barnabas, Homerton, Henry Layman, of Lewisham High-road, to Harriet, fourth daughter of Wm. Papineau, M.R.C.S., of Homerton.

MACFEE—CROSS.—On August 2, at the parish church, South Hackney, John Macfee, M.D., to Anne Eliza, eldest daughter of the late John Cross, historical painter.

MADDEN—MELDRUM.—On August 2, at East Teignmouth Church, Devonshire, William Herries Madden, M.D., F.R.C.P., of Torquay, to Mary Anne, daughter of James Buyers, Esq., of Rosebank, Bathgate, and widow of Edward Meldrum, Esq., of Dechmont, Linlithgowshire.

SHIVES—SMITH.—On July 26, at St. John's, Bradford, John Shives, M.D., Liversedge, Yorks, to Elizabeth Smith, of Horton, Bradford.

STIRLING—GILBERT.—On June 27, at Pewsey-vale, South Australia, Edward Charles Stirling, M.A., M.B., F.R.C.S., eldest son of the late Edward Stirling, Esq., of 34, Queen's-gardens, Lancaster-gate, and Adelaide, South Australia, to Jane, eldest daughter of Joseph Gilbert, J.P., of Pewsey-vale.

SWAYNE—CORMACK.—On August 8, at the British Embassy, Paris, Colonel James Dowell Swayne, of H.M.'s Bengal Staff Corps, to Mary Morris, daughter of Sir John Rose Cormack, M.D.

WOOD—HENRY.—On August 7, at Holy Trinity Church, Roehampton, Surrey, William Edward Ramsden Wood, M.A., M.B. Cantab., eldest son of William Wood, M.D., of 99, Harley-street, to Alice Louisa, youngest daughter of James Henry, Esq., of Blackdown, Sussex, formerly of the 72nd Highlanders.

DEATHS.

BROADBENT, EDWARD FARR, F.R.C.S. Eng., of Lincoln, on Aug. 5, aged 63.

GIMLETTE, HART, M.D., Fleet Surgeon R.N., at Sandford House, on August 1, in his 55th year.

LAWTON, JAMES, M.R.C.S. Eng., at Glebe House, Rochdale, on August 4, aged 63.

MAY, EDWARD CURTIS, F.R.C.S., at Bruce Grove, Tottenham, on August 7, aged 80.

MULLANE, TIMOTHY, M.D., late of H.M. 63rd Regiment, at Chexbores, Switzerland, on July 30.

SPARROW, EMILY, wife of Surgeon-Major J. Sparrow, M.R.C.S. Eng., late of the 89th P.V. Regiment, at Coonoor, Neilgherry Hills, Madras, on July 2.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

KENT AND CANTERBURY HOSPITAL.—House-Surgeon. "Bye-Law 58. No person shall be eligible for the office of House-Surgeon unless he bring proof that he is registered under the Medical Acts as legally qualified to practise medicine and surgery. He must be unmarried, and not more than forty years of age, and he shall reside in the house." Testimonials of qualification to be sent in on or before August 24.

ROYAL FREE HOSPITAL, GRAY'S INN-ROAD.—Assistant-Physician and Assistant-Surgeon. The Assistant-Physician must be a Member of the College of Physicians of London, and the Assistant-Surgeon a Fellow of the Royal College of Surgeons of England. Testimonials to James S. Blyth, Secretary, before September 1.

TAMWORTH UNION RURAL SANITARY AUTHORITY.—Medical Officer. Appointment will be made subject to approval of the Local Government Board, and will be from date of appointment until March 25, 1878. Salary after the rate of £120, including travelling and other expenses. Must be legally qualified medical practitioners, registered under the Medical Act of 1858, and must produce diplomas, etc. Applications, with testimonials, in own handwriting, before 10 a.m. on August 11, to John Shaw, Clerk, Tamworth.

TAMWORTH UNION.—Medical Officer. Salary for Workhouse £30, and District £75, which includes all extra fees, except vaccination. Would be appointed Public Vaccinator. Fees 1s. 6d., 2s. 6d., and 3s. 6d. Must be legally qualified. Sealed applications before 10 a.m. on August 11, to John Shaw, Clerk, Tamworth.

WILTS COUNTY LUNATIC ASYLUM.—Assistant Medical Officer. Candidates must be duly qualified and registered medical practitioners. Applications, stating age, and accompanied by not more than six recent testimonials, to "The Clerk to the Committee of Visitors of the Wilts County Lunatic Asylum, Devizes," marked "application," on or before Aug. 21.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATION.

Brentford Union.—Mr. Fredk. Davies has resigned the Workhouse; salary £140 per annum.

APPOINTMENTS.

Bath Union.—Angus Cameron, M.D. Edin., L.R.C.S. Edin., to the Second District.

Berkhampstead Union.—Thos. C. Lawson, M.R.C.S. Eng., L.S.A., to the Berkhampstead District and the Workhouse.

Epping Union.—Fredk. C. Cory, M.D., M.R.C.S. Eng., L.S.A., L.R.C.P., to the Chingford District.

Falmouth Union.—Jacob H. Bartlett, L.R.C.P. Edin., L.F.P. & S. Glasg., to the Constantine District.

DEATH FROM TWENTY GRAINS OF CHLORAL.—Dr. Ingalls reports that he gave to a German woman, about thirty-three years of age, and apparently healthy, ten grains of chloral, and repeated it in one hour. Soon after the second dose she manifested alarming symptoms of poisoning, and died, in spite of all efforts, in about fifteen minutes. No post-mortem examination was made. Only two doses of ten grains each, one hour apart, were taken.—*Boston Medical Journal*, July 7.

COMPOSITION AND QUALITY OF THE METROPOLITAN WATERS IN JULY.—The following are the returns (by Dr. Meymott Tidy) of the Society of Medical Officers of Health:—

Names of Water Companies.	Total Solid Matter per Gallon.	Oxygen required by Organic Matter, etc.	Nitrogen: As Nitrates, etc.	Ammonia.		Hardness. (Clarke's Scale).	
				Saline.	Organic.	Before Boiling.	After Boiling.
Thames Water Companies.	Grs.	Grs.	Grs.	Grs.	Grs.	Degs.	Degs.
Grand Junction	17·00	0·052	0·120	0·001	0·007	11·0	2·8
West Middlesex	17·10	0·053	0·105	0·000	0·007	11·8	3·3
Southwark and Vauxhall	20·70	0·050	0·090	0·001	0·008	12·1	2·8
Chelsea	17·40	0·057	0·090	0·000	0·007	12·1	2·4
Lambeth	17·00	0·052	0·120	0·000	0·009	11·8	3·3
Other Companies.							
Kent	26·70	0·015	0·300	0·000	0·003	17·0	5·1
New River	16·40	0·019	0·120	0·000	0·006	12·1	3·3
East London	18·30	0·046	0·090	0·000	0·007	12·1	3·3

Note.—The amount of oxygen required to oxidise the organic matter, nitrites, etc., is determined by a standard solution of permanganate of potash acting for three hours; and in the case of the metropolitan waters the quantity of organic matter is about eight times the amount of oxygen required by it.

The water was found to be clear and nearly colourless in all cases but the following, when it was slightly turbid—namely, in that of the Grand Junction, West Middlesex, Southwark and Vauxhall, Chelsea, and the Lambeth Companies.

HEALTH CONGRESS OF THE SANITARY INSTITUTE.—The Mayor and Corporation of Leamington have invited the Sanitary Institute to hold its Congress in their town, and the invitation has been accepted. The Congress will meet early in October.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Devonian.—John Huxham, a physician of celebrity in the West of England, took his doctor's degree at Leyden. He studied there under Boerhaave, and on his return to England settled at Plymouth, where he continued for thirty years to practise with success. He was a Fellow of the Royal Society, in whose *Transactions* are many of his papers. He also published various medical works; and his name is still popular through his well-known "tincture of bark." He was born at Halberton, in Devonshire, and died 1768.

Vice or Disease?—The paper was read by Dr. Bodington, before the annual meeting of the British Medical Association. Dr. Bodington's remark was: "The confusion between drunkenness as a *disease*, and drunkenness as a *vice*, must be cleared up. For my part, I look upon all habitual drunkenness as a disease, and I would boldly call it all *dipsomania*. It is in its character as a disease that we physicians are entitled to deal with it. I would sink the notion of its being a mere vicious propensity. When fully developed there are not two kinds of habitual drunkenness. The cases are one and all cases of *dipsomania*, of irresistible, uncontrollable, *morbid impulse* to drink stimulants."

Chemicus.—Liebig at the age of eighteen was at Bonn, then at Erlangen, where he graduated; and in 1822 he published his first chemical work. There was scarcely a branch of chemistry to which Liebig did not devote attention.

Phœbus.—It was an American editor who did not scruple to issue to the subscribers to his newspaper a sheet which contained, besides advertisements, only these words:—"The wife of our esteemed editor having, since our last issue, presented him with three boys at a birth, his emotions have prevented his supplying the usual leaders and other literary matter. He has caved. The prayers of subscribers are earnestly desired. No cards."

Cave Canem.—The deaths from hydrophobia, during the year 1875, were forty-seven. The largest number of cases (sixteen) occurred in Lancashire.

Hygienic.—The paper read by Mr. Binney last year to the Manchester Literary and Philosophical Society, contending that "the atmosphere of towns may be sensibly ozonised and improved in quality by the action of public fountains," states—"A water-fountain may be regarded as a hydro-electric machine, the friction of the water issuing through the jets developing electric action, materially assisted by the conversion of the spray into aqueous vapour. I would suggest that this fact should be prominently brought before municipal bodies, to induce them to erect fountains in all available places in large cities as sanitary agents. They might prove highly beneficial in crowded localities." The subject of ozone, in its various phases, is engaging the attention of scientific inquirers.

AN APPEAL TO THE HUMANE AND BENEVOLENT.

The following contributions have been received in answer to the above appeal, inserted in our number of July 28:—

	£	s.	d.
Royal Medical Benevolent Fund	20	0	0
Lord O'Hagan	3	3	0
John Leonard, Esq., J.P.	3	3	0

Reference kindly permitted to the following, by whom contributions will be thankfully received and acknowledged:—

George W. Abraham, Esq., LL.D., etc., 2, Oakland-villas, Rathgar; E. D. Mapother, Esq., M.D., F.R.C.S.I., 6, Merrion-square, N; Thomas M'Nally, Esq., A.M.T.C.D., 77, Lower Gardiner-street; Austin Meldon, Esq., F.R.C.S.I., etc., 15, Merrion-square North; Joseph Manly, Esq., Manager Hibernian Bank, 21, Lower Sackville-street; Arthur H. Lynch, Esq., Surgeon Army Medical Department, Killester, Raheny; Major A. H. Lynch, Killester, Raheny.

Senex.—The late Samuel Warren, Q.C., was educated at the University of Edinburgh for the medical profession, but afterwards became a law student, and was called to the bar in 1837. He obtained great celebrity as a writer by his "Diary of a Physician," and his novels "Ten Thousand a Year" and "Now and Then."

Secundus.—History tells us that the mother of Socrates was by profession a midwife.

WEATHER STATISTICS.

It appears from statistics issued by the Registrar-General that the most striking features of the weather in the second quarter of this year were the low temperature during the greater part of April and May, and the severe frosts early in May, while the temperature in June was considerably above the average.

COMMUNICATIONS have been received from—

Surgeon-Major R. BERISTEAD, London; THE REGISTRAR OF THE APOTHECARIES' HALL, London; THE REGISTRAR OF THE EDINBURGH UNIVERSITY; Dr. C. M. TIDY, London; Mr. E. M. BODDY, Camberwell; Dr. G. A. WOODS, Southport; Dr. ANDREW CLARK, London; Dr. M. A. EASON WILKINSON, Manchester; Dr. SPARKS, Dorchester: THE MANCHESTER AND SALFORD SANITARY ASSOCIATION; THE SECRETARY OF THE LOCAL GOVERNMENT BOARD, London; Dr. J. W. MOORE, Dublin; Dr. T. WHIPHAM, London; Mr. J. NEVINS HYDE, Chicago; Dr. G. E. HERMAN, London; Dr. W. RHYS WILLIAMS, London; Mr. T. M. STONE, London; Mr. T. SPENCER WELLS, London; Dr. BARLOW, London; Mr. R. BRUDENELL CARTER, London; Dr. ALEXANDER WALLACE, Colchester; Mr. JOHN CHATTO, London; Dr. JAMES RUSSELL, Birmingham; Mr. B. R. WHEATLEY, London; Dr. HENRY THOMPSON, London; Dr. PEARSON IRVINE, London.

BOOKS AND PAMPHLETS RECEIVED—

Charles Kelly, M.D., Third Annual Report on the Condition of the Combined Sanitary District of West Sussex—Water for Manchester from Thirlmere—Model By-laws issued by the Local Government Board for the use of Sanitary Authorities—Robert Bentley, F.L.S., and Henry Trimen, M.B., F.L.S., Medicinal Plants, part 23—Charles Higgens, F.R.C.S., Hints on Ophthalmic Out-Patient Practice - Charles F. Folsom, M.D., Disease of the Mind—J. L. W. Thudichum, M.D., A Treatise on the Pathology of the Urine, including a Complete Guide to its Analysis—George H. Savage, M.D., Some Relations of Mental Disease to Inheritance—Statistical Tables of the Patients under Treatment in the Wards of St. Bartholomew's Hospital during 1876.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—Medical Examiner—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Iron—Home Chronicler—La Province Médicale—Transactions of the Odontological Society of Great Britain—Analyst—Gazeta Medica da Bahia - American Journal of the Medical Sciences—Union Médicale—Night and Day—Practitioner—Students' Journal and Hospital Gazette—Toronto Sanitary Journal—Cincinnati Clinic.

APPOINTMENTS FOR THE WEEK.

August 11. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

13. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

14. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

15. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

16. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

17. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, August 4, 1877.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·88 in. The highest reading was 30·13 in. on Monday morning, and the lowest 29·69 in. on Wednesday morning.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

LECTURE IV.—HYPERMETROPIA AND MYOPIA.

(*Concluded from page* 135.)

I PASS on now to the opposite condition of Myopia, which, as contrasted with hypermetropia, presents a long visual axis instead of a short one, and a focus of parallel rays which is situated in front of the retina. In order that the focus of rays may fall upon the retina, the rays themselves must be divergent; and this divergence may be given to them either by the approximation of the object from which they proceed, or by refraction through a concave lens of the necessary power.

When a person is able to read small print easily and fluently in the hand, but has not the normal standard of vision for distant objects, we may at once infer that he is the subject of myopia; and, if his distant vision is improved by a concave glass, the inference may be accepted as a fact. We then proceed to estimate the degree of the myopia in dioptrics, by test-lenses applied in the ordinary way; always bearing in mind that the weakest concave which affords the best attainable vision must be taken as the standard of the defect. If we find, for instance, that a patient has normal vision, or nearly so, with a concave of three dioptrics, we must not at once conclude that this is the degree of his myopia, but must try whether a result equally good cannot be attained with two dioptrics and a half. Myopic persons often prefer over-correction for a time, and would choose glasses that were too strong if they were left wholly to their own devices. If the lens of two dioptrics and a half, although it improves vision, does not enable the person to decipher the same letters which were legible with three dioptrics, then the correctness of the original choice is confirmed.

The definition of myopia, it will be remembered, rests upon the fact that the *far-point* of clear vision is at some finite distance; and the degree as stated in dioptrics corresponds precisely with this finite distance. To say that a patient has a myopia equal to one dioptric, means, primarily, that a lens of one dioptric renders parallel rays sufficiently divergent to allow them to be united in a focus upon the retina. But a lens of one dioptric renders these parallel rays as divergent as if they proceeded from a point one metre distant; and it follows that the eye would not require any lens for rays which really proceeded from a point at this distance. In other words, the patient can see clearly at the distance of one metre, but not farther away. His far-point is one metre distant from the eye. The degree of myopia has reference to the far-point, and to that alone. If the myopia increases, the far-point approaches the eye; if the myopia diminishes, the far-point becomes more distant. The myopic eye, like all others, has a near-point as well as a far-point; and its near-point is determined by its power or range of accommodation, and recedes in the usual way as life advances. But the near-point has nothing to do with the degree of the myopia. From imperfect knowledge of this very simple matter, many errors have become firmly rooted in popular belief, and some errors have been promulgated by persons who ought never to have fallen into them. It is commonly said that myopia diminishes as life advances. The fact is, that a person who starts with a myopia say of nine dioptrics, and an accommodation of nine dioptrics, as in line four of Fig. 16, has his far-point at ten and his near-point at three inches from the eye. He can read at either of these distances, or at any point between them. At the age of forty, when he has lost half of his original accommodation, his far-point will still be at ten inches, but his near-point will have receded to about five inches, and he will be unable to read at any nearer distance. He will often say, "I am not so short-sighted as I was," although he has gained nothing, and has simply lost the front two inches of his range of vision. Some few years ago, certain operations upon the eye were vaunted on account of their supposed power to diminish myopia; but it is melancholy to relate that their only claim to this power was based upon recession of the near-point; the position of the far-point either not having been recorded, or having remained unaltered. The operations diminished the accommodation, and thus curtailed the range of vision at its proximal extremity, instead of extending it at its distal extremity. The belief that short-sight diminishes with the approach of old age does not, however, rest entirely upon the recession of the near-point, but also upon the contraction of the pupil which is incidental to advancing years. The pupils of young myopes are generally large, and the magnitude of the pupil increases the size of those diffusion circles on the retina, by which clear vision of objects beyond the far-point is hindered. As the pupils become smaller, the diffusion circles diminish; and thus, while the degree of myopia remains the same, remote objects are seen somewhat less indistinctly than before.

The immediate cause of myopia is, of course, the elongated shape of the eye; but the causes which originate this elongation are not completely understood. Myopia is a condition incidental to civilised life, and is said to be absolutely unknown among savage races. I am not aware of any trustworthy observations upon the eyes of new-born infants, such as to support or disprove the hypothesis that the myopic formation is sometimes congenital; but myopia is so often inherited from parents that the tendency to the formation must at least be congenital, whether the formation itself may or may not be so regarded. The affection does not declare itself in early childhood by any subjective signs, although it would be discoverable by the ophthalmoscope; and it is only at the age of five or six years that it is noticed by parents of average intelligence and observation. Very often it is first discovered at the commencement of school life; and only then after some blundering teacher has punished the child repeatedly for the offence of not knowing what was written on a black board situated beyond his range of vision. When once declared, however, the tendency of the higher degrees of myopia is to increase; and this increase seems to be almost entirely due to the enforced convergence which the affection renders necessary. If we consider the points of attachment of the interni, it is easy to see how the tension which they exert upon the ocular tunics must express itself in a tendency to bulging of the posterior hemisphere of the eye; and, when the tension is considerable and frequently repeated, the tunics soon become seriously weakened, and stretch with constantly increasing facility. As a rule, it may be said that all cases of myopia, which require habitual convergence to a distance of eight or nine inches as a condition of binocular vision, will undergo progressive increase; and it follows that every increase of the affection renders farther increase more inevitable and more rapid. Dr. Cohn, from whose highly meritorious work I have more than once quoted, was the first to investigate the occurrence of myopia in schools systematically; and he found that not only the amount of myopia, the numerical proportion to non-myopic pupils, increased with every year of school life, but also that the average degree of the myopia increased in a corresponding ratio. His inquiries have been repeated by other observers in various places, notably by Dr. Erismann in Russia, and by Dr. Agnew in America, always with full confirmation of his results; and it is now beyond doubt that schools form a great machinery for the cultivation of myopia. It is presumed that they may even originate the affection, as well as cause its active development; and the influences which may do either one or the other are mainly defective lighting, books printed in too small a character, and forms and desks so constructed that the pupils sit a long way from their work, and hence fall into stooping positions over it. All these conditions imply the unnecessary or avoidable approximation of the eyes to the books, with a consequent strain upon the accommodation and upon the convergence; and it is easy to perceive in what way myopia may result from such conditions, and how, once commenced, it must necessarily go on increasing.

According to Donders, who has analysed so many cases of myopia, and has observed them for so long a time, that he has left little to be learnt with regard to the facts of its natural history, there are three principal types of the affection: the stationary, the temporarily progressive, and the progressive. He describes as stationary a degree of myopia which does not exceed two dioptrics at ten years old, nor two and a quarter at forty; often declining to one and a quarter or one at eighty. The temporarily progressive may increase from

four to eight dioptrics between the ages of ten and thirty, the increase being most rapid between the ages of eighteen and twenty-two; and the progressive, starting from a high degree at an early period of life, increases steadily and constantly.

When myopia is increasing, the tension upon the ocular tunics, to which the increase must generally be ascribed, is apt to entail other consequences also. The most familiar of these is the so-called myopic crescent, a patch of choroidal atrophy on the outer side of the optic nerve, just where the tension upon the tunics would be most powerfully exerted. As the choroidal tissue wastes, it no longer conceals the sclerotic, which is seen with the ophthalmoscope in its glistening whiteness at the affected part; and the patch of atrophy, losing its originally crescentic form, increases in size, and sometimes completely encircles the optic nerve. Many hypotheses have been framed to account for this crescent; but I think that the most simple of them has most to recommend it to our acceptance. The wasting commences at a place where the choroid is firmly united to the sclerotic, and where, from the mechanical relations of the eyeball, the strain produced by convergence must be chiefly felt. The mere stretching of the delicate vascular membrane impedes its circulation, interferes with its blood-supply, and inflicts a shock upon its nutrition. At the point where these effects are produced in the greatest degree, atrophic changes are first set on foot, and they gradually extend to neighbouring parts as the causes which produced them are increased in intensity. Beyond the region of the white patch, we may often discover by careful examination that the choroid is thinned and weakened; and, as in nearly all the disturbances of choroidal nutrition, there is often an unnatural formation or deposition of pigment about the affected part. In some instances, we may see cloudiness of the retina, effusion from its vessels or from those of the choroid, and manifest signs of inflammation.

When the myopic crescent was first discovered, it was looked upon as an inflammatory change, and the higher degrees of myopia, in which there were large crescents, were said to be attended by *sclerotico-choroiditis posterior*. Such an appellation is sufficient to excite in the minds of all who hear it an intense longing to be able to lay it aside; and I confess that I have not been able to satisfy myself that any kind or degree of inflammation is at all essential to the most complete development of the choroidal atrophy of myopia; or that, supposing inflammation to occur, it is anything more than an accidental complication, probably due to stretching and irritation of the delicate structures which are involved. But, however produced, internal inflammation of the posterior hemisphere of a myopic eye is a very serious and alarming condition. It tends to obscure the transparency of the vitreous body by the formation of films or floating opacities, to extend to the region of the macula lutea, and destroy central vision; and even, in many cases, to produce detachment of the retina and hopeless and complete extinction of sight. To speak at length of these conditions would be foreign to the scope of discourses which profess to deal only with conditions remediable by optical appliances; and I must therefore pursue this part of my subject no farther. I have only referred to it in order to point out some of the chief dangers to which the myopic eye is exposed, and to say that against these dangers optical appliances will often furnish us with effectual safeguards.

It is necessary in this place to refer to a hypothesis, with regard to the formation of the myopic crescent, which has been put forward and defended with conspicuous ability by Dr. Thomson, of Philadelphia. He looks upon the crescent as a change which occurs only in eyes in which myopia is complicated by astigmatism; and he holds that the width of the crescent corresponds to the direction of the meridian of greatest curvature. My own observations have not allowed me either to confirm or to controvert Dr. Thomson's conclusions; but it is undeniable that there is discoverable astigmatism in nearly every instance of a high degree of myopia.

As, in hypermetropia, the eyes are constantly called upon to exert accommodation in excess of their convergence, so in the opposite condition of myopia they are constantly called upon to exert convergence in excess of their accommodation. A person with a myopia of four dioptrics, for example—and hence with a far-point only ten inches distant,—would scarcely ever be required to exert accommodation at all. He would scarcely ever desire to bring an object of vision nearer than ten inches, and he would be unable to see it clearly when farther away. His ordinary visual effort, therefore, would be convergence to ten inches in repose of his accommodatio but in many persons, if not in all, repose of the accommod tion cannot be maintained during convergence to ten inche while any effort of accommodation which the convergen produced would bring the point for distinct vision still near to the eyes, and would thus require a further increase convergence to keep pace with it. In this way, by t reaction of the two functions upon each other, we have potent influence towards rendering the myopia progressiv and it seems probable that this influence would be most powe fully exerted in those eyes in which the union between acco modation and convergence retained most nearly its natural typical character. The liability to accommodation effort as consequence of convergence effort should never be lost sight in estimating the degree of myopia; and we shall frequent find, in the higher degrees of the affection, that saturation the eye with atropine will reduce the apparent myopia by much as one or two dioptrics. In all cases of myopia abo 6·0 I am accustomed, after determining the degree in t ordinary way, to determine it again under the influence atropine. If any material difference is occasioned by t mydriatic, the fact serves as a valuable guide to the prop management of the case.

The indications of treatment in myopia are mainly thes to display the world; to prevent an injurious degree of co vergence; and to prevent spasm of accommodation.

If we consider for a moment what must be the state of person who has grown up to manhood or womanhood with uncorrected myopia say of only two dioptrics, we shall fail to perceive that the first-named indication is one of small importance. An emmetropic subject may produce t condition artificially by placing convex spectacles of t dioptrics before the eyes. The artificial myopia thus produc would be deprived of half its inconveniences by the previou acquired knowledge of the exact forms and characters numerous objects which would be only dimly seen; but t subject of it would find, for example, that instead of bei able to tell the hour by an ordinary drawing-room clock fr any part of the room, he would have to approach within th or four feet of the dial in order to perceive dim indications of hands. He would lose all the play of expression on the faces persons with whom he was engaged in conversation. I once p scribed glasses to correct the myopia of a lady who had for ma years been engaged in teaching, and who had never bef worn them. Her first exclamation of pleasurable surprise, she put the glasses on and looked around her, was a curi commentary on the state in which her life had until then b passed. She said, "Why! I shall be able to see the faces the children!" If we think what this exclamation mea and if we apply the lesson which it teaches to other pursu we shall not fail to perceive that the practical effect of myo is to shut out the subject of it from a very large amount the unconscious education which the process of seeing world involves, and thus to occasion losses which can hai be made up in any other way. Taken in detail, these los the mere not seeing of this or that seeming trifle, may apj insignificant; it is their aggregate which becomes import A very distinguished man of science, who is myopic in a l degree, and who did not receive glasses until he was ninet or twenty years old, has often told me how much he had t in order to place himself upon the same level, with regar experience of quite common things, with many of his norm sighted contemporaries; and it will be manifest on reflec that the matters which are lost by the short-sighted, a the partially deaf, make up a very large proportion of pleasures of existence. I am accustomed, on this grou strongly to urge upon parents the necessity of correc myopia in their children; and I am sure that a visual hor of ten or even twenty inches, with no distinct perceptio objects at a greater distance, has a marked tendency to pro habits of introspection and reverie, and of habitual inatten to outward things, which may lay the foundation of g defects of character. Landscape painters are the only peop whom a small degree of myopia can be useful. I once ac panied a landscape painter on a sketching expedition, and a time asked him whether he intended to omit a certain h from his sketch. He looked up with surprise, and said, "V house? There is no house there!" I at once understo certain haziness of aspect with which it was his custo clothe distant scenery in his pictures, and which was much admired by persons who mistook it for a skilful rende of an uncommon atmospheric effect. In fact, it was only

ie short-sighted man saw always before him; and I am sure e must himself have been greatly puzzled by much of the raise which he received. Soon after I first published a ference to this effect of myopia upon painting, in the *ractitioner* for 1874, Mr. Liebreich attempted to explain some the peculiarities of Turner's style by the peculiarities of his sion; but, as I shall have to explain when speaking of stigmatism, Mr. Liebreich's view of this matter appears to me be wholly untenable.

The indication to display the world may be fulfilled, enerally speaking, by complete correction of the myopia; at is to say, by the use of glasses of the same strength as ose which express the measure of the defect. If the commodation were perfect, and bearing its proper relation the convergence, these glasses would obviously convert the yopic eye into a normal one; giving it clear vision at infinite stance without accommodation, and rendering the assistance accommodation necessary in looking at near objects. We id some myopic eyes in which these conditions are nearly lfilled; and, in most cases when the myopia does not exceed ur dioptrics, and when the range of accommodation is fairly ood, we may prescribe full correction of the defect for all irposes; always remembering that this prescription may quire to be modified after experience of its effects. In many stances, and probably in most of those in which the myopia ceeds four dioptrics, the range of accommodation is only nited; and then, whether the limitation be due to mere dis- e of the muscle, from the absence of any demand for its rvices, or to the structural formation described by Iwanoff, id shown by the dotted line in Fig. 23, the practical result ll be that the eyes, when corrected for the horizon, cannot ercise enough accommodation to bring their near-point ithin reading distance, or cannot exercise this amount for ore than a short period without fatigue and distress. When is happens we must lay aside the full correction when the es are to be employed about near objects, and must be con- nt to fulfil the second indication—the prevention of undue nvergence—by the use of glasses which are just sufficient keep the visual distance at about fourteen or fifteen inches om the eyes. For this purpose, it is a good general rule to ave two dioptrics of myopia uncorrected by the reading- asses; as by giving reading-glasses of three dioptrics for nyopia of five. With glasses of three dioptrics, the two corrected dioptrics of myopia will leave the far-point enty inches from the eye; and there will generally, except very high degrees, be sufficient range of accommodation bring the reading distance five or six inches nearer without tigue. With myopia under four dioptrics, therefore, my le is to prescribe full correction for all purposes, ordering e glasses to be worn from morning to night, and warning e patient that a book must never be brought nearer than urteen inches from the eyes. In order that this injunction ay be fulfilled, it is necessary to give a caution against the e of books printed in very small type, and also against empts to read by defective light, whether natural or arti- ial, as this requires the approximation of the object. Myopic ople, because they can see at a nearer point than others, can e also by a smaller degree of illumination; and hence, children, they often contract a habit of reading by twi- ht, or moonlight, or firelight. It is also necessary to warn e patients that the spectacles will call upon the ocular muscles work under conditions which, although better than those ich preceded them, are still new; and which, while they are w, will inevitably be more or less irksome. If, after two or ee weeks of trial, any discomfort which was felt at first sses away and is forgotten, then the completely correcting ctacles may be used continuously; but if fatigue in reading experienced, we may infer that the full correction throws great a strain upon the accommodation when the eyes are ployed about near objects, and we may order weaker spec- les, which leave two dioptrics of myopia uncorrected, to be d only for reading and analogous occupations. When the opia exceeds four dioptrics, it is usually best to prescribe o pairs of glasses in the first instance, so commonly will they required; and, in every case, we should endeavour to make patient understand that the use of glasses for distance, ough it will enable him to see the world, and to participate ll the advantages of doing so, is of small importance as ards the preservation of sight. On the other hand, the of glasses for reading, "not that the patient may see ter, but that he may see farther off," is an absolute essity in all cases of progressive myopia, and should always be enjoined during school life, or during periods of close study, as the only means of preventing increase of the myopia in consequence of habitual over-convergence. It is the more necessary to render this clearly understood, because patients are naturally most disposed to prize and to use glasses for doing what cannot be accomplished without them; that is, for seeing distant objects. They are often unwilling to use them for near work, alleging, and with perfect truth, that they can see better and more comfortably without them. It is not uncommon, indeed, for short-sighted people, when asked if they have used glasses for reading, to assume a tone almost of self-righteousness in their denial of the imputation. They say, "Oh no, I have never done that!" and are often greatly exercised in their minds when the urgent necessity for a total change of their habits in this respect is explained to them.

The last indication—the avoidance of spasm of the accommodation—is sufficiently fulfilled by spectacles which keep the work at a distance, and thus exclude the excessive convergence by which the spasm is generally excited. Where spasm exists in a marked degree—that is, where the full use of atropine much diminishes the apparent myopia, it is usually prudent to cause the application of atropine to be continued for some two or three weeks, until the habit of spasm has been effectually broken, and the eyes placed, by proper optical aid, under such conditions that the habit is not likely to recur when the drug is laid aside. For this purpose, after the muscle has once been thoroughly relaxed, it is not necessary to use a very strong solution; and one containing a grain of the salt to an ounce of water will generally fulfil all that is desired. A solution of this strength may be applied twice daily for several weeks, unless it should produce symptoms of local irritation.

In either high or low degrees of myopia, if the above described method of treatment should leave the eyes incapable of prolonged exertion, or liable to suffer pain from use, the case passes into the category of asthenopia, and under that designation will be considered in the concluding lecture.

THE LONDON HOSPITAL.—Dr. Thomas Barlow, of the Charing-cross Hospital, was unanimously elected to the vacant Assistant-Physiciancy of this Hospital on Tuesday last. There were two other candidates for the appointment, but they retired from the contest as soon as the wishes of the Medical Staff that Dr. Barlow should be selected had been made known. We congratulate them on their conduct. It is highly important that the staff should practically fill up vacancies as they occur among themselves. Nothing will tend more to cherish that *esprit de corps* without which there can be neither unity nor success, and on the other hand it will increase public confidence in the Committee of Management of a Hospital which is entirely dependent on the public for its maintenance.

ALCOHOL DRESSINGS IN WOUNDS OF THE SCALP.—Prof. Gosselin, in a recent clinical lecture, called attention to a patient with an extensive contused superficial wound of the scalp, unaccompanied by detachment or denudation. He did so because it was an example of the rapid healing of such wounds which has been so frequently observed under dressing with pure alcohol, without the development of any diffused or erysipelatous inflammation. The rapid cicatrisation that takes place is not the result of healing by the first intention, for the edges of the wound still remain a little apart, while the lips and bottom of the wound give issue to sanguinolent sero-purulent secretion, in nowise resembling good pus. This secretion gradually ceases, and the wound becomes dry without ever having been covered with granulations. This instance is a good example of the cases which have for some time attracted Prof. Gosselin's attention, in which wounds are healed by this intermediate mechanism, which is neither immediate cicatrisation, nor cicatrisation after granulation and suppuration. This mode of cicatrisation in wounds of the head especially occurs when these are dressed with pure alcohol; other modes of dressing requiring the formation of granulations for healing. Whatever this dressing may be with regard to other parts of the body, in wounds of the head it seems to be that which gives the patient the most protection from consecutive accidents, and leads to the quickest cicatrisation. So treated these wounds have less tendency to inflammation and suppuration, are cured quickly, and are less often attended with erysipelas and phlegmonous inflammation.—*Gaz. des Hôp.* August 2.

FORTY-FIFTH MEETING

OF THE

BRITISH MEDICAL ASSOCIATION,

HELD IN MANCHESTER, AUGUST 7, 8, 9, AND 10, 1877.

THE ADDRESS IN OBSTETRIC MEDICINE.

By ROBERT BARNES, M.D., F.R.C.P.,
Obstetric Physician and Lecturer on Midwifery and Diseases of Women at St. George's Hospital; etc.

MR. PRESIDENT AND GENTLEMEN,—The more favoured sisters Medicine and Surgery having presented their Addresses, Cinderella, in the guise of Obstetrics, takes her turn.

The President of the Obstetric Section has said fitly and gracefully that there was something specially becoming in giving an Addresss on Obstetrics here in Manchester, the spring whence so much obstetric knowledge has flowed. Manchester in return, I hope, will not frown on obstetrics as Jupiter tonans et pluvius frowned upon her elder sister on Wednesday. I could not hope to charm, notwithstanding, as she did. But I have misgivings I am now suffering the just penalty for my rashness in accepting the task proposed to me by the Council to give the Address on Obstetrics to an audience so peculiarly qualified to criticise, as they ought to do, any short measure of justice to a subject which is so much their own. It is very easy for the Council to select a victim from its flock, and bid him be eloquent, profound, and instructive for their entertainment. But the victim looks upon the matter in another light. To him it may be torture; a process of mental vivisection which ought to fall under the ban of that mediæval Act which our collective wisdom and humanity enacted a year ago when in a hurry to get away to their shooting. I have heard men express gratitude for honours like this conferred upon me. No such sentiment glows in me. The feeling that possesses me is of an opposito character. I mean to indulge it. The personal grievance will find relief in telling some things which, I fear, will not be universally acceptable. But you have given me your ears for an hour; and courtesy, if not duty or inclination, will compel you to listen.

In selecting me for this Address, it is to be presumed that the Council wished to give an opportunity of putting the case of the obstetric branch of medicine in a conspicuous manner before this representative assembly. Some who have preceded me in this task have chosen to make a retrospective survey of the scientific work done in the department, recording its gains, and pointing the road to future achievements. Others, less expansive, have sought to illustrate some particular subject. I will not attempt to emulate either, unwilling to excite comparisons little flattering to myself. My theme will be the scientific and political relations of obstetrics to medical science and the organisation of the profession. The theme is ambitious enough. I cannot hope to do it justice; but I may succeed in awakening attention to some points scientific and political, which it may be to the interest of us all to consider.

In these days, there is a rapidly growing tendency to split up the study and practice of the healing heart into sections. This tendency is in great measure forced upon us by the prejudices of the public, our employers, who, out of excessive veneration, I suppose, for that incontestable maxim of the father of medicine, "Art is long, and life is short," will not believe that life is long enough for any man to acquire a competent "all round" skill in medicine. I am afraid it is hopeless to struggle against this tendency. It is not unsupported by facts and reason. But it entails obvious and serious drawbacks. Against these it is our duty to guard. Medical science naturally takes its form, its direction, its laws, from the great centres of civilised life. In these centres are brought together the means and the great inducements for the cultivation of medicine by theoretical study, by practice, and by teaching. And the social, commercial, and political supremacy of these centres is naturally asserted in the diffusion of medical law. Now, it is in these centres, the seats of scientific culture, that this process of splitting-up exerts itself with irresistible force. In the periphery of our human system, the necessities of the detached communities compel to the concentrated application of knowledge. Here a man will only be credited with knowing one thing. In the outskirts of the world, a man must treat as best he may all the ills that fl is heir to. It is very possible that we, who stand at the cen and therefore flatter ourselves at the head, whence science flo over the globe, might receive our own knowledge returned us fructified a hundredfold under conditions beyond our ran knowledge that would extend, correct, it may be rebuke, o own. But it is unfortunate that the very conditions wh compel our distant brethren to cultivate all department medicine alike, also too frequently prevent them from mov ing their experience into forms, from deducing principles laws which can be sent home to us. Hence, an enorm waste of absolute knowledge, and of suggestion for crit comparison and correction. Hence, the increasing adorat and tyranny of the *idola fori*, that is, of our own cen authority; and the perpetuation of a state of things whic tending more and more to the study of medicine in disjoi bits, to the neglect of those grander lights which can only caught by a well-balanced study of all in their mutual relati There cannot be a doubt that this fragmentary study oppo and retards those generalisations which are the natural c come of extensive and varied observations; and which, revealing the dominion of universal laws, are the high expression, the culminating triumphs of science. So long medicine shall be studied in fragments, and not as a whole long must we be content to grope in the dark, happy to ca a glimpse here and there of a law working in the narrow f of our observation, never to realise the truth that the little of law we see dimly is but a particular application of a ruling all the functions of life. Thus, what we see bit by by accidental flashes of intuition, will almost necessarily k us floundering in a turbid sea of contradictions. So various unequal are the powers of men for observation, for reflection, especially for questioning nature by experiment, that, when one attempts to bring together into one focus the experienc other men who have been examining one subject—say particular subject, physiology, and its outcome patholo from different aspects—he is sure to be perplexed by end diversities of opinion. And yet we are confident that th diversities of opinion are not diversities of fact. There i faith in the world of law, of politics, or of theology, so c so firm, as the faith of the student of nature in the harmo the unity of nature's laws. We do not believe that the op tion of these laws can be for a moment suspended—that t are ever in conflict. The opposite belief, the most degrad form of superstition, the most arrogant form of sceptic which attributes to the Almighty Power the fickleness of negro fetish, is not ours. Whenever we, observing nat see, or think we see, facts or processes that cannot be reconc we conclude humbly either that our observations or our rea ing are at fault. Thus we are driven to renew and ex our observations. And, ever guided and sustained by abi faith, we possess a sure touchstone of truth.

But how, you will ask, am I justified in dwelling on t general and trite reflections? Simply because, however versally their abstract truth is recognised, in practice they too much neglected. Is medicine studied as a whole? entire course of education and practice, at least in this cou declare that it is not. I therefore proceed to the strict cussion of my theme. I procced to show, by a few impe but striking illustrations, how medical science and huma suffer by our neglect.

It will be admitted that the true foundation of all med lies in the study of physiology. It will also be admitted the study of physiology cannot be thoroughly pursued w out the aid of experiments. We must observe nature only in her ordinary moods; we must question her work under conditions devised by science. It may be said truth that the whole study of medicine is but a part of study of physiology. All disease is the reaction of the li economy under the influence of conditions accidentally app These accidental conditions are in reality experiments. could watch and take accurate note of all the actions reactions of the economy under these accidental experim many pathological problems that continue to baffle our sp lations would be solved; we should certainly detect in m cases the links that are now missing in the chain of evid We should thus seize the clue to the institution of specia periments, crucial and luciferous. There is great hope al in this direction in the study of the specific or zymotic fe and syphilis has been studied with considerable success in way. But in a vast number of instances, embracing which follow upon or which induce chronic organic or s

al alterations, the factors concurring to the results we see often so manifold, so intricate, so complicated, so pro-ted in their operation, as to defy continuous or complete ervation and analysis. Their origin is seen dimly through mist of time; their progress is traced doubtfully through myth of history. Now, it is precisely in many of these ases that woman presents the pathological factors in the plest form under conditions of time that admit of the st complete and satisfactory observation. Pregnancy taking ce in a healthy woman may be regarded as an experiment formed under the most simple conditions, from which complications that disturb and thwart observation disease in man are eliminated. Starting with a young healthy woman, we are enabled in the first place to ness a series of the most interesting and instructive siological phenomena. Body and soul are changed. e nervous system, cerebral, spinal, ganglionic, suddenly elopes new forces. The natural, quick, sensitive, mobile ve-action of woman is rapidly exalted. Concurrently with new nervous force, the vascular system undergoes a re-kable development of growth and tension. The blood is longer the same in constitution or in volume. The machi-y which has to distribute the altered blood acquires new ce. These changes in the blood, in the circulatory appa-us, in the nervous system, occur so closely together in time t it is a matter of reasoning rather than of observation to ermine which takes precedence. It is difficult to under-nd how the constitution of the blood can be suddenly cted. The passage from its ordinary state to that in which find diminution of red globules, increase of the white bules, increase of the fibrine and water, must surely take a le time. It is probably the result of certain processes of rition going on in the uterus. But the nervous commotion almost instant; it is at once manifested in the increased bility of the emotional and diastaltic functions. The sub-is at once more responsive to external impressions, sical and moral. The frog itself will not furnish to the erimental physiologist more striking evidence of the play he diastaltic function than the pregnant woman—not alone ing the almost purely diastaltic action of labour, but often oughout the course of pregnancy. One of the most remark-e phenomena, where all are remarkable, is, however, the den direction of newly developed nerve-force to one particular ion—the uterus. At least, whether we detect growth of nerve re, or not, we must perforce assume that nerve-force goes re in increased supply, to direct and maintain the increased ply of blood, to furnish the materials of growth of the rus and the embryo. This new regional vascular develop-nt and concentration of nutritive activity asserts its pre-minance over the whole organism, for elsewhere muscle l fat and other tissue commonly waste. Although the st active building work is going on in the uterus, the rest he organism is affected. It is probably as a consequence of great local constructive work that the blood undergoes its difications, and that the heart and vessels generally are nged in structure. The work going on in the uterus, ing for more and more blood, induces greater vascular ivity; greater driving force; and, wherever this is exerted, driving organ must increase in force—that is, in bulk. It lso more than probable that the altered quality of the od exerts a special influence upon the dynamics of the culation. These new conditions involve augmented vascular sion—a condition that is now expressed and measured by sphygmograph.

Now I must crave indulgence whilst I glance at some ociated phenomena that keep within the range of physiology. m the moment, often, after impregnation, the exalted nerve-sion is manifested in the increased play of the diastaltic func-n. The legs are liable to sudden uncontrollable twitches; niting, the old familiar symptom, sets in. Under no other tes do we ever see such proofs of the intimate interdepen-ce and play of the cerebral, spinal, and ganglionic systems. e emotional exaltation acts upon the diastaltic system, and se together upon the ganglionic or vaso-motor. The pro-ity to convulsion is singularly increased. Concurrently h this augmented nerve and vascular tension, there arises reased strain upon, and therefore increased development of, entire glandular system. This change may be assumed to rt from the new development of the lymphatic vessels in the rine vascular region. Once started, every gland in the ly feels the impulse, and assumes unknown activity. The asts grow under a special impulse analogous to that which moves the uterus; they form a secondary centre of vascular activity. But all the other glands are called upon to act in a subsidiary manner. The respiration is increased; more carbon is exhaled; the skin is more active, throws off more water; the liver and kidneys, the intestinal glands, do more work. The waste materials resulting from the active building process going on in the uterus, added to the ordinary waste from the general economy, demand more active emunctories; and the reply to this demand is seen in the work and products of the glandular system. The glands are doing double duty. The first—the discharge of used-up matter—is obvious enough. But there is another hardly less important, although less commonly recognised; it is the regulating action upon the nervous and vascular system, for which the safety-valve and the governor of the steam-engine offer the readiest illustration. The ordinary degree of vomiting, we know, is attended by relief. Two phenomena especially are observed. There is the nervous explosion, a kind of passing storm, in which I see the characteristics of convulsion. This is a mode of discharge of excess of nerve-force—of reducing tension. Then there is the secretion, the discharge of a quantity of fluid from the glands of the stomach. This gives relief to the vascular system, reducing vascular tension. Applying this reasoning to other phenomena, we shall observe numerous illustrations. The excessive secretion of liquor amnii; the frequent copious discharges of water from the uterus; the occasional attacks of diarrhœa; the not infrequent hæmorrhages from the mucous membranes, as of the lungs, the intestinal canal, the kidneys and bladder even—tell the same tale of discharges designed to relieve excessive vascular tension. If, as is most commonly the case, the overstrained circulating apparatus give way in the uterus, abortion may result; and we may, I am convinced, regard abortion in many cases as a conservative process, averting greater perils. As in the case of vomiting, so in abortion, we see a natural means for the relief of vascular tension and the moderation of nervous tension, which, unless so relieved, might issue in cerebral apoplexy or some other catastrophe.

But the dangers at hand are not always cataclysmic. Other modes in which high vascular tension evinces its influence are manifested more slowly and gradually, yet sometimes swiftly. Such are seen in the behaviour of the glands. The thyroid gland sometimes enlarges notably, and a more or less marked degree of exophthalmos attends. The breasts sometimes pass from engorgement into inflammation and suppuration. But the most important effect is manifested in the kidney. This organ has to bear the strain of two influences, both acting in unaccustomed measure. There is the dynamic hydraulic pressure; there is the irritation of the ingredients brought to it for secretion. Under this double trial, the discriminating faculty of the kidney is apt to be impaired. It lets through albumen; it throws back urea and uric acid upon the circulation. And if this trial be long continued, structural changes are induced in the kidney, and probably in other organs, notably the liver and in the whole circulating apparatus. The passing of the boundary of physiology is made; the precipitance into pathology is almost sudden. Still, the kidney, the heart, and the bloodvessels may recover their pristine integrity; all may be as sound as before, if we take off the arterial tension, if we lesson the irritating qualities of the blood in time. Here we touch upon one of the most interesting and agitating problems in medicine, now being contested by some of the most able physicians of the day: What are the factors, the essential conditions of Bright's disease? Is the starting-point and the main seat of disease in the kidney? Is it found in the central, or peripheral, arterial and venous, or capillary, vessels? Or is it to be sought in the blood? One of the most striking features of pregnancy is the general peripheral development of the vascular system; there is a fulness, a lingering of blood in the capillary vessels, and a development of the veins which amounts to venectasis, which in many cases is never wholly recovered from. This condition is often so marked that it constitutes one of the best tests in the diagnosis of early pregnancy.

I feel very confident that the careful study of the reactions of the kidney and the general vascular system, the nervous system and the blood, under the dominion of pregnancy, will go far to solve the mystery. Whatever the solution offered, it must be in harmony with this history. It must be consistent with the fact that albuminuria may be transitory, last for a time without any organic alteration of structure, and disappear, leaving no trace behind. A distinct experiment has

been instituted and carried through, as if on purpose to illustrate the causes and conditions of albuminuria. I will not in this place do more than refer to the eclampsia, so often associated with albuminuria in pregnant women. I have dwelt upon the subject with some detail in my Lumleian Lectures, on the convulsive diseases of women. Under no other circumstances can we see the phenomena of convulsion so clearly through origin, progress, and decline—through every phase of its history. We start with a healthy subject. Pregnancy is induced. Under the consequent exaltation of nerve and vascular tension, the proclivity to convulsions, we have seen, grows; the twitchings of the limbs, the vomiting, the increased mobility of the cerebral centres, are indications of the exaggerated disposition to convulsions. Then there comes a *tertium quid*, which seems to be necessary to produce the outbreak of convulsion. This is found in the blood, which, carrying elements that ought to be excreted by the kidney or other emunctories, to the nervous centres, by some mode of irritation excite the convulsion. We may trace a similar process in the albuminuria and convulsion that sometimes complicate scarlatina, and in other forms of acute albuminuria. But nowhere but in pregnant women can we observe all the stages of a pathological struggle so closely and completely, from the moment of departure from health to complete recovery.

Illustrations of the history of other forms of convulsions are numerous and instructive. Chorea, for example, must be studied through its relation to menstruation and pregnancy. In the great majority of cases of chorea in children which come under the physician, the convulsive disorder yields after a time. The return to health, *quoad* the liability to convulsion at least, seems complete. And so it is, unless we test the soundness of the recovery by pregnancy. Apply this test, and back comes the chorea, and that with an intensity unknown before, even issuing in insanity or death. Here, then, we see new illustrations of the fundamental conditions of exalted nerves and vascular tension belonging to pregnancy; we see how pregnancy becomes a test of physical soundness; we see that the study of chorea, if limited to the observation of ordinary cases, would lead to false conclusions; we discover that, even after apparent recovery, there must linger in the nervous centres some latent infirmity that, but for pregnancy, would have remained unsuspected, but perhaps important in its future influence under any conditions of the subject, but which is revived with unmistakable force under the trial of pregnancy. A like remarkable illustration is furnished by ague. The pertinacity of this disease is well known. We are accustomed to see marks of its abiding influence long after the fits have ceased, long after the patient has lost all consciousness of suffering. But here, as in the case of chorea, I have seen ague fits reproduced years after under the condition of pregnancy. We cannot fail, then, here to see that there lingers somewhere in the system some change, the stamp of the original disease; and we may fairly presume that this change is in the nervous centres. Perhaps the precise organic change may long baffle the skill of the microscopical analyst to detect; but there it is proved by anticipation to exist, as real a thing as the planet discovered by Adams and Leverrier before it was seen by mortal eye through the telescope.

This chapter in the history of chorea and ague leads, by natural process of reasoning, to the relation of pregnancy to hereditary or transmitted disease. I cannot do more than glance at syphilis, that terrible scourge that works with the more disastrous effects because it works unseen through generations. It is obvious that, if we would pick up many of the links in the often broken chain of the history of this disease, which has nevertheless been working continuously, silently, producing pathological states of the most varied and diverse nature, we must not omit that most important epoch of its history: its relation to pregnancy. Nor can I do more than glance at the history of insanity. The appearance of insanity under the trial of pregnancy is a familiar fact. It is also established as a general fact, by obstetrical operations, that, in a considerable proportion of cases, there is a transmitted diathesis, working through one or more generations. If we take into account, not alone overt insanity in ancestors, but other pathological manifestations, as chorea, other neuroses, tuberculosis, syphilis, we shall attain to a far more general and accurate law. We shall discover, by the observation of the reactions of the nervous system under the trial of pregnancy, new evidence of the transmission and perpetuation, it may be, of morbid peculiarities of structure, of nutrition, which, under the ordinary conditions of li would remain latent, undreamed of.

Reverting for a moment to the glandular system, let call attention to the fact, that that most striking form jaundice associated with acute yellow atrophy of the liver m be investigated through pregnancy, since it is under pregnan that the greater number of cases occur. I think it more th probable that the light to be thrown upon this disease, a other forms of jaundice, will strengthen the theory that chief factor must be sought in the disturbed action of t nervous system, aided by pre-existing or induced alterations the blood. The influence of emotions upon glandular acti is familiar; but it is during pregnancy, when the nervo system is in a peculiarly exaggerated state of excitation, th we may witness the most striking illustrations of this influen and found conclusions which observations detached from t history of pregnancy would not justify.

I might here refer to glycosuria. Physiologists have lo investigated this condition almost solely by aid of experime upon animals, but here in pregnant women we often ha experiments instituted under conditions equally, if not mo deserving consideration. Many women exhibit the phenomen of sugar in the urine at every pregnancy; it disappears wh the pregnancy is over. The subject calls for examination connexion with the function of the breasts as well as with t functions of the liver and kidney, and especially the action the nervous system must be borne in mind.

I might, did time permit, dwell upon some of the conditio of the skin during pregnancy. I can only suggest the i portance of observing these conditions in connexion with t fundamental nervous, vascular, and blood-changes. I cann doubt that by this study we shall one day unravel the myste of pigmentation; and who shall tell, when this mystery sh be unravelled, what light will not be thrown upon otl problems in physiology and pathology? There are few phen mena so marvellous as the darkening of the skin in particul regions of the body under the influence of pregnancy. M it be associated in any way with changes in the supra-re gland, and thus be a phase in the history of Addison's disea That it is in some way dependent upon nerve-distribution a tension I have seen unmistakable evidence.

Before leaving this topic, and sparing you many reflectio connected with it, I cannot help referring to the light that t study of obstetrics throws upon thrombosis and embolism. is not too much to say that pregnancy furnishes the m frequent and the most uncomplicated illustrations of th blood-change. Any speculation, any theory, of this proc must embrace, and be in harmony with, the examples we s in pregnancy. It is well known that phlegmasia dole most commonly occurs after labour, and other forms thrombosis and embolia are equally rare during pregnanc But cases do occur. Why, we naturally ask, does t blood show such special disposition to clot in the vess quickly after labour? Observation suggests a solution. T predisposition is that found in the increase of fibrine a other changes in the constitution of the blood. The fibrine precipitable; something is wanted to precipitate it, and th something is at hand. It is found in the products of invol tion of the uterus, of decomposition of blood in the uteri sinuses, in short, in some form of septic matter, which, ent ing the lymphatics and veins, precipitates the fibrine. T suddenness with which the phenomena are developed points this direct chemical action. Now, during pregnancy th source of septic invasion can rarely exist. Hence, althou the blood is eminently coagulable, for want of the coagulati factor it preserves its fluidity. And the exceptions, I suspe are more apparent than real. Thus, in one case which I ha recently seen in St. George's Hospital, of a young wom four months pregnant, in whom phlegmasia dolens of the le supervened, I found that the embryo was dead, and tha process of separation of the ovum had set in. But there another coagulating power apart from septicæmia, that found in nervous action, in the influence of emotion. T influence is nowhere so remarkably shown as in pregnanc I have seen violent emotion followed almost instantly thrombosis in the iliac and femoral arteries, issuing gangrene.

Here we approach the wide subject of septicæmia, puerpe fever, and we might trace endless instructive relations betwe these states and the various blood-poisonings, with whi surgeons are familiar at the bedside, although their intim history is still imperfectly known. This history will alwa

main obscure until studied by the aid of obstetric observa-
n; for labour is still the grandest of all surgical operations.
hy do I weary you with these speculations? I do it to
nt my theme. I do it because they are practically neg-
ted. Search our medical literature; you will hardly find,
n in our special obstetric works, evidence of due apprecia-
n of them in their togetherhood; and in our standard works
general pathology there is barely a hint, a suspicion, of the
ce they challenge in the science of medicine. Medicine
l surgery are studied far too specially, in isolated parts.
e hear sometimes of "pure" physicians and "pure"
geons; and I presume, by implication, that other prac-
oners are "impure." But if it be shown, as I think I have
least partly done, that a philosophical comprehensive science
medicine or surgery cannot be built up without an earnest
dy of obstetrics, then it will appear that the word
ure" must change its accepted significance. Is it unfair to
ggest, if only under the justification of retort, that a "pure
ysician" is one who is purely ignorant of much that is
ential to the right intelligence of his subject? We hear a
od deal about specialists. Shall I venture upon a definition
the specialist? The specialist in medicine is one who,
iting his attention to one or more detached parts of his art,
cially neglects other parts which are essential to the making
the true physician. Tried by this test, who is the specialist?
it the obstetric practitioner, who embraces within his range
study all the knowledge he can collect from every source?
it not rather the pure physician or pure surgeon who care-
ly shuns all knowledge of obstetrics, and shuts his eyes to
light which this study can throw upon the subjects he
re especially professes to understand?

I may fairly sum up the scientific head of my theme with
s proposition—*As pregnancy is the test of soundness in the
ividual, it may be of all her blood-relations too, so is pregnancy
n a crucial test of the soundness of pathological doctrines.*

Upon this basis let me pass to the political corollary. If the
entific study of obstetrics has been neglected, it will not
m strange that the position of those who practise obstetrics
uld be ambiguous and unsatisfactory. Men in authority
n hardly be expected to recognise merits of which they are
norant. There is a College of Physicians and a College of
geons; there is no College of Obstetrists. I do not think
lesirable that there should be. But this is no reason for
ng left out in the cold. It is to the interest of the medical
porations no less than of the community that obstetric
dicine should be fairly represented. Men who professedly,
ost boastfully, disclaim all knowledge of obstetrics can
dly be the best fitted to define the limits of obstetric educa-
n, to decide upon the amount of knowledge or the degree
ignorance upon which candidates for diplomas may be
mitted to practise. Nor is it reasonable to expect that
h men will, in these matters, command the confidence of
profession or of the public. Obstetric practitioners stand
ween medicine and surgery, embracing both. But, strangely
ugh, it is the College of Physicians alone that gives them
honourable place.

n the College of Surgeons, the spirit of Sir Anthony Carlisle
l seems to rule. Sir Anthony said that the midwifery of the
ntry might be undertaken by the wives of the general
ctitioners. The councils of the College during this time
re making surgeons who went forth over the world
horised to practise every branch of medicine and surgery,
of whose knowledge or ignorance of medicine and ob-
ric surgery they took no heed. Young men under the
hority of the College assumed the responsibility of unlimited
fessional skill on the most limited professional knowledge.
e councils trusted, if they thought the matter worthy of
ntion, that their members had, by bringing certificates of
ing attended a few months' hospital practice, a few lectures,
a few cases, given sufficient evidence of competency in
dicine and surgery. But they might have known, as every
her and examiner knows too well, that a large proportion
candidates endowed with "practical minds" get up what
ys" at the examining boards, and no more. What the
miners neglected as superfluous, candidates would hardly
e the trouble to acquire. Few things, in my experience as
examiner, have given me more pain than to be called upon
xamine men older than myself, who had been many years
led in practice, holding honourable positions, some
inguished surgeons in the army, of good repute, enjoying
lic and professional esteem. That such men should, at
advanced period of their career, be suddenly called upon
to prove their fitness to do what they had long been engaged in doing; that such men should, at the busiest and most anxious periods of their lives, be suddenly challenged, be compelled to stake reputation, all they had achieved, on the hazard of an examination, is surely a cruel wrong, and a just reproach to our political constitution. It seems impossible to fix the responsibility for this wrong elsewhere than upon the College of Surgeons. The University of London, from the beginning, made obstetrics an integral and equal part of the examinations for its degrees. So does the College of Physicians in the case of its licence. Both these bodies are continually holding before the College of Surgeons a practical example of what is right and feasible. And the College of Physicians is doing the further public service of correcting, to a certain extent, the evil wrought by the College of Surgeons. Men who have for years been practising on the diploma of the College of Surgeons are constantly presenting themselves at the College of Physicians, anxious to undergo the perils of a new examination. To this they are driven by the pressure of public opinion, by the suggestions, more or less disinterested, of rival practitioners, by the disqualification for certain public appointments, and by their own sense of duty, which all concur in declaring that their surgical diploma is an imperfect guarantee of fitness to practise, an inadequate claim to public confidence.

Herein lies the new strength of the College of Physicians, the explanation why, within a few years, it has made more than 1100 licentiates; why the number of candidates is steadily increasing.

Why, in the face of all this evidence of the evil they are working, does the College of Surgeons still persist in a course condemned alike by professional and public opinion? The College contends, I believe, that its mission is to supply surgeons; and that it is for other bodies to make physicians. The plea is plausible, but vitiated by fatal fallacies. If the argument I have set forth be sound, it is impossible to make a good surgeon without training him in medicine and obstetrics. And granting that the College diploma guarantees competent skill in surgery, the Council very well knows that this diploma, being registered, confers legal right to practise in all departments; that is, far beyond the actual and moral scope of the diploma.

And even at the present day things have not much mended. A few years ago, the Council of the College of Surgeons, under a by-law, appointed two examiners in medicine. They chose two physicians of conspicuous merit—men able and anxious to give due prominence to medicine, and to improve the standard of the diploma. But I do not think those physicians will affirm that the powers entrusted to them were sufficient to insure a satisfactory degree of proficiency in medical knowledge. It was better than nothing; but it was vey little.

But, having recognised the truth that a little medicine was a desirable accomplishment for the surgeon, why did it not, at the same time, occur to the College that a little obstetric knowledge might be useful? The same power which enabled them to appoint examiners in medicine would enable them to attach examiners in obstetrics, and to make obstetrics an integral part of the examination for the member's diploma. But, with stupendous inconsistency, they stopped short in a course of reform which, fairly carried out, would have redeemed the College from the reproach it must continue to bear, that it licenses men to practise all departments of medicine, whilst it tests proficiency only in part.

The answer to this, of course, is that the College had instituted a special separate board of examiners in obstetrics, to which members of the College and others might, if they pleased, go to supplement their imperfect diplomas by a special licence. Now, the institution of this board, useful as its design was, suggests some reflections. Why was it necessary to create it? Why should a College of Surgeons, a College which is never tired of telling the world that its function is to make surgeons proper, create a special board of examiners in obstetrics? Well, was it a confession of laches on their part, a means of repairing the fault of omission of which they had been guilty by issuing licences to practise beyond the scope of their ordinary diplomas? It undoubtedly enabled many men who had gone into practice on the surgical diploma to come back and supplement this diploma by a special obstetric licence. If this were a right thing to do, right to correct the original defect in the surgical diploma, why should they all the time go on perpetuating this original error? Would it not have been a far more simple and effectual

plan to enable those members of the College who had gone into practice with the imperfect diploma to come up for this supplementary obstetric licence, and to make obstetrics an integral part, like medicine, of the general examination for the members' diploma? Why go on repeating *ad infinitum* the error which made the special obstetric licence necessary? Why inflict upon their members the cruelty of compelling them to submit to a new examination many years perhaps after they had been established in practice?—for cruelty it undoubtedly is. Well, but the College is waiting, waiting for the realisation of a scheme—the Conjoint Scheme! Suspended on this doubtful scheme, it still, acknowledging the right, continues to do the wrong. It still grants its imperfect diplomas; it still licenses to practise what it ignores; it still inflicts a double injury upon the public and upon its members. And in this pernicious action it stands alone. Why should it not, whilst waiting for the accomplishment of the Conjoint Scheme, reciprocate the action of the College of Physicians? This body will not issue its licence except to candidates who shall either have passed the examiners in surgery who form part of its own board, or who shall have produced the diploma of the College of Surgeons, or other satisfactory evidence of possessing surgical knowledge. Why should not the College of Surgeons, in like manner, call for the licence of the sister College as evidence of competent knowledge in medicine and obstetrics, and thus put an end to a gross professional scandal? If the College of Surgeons will not do this, there is another alternative. Let the diploma which it grants to members state plainly in terms the fact that it guarantees no knowledge of anything but a modicum of surgery; that it is only a fragmentary diploma.

The College of Surgeons will not escape from the dilemma; it will not do its duty by the revival of the lame expedient of a separate board of examiners in obstetrics. The time has gone by for bit-by-bit qualifications. The surgical fragment cannot be adequately supplemented by an obstetric fragment. Nor will the College be permitted to issue the obstetric fragment alone. Common sense has been outraged by this proposition. The voice of the profession has unmistakably condemned it.

Accustomed to the fragmentary study and practice of medicine, it is not altogether surprising that, in accordance with its traditions, it should treat obstetrics as it had long treated surgery; that is, as a distinct limb capable of being disjointed from the general body of medicine. All this muddle and confusion into which the College has drifted spring from this fundamental error. The political blunder is the natural fruit of the scientific error. It is only in this way that we can understand the strange perversity which led the Council of the College of Surgeons to attempt to create a new order of medical beings, male and female, specially licensed to practise midwifery and to treat the diseases of women. Those who could thus declare that a little bit of medical knowledge was good enough for women—that is, good enough for medical women to possess, and good enough for the women who would be their patients—might be expected to do almost anything; but they certainly touched the climax of *naïveté* when they called upon men who taught and represented obstetric science to be the instruments of their own degradation of this wrong to womankind.

The pertinacious attack waged upon the University of London calls for an observation. The attempt to turn Russell Gurney's Act into a weapon of offence is well known. The rashness of lawyers, by education and training generally innocent of science, and too often by instinct the enemies of science, of pedagogues and their fledgelings, of anti-vivisectionists, the advocates of the rights of women, of the opponents of the Contagious Diseases Acts, of homœopaths, mesmerists, *et hoc genus omne*, may be understood, if not forgiven; but that this restless band of crotchet-mongers should be supported, in this mischievous attack upon the constitution of the University of London, by members of the Council of the College of Surgeons appointed to seats in the Senate by the Crown, is what the medical graduates naturally resent. It is a fundamental principle of the University that its medical degrees imply full and equal knowledge in all departments, in this respect differing entirely from the fragmentary diplomas of the College of Surgeons. It was a grievous wrong to import this worn-out tradition of the College into the University. The University was founded, it may be said, for the express purpose of protesting, by example and precept, against the imperfect schemes of education and qualification which had hitherto ruled in the schools and corporate bodie In any way to recede from this principle is to attack the ver spirit and life of the University. The governing principle i unity of standard, and that the highest. Medicine is one, a parts concurring to form a perfect whole. We have n place for specialism. We recognise no detached qualifica tions or degrees in medicine. We repudiate utterly th proposition that there is one standard which it is neces sary to attain to qualify for the treatment of the disease of men; and another, a lower, standard to qualify for th treatment of diseases of women. The new doctrine, tha there is a special, an inferior, kind of medical knowledg that is good enough to apply to the care of women, is th most transcendent of all medical heresies, the most flagran wrong, the grossest insult, ever inflicted on woman. And a this under the plea of doing justice to woman! Do the right of women consist in giving way to the clamour of a score o strong-minded persons, in arming them with the legal righ to exercise skill which, *ex necessitate rei*, must be of low orde upon womankind in general? Have the mass of women n right? Is it not their dearest right to be protected by man Even against their own sex?

I am not going to discuss the vexed question of the relativ intellectual powers of man and woman, and the dependen question of the absolute fitness of women for the various pro fessions. I will not question that the feminine intellect i equal to the duties of the pulpit or the bar. *Crede experto* There are lawyers and parsons who declare that it is. But a to medicine, the discussion is superfluous. It is conceded, eve by the most strenuous medical advocates for medical wome that the attainments of women must be inferior. It is admitte that there are things that men cannot teach women. Justl or unjustly, the present order of things forbids the possibilit of opening equal means of professional instruction to men an women. And so long will this continue as men and wome retain the physical and mental attributes which have dis tinguished the sexes from the time of the Creation.

Accordingly, in the College of Surgeons, it was propose to make a special medical order of persons to be put on th Register, after a reduced or diluted examination *ad hoc*, to b licensed to practise on women. Accordingly, the female-part in the University contemplate modifying the curriculum an examination for women-candidates. Now, is not this to giv up the whole argument? If we recognise the great principle that medicine is one, and indivisible; that our physiology, ou pathology, rule alike over the organisation of men, women and children, then it follows inexorably that the attempt t split up medicine into parts, one of which can be safel practised by women upon women, is doomed to failure.

The College of Surgeons is actually without examiners i obstetrics, either as forming a supplementary board or as a integral part of the general board; and it appears from th report of its late President, that it is now considering wha measures to adopt in relation to this question: "At an extra ordinary meeting it was resolved that the Council of th College of Surgeons, regarding women as not eligible t become Members or Fellows of the College, is therefore no prepared to admit them to be examined for these qualification whether at the examinations as now conducted, or with th proposed machinery of joint-examinations. But it was als resolved that the Council, if legally authorised, would b willing to take part in special joint arrangements under whic women should be able to acquire the registrable titles fo practice; and the Council authorised the President and Vic Presidents to take such steps as they may find expedient, i order to promote the amendment of the law which may b necessary for this purpose. The President and Vice-President are now engaged in the consideration of the best mode o giving effect to the decisions of the Council in this matter."

Thero this matter stands. Let us hope that the College, b the voice of its Fellows and Members, may be able to ratii the decision that its Council shall arrive at.

I am tempted to cite the most recent illustration of the mis taken spirit that governs some of our professional bodies. Th Council of the Pathological Society of London has issued circular to its members, announcing that an investigation ha been undertaken by the Society relating to the nature, cause and prevention of the infectious diseases known as pyæmi septicæmia, purulent infection, and puerperal fever. Th inquiry has been entrusted to a committee, consisting, first, four members of the Society specially qualified to engage i the necessary anatomical and chemical investigations; secondly

a number of surgeons and physicians representing the spitals of the metropolis, who have undertaken to co-operate ith the first body in organising and carrying ont the quiry. Now, in this work of wide-reaching inquiry it has t been thought necessary to associate a single member who actises or who has any practical acquaintance with obstetrics. ere is an inquiry into the nature and causes of puerperal ver, without the aid of those who almost exclusively see it, udy it, and treat it! To play *Hamlet*, omitting Hamlet, is thing to this! Those who drew up this scheme must lieve in the spontaneous generation of knowledge; in *Lucina ne concubitu*.

Now, I think it is time, more than time, to sum up my litical argument, and conclude a discourse undertaken under vere pressure, and therefore loaded with more faults than ight otherwise have been expected. The political error hich mars the usefulness of some of our medical institutions ws from the scientific fault; a want of due appreciation of e place which obstetric science and practice should hold.

I am sure that, in Manchester at least, that art will be vin-cated by which White, Hull, Kinder Wood, Robertson, and adford have added lustre to the great traditions of their city.

THE SECTION OF MEDICINE.

OPENING ADDRESS.

y Sir WILLIAM JENNER, Bart., K.C.B., D.C.L., F.R.S.,
President of the Section.

THE OBJECTS AND USES OF ASSOCIATION IN THE MEDICAL PROFESSION.

ENTLEMEN,—My duty and desire is to thank the Council of e Association for the great honour they have done me in pointing me to preside on this occasion over the Medical ction of the meeting. At the same time, I must own that feel there is some fitness in the selection made by the Council that I am to some extent in my proper place as President of e Medical Section at this special meeting—for the Address Medicine has been delivered by a physician I am proud to able to claim as a former pupil, and two of the three vice-esidents and one of the two secretaries of the Section owe me, at least, of their rudimentary knowledge of medicine to y teaching.

Seeing that an Address on Medicine of great ability and of nsiderable length, as well as an able and lengthy address on e present condition of State Medicine, has already been livered to the Association, and that gentlemen of the highest stinction in their own branches of the profession are to give ddresses on Surgery and on Obstetric Medicine; that these ldresses are exclusive of those by the President and the esident-elect,—it appears to me that the success of the edical Section, which has so much legitimate business to ansact, will be better advanced by me, as President of the ction, refraining from delivering any special address. The pers to be brought before the Section are so numerous, and any of them of so much interest, and the two discussions to held are of so much importance, that I shall trouble you ith few words and detain you but a few minutes from the oper business of the Section. I shall limit myself, by ay of introduction to that business, to a brief statement of hat appear to me to be the uses, the aims, and ends of these eetings.

All gatherings such as this of scientific men effect, I think, vofold good. They enable men to bring before their fellows—., before an audience capable of appreciating their worth—servations, and conclusions founded on those observations, in e special science represented at the meeting.

The consciousness that their labours will certainly be laid fore an appreciating audience, and be by them at once sub-itted to oral criticism, stimulates men to labour with greater al; to test again and again the accuracy of their observa-ons, in order themselves to detect their flaws; to think out r themselves the objections that may be taken to their ethods of observation, and the arguments that may be lduced against the accuracy of their conclusions; and thus e zealous worker is stimulated in his zeal, the accurate server is encouraged to yet greater accuracy, and the logical asoner more closely trained to admit even to himself only the ost strictly deducible conclusion.

The second and greater good flowing from *all* such meetings is, that the discussions which of necessity arise awake, in those who take part in them and in those who are listeners only, new ideas, and give form to ideas heretofore imperfectly defined in their minds, and do that which for all men is so essential—force them to think. For intellectual and scientific progress, the giving to others and the receiving from others of ideas is essential—the circulation of ideas is as necessary for intellectual and scientific life and growth as is the circulation of blood for physical life and growth. The ideas of others are the seed for new ideas in ourselves—we give, we receive, and new ideas are begotten; a third, differing from its parents, is the outcome of the two. The new ideas thus created open out wider fields for research, and fresh methods of testing the value of the produce of research. Again, as men talk one with another, new modes are discovered of looking at old things—prejudices fade away—identity of fact and meaning are found to underlie differences in words; and, by comparing their own observations and their own conclusions with those of others, they correct the former and rectify the latter.

And thus, although at the dispersion of gatherings such as this, of men of science, it may not be able to be said that any branch of the science represented at the meeting has received an addition which might not have been made in other ways, it can be asserted without fear of question that, not only has knowledge been spread, but also that an impetus has been given of the most forcible and purest kind to the advancement of knowledge in the future, which impetus could not have been given in any other way. Men's minds have been excited to think in new directions, to carry their thoughts into action; and prejudices, those drags on the acquisition of knowledge, have been lightened.

These advantages, I say, flow from all gatherings such as this of scientific men; but from our own annual meetings another and a better good flows. In the social associations which form a part of them, hearts are opened to feel more kindly to all their professional brethren. We become conscious of a real common brotherhood. We see how appropriate is the fable of the bundle of sticks. We find ourselves—how, we know not—regarding facts morally as well as scientifically professional from others' points of view, appreciating more highly others' merits, and looking less hardly on others' faults; feeling less confident that we are right and others wrong; estimating our own merits somewhat less highly, and our professional brothers' somewhat more highly; rejoicing rather that a new fact has been discovered, or a new and more correct conclusion drawn from old facts, than glorying in the part we have played in the discovery; rejoicing in the fact that a discovery of service to the race has been made, and not in the accident that we made it; rejoicing that our generation will hand down the torch of medical knowledge we received from the generation before us with a brighter flame to the generation which succeeds us, and not disputing how much of the brightness is due to a ray emanating from our own tiny taper.

The founders of this Association, appreciating the great advantages the members of our profession resident in London and other large towns derived from the intellectual movements consequent on the opportunities they enjoyed of meeting each other, endeavoured to confer the same advantages on the members of the profession resident in the country, and the increased facilities for travel enabled their aims to be fully realised, and at last an association of the whole profession to be formed, which not only gives the profession the intellectual advantage flowing from intellectual and scientific communion, but also the social and moral advantages which, we hope, the Association confers.

There will be a new feature this year in the section, viz., two papers will be read by distinguished physicians, for the express purpose of eliciting the opinions of members on two subjects of great practical importance, viz., one on Aortic Aneurism and one on the Treatment of Pleuritic Effusion. I have been present at several discussions of the kind at the Pathological Society. The advantages which resulted from those discussions were great. As the time of the oration to be devoted to these discussions is necessarily short, I have to ask the speakers to condense their remarks as much as possible; and to bear in mind that the value of a speech in these discussions is by no means necessarily in proportion to its length. I would, then, strongly urge on the speakers to keep closely to the subject under consideration, and to avoid, as far as possible, all discursions and episodes.

I cannot conclude without expressing, in the name of the section, the pleasure it will give us all if our foreign visitors —men renowned throughout the world—will take part in our discussions. I have said our foreign visitors; but in science generally, and in our profession especially, there should be no foreigners. We have a common language, and seek one treasure—truth—a treasure which, as soon as it is discovered, is the common property of all. In the world of science, and of medical science in particular, all worthy workers are true communists; they know nought of geographical nations, and race for them has no existence.

THE SECTION OF PUBLIC MEDICINE.

OPENING ADDRESS.

By F. De CHAUMONT, M.D.,
Professor of Military Hygiene, Army Medical School, Netley;
President of the Section.

SCIENTIFIC RESEARCH IN RELATION TO SANITARY PROGRESS.

Gentlemen,—It was with feelings of great gratification that I accepted the flattering invitation of the Council to take the chair in this Section, but it was not without some diffidence that I did so. Tempting as it may be to assume that it is a personal honour, I think I ought the rather to take it as a compliment to the institution I represent, the more so as the chair I hold is one that is inseparably connected with the loved and honoured name of Parkes. To him, and to many others of the medical officers connected with the public services of the Crown, a great debt of gratitude is due, both for the work they actually did and for the start they gave to the great principles of sanitation. The opportunities furnished by our troops and scamen for observations on an extended scale have been of great value, and have, I venture to hope, not been neglected; whilst the vast field of observation in our Indian empire has been productive of a great mass of sanitary knowledge. I may refer to the works of two eminent observers—Dr. Timothy Lewis, of the British Service, and Dr. D. Douglas Cunningham, of the Indian Medical Service—who have been employed for a number of years as special commissioners, primarily for the investigation of the causes of cholera, but secondarily for various other inquiries, which have proved of marked importance. Their appointment to this work is greatly to the credit of the Indian Government, and the productive character of their labours has been most encouraging. Among these, I may cite their valuable contributions to the history of cholera, in the course of which they have cleared away much that was of an untrustworthy and misleading character; their researches on the nature of the soil, air, and the ground-water fluctuations of Calcutta: the observations on the suspended matter of the atmospheric air; the discovery of the *Filaria sanguinis hominis;* and their more recent researches on the Madura foot, the Delhi ulcer, and upon Indian leprosy. It is not, of course, my object to praise one class of medical men as sanitarians above another; and, indeed, it would be unbecoming in me to do so; but my desire is twofold: first, to point out the advantages to the community of special scientific inquiries on an independent basis; and, second, to vindicate to some extent the position of our profession in sanitary work.

With regard to the first point—the encouragement of special scientific research—this touches the much vexed question of the "endowment of research," about which so much has been said and written in late years. To a certain extent, the principle has been recognised by the Government in the admirable series of inquiries first carried on under the enlightened direction of Mr. John Simon; but, excellent as these were, and as those still are which are continued under his successor, they are far too limited in scope for the requirements of the age; and it would have been a movement particularly appropriate for a Government whose motto *was*, "*Sanitas, sanitatum, omnia sanitas*," to extend such inquiries in a much wider circle, and so encourage investigations which can seldom be adequately conducted by means of private resources. In private life, those who have the means sufficient have rarely the knowledge or the inclination proper for such researches, whilst "chill penury" too often "represses the noble rage" of those who could most effectually carry them out. Such men as Cavendish are rare, of whom his French biographer said, "Il était le plus riche de tous les savans, et le plus savant de tous les riches." But it does seem a strange anomaly that almost unlimited sums can be obtained for experiments on "Woolwich Infants," "torpedoes," and the like—in short, anything that will most effectually destroy the human family on the largest scale; whereas there is untold difficulty in getting the most modest amount if the experiment be merely for the purpose of *saving* life. Of course I know it will be said that this is a trite complaint—one that has been made over and over again; also that upon the efficiency of our torpedoes and big guns depends our existence as a nation. Well, I can only answer that, if the complaint is trite, it is all the greater reason that the evil should be redressed; and that, if our existence depends upon our means of defence against a foreign enemy, it depends tenfold more upon the efficiency of our defence against a host of enemies, most of whom we carefully nurture in our own homes, and to which a foreign army is mere child's play. Preventable disease kills annually in this country not less than a quarter of a million—a number more than ten times greater than the "horrible and heart-rending" loss which our army sustained in the Crimean war—a loss which stirred the feelings of the country from one end to the other. It is true that ours was an invading army, and that the sufferings of an invaded country are greatly enhanced. The siege of Paris cost the city 50,000 lives; but, even with this large number, the whole losses of that great war were probably little more than perish in a year from preventable disease. War, besides, is a rare occurrence in a country; whereas our other foes are always with us, hardly ever ceasing from their destructive work. While, therefore, admitting that war is a gigantic evil, against which every precaution ought to be taken, it cannot be too often repeated that there are other even greater evils constantly in our midst, against which at least equal precautions ought to be provided, but which have as yet, unfortunately, failed to impress the governing classes with their immense importance. It is not that we would stop the attempts to keep ourselves in the van of science as regards war, but that we should devote more time and money to other matters too, so that, while the one thing is done, the other shall not be left undone. It is true that much has been accomplished—more, perhaps, than might have been expected not many years ago; but still so much of our legislstion in sanitary matters remains merely permissive, that a great deal less is really done than might be hoped for from the machinery. For true sanitary progress, we require an accumulation of facts and observations, as well as an organised series of original researches and investigations, such as can only be done on a great scale by State help and authority: a department of health, in fact, which shall be looked upon as equal in importance to any of the other great departments of the Crown.(a) Part of its duties ought to be to organise a system of extended and continuous investigations into the conditions of the soil, the air, and the water of the kingdom, such as could not fail ultimately to add vastly to our sanitary knowledge. As regards water, much is being done by individuals in different places, chiefly in the way of chemical analysis; but the microscopical examination is comparatively little studied, whilst anything like a systematic method of inquiry has still to be organised. Of course I do not forget the large mass of information collected by the Rivers Pollution Commission; but that is by no means enough. There is no "rest and be thankful" in such a matter. As regards air, a step in the right direction has lately been taken by the establishment of a section of sanitary meteorology in the Government Meteorological Office; but chemical and microscopic investigations are also necessary, and ought to be continuous and in a multiplicity of stations. For the soil, we may say that nothing is being done. It is true we have many details about its geology, so far as its solid constituents and their arrangement go; but the study of the soil-atmosphere and its variation under different conditions has been hardly even touched upon in this country.

Another most important inquiry has been much urged of late upon the attention of the profession and the authorities; namely, the registration of disease. Without the information that would thus be obtained, it is hardly possible to know the history and etiology of maladies—points so essential to a true knowledge of their means of prevention. Almost the only records of the kind are those of the army and navy, and they give information only about certain classes and ages, in numbers too small to have more than a limited value. Still,

(a) In reference to this, I may recall the eloquent address of Dr. B. W. Richardson, F.R.S., at the opening of the Sanitary Institute of Great Britain.

from them much information of a valuable character has been obtained. I may cite the important statistics of the influence of the Contagious Diseases Acts, which up to the year 1873 gave much valuable information. The unfortunate concession to pharisaical clamour in that year—viz., the infliction of a fine upon soldiers suffering from venereal disease—has done much to vitiate the returns as true statements of its amount. At all events, it has unfortunately given a handle to the opponents of the Acts, of which they have not been slow to avail themselves. Still, the statistics that are even now published, notwithstanding the somewhat modified value which must be attached to them, are, let us trust, sufficiently instructive to render the repeal of the Acts improbable. Few pieces of legislation have, to my mind, been more successful, and it would be a lasting pity if the good were arrested by the well-meaning but misguided efforts of its opponents. At the same time the preposterous way in which the latter handle statistics makes them no more formidable than the anti-vaccinationists, al least so long as our legislation is conducted by people of ordinary sense and perception, who will be content to deal with facts and not with fancies, and not make or repeal laws in a fit of hysterics.

I have said that I proposed, in the course of this brief address, to vindicate to some extent the position of our profession in sanitary work. It may seem to many somewhat strange that this should be at all necessary. One would have thought that, if sanitarians were to be drawn from any profession, it would certainly be from the medical; yet it is remarkable how strong a tendency there is in some quarters not only to disregard the advice and counsel of medical men, but even to shoulder them out of the work altogether. Were medical men nowadays, as used to be said of them formerly, merely givers of nasty pills and nauseous potions, with but a limited knowledge of disease itself and a blank ignorance of its causes, the opposition might have some fair ground; but, in the present day, even our sarcastic enemy Montaigne, who implored that he might get no physic until he was well and strong enough to bear it, might have looked with some favour upon a profession whose motto is not merely "*Venienti occurrite morbo*," but "*Principiis obsta*," whose most strenuous efforts are towards the prevention, and even, if possible, the extinction of disease. Again, in how many instances has our profession in vain called attention to sanitary evils and urged their remedy, with no other result than being sneered at first, and finally having their labours quietly appropriated, and the glory given to another! There are several forms which this opposition may take. The first is the purely *Philistine*, which from time to time finds its expression in local governing bodies when the necessity for a medical officer of health is gravely questioned. In one instance, it was objected that it was a waste of money to pay a salary for the office at all, on the ground that there was nothing so cheap as science, and that you might get one for nothing. In another case, it was gravely said that all that was wanted was a good inspector of nuisances, sanitary work consisting merely in the removal of dung-heaps, clearing out privies, and the like. The second form of opposition I may call the *obscurantist*, which in some points differs but little from the former in practice. This would resist the appointment or co-operation of any one who did not hold the particular view which they especially favour, who would, like the grammarian that cursed his opponent for his theory of irregular verbs, introduce what I may call an *odium ætiologicum;* and from participation in this form of opposition our own profession is, I regret to say, not altogether free. The third form is one which is a little complex and rather difficult to name in a single expression; it is partly "rest and be thankful," combined with a spirit of resentment against the medical profession as that which especially troubles their Israel, and partly an extreme timidity in the matter of expenditure. It is this that induces local authorities to give the Poor-law doctor an annual ten or fifteen pounds as health officer, really as a retaining fee to make him hold his tongue, instead of appointing a competent officer, who should have no interest in anything except keeping his district in the highest state of sanitary efficiency. It is this spirit that induces high official persons to disregard the sanitary counsels of medical men, and, if possible, to compass their exclusion from sanitary work on the plea that they are *impracticable*. Being *impracticable* usually means that the recommendations of the individual so styled will lead to the expenditure of money—a thing generally abhorrent to the official mind (unless it be for its own particular job). But it is farther asserted that mistakes are made, and that things directed to be done at one time are disapproved of at another, so that changes are rendered necessary, to the hindrance of true progress and (of course) waste of public money. But, I may ask, are mistakes peculiar to the medical profession? Do no others ever make them? Are there never any legal or engineering mistakes; no military, naval, or political mistakes? Considering all things, it seems rather wonderful that the mistakes have been so few; and that may be taken as a proof that the teaching and habits of thought of the medical profession form an excellent training for sanitary work. At all events, we may safely say this, that, many as the mistakes may be that can be laid at our door, they would have been many times greater had the work been entrusted to any other class of men. If we have slain our thousands, they would have slain their tens of thousands. I am very far from being forgetful of the fact that many distinguished sanitarians have come from ranks non-medical; but I do uphold that it is from our ranks chiefly that sanitarians must and ought to come, for in no other profession is that class of knowledge acquired that best fits a man for sanitary work. Not that I wish by any means to exclude members of other professions. We require the assistance of all, and desire the co-operation of all; but to attempt to work sanitary reform without the medical profession would be like making wine without grapes; it might be wine of a sort, but it would only be gooseberry after all. We are not without illustrations of the results of attempting to act without, or contrary to the advice of, the profession. Let the history of the Crimean war serve as an example. Perhaps the best abused man of that time was the late Sir Andrew Smith, the Director-General of the Army Medical Department; and yet, when the true story of the war came to be told, it was found that he had foreseen only too well the breakdown that must occur, and proposed measures which, had they been adopted, would have at least greatly mitigated the terrible evil. The French Government were not more wise than our own, for they disregarded the warnings of their medical staff in the autumn of 1855, when it was plain to the eye of science that a terrible invasion of typhus was imminent. The ruling powers were deaf, the blow fell, and many of the unfortunate doctors fulfilled their prophecy in their own persons. Look at the history of the last Arctic Expedition and of the present Indian Famine, and say whether dire disaster might not have been averted had medical counsel been listened to. On the other hand, we have the history of the campaigns in China in 1860, in Abyssinia in 1868, and in Ashanti in 1873, in which medical counsel was sought, and, still more, acted upon; and what do we find? A series of triumphs won at a cost that was positively insignificant; a sanitary success that was little short of perfect, even in the terribly trying climate of the Gold Coast. This last was appropriately called a doctors' war; and it will be golden wisdom in governments to try and make all other wars more and more doctors wars, as well as to listen to their counsel in times of peace, whether they deal with soldier or civilian. To attempt to do without the doctor now is hopeless, although it is possible to conceive a time when such a consummation may arrive. Indeed, the progress of medical science has been constantly tending towards abolishing the necessity for the physician; so that, in a remote future, a physician will be honoured less for the uses men may have of him, than because by his prevenient science he renders it unnecessary to use him as a physician. And this is a healthy sign of progress. Every pursuit has its own mission to fulfil; and, if it do it well, its highest point of aspiration must in many instances be its own effacement. When the prophecy is fulfilled, the mission of the prophet is accomplished. All the world holds his secret, and he passes away out of notice; the time and place know him no more. Thus, as I have said in a former lecture, "State medicine will have both reached its perfection and extinguished itself when both sanitarian, as differentiated from the community generally, and State, as a controlling and interfering influence, shall have ceased to be; the one, because every member of a perfected community will be a sanitarian in the best and truest sense of the word; and the other because, from the very condition of the community, State interference will have become perfectly unnecessary."—("Lectures on State Medicine," 1875, page 6.) But, gentlemen, this is an ideal time, and, for the present at least, an Utopia; between it and us lies a wide and stormy sea of doubt and difficulty, across which our profession will unquestionably furnish the most trustworthy pilots. The saying

of Descartes is still true, that, "if the perfectability of man be possible, it will be through the medium of the medical sciences."

ORIGINAL COMMUNICATIONS.

STATISTICS OF DISEASE IN KING WILLIAM'S TOWN, BRITISH KAFFRARIA.

By CHAS. JAS. EGAN, A.B.T.C.D., M.R.C.S., etc.

In continuation of my account of disease as met with, in practice, in Kaffraria, I will consider next those of the liver, as this is one of the organs most usually affected by residence in a hot climate.

The statistics are taken from the same source as those used in the former paper on disease of the respiratory organs, and for the same years—viz., 1870 to 1875, both inclusive.

The total number of cases brought under review here is 718, and their classification is shown in the following table :—

Table I.—*Diseases of the Liver.*

	1870.	1871.	1872.	1873.	1874.	1875.	
Functional . .	26	58	53	83	52	76	= 348
Congestion . .	42	41	33	73	24	97	= 310
Hepatitis . . .	1	—	1	4	4	2	= 12
Abscess . . .	—	3	—	1	2	—	= 6
Gall-stones . .	3	6	4	4	5	4	= 26
Amyloid degeneration	3	3	—	—	4	6	= 16
	75	111	91	165	91	185	= 718

The first class includes all ordinary attacks of functional disorder of the liver unaccompanied by congestion or inflammation, often attended with colicky pains of very violent character, and followed by diarrhœa, or else nausea, loss of appetite, and other feelings of uneasiness and ill-health, usually referred to, and depending on, inactivity of the organ or depraved secretion. Indeed, many of the cases included in this class might be considered in the first stage of congestion. In many of them the old treatment by blue pill and seidlitz-powder, or podophyllin, is sufficient to remove the symptoms. This latter medicine I find most uncertain in its action, not only in the manner in which it affects different individuals, but also in its different effects on the same person at different times.

Twelve deaths occurred among the 718 cases while under my care—viz., 4 from abscess, 3 from gall-stones, and 5 from amyloid degeneration—making a percentage of 1·62 on the total number.

The percentage of deaths from disease of the respiratory organs was found to be 2·17, showing that they are more fatal in this country than disease of the liver.

The frequency with which functional disorder occurred in the different quarters of the year is shown in the following table :—

Table II.—*Functional Disease of the Liver.*

	1870.	1871.	1872.	1873.	1874.	1875.		
Spring ...	4	16	8	20	14	17	= 79, or 22·70	p. cent.
Summer..	10	21	20	33	18	22	= 124, or 35·65	,,
Autumn.	4	16	12	19	4	23	= 78, or 22·43	,,
Winter ...	8	5	13	11	16	14	= 67, or 19·25	,,
	26	58	53	83	52	76	= 348	

It will be seen that the hot weather of summer makes these affections largely predominate, spring and autumn have an almost equal ratio, and the winter the least.

The next class is congestion, distinguished from the above by fulness and slight enlargement of the liver, heaviness, and pain, with a tendency to jaundice, and continuing longer than cases of the former class :—

Table III.—*Congestion of the Liver.*

	1870.	1871.	1872.	1873.	1874.	1875.		
Spring ...	11	8	11	24	3	20	= 77, or 24·84	p. cent.
Summer..	12	12	7	24	14	30	= 99, or 31·93	,,
Autumn.	9	11	5	13	4	30	= 72, or 23·21	,,
Winter ...	10	10	10	12	3	17	= 62, or 20·00	,,
	42	41	33	73	24	97	= 310	

Acute inflammation of the liver is not at all common in this country. The statistics of it are shown in the next table :—

Table IV.—*Inflammation of the Liver.*

	1870.	1871.	1872.	1873.	1874.	1875.		
Spring ...	—	—	—	3	4	—	= 7, or 58·33	p. cent.
Summer..	—	—	—	—	—	—	= —	—
Autumn .	—	—	—	1	—	2	= 3, or 25·00	,,
Winter ...	1	—	1	—	—	—	= 2, or 16·67	,,
	1	—	1	4	4	2	= 12	

Besides these cases of hepatitis, all of which recovered, six cases of abscess occurred; all of them belonging to the class named "pyæmic" by Dr. Murchison. In one case the patient contracted the disease in India after dysentery. In this, signs of pointing appeared near the umbilicus, and a trocar was used; and a canula with indiarubber drainage-tube was left in the wound. The patient progressed favourably, and returned to Europe; but after a residence of about four months in England the disease returned, and he died. Another of the deaths from this disease took place from the matter escaping through the lungs, and the two others from the abscess bursting into the peritoneum. In the case of recovery the matter found an entrance into the bowels, and was evacuated by stool.

Of amyloid degeneration of the liver, sixteen cases came under my notice during the six years, of which five died while under my care. The others removed to other parts of the country, and I have not heard how they terminated.

Cases of gall-stones are not infrequent, twenty-six cases, with three deaths, having been noted. These cases represent twenty-four individuals, as there have been many cases of second and third attacks in the same person. Among these three deaths occurred: one from collapse, in a person suffering from great debility brought on by over-lactation, and also the subject of valvular disease of the heart; in another case the gall-bladder ruptured into the peritoneum; and in the third, death resulted from jaundice after repeated attacks of bilious colic.

I have not met with any case of hydatid disease of the liver, although tapeworm is very common in this place, especially among the natives.

Of the total number of cases of these diseases now brought under notice, 24·11 per cent. occurred in the spring months, 33·43 per cent. in the summer, 22·93 per cent. in the autumn, and 19·72 per cent. in winter.

The next class of diseases that I will consider are those of the bowels—viz., diarrhœa and dysentery. The frequency of diarrhœa in the different quarters of the year is shown in the following table :—

Table V.—*Diarrhœa.*

	1870.	1871.	1872.	1873.	1874.	1875.		
Spring ...	10	32	20	21	29	17	= 129, or 20·84	p. cent.
Summer..	32	31	42	39	66	40	= 250, or 40·39	,,
Autumn .	13	13	34	28	48	22	= 158, or 25·52	,,
Winter ...	9	9	11	23	16	14	= 82, or 13·25	,,
	64	85	107	111	159	93	= 619	

This table includes all cases of diarrhœa, both in adults and children, but I have excepted from it cases of cholera infantum, characterised by violent vomiting and purging, coming on suddenly, and producing great prostration, the child soon becoming thin, with sinking-in of the eyes, and, if the sutures have not closed, sinking-in of the fontanelle. It is most common in children when they are cutting the first set of molars, and is very fatal. Out of thirty-six cases attended, nine died, or about 25 per cent. Among the other cases of diarrhœa nineteen deaths occurred, or about 3·07 per cent.

Dysentery is not, I should think, more common here than in England, and is not more fatal. The following table shows the number of cases which I attended in the six years :—

Table VI.—*Dysentery.*

	1870.	1871.	1872.	1873.	1874.	1875.		
Spring ...	—	4	—	4	4	2	= 14, or 23·73	p. cent.
Summer..	1	—	1	—	3	4	= 9, or 15·25	,,
Autumn .	4	3	2	3	12	3	= 27, or 45·77	,,
Winter ...	2	2	2	1	—	2	= 9, or 15·25	,,
	7	9	5	8	19	11	= 59	

The number of deaths which occurred was five, or 5·08 per cent. It will be seen that the disease was more prevalent in 1874 than in any other year, and it will be found that the rainfall in that year amounted to 37·15 inches, being ten inches above the mean annual rainfall.

We have thus analysed 714 cases of disease of the bowels, among which occurred thirty-one deaths, or about 4·34 per cent., being the highest death-rate of the three classes of disease brought under notice. Disease of respiratory organs, giving a death-rate of 2·17 per cent.; disease of liver, 1·62 per cent.; disease of the bowels, 4·34 per cent.; and on the whole number of cases (viz., 2233) the death-rate is 3 31 per cent. This, I think, will compare favourably with the statistics of disease as met with at home, though I must confess I am not in a position out here to make any positive statement on this subject.

No regular registration of births and deaths is kept here, so that it is impossible to give the death-rate of the population, but I hope to be able at some future time to make some approach to an estimate of the death-rate by examining the books of the cemetery, and distinguishing the burials of residents of the town from those of persons brought in from the country for interment here.

Affections of the kidneys are those least met with here of all diseases of the internal organs. In the six years only nine cases of degenerative disease of the kidneys are recorded. Of these two died while under my care; and no case of acute nephritis was met with.

Calculous disease is also very infrequent. I have not met with any case of calculus in a person who has been long resident here. During the twenty years that the Civil Hospital has been established here, only three cases of urinary calculus have been admitted and operated on (all successfully), and these cases came from other districts of the colony. I have had a few cases of gravel under my care, of the lithic acid diathesis.

King William's Town.

CASE OF

DOUBLE OVARIAN DISEASE: REMOVAL OF ONE OVARY.

By FREDERICK ENSOR, M.R.C.S. Eng., L.S.A.

Iaria, a Cape Malay, aged thirty-eight, widow. Had one child, which lived to eighteen months; ten miscarriages. Menstruation regular; profuse for last two years. Treated for ozæna and syphilitic headache (?) in February last. Got well by hyd. bichlor. and pot. iod. Had pain in left groin in November last. Six months ago found her stays uncomfortable.

June 17, 1875.—Admitted into Port Elizabeth Hospital. Measurement round umbilicus 31 in., ensiform cartilage to umbilicus 7½ in., umbilicus to pubis 6¾ in., right anterior spine of ilium to umbilicus 6½ in., left anterior spine of ilium to umbilicus 6½ in. Not emaciated; sober, temperate. No œdema of face or feet; mammary areolæ not darker than usual; micturition frequent and difficult; bowels obstinate; tumour movable in front; fluctuation distinct; crepitus felt on first day in front, but not afterwards; some tenderness; dull sounds on percussion in front of abdomen and in *left* hypogastric and *left lumbar* regions, as if there was another cyst extending to the left (or is this colon?); auscultatory sounds *nil;* uterus pulled up and movable; anterior vaginal wall depressed, and fluctuation felt through it; catamenia rather free last period; hysterical and very talkative; heart and lung sounds good; sleeps best on her left side; pulse normal.

Diagnosis.—Ovarian cyst, possibly double, springing from left ovary. Ordered a quarter of a grain of belladonna extract and half a grain of opium occasionally for the pain.

July 7.—With the largest aspirator needle drew off fifty-five ounces of gelatinous fluid, occasionally tinged with blood; punctured three inches below umbilicus in linea alba. Ordered a quarter of a grain of belladonna and one grain of opium every twelve hours.

8th.—Distension relieved, and sickness, which had been troublesome for days before, subsided.

August 18.—Has suffered much from pain in the groin and over the pubis; cyst has apparently refilled, and the tumour to the left has grown larger; vomits daily; looks distressed and worn; occasionally passes abundance of lithates, but urine has cleared in the last few days by use of lithia and potash water. Had a warm bath for last two nights; to have an enema to-morrow morning.

19th.—In a separate apartment of the Hospital, especially prepared by previous cleaning, ventilation, etc. (weather bright and warm for the season; temperature in room 65°), in presence of my two colleagues and three visiting medical men, I made an incision an inch below umbilicus in median line to two inches above the pubis; came nicely down on the peritoneum, and opened it on a director the length of the incision. A considerable amount of peritoneal fluid escaped. Some slight adhesion of tumour to abdominal wall in front, and a little to the right, was easily overcome, and the ovarian tumour (about the size of a large cocoanut) was punctured and drained in usual way. A second cyst was then made out, and punctured through the septum, but fluid was too viscid to flow freely. The tumour was then drawn out without much tension on the aperture; the pedicle (of moderate bulk, and rather short) was attended to. It was found that a portion of what seemed small intestine was so firmly adherent to it as to require careful dissection, to make a space for the application of the clamp. After the clamp was screwed fast, and tumour removed, some difficulty was experienced in arresting bleeding from the patch of tissue which had been dissected off the pedicle with the adherent intestine. It was stopped by fine silk ligature holding the cut surface *en masse*, no one particular vessel being tied. The intestines and abdominal walls showed signs of active peritonitis. On this tumour being removed, another tumour presented itself, apparently filling up the pelvis, right in the median line, just above the pubis. It was very firmly attached on its site, had large vessels ramifying over its surface, and evidently contained fluid. It looked like a cyst, but seemed too dark and freely supplied with vessels to be an ovarian cyst. It could not be the bladder; the urine had been carefully removed previous to operation. It seemed too firm and immovable for an ovarian cyst. The finger in the vagina came on the os uteri, and then the finger seemed to pass up and around a swelling, apparently the uterus. All present inclined to the opinion it was uterus, and it was consequently left alone. All bleeding having ceased, the parts were sponged and cleaned. Five deep silk ligatures were inserted, and strapping, cotton-wool, and bandage applied. The woman bore the chloroform and operation well, without causing any alarm. An injection of tinct. opii ℥xl., tinct. belladon. ℥xxx. was thrown up into the rectum. The patient was removed to bed, and her legs supported by pillows. The operation took one hour and ten minutes in performance. To make the story as short as possible, I will remark that vomiting set in the same evening. Pulse rose to 140; temperature 101·2°.

22nd.—Pulse came down to 110; temperature 99°; vomiting less, but still present; can only keep milk and lime-water on stomach.

23rd.—Pulse 120; temperature 97°; deep sutures removed; vomiting same.

24th.—Clamp came away itself this morning; pulse weak, 120 to 140; evening temperature 99·2°; vomiting continues.

25th.—Died quietly, vomiting having ceased from yesterday. The urine was drained off every four or six hours, and enemata of tincture of opium and belladonna gave much comfort as regards pain; no medicine given by the mouth; enemata of egg, milk, and brandy were administered to no good effect.

Post-mortem (August 25, 1875, 5 p.m.)—Body still warm. Abdominal section quite firmly united to within a short distance of where the clamp had been situated; soft fibrinous effusion slightly gluing the intestines together; not much fluid in the peritoneal cavity. The tumour which we had come upon at the time of the operation had risen nearly as far as the umbilicus. On cutting into it, it proved to be a multilocular ovarian cyst; four or five septa, very thick, and filled with very thick colloid fluid. The tumour adhered so firmly to the pelvic brim and sides, also the back of a very small wasted uterus and bladder, that on using much force I could not even lift it out of the pelvis, the adhesions were so universal and strong. The evidences of peritonitis were not much more marked than those observed at the time of operation. The patient seemed to die exhausted from vomiting; vomiting before the operation was the most distressing symptom. I believe this is the first case of ovariotomy which has been performed in South Africa.

I must confess that I was not prepared to meet a second tumour; and the question arises, whether, with a second

*

ovarian tumour so adherent, could I have done better; or had I evacuated, would there have been a better chance of life? The fixity, the position, the dark surface, the enlarged vessels, made us think it was the uterus. I am sorry that the first case in Africa has been a failure. But what surgeon does not learn more by his failures than by his successes?

Port Elizabeth, South Africa.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

ST. BARTHOLOMEW'S HOSPITAL.

CASES OF "GASTRIC CRISIS" IN LOCOMOTOR ATAXY.

(Under the care of Dr. PATRICK BLACK.)

[Recorded by Dr. ROBERT BRIDGES, Casualty Physician to St. Bartholomew's Hospital.]

Case 1.—D. C., aged thirty-nine, a loader of ships, admitted to St. Bartholomew's Hospital on April 24, 1876, suffering from obstinato vomiting and pain in the lower part of the belly, running round the flanks, these symptoms having come on on the fourth day before admission. Patient has a light complexion and red beard; appears strong and in good health, and does not look as if he was troubled with dyspepsia, or as if he had suffered much pain. Pulse 80, regular, full, rather sudden. Skin natural to touch; body-heat normal. Pupils equal and natural. Tongue rather furred, and yellow at the back. He states that he has had similar attacks of obstinate and continued vomiting before. He never had jaundice; he is in no pain at present. when he vomits he sees double; his sight is dim now. He has a great sense of weakness in the knees, and a trifling pain there, but no other pain in the legs. On exposing the legs, they exhibit a great contrast to the upper part of the body, being thin and wasted. No local swelling nor trace of anasarca; no anæsthesia nor retardation of sensation. On examination of chest and abdomen all physical signs were normal. There is no blue line on the gums. The urine, on boiling, precipitates a thick cloud, dissolved entirely by nitric acid. He states that he has difficulty in passing his water at present. Examination of the eyes: Slight internal squint of left eye. causing double images to be seen looking to left (due to weak external rectus of left side). Both optic discs depressed, and paler than natural; right decidedly paler than left; arteries small. [Two examinations were made, one by the Ophthalmic Surgeon, Mr. Vernon, and one by the House-Surgeon, Mr. Barton]. On questioning him about his history, he cannot say exactly how many attacks of sickness he has had; the first attack he remembers was five years ago, the first few attacks were more widely separated than the later ones; the only accurate dates he can give are these—that the last attack was six weeks ago, lasting eleven days; the one before that commenced the first Monday in August, 1875, lasting about the same time; the one before that was this time last year, when he was in Poplar Hospital for an accident. When questioned about ataxic symptoms, it is evident that he has attached no importance to them. The "weakness in his legs," as he terms it, came on after the attack last year. He has not remarked weakness in any other part of the body, and does not remember to have felt weak in the legs before one year ago. This weakness is worse during the periods of sickness. As for his sight, he has remarked no actual loss of vision; but a dimness of sight, especially in the left eye, has come on after his attacks of sickness. During the last attack he had decided diplopia, having to move his head to the left, over the left shoulder, to see with distinctness objects in front of him. He has not seen double since. The ataxic symptoms, when the patient was asked to walk, were very marked. He was himself evidently not aware how weak he was, and when he shut his eyes he would have fallen at once but for assistance. The sickness lasted about ten days altogether. The vomit was green, fluid, and much mixed with mucus. The patient was very thirsty; there was a tendency to constipation; the difficulty in micturition was but slight; he slept badly; subcutaneous injections of morphia had some soothing effect. The sickness stopped the day after counter-irritation was applied to the spine. Sleep returned as soon as the vomiting subsided.

Case 2.—J. M., a carpenter, aged thirty-seven, from Sydney, admitted on October 13, 1875. A spare but hearty-looking man, unable to walk or stand without assistance; gave the following history:—He has not done any work for twenty-one months. Illness began two years ago, with darting pains in the legs, which came on at night, and would last thirty hours; sensation of cold in knee-caps; loss of power in running, and ataxy in the dark. His disease has gradually increased on him, with loss of power and inability to use his legs. He has had occasional difficulty in passing water. Arthritis: Eighteen months ago the right knee-cap swelled, and was painful; this lasted a month; it seems to have left no trace. Gastric Crises: At Sydney, just before embarking, he had an attack of pain in the stomach with retching, which lasted a week; the pain was so great that he groaned with it. This was May, 1875. There was difficulty in micturition. The second attack was during the last fortnight of the voyage (October 1 to 13, 1875). He had never been sea-sick during this voyage, nor before; the weather would not account for it. The difficulty in micturition was so great that the ship's surgeon passed a catheter. The third attack was while under observation; it lasted only one day, but some discomfort for three days. This sickness was again accompanied with difficulty of micturition—a catheter passed easily; the pain he described as heavy and dull; the body-heat neither rose nor sank. Examination of Eyes: Ophthalmoscope showed no certain change in discs; sight was good. There was ataxy of both legs, which were also wasted and weak, not paralysed; there was some loss of sensation, nowhere complete; there was no retardation of sensation; the disease was from the hips downwards; the patient seemed free of other disease; the urine was natural, no albumen.

SATURDAY, AUGUST 18, 1877.

THE ADDRESS IN SURGERY.

THE name of Mr. Spencer Wells, as the author of this very interesting Address, is a sufficient guarantee of its excellence, and therefore there is little need for us to preface any remarks we may make, by eulogisms which can add nothing, either to the value of the Address, or to the surgical reputation of its author. We shall endeavour to briefly summarise the chief points of the Address, and then commend it to the careful study of all our readers.

Mr. Spencer Wells, in order to point out how, individually as well as collectively, every one of us may assist in the advancement of the "surgery of the future," traced the history of the past, so that "our followers, taught by our success, warned by our failures, knowing where our knowledge is defective, our methods faulty, may so work and so observe that in each succeeding year surgery may become more perfect as an art, more exact as a science, and more honourable as a profession." Indeed a retrospect of the practice of surgery is absolutely necessary if we would rightly appreciate the rapid strides with which this art is now advancing. Few amongst us at the present day can remember what surgery was before the introduction of chloroform, and most of us are so used to it that the dangers and difficulties which attended its introduction are as little appreciated by us as are the obstacles which, before its use, beset every large or even small operation that the surgeon might be called upon to perform. In saying this we are not glorifying ourselves at the expense of our old and bygone predecessors. We point out the fact simply that chloroform has opened up a road which rendered progress—and rapid progress—almost inevitable. The mere fact of the artificial but beneficent slumber which chloroform brings about, allows the surgeon to peacefully think out and perform his operation, unharassed by any of the humane but bewildering consideration which the cries and sufferings of one's patients must needs give rise to in the most callous and indifferent surgeon. Such a revolution has taken place since chloroform came into use as never before happened, and Mr. Wells justly characterises this as the "commencement of a new era in surgery." There had, no doubt, been other and great changes in the practice of surgery, such as the ligature of arteries instead of the old and barbarous method of "choke-bands," boiling pitch, and hot irons for the staunching of blood after amputations and other wounds, but the introduction of chloroform threw this and all others into the shade.

Mr. Wells showed how the "age of Victoria" is inseparably connected with all the most recent and most important advances in surgery as an art and as a science, and he pointed out too how this advance has corresponded with the development and growth of the British Medical Association. "Almost coincidently with the formation of this society in 1832, there began to be spoken about vaguely, and as curiosities, things which are now so universally practised, that probably very few of those who listen to me recollect how very recently they have been accepted as part and parcel of surgical practice. I am not one of the oldest here, but I can well remember when lithotrity was a novelty, when the subcutaneous section of tendons was absolutely new, when orthopædic surgery was unknown, when the torsion of arteries was spoken of as a barely possible substitute for the ligature, when the radical cure of hernia was scoffed at as a French delusion, when the treatment of aneurism by compression had hardly even entered into the professional imagination." "In 1835, at Oxford, Costello publicly demonstrated lithotrity as a novelty before the assembled Association, and I think we may fairly date the establishment of that operation, now so carefully and generally practised by so many of our associates, from that meeting."

Passing on from general topics to special ones, the orator referred in turn to anæsthesia and anæsthetics, the radical cure of hernia, and the use of electricity as a therapeutic agent. In reference to the last subject, Mr. Wells referred to the electrolytic dispersion of tumours—a subject which is yet quite in its infancy, but which is well worthy the attention and study of all surgeons. That tumours have been completely dispersed by the continued action of the electrolytic needles is a well-known fact; that bronchoceles may also be dispersed, and subcutaneous nævi destroyed in such a way that little or no scar is left behind, are things now established beyond a doubt. Such facts should surely lead to further study and researches. Speaking of the value of accurately knowing the temperature of our patients, Mr. Wells compared the sensitive clinical thermometers of to-day with the rough-and-ready guesses at temperature of olden times before these instruments were invented. Many of our readers will scarcely credit, what is nevertheless a fact, that the ophthalmoscope was jeered at and "ridiculed in print as a toy." And yet what surgeon or physician would now venture into our hospital clinical wards without this little companion and aid to diagnosis in his pocket? Esmarch's bandage was next referred to, and the orator thought "that many of the inconveniences ascribed to its use will be avoided when it comes to be more generally practised." Transfusion of blood by Dr. Roussel's apparatus was spoken of: "I need only express my hope that everyone who practises surgery hereafter will make himself competent to transfuse safely, not only when a patient is bleeding to death after childbirth, or some accident, or operation, but in other cases when the blood is insufficient in quantity or deteriorated in its composition." It may interest our readers to know that, while Mr. Wells was even speaking these words, Dr. Roussel was engaged in consultation with Dr. Thorburn in transfusing blood for post-partum hæmorrhage. The husband of the woman supplied the blood, and it is satisfactory to know that the operation has been highly successful, although the woman at the time of its performance was almost past hope.

Speaking of vivisection and recent legislation on the subject, Mr. Wells said "anybody may slaughter oxen and sheep by thousands for human food in any way he pleases; oysters may be eaten alive; the pheasant or the partridge, the fox or the deer, may be expressly reared to supply the sportsman with exercise or *the amusement of killing*—in a word, the lower animals may be devoted to the use of man for *any* purpose that is *not* scientific. But if a surgeon experimentally sacrifices half a dozen dogs or rabbits in the hope of improving some operation which may prevent the loss of human life or lessen human suffering, he is branded as inhuman, and barely escapes the supervision of the police."

One of the last subjects, though by no means the least, to be considered was ovariotomy. This operation, said Mr. Wells, had been almost denounced from the chair of the Royal Medical and Chirurgical Society in 1850 by Lawrence, who asked "whether this operation can be encouraged and continued without danger to the character of the profession." Mr. Spencer Wells's name is so intimately associated with this operation that it is impossible to think of the one without the other; and his 800 cases will ever stand out as a gigantic landmark, not only in the history of surgery in all time, but as the unparalleled achievement of one great master-hand in the lifetime of a single generation. We can appreciate Mr. Wells's pride and pleasure in hearing from the same chair, less than thirty years later, that "his (Mr. Wells's) improvements in the operation of ovariotomy were among the greatest achievements of surgery in this century, and that the influence for good extended through every department of operative surgery." This was indeed a recompense for all the thought and anxiety which must have been given to the perfecting of an operation which at one time was considered so "fearful in its nature, often so immediately fatal in its results, that, whenever performed, a fundamental principle of medical morality is outraged."

In concluding, the orator impressed on his hearers the great value of scientific education, not for doctors only, but for the lay public. "At home, until we can disband the great army of paupers, we must at least save them from preventable disease, and the multitudes of our neglected children must be taught some elementary facts necessary for the preservation of their health and the prolongation of their lives. The day cannot be far distant when this will be done by Parliament, under medical guidance." "There is ample encouragement to set to work at

once, earnestly and with set purpose, acting in the spirit of the noble motto—

"'Vérité dans la Science,
Moralité dans l'Art.'"

THE ADDRESS IN OBSTETRICS.

The Oration in Obstetrics is one which the profession to whom it is addressed will read with interest, if not with conviction. It is marked by the author's wonted force of style and fertility of illustration; and the high position which he holds in the department for which he spoke, gives it the more weight. Looking at it, as it is our duty to do, from a critical point of view, it seems to us to possess the one fault which an utterance inspired by strong feeling and firm opinion is almost sure to have: it is the address of a counsel, strong, able, and convinced that right is on his side; but it does not, like the judicial summing up, unfold with equal care each side of the case. Its argument is a simple one, and is developed with that abundance of apposite illustration which is the mark of a full mind.

Dr. Barnes first enters a preliminary protest—not put one bit too strongly—against "the rapidly growing tendency to split up the study of the healing art into sections," tending to "the study of medicine in disjointed bits, to the neglect of those grander lights which can only be caught by a well-balanced study of all in their mutual relations." Reflections such as these, he goes on to say, "however universally their abstract truth is recognised, in practice are too much neglected." The principle here stated is then illustrated from the author's special subject. He takes pregnancy as his example; and about half the Address consists of a brief, though full, summary of those changes in the whole organism which accompany the gravid condition—not a mere catalogue of separate facts, but a philosophical survey of them, showing how they are brought about, and their relations to one another. Having set before us the physiology of the pregnant state, Dr. Barnes takes us to its pathology, and cites many examples of the remarkable influence which gestation has in determining or modifying the phenomena of disease. This part of the Address is summed up in the proposition:—"*As pregnancy is the test of soundness in the individual, it may be of all her blood relations too, so is pregnancy often a crucial test of the soundness of pathological doctrines.*" This section will be read with profit by all. So compressed and so accurate as to be useful to the student, it is yet so full of thought as to be instructive and suggestive to those of larger acquirements.

The scientific basis thus laid, Dr. Barnes passes to his political corollary, which is this: "A philosophic comprehensive science of medicine or surgery cannot be built up without an earnest study of obstetrics." "It is impossible to make a good surgeon without training him in medicine and obstetrics." It is therefore a reproach to the College of Surgeons that it licenses men to practise *every* branch of medicine and surgery of whose obstetric knowledge it takes no heed. "It grants imperfect diplomas; it licenses to practise what it ignores." If this proposition be true, it is a still worse step to propose to license persons to practise upon women, whose knowledge in the larger branches has not been tested. Such a thing is a degradation to obstetrics, and a wrong to womankind. So far, we think, Dr. Barnes will carry his readers with him. His premises are undeniable, his reasoning sound, and his language not at all too forcible.

The Address concludes with a vehement condemnation of the recent step which the Senate of the University of London has taken. It is to this part that our criticism most applies. His refereuce to it is but a vigorous expression of opinion, not an exhaustive argument—a mode of treatment probably imposed upon him by limited time. His words, "We repudiate utterly the proposition that there is one standard which it is necessary to attain to qualify for the treatment of diseases of men, and another, a lower, to qualify for the treatment of diseases of women"; "Medicine is one and indivisible,"—all this we heartily endorse. But his utterance is so outspoken, his attitude so uncompromising, that we do not think it will win over many of the opposite side.

He lastly refers to the appointment by the Council of the Pathological Society of a Committee to investigate, among other infectious diseases, puerperal fever,—this Committee not including anyone practically acquainted with the disease in question. We here differ from Dr. Barnes. We look upon this Committee with feelings precisely opposite to his, and yet prompted by the same reasons. It seems to us a proof of that interest in obstetric science which, we agree with Dr. Barnes, is wanted; and surely it would not be considerate to ask men whose line of practice is such that they cannot safely enter a post-mortem room, to assist at an investigation which must be chiefly concerned with the dead subject.

The drift of the whole Address is summed up at the end, in this sentence, which is the last that we shall quote:—"The political error which mars the usefulness of some of our medical institutions flows from the scientific fault—a want of due appreciation of the place which obstetric science and practice should hold."

We have said enough to show that in Dr. Barnes's main position we entirely agree. No one can be a sound physician or surgeon who has not laid a good broad foundation, and learnt the facts of disease as it affects every part. It is no more safe for a man to leave out of his studies the diseases of one set of organs than it would be to overlook their anatomy and their physiology. In the latter case the principle is recognised; in the former not. We would add the converse proposition: No man can be a good obstetrician (or specialist of any other sort) who is not well grounded in general medicine and surgery.

The importance of obstetric knowledge to the general practitioner is obvious, for he has to practise it. And that the education of the pure physician, and pure surgeon, should not be thought complete without a knowledge of obstetrics is also to be wished, not only for the light that such knowledge may throw on other diseases which he has to investigate and treat, but because it would give obstetricians the advantage of better criticism and help.

The position which obstetric science and practice will hold must depend upon those who practise it. If all obstetric works were written with the full knowledge and scientific method which characterise those for which the profession is indebted to Dr. Barnes, the boastful contempt of obstetrics which he refers to would not exist. But when we find, written nine years ago, by an obstetrician whose name we are sure Dr. Barnes holds in honour—"The fittest of fates, oblivion, awaits much that is now vaunted: the discovery and diligent treatment of diseases which do not exist; the use of treatment the danger of which is greater than that of the disease; the recommendation of remedies and operations regarding which little more is known than their names; the facile juggling with remedies of which it is the one sufficient recommendation to have a new name; the systematic concealment of disasters resulting from such treatment,"—all we can say is, that if the profession acquiesce in these sweeping sentences, no regulations can make obstetric science highly thought of. The remedy for such things as these, if they exist, is *light*. In proportion as obstetricians show that they possess a body of verified truth, and that they investigate this class of diseases according to scientific method, so the more eager and the more competent will become other members of the profession to appreciate the value of their work.

THE PUBLIC HEALTH (IRELAND) BILL, 1877.

Notwithstanding its untimely fate at the hands of Messrs. Parnell and Biggar, in Committee of the House of Commons last Thursday week, the Public Health (Ireland) Bill, 1877, cannot be allowed to pass out of sight without some notice in our columns.

For many reasons the withdrawal of the measure by the Chief Secretary for Ireland is to be regretted. If, however, the emendations introduced by the Select Committee which recently considered the Bill are included in a similar measure next session, and if the delay in legislation affords further opportunity of developing and perfecting a sanitary code for Ireland, the present evil of withdrawing the measure may ultimately become a boon to the sister country. For, numerous as are the improvements already introduced, much yet remains to be done in the way of amendment and of further legislation.

The Bill, as amended by the Select Committee, consists of 292 clauses—four more than were in the original draft. The introductory memorandum by Sir Alfred Power, Bart., Vice-President of the Irish Local Government Board, is omitted.

The new clauses are the following, viz.:—Clause 5, which enables an urban sanitary authority to delegate to a committee certain of its functions under the Bill. Clause 46, which allows other means of removing house-refuse than by the watercloset or dry-earth systems—*e.g.*, by the pail system. Clause 145, which imposes a penalty on persons sending to school any child "who, within the space of three months, has been suffering from any dangerous infectious disorder, or who has been resident in any house in which such dangerous infectious disorder shall have existed within the space of six weeks," without a medical certificate that such child is free from infection, and unless his or her clothes have been *properly* disinfected. Clause 154, which empowers any sanitary authority to provide hospital accommodation, *including convalescent homes*, for its district. Clause 155, which enables the said sanitary authority to recover from patients who are not paupers the cost of their maintenance in such hospitals. Clause 256, which provides that *every* sanitary officer shall attend and assist at prosecutions by the sanitary authority, *any medical officer so attending being entitled to remuneration from the sanitary authority at such rate as the Local Government Board shall approve, unless it shall have been agreed that the duty of affording such attendance and assistance shall be included in his salary, or that his whole time shall be occupied in the discharge of the duties of his office*"; and Clause 277, which relates to the construction of Schedules.

Of these new provisions, Clauses 46, 145, and 154 are most important from a sanitary point of view, and Clause 256 removes a grievance to which the Irish dispensary medical officers, acting as sanitary officers, have been subjected since the passing of the Act of 1874. It marks one of the decided successes gained by the Colleges of Physicians and Surgeons of Ireland, and by the Irish Medical Association, in their representations to the Chief Secretary on the Bill.

It is with great pleasure that we approach the consideration of Clause 11, which as "Clause 10" in the original Bill so intimately concerned the interests of the members of the profession. The commencement of the clause now reads—"Every medical officer of a dispensary district shall be a sanitary officer for such district, or for such part thereof as he shall personally be in charge of, *under the title of Medical Officer of Health*," etc. The words which we have italicised embody one of the emendations in the law which was most eagerly sought for by the profession in Ireland. The medical officer's status under the sanitary code is secured by those words, and he can no longer be regarded by obtuse sanitary authorities as an inspector of nuisances or a general sanitary drudge.

In the same clause occurs the objectionable provision as to the payment of the medical officers in accordance with a scale to be approved by the Commissioners of her Majesty's Treasury. Under the Act of 1874 the Local Government Board fixed as a *maximal* scale one-fourth of the salaries enjoyed by the sanitary officers in their capacity of dispensary medical officers. Had such a scale been a *minimal* one, no reasonable objection could have been taken to it; but, as it is, the dispensary medical officers are almost to a man in open rebellion against the existing system of payment by scale. Although the obnoxious words still stand part of Clause 11 of the amended Bill, we are happy to say that Sir M. Hicks Beach has given a positive verbal assurance that the scale will be altogether withdrawn. He has said so to the Chairman of Council of the Irish Medical Association, and there can be no doubt that he would himself have proposed the omission of the words in question in committee of the whole House. As the Bill is withdrawn for this session, we must only hope that Sir Michael will be in a position next year to redeem his promise.

With a view of protecting the medical officers in the discharge of their onerous duties—duties which are often calculated to bring them into opposition with their clients in private practice—the necessity of providing supervision was strongly urged upon the Government. The Conjoint Sanitary Legislation Committee for Ireland drafted the following clauses to be added to Clause 10 (now 11) of the Bill:—"The Local Government Board shall, from time to time, appoint so many fit persons as the Lords Commissioners of her Majesty's Treasury shall sanction, being practising physicians or surgeons, to be inspecting medical officers of health, to assist in carrying out the provisions of this Act, and may remove all or any of such officers and appoint others in their stead. There shall be paid to such inspecting medical officers of health such salaries as shall from time to time be appointed by the Lords Commissioners of her Majesty's Treasury, out of any moneys which may from time to time be provided by Parliament for that purpose. Within *six* calendar months after the passing of this Act, the Local Government Board shall divide the whole of Ireland into districts, for the purposes of sanitary inspection, and every such district shall be subject to the supervision of an inspecting medical officer of health."

The Select Committee did not adopt and introduce these clauses, but the desirability of—nay, the necessity for—supervision has been fully recognised by the Chief Secretary and by the Select Committee, and the reason the clauses were not adopted, is simply that the Local Government Board already has the power of appointing inspectors for the purposes contemplated by the amendment.

Among other improvements in the amended Bill, we observe that Clause 139, providing conveyances for removing the sick to hospital, is made compulsory on every sanitary authority, instead of being permissive as heretofore. Clause 144 now extends the penalty hitherto inflicted only on persons *letting* houses, to persons *taking* houses, who may make false statements as to the existence of infectious disease. Under Clause 151 the Poor-law Medical Officer becomes entitled to costs for attendance on board vessels *at a rate to be fixed by the Local Government Board*. In connexion with this mention of remuneration for skilled services, we must express our regret that, in Clause 157, the fee for a certificate by a qualified medical practitioner has, apparently by an oversight, been allowed to remain at *ten shillings*. It should certainly be not less than one guinea. Clause 157 now includes the following provision against the dangerous practice of "waking" those who have died of zymotic disease:—"The body of any person who has died of any dangerous infectious disease in any hospital or place for the treatment of the sick shall not be removed from such hospital until removed direct to a mortuary or cemetery; and

any person violating, or any officer of a hospital, or other person, who knowingly permits the violation of this provision, shall be liable to a penalty not exceeding *five pounds*."

With a view of improving the registration of deaths, the following addition has been made to Clause 190 :—"The clerk or secretary, or registrar to any burial board and cemetery company, shall make or cause to be made at such times and in such manner as the Local Government Board may direct, a return of the names, addresses, dates of death, and causes of death, so far as ascertained by him, of the persons whose bodies have been interred in such burial-ground to the registrar of the district in which the burial-ground is situated."

Space would fail us in an attempt to give in detail the minor amendments introduced by the Select Committee. The more important ones, already specified, show how energetic were the labours of that Committee while sitting, and increase the regret we feel at the withdrawal of a really good measure. Let us hope that the Chief Secretary will introduce a similar and even better Bill at the beginning of the next session of Parliament, so that Ireland shall no longer be deprived of the advantages of a sanitary code—for the present lost to her by shipwreck among the many shoals and quicksands that, towards the end of a Parliamentary session, endanger the course of vessels, however goodly, well officered, and well manned they may be.

THE WEEK.

TOPICS OF THE DAY.

Of late years the neighbourhood of Battersea has been selected by chemical manufacturers as a convenient spot for their operations, but the Wandsworth Board of Health are not altogether satisfied with the arrangement, and last week they instituted proceedings against two firms at the Croydon Assizes. The first prosecution was against Messrs. Wallace, who manufacture sulphate of ammonia, a product of the refuse liquor of gas works, treated with sulphuric acid and lime, etc. In this process it was sought to be proved that baleful fumes were emitted, not only odious and sickening to the smell, but distinctly injurious to health. Indeed, one sewer man is said to have died of these fumes. Many witnesses, including some medical men, were called to prove the case. The defence was, that although the smell was certainly bad, it produced no ill effects. After a trial lasting five days, however, the jury were unable to come to a conclusion, and were discharged without giving a verdict. The other case was a prosecution against the Alum and Ammonia Company, whose process is different, though dealing with a similar material, and also with the aid of sulphuric acid. It was found impossible to form a jury, and the case was ordered to stand over.

The *Sanitary Record* remarks that since civil registration was established in England, there has been a considerable increase in the relative proportion of the male death-rate to the death-rate amongst females. According to the English Life Table, in equal numbers living the deaths of males (at all ages) are somewhat less than 105 to 100 deaths of females. During the last quarter the annual death-rate amongst males was equal to 23·1 per 1000, whereas that among females did not exceed 19·9 per 1000; thus, in equal numbers living, the deaths of males were as 116 to 100 deaths of females. In urban populations the relative excess of the male death-rate is more marked. In Lancashire, for instance, the death-rate of males to that of females was as 121 to 100, and in the West Riding of Yorkshire as 123 to 100.

Last week the town of Barnsley was presented with a park, being a large addition to the piece of ground already in possession of the Corporation, at the cost of Miss McCreery, of London, sister-in-law of the late Mr. Joseph Locke, the eminent engineer. The occasion was celebrated as a holiday in the neighbourhood, all the shops and works being closed. The new park consists of about twenty acres of well laid-out ground, together with a handsome tower erected at a cost of £3000, which bears the inscription, "To the memory of the donor of the park, Phœbe, widow of Joseph Locke, M.P., this tower was erected, and twenty acres of land added to the park by her sister Sarah McCreery, 1877." The handing over of the park to the Corporation was undertaken by Lord Halifax, whose family originally belonged to Barnsley.

A very satisfactory report has been issued by Mr. Henderson, Sub-Inspector of Factories for the Western Division of the Metropolis, on the working of the Factory and Workshop Act of 1867. Although great fears were at first expressed by employers that this piece of legislation would be ruinous to them, the result has proved entirely the opposite, and masters confess themselves astonished at the result, which has been to reduce the unreasonable demands made upon them by merchants, and to enable them to employ their workpeople under conditions at once more healthy and more profitable to all concerned. The tendency in all manufacturing industries to the concentration of the workpeople in large factories allows better sanitary arrangements to be made for them, and manufacturers now know that if they desire good work, they must surround their workpeople with conditions which will enable them to exercise all their faculties and energies freely. Not many are now ignorant of the baneful influence of overcrowding, bad air, insufficient meal-times, and uncomfortable workrooms. It is admitted that there is still much room for improvement, but the experiences of the last ten years hold out a good promise for increased reform in the future.

The special correspondent of a contemporary with the Russian army, writing from Sistova, reports that the Russians are beginning to suffer in health, owing, in some corps, to irregular rations, in others to hard marching, in all to heat; but the greatest predisposing cause is the total neglect of all sanitary precautions. They never bury dead horses or oxen, or the entrails of slaughtered cattle; they never dream, seemingly, of the wisdom of the latrine system. The result is a general tainting of the air, which poisons men predisposed to fall ill by reason of lassitude from over-fatigue or long abstinence from food, although men in stalwart health escape. It is a little singular that the greatest proportion of illness has manifested itself in the suite of the Emperor. Out of five officers on personal service about him, four are ill. Nearly everybody is more or less sick, squeamish, and out of sorts, and the reason is not far to seek—the air of Biela is tainted thick and heavy with filth and rotting offal. Even tobacco-smoke and brandy are powerless to avert nausea.

The Lavoisier Medal of the Société d'Encouragement pour l'Industrie Nationale has just been given to an Englishman—Mr. Walter Weldon, F.R.S.E. In presenting it, M. Dumas congratulated Mr. Weldon upon having cheapened every sheet of paper and every yard of calico made in the world; and, at the meeting at which the presentation took place, Professor Lamy stated that whereas at the date of the introduction of Mr. Weldon's invention, seven or eight years ago, the total bleaching-powder made in the world was only about 55,000 tons per annum, it was now over 150,000 tons per annum, and of this vast quantity fully 90 per cent. is made by the Weldon process. The only other recipients of this Society's "great medal," which bears different effigies according to the class of service for which it is given, are Ferdinand de Lesseps, Boussingault, Jaques, Siegfried, Henri Giffard, and Sir Chas. Wheatstone.

A case which was heard this week at the Marlborough-

street Police-court rather forcibly illustrates the necessity for caution before indulging in the practice of bathing in the Serpentine. A man was charged with using soap whilst bathing, and also with washing rags; it was also shown that he had running wounds, and one of the witnesses wished to know if a person suffering in this way could not be prevented from bathing in the limited space assigned to bathers by the Park authorities, as it seemed not impossible that those near might catch some disease. The magistrate, however, said the regulations stated nothing about a man bathing his wounds in the Serpentine, but they did forbid the use of soap by bathers. It appeared to him that a common sense of decency ought to prevent an afflicted person from exposing his wounds publicly. The defendant said he had been ordered by the doctor at St. George's Hospital to use plenty of water; he was only washhis hands and arms, and would not do so again; he also promised to discontinue bathing, and was then fined 20s., or fourteen days. "Common sense," of all varieties, is very often wanting; and certainly the use of a public bathing-pool for the treatment of sores or eruptions ought to be prohibited.

The Commissioners appointed to inquire into the discipline and management of Christ's Hospital, and the circumstances which led to the suicide of the boy W. A. Gibbs, have presented their report to the Home Secretary. The authorities and the monitors are exonerated from any special blame in the matter of Gibbs' death, but the present method of managing the school is strongly objected to, although it is admitted that the system now in force is necessary so long as the school is retained in London. Therefore, the Commissioners suggest its removal to the country, where probably all the defects in management and discipline which are now complained of, and which cannot be effectually cured so long as the school remains in its present cramped situation, would disappear under the government of an able and judicious head-master. Under the present system the masters have no control over the boys out of school-hours, and their engagements do not bind them to be present at any time but the hours for lessons. This is an entirely wrong system, as everybody knows the importance of masters mixing with their pupils during the hours of recreation; and as the retention of the London site precludes the introduction of reform in this matter, it is to be hoped that we shall shortly hear that the school is about to be removed to an appropriate and convenient suburban site.

In view of the deplorable loss of life which annually occurs about this time from injudicious bathing, and which, according to the Registrar-General's returns, has increased between 30 and 40 per cent. during the past year as compared with corresponding periods of the previous year, the Royal Humane Society have again published their often circulated advice to bathers. It runs as follows:—"Avoid bathing within two hours after a meal, or when exhausted by fatigue or from any other causes, or when the body is cooling after perspiration; and avoid bathing altogether in the open-air, if, after being a short time in the water, there is a sense of chilliness, with numbness of the hands and feet; but bathe when the body is warm, provided no time is lost in getting into the water. Avoid chilling the body by sitting or standing undressed on the banks or in boats after having been in the water, or remaining too long in the water, but leave the water immediately there is the slightest feeling of chilliness. The vigorous and strong may bathe early in the morning on an empty stomach; but the young and those who are weak had better bathe two or three hours after a meal, say after breakfast. Those who are subject to attacks of giddiness or faintness, and who suffer from palpitation and other senses of discomfort at the heart, should not bathe at all without first consulting their medical adviser." These rules are simple and good, but in the matter of bathing the public may almost be said to scorn advice.

An extraordinary state of affairs apparently existing in St. Giles's Workhouse was revealed at a recent inquest held upon the body of an old woman, seventy-six years of age, who lately died in that establishment. Evidence was given that the aged paupers in the infirmary have no one to render them any assistance if required at night; and occasionally, for want of better accommodation, they have to walk across the flagstones of a yard, the distance being between fifty and sixty feet. The deceased, about 4 a.m. on the 10th ult., rose and walked across the yard without shoes or stockings, fractured one of her thigh-bones, and lay on the ground in the rain upwards of two hours before she was discovered. The jury censured the guardians for their neglect.

THE MADRAS FAMINE.

We are thankful to be able to state that there is now more than a chance that public feeling will be roused to a full understanding of the terrible state of things in the famine-districts of the Madras Presidency. On the 9th inst. a public meeting, presided over by the Duke of Buckingham, was held at Madras, to consider what steps should be taken to secure help from England. The Duke stated that the affected area contained 18,000,000 people, of whom a large proportion was dependent for its daily food on the exertions and activity of those connected with the transport of grain to the country. His own journeys in the famine districts had convinced him that two-thirds of the Presidency was subjected to such a crisis as had never yet been experienced in Bengal or elsewhere. The failure of the south-west monsoon was admitted, and a more severe famine had to be encountered with a weakened population and diminished resources. Surgeon-Major Cornish stated that there were already 1,500,000 people to be fed; that up to the end of July 500,000 had died; and that the condition of the famine districts was going from bad to worse. Resolutions were passed that appeals should be made to the English people, and to the mayors of the principal cities in England, for help. The *Times* now fully acknowledges the urgency that exists for assistance. And "the visitation which has fallen" upon our fellow-subjects in Madras and Bombay, and in Mysore, has been made the subject of a paragraph in the Queen's Speech on the prorogation of Parliament. We shall take an early opportunity of recurring to the subject, but we have no doubt that the cry from India for help will be nobly responded to.

RECENT DEATHS UNDER ANÆSTHETICS.

Two more deaths in consequence of the administration of anæsthetics have occurred during the past week—one at the London Hospital on the 11th inst., and one at the Royal Ophthalmic Hospital, Moorfields, on the 14th inst. That at the London Hospital occurred about midnight. A man applied with an irreducible paraphimosis. After several ineffectual attempts at reduction, which caused the man very great pain, Mr. Hovell, the House-Surgeon, asked one of his colleagues to administer chloroform. A very small quantity was given on a piece of lint. The patient was quickly under its influence. However, in about two minutes the breathing suddenly ceased, his face became livid, and the pulse failed. Sylvester's method of artificial respiration was at once resorted to, and other measures were adopted, and failed. At the post-mortem examination the heart was found to be flaccid and dilated, and the muscular tissue fatty; it contained a little loose dark clot; there was no valvular disease. No other organic disease. The second death, at Moorfields, befell a woman, aged forty-six; she was extremely fat, and of slow intelligence. She had complained of shortness of breath on exertion, but was not known to be the subject of organic disease. She was to be operated on for senile cataract. A mixture of chloroform and ether, in a modified Clover's apparatus, was being administered

by the House-Surgeon. From the commencement of the administration, respiration was noticed to be shallow, but there was struggling. The pulse was feeble but not intermittent. There was some slight lividity of cheeks and forehead. Chloroform was at once removed, and a few whiffs of pure ether administered as a stimulant. Other means for restoring circulation were tried, but in vain; the patient died. At the post-mortem examination the heart was found flaccid and empty; the mitral valve was contracted, and the aortic valves were incompetent. Kidneys were fatty and granular.

THE PARKES MEMORIAL FUND.

At a meeting of the Committee of the Parkes Memorial Fund, held at the Royal Victoria Hospital, Netley, August 6, 1877, letters received from subscribers, in reply to circular of March, 1877, were read; and, being found to agree together unanimously in approving of the resolution provisionally adopted by the Committee relative to the disposal of the collected money—namely, "That the balance of the money which may remain after paying for the portrait of the late Dr. Parkes, and defraying other expenses incurred by having heliotype copies of the portrait distributed among the subscribers, printing circulars, postages, etc., be placed at interest; that such interest be allowed to accumulate for periods not exceeding three years, and that the amount (about £100) then available be offered for the best essay on a subject connected with hygiene, to be declared at the commencement of each triennial period, the prize to be open to all executive medical officers of the army, navy, and Indian army, on full pay (except the officers of the Army Medical School during their term of office)"—it was carried unanimously: "1. That this resolution be adopted. 2. That, if the Fund admit, a gold medal, bearing the portrait of the late Dr. Parkes, of value not exceeding £15, be given in addition to the £100 prize to the successful competitor, and that a sum not exceeding £50 be set apart for the die. 3. That December 1, 1880, be the date for sending in essays. 4. That the subject for the prize essay be determined by the Professor of Hygiene in the Army Medical School, in conjunction with a Committee formed by the Director-General of the Army Medical Department, the Director-General of the Naval Medical Department, and the Physician to the Council of India."

THE DIAPHANOSCOPE.

Attempts at lighting up the abdominal cavity for the purpose of diagnosis date from 1860. Milliot in 1867 made an instrument, but only used it on animals and dead bodies. His experiments led Lazarewitsch to apply it to gynæcology. He, however, failed to get light without at the same time getting heat, and so burning the patient. Dr. Justus Schramm, of Dresden, has overcome this difficulty, and made an instrument which can be used for any length of time. It consists of two glass tubes, the smaller within the larger, round at one end, at the other fixed to a wooden handle (made, for convenience of cleaning, to screw off). In the inner tube lie two copper wires, connected at one end with a galvanic battery, at the other joined by a slip of platinum. In the outer chamber cold water circulates, to absorb the heat given out by the platinum. In the handle is a button, by which the operator can make and break the current at will. The diaphanoscope is used in a dark room. The patient should be on her back, and her thighs extended. The tube is put into the vagina or rectum; the current is made, and the platinum soon gets white hot, giving a brilliant light. Then a wooden ring is pressed down, and at the same time moved about, so as to stretch and bring near to the light successive parts of the abdominal walls. The contrivance can only be used where the abdominal walls are thin, yielding, and not irritable; and there are many morbid conditions, which we need not specify, in which it is plainly inadmissible. Lazarewitsch has described appearances seen with his instrument, which, if confirmed by extended observations, would give it a certain diagnostic value. Dr. Schramm, however, in the few trials he has made with his more perfect apparatus, has failed to get results anything like so satisfactory. But his observations are as yet very few; and it is to be hoped that further experience with it may lead to something better. Meanwhile we agree with Dr. Schramm's wise remark, that an addition to our resources is always to be greeted with thanks. Although he cannot at present tell us that it is of real use, yet by making known his apparatus he may lead others to experiment with it and improve upon it, and so time may bring practical fruits from it.

THE STIRLING DISTRICT LUNATIC ASYLUM.

In his annual report on the Stirling Lunatic Asylum for the year 1876, the Medical Superintendent, Mr. James Maclaren, remarks that, as compared with the previous year, the chief facts to be noted are the diminished male admissions, these being seventeen less than in 1875; and the increased female admissions, which were eleven more than in the last year. The total removals during the year under notice were twenty-eight less than during the year 1875. Mr. Maclaren calls attention to the fact that one noteworthy circumstance with regard to the admissions for the period is the absence of any preponderance of one kind of insanity over another, or the existence of any special exciting cause in the district. The types of cases were very equally divided between the ordinary forms of mania, melancholia, and delusional insanity. From a study of the individual cases, and their causation so far as he could obtain it, he was led to think that the year 1876 may be taken as a very typical one as regards the amount of insanity likely to be permanent in the district. In a large majority of the cases the exciting and predisposing causes were of a natural character, or of a description likely to remain permanently in operation. There was, in fact, a marked absence of anything exceptional under the head of causation. As a proof of the necessity of early removal on the development of insanity, not only for the benefit (and even actual safety) of the patient, but also for the due protection of others, it is shown that no fewer than three patients died at periods of under one week from admission, whilst delay in another case led to homicide. Mr. Maclaren has succeeded Dr. Skae in the management of the Stirling Asylum, the latter gentleman having received the appointment of Government Inspector of Lunatic Asylums in New Zealand.

THE WATER-SUPPLY OF THE METROPOLIS.

Public attention is being prominently called to the impurity and inadequacy of the metropolitan water-supply, and the general opinion appears to be that the control and supply of such a necessity of life ought to be in the hands of a directly responsible body, instead of under the administration of a number of commercial companies. Such a body exists in the Metropolitan Board of Works, and accordingly it has been already provided that this Board should have power to purchase the undertakings of the several water companies. But even the Board of Works would find it beyond their power to render Thames and Lea water pure, and they have thus been compelled to inquire whether they could obtain a supply for the metropolis beyond the present existing sources. The result has been to obtain an assurance that by sinking wells and borings in the great water-bearing strata in the districts surrounding London an ample supply could be procured for the use of the metropolis. These sinkings would occur at distances varying from fifteen to twenty miles from the centre of London, and the necessary pumping-stations would be provided for lifting the water into four covered service reservoirs. It is suggested that a Bill to carry out the new scheme should

be deposited in Parliament next November; it could then scarcely be expected to lead to an Act before a year hence, and it would take another four years to carry out the details. Meanwhile, if immediate action be not taken, and the Bill deposited by November, another year will be lost, and the improvement in our water-supply will be retarded by that space of time.

THE HEALTH OF ST. PANCRAS PARISH.

The twenty-first annual report of Dr. Thomas Stevenson, the Medical Officer of Health for the parish of St. Pancras, on the sanitary condition of the district for the year 1876, among other information contains a table showing the mortality from each of the zymotic class of diseases, and their variableness, during a period of eleven years. From this it is to be gathered that the gross death-rate in the parish from measles, diphtheria, whooping-cough, and diarrhœa was in 1876 above, and from small-pox, scarlet fever, and continued fevers, below the average of the preceding ten years. From pulmonary diseases (other than phthisis), tubercular diseases (including phthisis), wasting diseases of childhood, and the convulsive diseases of infants, the mortality was in each case lower than during the preceding year. Dr. Stevenson explains that towards the close of the year under notice the rapid spread of small-pox in the metropolis, and its more limited extension in St. Pancras, induced him to advise the re-opening of the St. Pancras temporary hospital. The Sanitary Committee and Vestry at once adopted the suggestion, and entered into arrangements with the authorities of the Small-pox Hospital at Highgate for the reception of patients on payment of a fee by the Vestry for each case. In the temporary hospital on only one day during the present epidemic of small-pox was there insufficient accommodation for those applying for it. Further, to complete the sanitary organisation of the parish, the Vestry have entered into arrangements with the authorities of the London Fever Hospital for the reception of patients who are not admissible into the hospitals of the Metropolitan Asylums Board, and who are without proper lodging and accommodation.

EXPERIMENTS ON HAY FEVER.

At the suggestion of Professor Binz, Dr. G. F. Patton (*Virchow's Archiv.*, lxix., S. 410) applied the pollen of *Festuca pratensis*, *Dachtylis glomerata*, and *Secale cereale*—grasses which flower in early summer—to the mucous membrane of the nose, to the conjunctiva, and to portions of scarified skin, without exciting anything more than temporary irritation. Hence, as far as these plants are concerned, the notion that their pollen is an exciting cause of hay fever may be probably abandoned. Patton recommends a solution of one part salicylic acid and three parts common salt in 500 parts water as a local application in hay fever, in preference to quinine, which Helmholtz suggested, but which is very irritating to the mucous membrane.

HEALTH OF H.R.H. PRINCE ALBERT VICTOR.

We regret having to report that H.R.H. Prince Albert Victor has suffered a relapse. During the fifth week of the illness, from the 4th to the 11th inst., there was an intermission of the febrile state, and H.R.H.'s condition seemed to promise an uninterrupted convalescence. On Saturday last, the first day of the sixth week, the fever sharply returned, though with moderate intensity. We are glad, however, to be able to add that there have been no local complications, and that the case on the whole is progressing satisfactorily.

THE ACTION OF FUCHSIN.

According to some new experiments made by MM. Feltz and Duclos (*Gazette Hebd.*, No. 7, 1877), while the fuchsin of commerce which contains arsenic excites diarrhœa in adults if from eight to ten grammes are taken in about the same number of days, pure fuchsin has no such action. Commercial fuchsin in the dose mentioned does not cause albuminuria or general systemic disturbance. The urine has a rose tint, and is very rich in phosphates. According to Feltz and Duclos, wine adulterated with fuchsin must not contain more than *five milligrammes* per litre if the fraud is to pass undetected, for large quantities tinge the froth of the urine red, cause a large deposit in it, and eventually impart a rose colour to the whole urine. In such small quantities as 0·005, however, fuchsin is unlikely to do any harm. Fuchsin is only excreted by the kidneys when in solution, and not if given in the solid form.

ASTLEY COOPER PRIZE.

We learn that the prize for 1877 has been awarded to the essay bearing the motto "*Facta non verba*," the sealed envelope accompanying which contained the names of Drs. Eulenburg and Guttmann. The subject selected for the next prize is "The Cranial Nerves, with reference to their Anatomy and its Relations to Surgical Diseases and Injuries." The essay to be accompanied by preparations and drawings clearly displaying the course and distribution of the nerves, and especially their mutual connexions. Essays in competition, either written in the English language, or if in a foreign language accompanied by an English translation, must be sent to Guy's Hospital on or before January 1, 1880, addressed to the Physicians and Surgeons of Guy's Hospital.

MEDICAL PARLIAMENTARY AFFAIRS.

Superannuation Allowances.—The Medical Officer of the Handsworth District having resigned his appointment, made application to the guardians for a superannuation allowance in due course, which was refused. Mr. Sclater-Booth said it was in the discretion of the guardians to grant or withhold such an allowance, and the Local Government Board could not interfere. Judging from the information supplied them, he thought this a hard case.

Cattle Plague.—The report of the Select Committee on Cattle Plague and the Importation of Live Stock having been submitted to the House, Mr. Dodson inquired whether during the recess the recommendations of the Committee would be adopted. The Chancellor of the Exchequer replied that the measures hitherto adopted had been successful in checking and stamping out the disease. No alterations were contemplated in the carrying out of existing regulations. The report would be carefully considered during the recess, and, should the outbreak become more threatening, further steps would have to be taken.

Public Health.—Notwithstanding the confident assurances that the Government intended to push forward and pass the Public Health Bill for Ireland, it, along with that for London, has been withdrawn for the present session, three of the most notorious "obstructives" in the House of Commons having opposed the passing of this Bill. Sir Michael Hicks Beach said that he very reluctantly postponed the further consideration of this measure until next session. It was hopeless to proceed to consider an opposed Bill in committee, consisting of 300 clauses, at the close of a session. The order was therefore discharged.

Sale of Food and Drugs.—Mr. Meldon having proposed to insert a provision in the Sale of Food and Drugs Act Amendment Bill, to the effect that where spirits (not being gin) had been reduced below an alcoholic strength of 25 per cent. under proof, this Act should not apply, Mr. Sclater-Booth accepted the clause in question, but he could not approve of the limitation of 25 per cent. He thought it better to decide this point after further inquiry by a Select Committee. Mr. Herschell remarked that the law certainly required amendment. The House, however, was counted out, and the debate adjourned.

The *Destructive Insects* Bill, specially framed for controlling or preventing the ravages of the Colorado beetle in this country, and the *Canal Boats* Bill, made rapid progress through both Houses of Parliament during the latter days of the just expired session of Parliament.

Agricultural Dwellings in Ireland.—Complaint was made by Mr. Callan that no attempt had been made by Government to improve the dwellings of the labouring class in Ireland by

loans for purposes authorised by the Legislature. He said that no class of men were more badly treated; they were badly fed, badly clothed, and badly housed. Sir M. H. Beach said he did not see what advantage would be gained by a new Royal Commission to inquire into this subject. The attempt to consolidate the Public Health Acts having failed, the powers of local authorities to improve the dwellings of the labouring classes would still be very restricted. There was an increasing demand for loans from the Government on very favourable terms.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION.

MANCHESTER.

In my last account of this meeting I left off with Wednesday evening and the *soirée* given by the Mayor and Corporation of Manchester. I should like to say a word or two on this subject beyond what I have already addressed to you. And first, as regards the Town Hall. The building is of great size, and probably well suited to its purposes, but the structure is not one all of us can admire. It is intensely heavy and sleepily ornate. The idea it forces on you is not that of massiveness, but of weight. The ornamentation is not beauty unadorned, nor the gorgeousness exhausting itself in minute detail, but the cheap finery which pleases the bucolic eye. I will try to give an example of what I mean. Take any of the plainer cathedrals you please—best of all, if you know them, the two Scotch cathedrals of Glasgow and Aberdeen, where simplicity and severity are carried out almost to meagreness, but where massiveness is also impressed on the mind; take again, as the thought arises in our mind, the Houses of Parliament, where ornament is carried to such an extent as to conceal massiveness,—in the Manchester Town Hall we have neither the one nor the other. Take, as a sample, its great archway under the tower opposite the Albert Monument. The arch is pointed, but the point is so rounded that the arch almost seems a Norman one; but the impression forced on the spectator is that the arch might have been at some period sharply pointed, but that the intense weight of the tower above had forced it nearly flat. Nearly all the windows are lancet-shaped; but, medically speaking, the lancets are blunt. In the interior the main feature is corridors—corridors leading everywhere. Doubtless these corridors are useful, and they are not without a sombre magnificence; but my remarks have been mainly addressed to the elevation of the building. One would willingly leave off here, but it would be unfair to do so; for the meagreness of the reception given to the visitors was in such strong contrast with that offered by bodies at whom the Manchester Corporation would turn up their noses, as to attract universal comment. They might have borne in mind the old adage, that "What is worth doing, is worth doing well." Those, however, who carried off their notions of Lancashire hospitality from this *soirée* would have been grievously misled.

On Thursday, the first great feature of the day's proceedings was the Address in Surgery, by Mr. Spencer Wells, that has already been published, and is elsewhere commented on, so here I need say nothing further on the subject. Dr. Sayre, too, gave a demonstration in Owens College of his method of treating curvature of the spine. The Sections resumed at two o'clock, when, in the Physiological Section, a long address on physiological advances was given; and this meeting was graced by the presence of the man who, more than any other, has, by his personal example and influence, contributed to the advance of practical physiology and to the application of exact methods in physiological research. Unfortunately for us, he does not speak English, so that no public address could well be made by him. It could not but be matter for regret that one so distinguished as Ludwig, who had never been in England before, should come to this country at a time when the dull season had already commenced, and when many who would have been glad to try to pay their meed of gratitude to him were necessarily prevented from doing so.

Probably the most interesting discussion which turned up on Thursday was that in the Medical Section under the presidency of Sir William Jenner. The subject selected was Tapping in Pleuritic Effusions, and to this the President adhered firmly and closely. Two papers were read first of all—one by Dr. Wilson Fox, who had come expressly from London for that day on purpose to read it; and another by Dr. Clifford Allbutt, of Leeds. Need I say that both were excellent in their way; and the subject was further illustrated, from a special point of view, by a capital paper on Pleuritic Effusion in Childhood, by Dr. Barlow and Mr. Parker, of London. I will not say more of the papers and discussions now, for the whole subject will well bear a separate and special consideration, but I shall pass on to the next great feature in the programme—the annual dinner. This annual dinner is no doubt an institution, but there is sometimes the risk of its becoming an annual nuisance; and, as it seems to me, the reason is not hard to seek. There are too many toasts, and the corollary to this is that the party sits too long. If with this sitting there is, let us say, nothing more than a very moderate consumption of wine, it is certain that many members accustomed to early hours would have been far better in bed for some hours before the dinner party separated. There was no more popular speech on the occasion than that of Sir Henry de Bathe, the General commanding in the Manchester district, who pronounced strongly and decidedly against the present army system as regards medical men. "This system," he said, "as all of us know well, gives satisfaction to nobody—neither to the soldier, nor to the new-fangled army doctor." It is a good thing that the combatant element begins to recognise this.

On Friday, which was the last real working-day, the Association entered on its work early. At ten o'clock Dr. Barnes gave his Address, elsewhere published. The sectional meetings, which began about eleven o'clock, were not so numerously attended as on previous days, and at half-past one the last general meeting was held in the Chemistry Lecture Theatre. At this meeting it has been customary to announce the next place of meeting, and to elect the President for the ensuing year. On the present occasion this was not done, inasmuch as no place of meeting had been fixed on, and, in point of fact, no really acceptable invitation had been received. We can hardly wonder at this, in view of the labour and expense of getting up the programme of a meeting such as that just concluded at Manchester. It costs weeks of labour, and the labour falls more especially on a few—the energetic few. The labour undergone by Dr. Leech, Dr. Hardie, and Mr. Cullingworth, as local secretaries, has been enormous, and can only be rivalled by that of Dr. Thorburn, Dr. Ross, and Mr. Jones, Secretaries to the Museum Committee. The local fund, too, had not only to pay all kinds of expenses, but was specially devoted to the payment of the cost of all wines at the annual dinner, and of the garden party held on Friday afternoon. Upwards of 1200 visitors were assembled from all parts of the world; and to accommodate and provide for these, though many were going backwards and forwards day by day, even Manchester hotels were pretty well filled. What could be done by a small place in the face of such numbers? It is very unlikely that anything like the same numbers would assemble in a small place; nevertheless, it is true that the Association has been growing at an enormous rate, and there are not awanting symptoms of its developing Frankenstein qualities. However, we have no wish to act the pleasant part of the prophet of evil. The Manchester meeting has been thoroughly successful.

To the invariable relief of all, Saturday comes. During all the week there has been a continually growing tension, which is abruptly brought to an end by the last general meeting on Friday. The meeting is then practically over, and, upon the whole, the dinner parties on Friday are most enjoyable, provided there has not already been a surfeit of good things. There is on Friday evening no longer a question of how the meeting is likely to go. There are no evening meetings to attend; hence the dinner-hour is later, the meal itself is less hurried, and in all these and some other respects more comfortable. But on Saturday morning, dispersion, already begun, proceeds at a rapid rate. Excursions go north, south, east, and west, and few excursionists return to their headquarters in the city of the meeting. The chief excursions from Manchester were to Macclesfield, in Cheshire; to Castleton, in Derbyshire; to Lancaster, to Northwich salt mines, to Southport, and to Blackpool. By far the largest numbers proceeded to Southport and Blackpool. In both instances special trains were provided free of charge. I do not know how fellow-visitors fared at Blackpool, but it would be hard indeed to rival the reception given to those who elected

to go to Southport. On arrival there, the visitors, who numbered about 100, were received by the local profession, carriages were provided, and a pleasant drive through the town led in no long time to the esplanade in front of the sea, where the fresh breeze was not ungrateful to men somewhat tired and jaded. It is difficult to say how much one must be struck with the energy displayed in making Southport what it is. It is built on a sandy soil, where it has been facetiously said that every blade of grass cost a shilling. It is not specially benefited by nature, yet it is one of the most flourishing and most enticing seaside resorts on the north-west coast. It has one of the longest piers in England; its public baths of filtered sea-water are by far the most magnificent we have seen; it has got fine winter gardens with a large concert-hall, where a play was provided for the evening amusement of the visitors, and the largest real-ice skating-rink yet introduced. It is, moreover, exceptionally healthy, as the Medical Officer of Health cruelly and relentlessly made us know; but its healthfulness was, in still worse taste, contrasted by certain well-known dealers in climatism with that of Mentone and Torquay. Though personally I deeply felt the importance of bringing out London, Norway, Iceland, and the Hebrides, together with many other places too numerous to mention, scathless from the heat of such a fierce fire, I had not the heart to do it. On such occasions the eating and the drinking are not to be forgotten; and I do not think anyone who partook of the hospitality of our medical brethren at Southport will easily forget the way in which we were entertained by these gentlemen. Details of eating and drinking require one born to the art to make them palatable to the public. I shall not attempt the unattainable. But, to contrast small things with great, I would again refer to and contrast the hospitality offered to us by the Mayor and Corporation of a great city like Manchester, with that of a few private gentlemen in a comparatively small place like Southport. Strange that the small things should be the great Corporation; the great, the little body at Southport.

In connexion with this excursion, it would be unpardonable not to record in a more distinct manner than was at the time possible how much we all appreciated the kindness of our entertainers. To none were our thanks more especially due, as I believe, than to the father and son, Dr. Woods, sen., and Dr. Woods, jun., who acted as our chairman and local secretary.

FROM ABROAD.

Prof. Nussbaum on Lister's Method in Military Surgery. The *Feldarzt*, Nos. 11 and 12 (supplement to the *Wiener Allg. Med. Zeit.*), contains an abstract of a clinical lecture recently delivered at Munich by the distinguished military surgeon Prof. Nussbaum.

The greatest step in advance which military surgery had made for centuries was, he observes, the introduction of "centrifugal evacuation" in 1859, the efficacy of which was strikingly proved in 1866 and 1870. The disburdening the centres made room for the newly arrived wounded, while the patients, who formerly were kept penned up together for months in narrow spaces, generating a fearful poison that carried off hundreds of them by pyæmia and hospital gangrene, or early fell victims to the pain, want, and misery amidst which they were, are not allowed by the evacuation system to remain long enough for the production of these poisonous effects. Often, even during their very transport, they become infinitely revived and improved, and continue improving as they approach the better condition of things attainable at the periphery. During the war of 1870 many of the very sick were eating their last morsels of pea-sausage cooked in impure water (no fit food for such cases, but still better than none), and while these sufferers were lying in the hard and dirty camps, those at the periphery were in the enjoyment of clean and comfortable beds, and good and even luxurious food. While at the centre even necessaries were wanting, at the periphery brotherly love provided every means of restoration. Through this masterly disposition, that fearful disease hospital gangrene, which in the Napoleon wars carried off in the hospitals more than the enemies' bullets did on the battle-fields, became so great a rarity, that during the war of 1870-71 Prof. Nussbaum never met with a single bad case of it among more than 10,000 wounded.

Another very great discovery has been made recently, which has effected an entire change in our ideas concerning the treatment of wounds. It is that the unfavourable course of a wound does not depend on the nature of the injury or the peculiarities of the individual, but is caused by external circumstances arising from causes that are now pretty well known, and therefore able to be combated. Antiseptics have, in fact, worked wonders. The question has often been put to the Professor by his pupils, How can this masterly method be best employed in military surgery?—for all at once see that so complex and troublesome a mode of dressing is impossible on the field of battle. In answer to this, it may be first stated that there is no longer any doubt that the Lister method of treating wounds is the best; for even those who used to treat it in a rather "step-motherly" fashion were unable at the last Berlin Congress of Surgeons any longer to deny its efficacy. Now that the most important operations have been performed without danger, the open treatment can no longer rival it. Who ever before treated seventy or eighty compound fractures without a death? and who could have imagined dozens of persons living after amputation of the thigh? Lister's method alone can show successes like these. In Italy and the Crimea from 94 to 98 per cent. of amputations of the thigh proved fatal; under Lister's method well-nigh all recover. "You have only to look at our own clinic! Prior to the introduction of this method we had erysipelas in nearly every bed, while dozens died yearly of pyæmia. Of wounds and ulcers, 80 per cent. were affected with hospital gangrene, and the actual cautery had to be employed daily in this frightful disease, or we were in expectation of death from hæmorrhage owing to destruction of vessels. Go through my clinic now! All this has vanished as if by magic. You will not find a single case of erysipelas, not one of pyæmia, not one of hospital gangrene. No longer do you see wounds and ulcers treated by the actual cautery. In the same number of cases we have, since the introduction of this glorious method, not more than one-half the number of deaths, these taking place almost exclusively in aged persons in the subjects of pulmonary disease, and in the badly wounded."

It is not surprising, therefore, that this method should excite enthusiasm, and that the question should be asked how it can be utilised in war-time. Without doubt, all those in military hospitals who do not wish to heavily burthen their conscience can, and must, "listern"; and, indeed, Lister's gauze-dressing is to be preferred to all its modifications, none other being so porous and so quickly absorbing and disinfecting the secretions of the wound. Thiersch's salicylated wadding is without doubt a good antiseptic dressing, but not so good as Lister's. This and other simplifications, especially Bardelebeu's carbolised jute, if Lister's principles be strictly observed, will furnish favourable results; and, on account of their simplicity, one or other of these modifications may be resorted to in time of war.

The Lister method will only furnish its brilliant results when it is carried out in the most accurate manner, and on the battle-field, when we may have to work on barn-floors, court-yards, grass-plots, and in pits, this complicated procedure is impracticable. And yet it is immediately after the reception of the wound that it is of the highest importance, this being the time which is most favourable to the penetration of the generators of putrefaction diffused in the air. At a later period the depths of the wound are protected by a dried covering, while this concentrated condition of the secretions of the wound produced by the evaporation of their water is (as shown by the researches of Nägeli) inimical to the development of these agents of putrefaction. So that it is shortly after the infliction of the wounds that the agency of antiseptics is all-important. Hence arises the weighty question, How is a wound to be treated on the field of battle in order to guard it against these pernicious putrefactive influences? This question Prof. Esmarch has sought to answer by requiring that the wounds shall not be touched by the hands, but closed rapidly by antiseptic plugs, in order to preserve them from the contact of putrefactive agents until they can undergo the Lister treatment in the hospitals. For this purpose he proposes that every soldier should carry in the lining of his uniform two balls of salicylated jute wrapped up in gauze; and when we consider how long the wounded may have to remain before aid can reach them, we thankfully receive this plan, which would enable one comrade promptly to aid another. Still, a soldier's uniform undergoes too many vicissitudes to allow of our supposing

that these balls would retain their antiseptic powers uninjured. Of all antiseptics, salicylic acid seems best suited for the purpose, not being fluid, retaining its power longest, easy to procure and to stow away; so that, while packing these balls away in the soldier's uniform is a doubtful procedure, yet the bearers and the surgeons should be supplied with an ample stock. Perhaps room might be found for stowing away in the soldier's knapsack these salicylated plugs. Between the reception of the wound and the arrival of surgical aid is a fearful interval, and many of the wounded have to lie for eight or ten hours, far into the night, before they are found, and that often by mere accident. As soon as this happens the tragedy is at an end, for from this moment the most loving care is lavished upon them. But the previous terrible time is the black spot in our present war-procedures. The new weapons and the mode of their employment produce in so short a time such a mass of wounded that even the greatest exertions do not enable the sanitary service to rapidly clear the field of battle.

Several surgeons have objected to these balls that they will not enter into all the angles of the wound, and recommend before using them the sprinkling of some kind of antiseptic powder into all its corners. Prof. Nussbaum has tried the effect of thus powdering the wound by means of a small pounce-box with finely powdered salicylic acid prior to applying Esmarch's balls, but he has been obliged to give the plan up, as the powder when thus directly applied proves too irritating to the wound; while the balls really answer every purpose, for let the wound be as narrow or angular as it will, and even when the smaller plug does not penetrate into all its recesses, yet as soon as the salicylic acid becomes dissolved by the blood and secretions of the wound it spreads over all parts of it. This plan of Esmarch's seems simple enough, but it has been well thought out by a man of great experience, and has a great future before it. If the balls are not filled too full, and are made with salicylated gauze and wadding or jute, they will be found of great practical use. By reason of the lasting action of the salicylic acid, a wound may in this way be protected from septic influences for several days; and every hospital surgeon will be delighted to receive the wounded in such a condition. Often a sort of healing process will have been already set up, so that the adherent plug will sometimes have to be left in, complete healing of superficial wounds taking place in this way when there is no foreign body present. In other cases, when the periphery of the wound has been carefully cleansed, the plug is removed under the action of the spray; and after foreign bodies have been sought for and a drainage-tube introduced, the wound is treated by Lister's dressing. The course and final results of cases so treated will far surpass anything that has yet been met with in military surgery. The statistics will excite astonishment, and every wounded person will consider himself fortunate in having undergone such treatment. Several trials have been made of packing away these balls. Each soldier would require only two, and both together would not exceed a child's fist in size—one being as small as a plum, and the other not larger than an apricot. When packed they only weigh eight grammes, which is no great addition to the weight of the knapsack. They should be soft and not filled too full, so that they can be pressed into the angles of the wound. They should be composed of 11 per cent. salicylated wadding or jute, and bound up in salicylated gauze. Before packing they should be protected by parchment-paper—tin-foil or guttapercha paper not answering so well, while leaden capsules are too troublesome and heavy. With a little instruction, one comrade may easily be taught to render to another infinitely important service; and thousands who would otherwise have died of pyæmia may in this way be saved.

The "William and Samuel Tuke Prize" of 100 guineas, offered in 1874, by some of their descendants, for the best essay on a specified subject relating to Insanity, has just been awarded by the Medico-Psychological Society to Dr. Edward C. Spitzka, of New York.

The following City Companies have contributed to the Repairs and Improvement Fund of the Westminster Hospital, as follows: Grocers, £100; Goldsmiths, £100; Mercers, £105; Fishmongers, £52 10s.; Merchant Taylors, £26 5s.; Cutlers, £26 5s.; Skinners, £21; and the Clothworkers, £21 annually to the general fund. In addition to these sums, her Majesty the Queen has also been graciously pleased to forward £50 for the same object.

GENERAL CORRESPONDENCE.

THE HOMŒOPATHIC SCHISM.

Letter from Dr. G. Wyld.

[To the Editor of the Medical Times and Gazette.]

Sir,—As a sequel to my letter on this subject, which appeared in the *Times* and medical papers of June 1 and 2, I trust you will insert in your journal the following form of resolution. I am the more anxious about this because my first letter emanated almost from myself; but this resolution has been signed by every member of our body to whom I have applied *personally*, and the names are those of our leaders.

I have shown the resolution to four members of your body, and they have all said—"If this resolution fairly represents the views of your school, we can see no *logical* objection to its leading to the freest professional intercourse."

Such being the case, I trust you will influence the body of the profession in this direction, because the resolution, although an abstract one, yet comprehends the entire quarrel, and must, if acted upon, end the schismatic element in question.

I am, &c., George Wyld.

12, Great Cumberland-place, August 13.

Form of Resolution meant to be Signed by Both Sides.

We, the undersigned, believing medicine to be a progressive art and science, hold that it is competent for any qualified medical man to adopt any theory or practice which he believes to be best for his patients. Therefore, the adoption of any theory or practice should not exclude any qualified medical man from the freest professional intercourse, provided he does not trade on a distinctive name nor unprofessionally advertise his mode of practice. (Signed)

Frederick F. Quin.	F. Black, M.D. Edin.
Edward Hamilton, M.D.	J. Hamilton Mackechnie, M.D.
Hugh Cameron.	D. C. Lawrie, M.D. Edin.
R. E. Dudgeon, M.D. Edin.	D. Matheson, L.R.C.P. Edin.
George Wyld, M.D. Edin.	T. L. Marsden, M.D.
William Bayes, M.D.	Thos. Engall, M.R.C.S. Eng.
R. Hughes, L.R.C.P. Edin.	Alfred Pope, M.D.

THE DANGERS OF THORACENTESIS.

Letter from Dr. I. Burney Yeo.

[To the Editor of the Medical Times and Gazette.]

Sir,—The discussion on the treatment of pleuritic effusions, at Manchester last week, was conducted under such high pressure, and we were all so repeatedly warned of the virtue of brevity, that I fear, from the observations of subsequent speakers, the few remarks I made on this subject were more brief than clear, and were somewhat misunderstood; and as there was no opportunity at the meeting of correcting this misapprehension, I should be greatly obliged if you would allow me to do so now.

What I chiefly wished to say was this:—First, that when a lung, already the seat of tuberculous disease, is compressed by a serous pleuritic effusion, the phthisis will often remain quiescent so long as that pressure is maintained; and that the removal of the fluid by thoracentesis is sometimes followed by rapid progress of the phthisis. Of this fact I am perfectly sure, and I quoted a striking instance. Secondly, that the conversion of a serous into a purulent effusion, after paracentesis, is favoured by the presence of certain constitutional cachexiæ—as, *e.g.*, the scrofulous cachexia. Of this also I cannot doubt. My statements were in no respect inconsistent with the fact advanced subsequently by the President, that a lung compressed by pleuritic effusion often becomes the seat of tubercle.

Of the influence of the tuberculous cachexia in determining the rate of mortality after paracentesis, the statistics collected by Dr. Wilson Fox, and circulated at the meeting, offer many illustrations. Of the nine fatal cases reported by Messrs. Hughes and Cock, it existed in six; of Trousseau's seven fatal cases, five were complicated with "tubercle or cancer"; of Kussmaul's eight fatal cases, three were tuberculous; of six cases operated on in private and recorded by Dr. West, the only fatal case was a tuberculous one; of Tutschek's

six fatal cases, four were tuberculous; Oeri's two fatal cases, we are told, were both "phthisical," and in both the serous effusion underwent purulent transformation. But I need not continue to multiply evidence, which exists in abundance, in favour of the view I advocated.

I am, &c., I. Burney Yeo.

Hertford-street, Mayfair, August, 1877.

MEDICAL NEWS.

University of London.—The following are lists of candidates who have passed the recent examinations:—

First M.B. Examination (entire).

First Division.—William Banks, University College; Hutton Castle, St. Thomas's Hospital; Norman Dalton, King's College; William H. Russell Forsbrook, Westminster Hospital; Arthur Franklin, St. Bartholomew's Hospital; Richard Gill, St. Bartholomew's Hospital; Francis Gotch, B.A., B.Sc., University College; Robert Hagyard, Leeds School of Medicine; John Edward Hine, University College; Alfred Ernest Maylard, Guy's Hospital; Angel Money, University College; William Henry Neale, University College; James Isaac Paddle, B.A., B.Sc., University College; Edward Penny, Guy's Hospital; Bilton Pollard, University College; Tiaeliesin Wilim Owen Pughe, Liverpool Royal Infirmary and Guy's Hospital; Frank Rushworth, St. Bartholomew's Hospital; Harrington Sainsbury, University College; Robt. Percy Smith, St. Thomas's Hospital; Leonard Charles Wooldridge, Guy's Hospital.

Second Division.—James Balls, King's College; Gilbert Harry Barling, St. Bartholomew's Hospital; Arthur Edward Buckell, University College; Wayland Charles Chaffey, St. Bartholomew's Hospital; Daniel Colquhoun, Charing-cross Hospital; David Samuel Davies, St. Thomas's Hospital; William Whitfield Edwardes, St. Mary's Hospital; Thomas Warberton Fuller, Guy's Hospital; Robert Nightingale Hartley, Leeds School of Medicine; Alfred Harvey, Queen's College, Birmingham; Thomas Hahnemann Hayle, Owens College; John Davey Hayward, Liverpool Royal Infirmary; John Hodgson, Owens College; Arthur Jackson, St. Bartholomew's Hospital; Charles Henry Keep, Guy's Hospital; Greville Matheson MacDonald, King's College; Henry Jas. Michael, St. Thomas's Hospital; William Outhwaite, St. Bartholomew's Hospital; Leicester Cuthbertson Ponsford, University College; Arthur Cresswell Rich, Liverpool Royal Infirmary; Mark Feetham Sayer, University College; Robert Spence Walton, University College; William Hayle White, Guy's Hospital.

excluding physiology.

First Division.—Thomas Crisp, St. Thomas's Hospital; Cornelius William Suckling, Queen's College, Birmingham.

Second Division.—Henry Burry Pullen Burry, London Hospital and University College; George Ernest Fooks, St. Bartholomew's Hospital; George Arieh Herschell, St. Thomas's Hospital.

physiology only.

First Division.—Charles Edward Beevor, University College; Howard Griffiths Lowe, Queen's College, Birmingham; John William Meek, Guy's Hospital.

Second Division.—Frederick Rowland Barker, St. Thomas Hospital; George Shaw, Westminster Hospital; John Hinks Vinrace, Queen's College, Birmingham; Dawson Williams, University College.

University of Edinburgh.—The following is a list of candidates who received the degrees of Doctor of Medicine, Bachelor of Medicine, and Master in Surgery, respectively, on Wednesday, August 1:—

Doctor of Medicine.—Under the New Statutes: Balfour, Andrew, Hong-Kong, M.B. and C.M., 1873; Barbour, James, Scotland, M.B. and C.M., 1872; Bramwell, Byrom, England, M.B. (with Second-class Honours), 1869; Bramwell, John William, England, M.B., 1873; Cameron, John, Scotland, M.B. and C.M., 1872; Casley, Reginald Kennedy, England, M.B. and C.M., 1874; Clarke, John Henry, England, M.B. and C.M., 1875; Crabb, James (M.A. Aber.), Scotland, M.B. and C.M., 1875; Currie, Andrew Stark, Scotland, M.B. (with Second-class Honours), 1874; Eames, James Crompton, England, M.B., 1875; Fairbanks, William, England, M.B. and C.M., 1874; Garton, William, England, M.B. and C.M., 1875; Gibbons, Robert Alexander, Canada, M.B. and C.M., 1874; Henry, Alexander, Scotland, M.B., 1874; Holmes, James, Berwick, M.B. and C.M., 1875; Jamieson, William Allan, Scotland, M.B. and C.M., 1865; Johnston, John, Scotland, M.B. and C.M., 1874; Johnstone, Thomas, Scotland, M.B. and C.M., 1874; Jones, Abraham Emrys, Wales, M.B. and C.M., 1875; Lambert, Richard Anderson, France (B.A. Trinity College, Dublin), M.B., 1874; Little, James, England, M.B., 1874; Maccall, Thomas, Scotland, M.B. and C.M., 1873; Mackenzie, George Hunter, Scotland, M.B. and C.M., 1873; Nankivell, Frank, England, M.B. and C.M., 1875; Parker, Charles Arundel, England, M.B. and C.M., 1873; Pearce, Joseph Chaning, England, M.B. and C.M., 1871; Porteous, Robert Burnet, England, M.B. and C.M., 1868; Roberts, Henry Prescott, England, M.B., 1868; Saundby, Robert, England, M.B. and C.M., 1874; Scott, John Halliday, Scotland, M.B. and C.M., 1874; Scott, Robert, Scotland, M.B. and C.M., 1874; Steuart, Roger St. Clair, Scotland, M.B. and C.M., 1873; Steell, Graham, Scotland, M.B. and C.M., 1872. Under the Old Statutes: Stodart, Alexander Tweedie, Scotland.

Bachelor of Medicine and Master in Surgery.—Adam, John (M.A. Edin.), Scotland; Anderson, Robert Smail, Scotland; Archbold, James John, England; Baker, Henry Morton, England; Balfour, Isaac Bayley (Sc.D. Edin.), Scotland; Baxter, Robert, Scotland; Baxter, William, Scotland; Beaumont, Charles George, England; Birch, De Burgh, England; Black, Alexander, Scotland; Black, George, Scotland; Blanchard, Robert Johnstone, Nova Scotia; Boucaud, Albert Adolphus, Trinidad; Boucher, Arthur Henry, England; Brander, Edward Salisbury, India; Briggs, Hy., England; Burn-Murdoch, Thomas Monck, Scotland; Caird, Francis Mitchell, Scotland; Calder, Augustus Barclay, Scotland; Cameron, John, Scotland; Carmichael, Duncan, Scotland; Carstairs, William Barstow, India; Christie, William Joseph, America; Daniell, Herbert Edward, England; Davies, Ellis Thomas, Wales; Deverell, Henry George, India; Dick, William, Scotland; Dixon, Thomas, Australia; Douglas, Charles Edward, India; Drinkwater, Harry, England; Druitt, Lionel, England; Fairer, Matthew Robinson, England; Ferguson, Thomas, Scotland; Foster, Nelson Spershott, England; Frew, William Simpson, Scotland; Fyffe, John, Scotland; Gibson, William Robert, Scotland; Gloag, John, Scotland; Hardie, Robert, Scotland; Hart, David Berry, Scotland; Harvey, Alfred Joseph (B.A. M'Gill), Newfoundland; Henderson, George, Scotland; Horden, John Oke, Canada; I'Anson, Welby, England; Illingworth, Charles Rumney, England; Johnson, Peter Pearson, England; Johnston, Robert Colquhoun, Scotland; Kay, Walter Smith, Scotland; Law, Edward, England; Le Fevre, George, England; Leapingwell, Edward Jodrell, England; Lewis, Thomas Preston, England; Lindsay, Andrew Walker Herdman (B.A. Dalhousie), Nova Scotia; Lundy, Arthur Charles James Rudd, Canada; Lyon, James Abercrombie (M.A. Edin.), Scotland; MacCulloch, Stanhope Hastings, Australia; Mackenzie, Colin, Scotland; Mackenzie, Daniel, Scotland; M'Laren, Charles, England; MacLaren, James Farquharson, Scotland; M'Laughlin, Henry James, India; M'Neill, Roger, Scotland; Mann, Hugh William, Scotland; Mason, James Inglis, Scotland; Mowat, John (M.A. Edin.), Scotland; Murdoch, William, Scotland; Murray, Walter, Scotland; Penman, Peter Mitchell, Scotland; Plain, Albert, Wales; Playfair, David Thomson, Scotland; Pope, Thomas Henry, India; Potter, George William, England; Purdie, Robert, England; Reed, William Cash, England; Richardson, William, England; Robbins, James, England; Rowland, John, Wales; Rowland, John William, England; Rundle, Cubitt Sindall, India; Scott, James, Scotland; Shannon, Julius Henry, Barbadoes; Shaw, Oliver Cromwell, England; Smith, Thomas Henry, England; Snadden, James, India; Stewart, Douglas Edward, Tasmania; Stewart, John, Nova Scotia; Symington, Johnson, England; Taylor, Charles Vernon, England; Thom, Alexander (M.A. St. And.), Scotland; Thomson, John (M.A. Edin.), Scotland; Thurnam, Francis Wyatt, England; Turnbull, James, Scotland (received the degrees on November 25, 1876); Van Geyzel, Charles Walter, Ceylon; White, Howel Holland, Wales; Whitsed, John, England; Williamson, Robert Lamley, England; Wilson, Ralph William, England; Wood, Russell Elliott, Scotland.

Bachelor of Medicine.—Allen, Edward, England; Chapman, James Milne, Scotland; Daruty, Jean Aristide Clément, Mauritius; Flint, Horace, England; Forbes, Duncan (M.A. Edin.), Scotland; Massiah, Benjamin Jones, England; Strang, Walter James (M.A. Edin.), Scotland.

Master in Surgery.—Alexander, Henry, M.B., 1874, Scotland.

The Ettles Prize for 1877 has been awarded to William Richardson, M.B. and C.M.

The Syme Surgical Fellowship has been awarded to William Watson Cheyne, M.B. and C.M., 1875.

University of Aberdeen.—During the past year the following candidates, after the usual examinations, received degrees in Medicine and Surgery:—

The Degree of M.D.

Alexander, John, M.B., C.M., Western Infirmary, Glasgow; Allardyce, James, M.B., C.M., Rakwana, Ceylon; Bailey, Samuel Henry, M.B., C.M., Nottingham; Barron, John, M.B., C.M., Berks County Asylum; Brotchie, Theodore Rainy, M.B., C.M., Liverpool; Buckland, Alfred George, M.B., C.M., London Hospital, London; Carline, William Arthur, M.B., C.M., Lincoln; Churton, Thomas, M.B., C.M., Leeds; Cran, George, M.B., C.M., Banchory-Ternan; Cruickshank, Brodie, M.B., C.M., Nairn; Dantra, Sorabshaw Homasji, M.B., C.M., Calcutta; Donald, William, M.B., C.M., Bogside of Eden, Banff; Edmond, George Maitland, M.B., C.M., Stonehaven; Fehrsen, James M'Call, M.B., C.M., Cradock, Cape of Good Hope; Gordon, John, M.B., C.M., New Cross, London; Jack, William, M.B., C.M., Keighley, Yorks; Jackson, Francis Edward, M.B., Manchester; James, Arthur Culver, M.B., C.M., Kensington, London; Knowles, William Bisset, M.B., C.M., Murrurundi, New South Wales; Laws, Robert, M.B., C.M., Lake Nyassa; Mearns, John Herbert, M.B., C.M., Gunnerside, Yorkshire; Milne, Irvine Kempt, M.B., C.M., Shipdham, Norfolk; Shand, Henry Miller, M.B., C.M., Port Elliot, South Australia; Skene, Thomas Alexander, M.B., C.M., Stonehaven; Skinner, Charles Gordon Lennox, M.B., C.M., Pontefract; Thomson, John, M.B., C.M., Keighley, Yorks; Urquhart, Alexander Reid, M.B., C.M., Elgin; Weatherley, Lionel Alexander, M.B., C.M., Portishead; Westland, Albert, M.B., C.M., London; White, William Leavens, M.B., C.M., Southport Convalescent Hospital; Yule, Robert Mortimer, M.B., C.M., Towie.

The Degree of M.B.

Allan, James, M.A., Birnie, Elgin; Anderson, James, M.A., Aberdeen; Bartlett, Henry, London; Bennett, Arthur, Stawell, Victoria; Booth, James McKenzie, M.A., Aberdeen; Brenchley, Algernon Dutton, Brighton; Conry, John, Dublin; Eddie, Robert, M.A., Aberdeen; Evans, Frederick William, Cardiff; Ferguson, Alexander Frederick, Cove, Kincardine; Fergusson, William, Ellon; Goldsbrough, Giles Forward, Mere, Wiltshire; Gordon, James, M.A., Walsall, Staffordshire; Gould, Peter Buck, Aberdeen; Guy, John Rapsey, Bristol; Henderson, Alexander Milne, Keith; Huxley, John Charles, Birmingham; Jay, Henry Mason, Chippenham, Wiltshire; Jones, Llewelyn Robert, Denbigh, North Wales; MacGregor, Alexander Gibson, Canisbay, Caithness; Mackenzie, John Alexander, Gairloch, Ross-shire; Moore, Charles Arthur, Thetford, Norfolk; Napier, Thomas Wm. Adam, Montrose; Neil, James, Glengairn; Noble, James, M.A., Fraserburgh; Orlebar, Hotham George, St. Leonards-on-Sea; Philpots, Harris, Leamington; Porter, James, M.A., Monymusk; Richards, Thomas, Cardiff; Robertson, Frederick Freer Leslie, Cosham, Hants; Robertson, William Smith, Peterhead; Ross, James, M.A., Tullynessle and Forbes; Rudd, Leonard, Twyford, Berkshire; Schokman, George Peter, Ceylon; Shearer, Johnston, M.A., Aberdeen; Stewart, William Lemmon, M.A., Keith; Taylor, Seymour, Derby; Tough, Wm. Robb, M.A., Aberdeen; Trail, George Shewan, M.A., Monymusk; Venning, Edmund, Cornwall; Winchester, Henry, Elgin.

The Degree of C.M.

Allan, James; Anderson, James; Bartlett, Henry; Bennett, Arthur; Booth, James M.; Brenchley, Algernon D.; Conry, John; Eddie, Robert; Evans, Frederick Wm.; Ferguson, Alexander F.; Fergusson, William; Goldsbrough, Giles F.; Gordon, James; Gould, Peter Buck; Guy, John Rapsey; Henderson, Alexander M.; Huxley, John Charles; Jay, Henry Mason; Jones, Llewelyn R.; MacGregor, Alexander G.; Mackenzie, John Alex.; Moore, Charles Arthur; Napier, Thomas Wm. A.; Neil, James; Noble, James; Orlebar, Hotham G.; Philpots, Harris; Porter, James;

Richards, Thomas; Robertson, Frederick F. L.; Robertson, William Smith; Ross, James; Rudd, Leonard; Schokman, George Peter; Shearer, Johnston; Stewart, William L.; Taylor, Seymour; Tough, William R.; Trail, George S.; Venning, Edmund; Winchester, Henry.

Of the above-mentioned candidates, James Anderson, Wm. Fergusson, Peter Buck Gould, and Alexander Milne Henderson received their degrees in Medicine and Surgery with highest academical honours; James Allan, Arthur Bennett, Giles Forward Goldsbrough, Llewelyn Robert Jones, James Neil, Johnston Shearer, and William Robb Tough, their degrees in Medicine and Surgery with honourable distinction; and the following are now declared to have passed part of their examinations:—

Aiken, Andrew; Alexander, Lewis Daniel; Allardes, William; Argo, George Collie; Arthur, John Campbell; Barron, William; Benham, Harry Arthur; Campbell, Colin M'Iver; Compton, Thomas Joseph; Congreve, George Thomas; Dixey, Harry Edward; Dobson, Edwin F. H.; Findlater, Sylvester W.; Gayton, Francis C.; Gibbes, Heneage; Harvey, George Henry; Leslie, George; Liebstein, Herman J.; Logie, James; Low, Charles; Lyon, Adam Corbet; Macgregor, Alexander; MacMunn, John; M'Fayden, Alexander W.; Maver, David; Mumby, Bonner Harris; Murison, Alexander A. W. P.; Neilson, William Henry; Petrie, Alexander; Preston, Henry Tolver; Shepherd, Charles C.; Smith, James Murray; Thompson, Lavington G.; Tonge-Smith; Winckworth; Vaisey, Thomas F.; Van Geyzel, John L.; Walford, Robert; Walker, James Hutchison; Waller, Angustus D.; Watson, John Coatsworth; Welford, Charles Henry; White, William Robert.

ROYAL COLLEGES OF PHYSICIANS AND SURGEONS, EDINBURGH.—DOUBLE QUALIFICATION.—The following gentlemen passed their First Professional Examination during the July and August sittings of the examiners:—

Anderson, Joseph William Townsend, India.
Campbell, William, Caithness.
Chisholm, Duncan William Francis, Nova Scotia.
Conry, John Templer Crosbie, Roscommon.
Coward, Frank Augustus, Cape of Good Hope.
Cuscaden, George, Wexford.
Dartnell, William Abraham, Rochester.
Dunlop, John Jardine, Port William.
Hayes, William Edward, Wexford.
Herbert, Johnson, Whitby.
Mackenzie, Allan Grant, Strathspey.
Mawbry, William George, Northampton.
Miller, Hubert Lindsay, Tasmania.
Mitchell, George Dixon, Coldstream.
Philp, William Cornfoot, Kirkcaldy.
Powell, Henry Richard, South Pacific.
Roberts, Robert, North Wales.
Scanlan, Alfred Ernest, Chester.
Tant, John Yellowlees, Argyleshire.
Weston, Edwin, India.
Wheeler, Albert Victor, Dublin.

The following gentlemen passed their Final Examination, and were admitted L.R.C.P.E. and L.R.C.S.E.:—

Balmanya, Antonio, Cuba.
Baxter, Edward John, Middlesex.
Brannigan, Henry Cooke, County Mayo.
Campbell, Peter, Crieff.
Crane, Alfred Wyatt, France.
Dedrickson, Robert Forrest, Dublin.
Durand, Rudolphé, Mauritius.
Glaister, John, Lanark.
Graham, Andrew, Forfarshire.
Greasley, Joseph, Melton Mowbray.
Hartley, Harrison, New Malton.
Howard, John Albert, Bagborough.
Jenkinson, Alfred Samuel, Yorkshire.
Macgregor, Peter, Perthshire.
Mackenzie, William Gillespie, Belfast.
Macnaught, John, Glasgow.
Maxton, Laurence, Calcutta.
Miller, Alfred Henry, Rochester.
Murray, Hugh, Bonar Bridge.
Naismith, Charles Fergus, Bengal.
Noad, Hartley Innes, Herne-hill.
Reckitt, John Denis Thorpe, Hull.
Stowell, William Hall, City of Wells.
Tait, Richard Knox, Eyemouth.
Vanes, Arthur Bayly, Worcestershire.
Walker, Henry Bournes, Nenagh.

ROYAL COLLEGE OF SURGEONS, EDINBURGH.—The following gentlemen passed their First Professional Examination during the recent sittings of the examiners:—

Dall, John Cameron, Bedlington.
Innes, John Caithness, Marykirk.
Smith, James Alexander John, Stornoway.
Walker, Thomas Charles, Linlithgowshire.

The following gentlemen passed their Final Examination, and were admitted Licentiates of the College:—

Baldwin, Edmund St. George, Toronto.
Croudace, James Henry, County Dnrham.
Duncan, George, Perthshire.
Gordon, Richard, County Sligo.
Hodgson, William Bacon, Middlesex.
Hoernlé, Edward Frederick, India.
Holmes, David, Malta.
Jervis, Henry Prnce, Bombay.
Khambata, Hiraji Jehangir, Bombay.
Koyaji, Beramji Nasarvanji, Bombay.
Lauder, William, Port Glasgow.
M'Nicoll, Edward Day, Liverpool.
Mickle, Arthur William Thomas Flintoff, Yorkshire.
Nariman, Kaikhosro Sorabji, Surat.
Norcop, Percy Grant Hickson, Plymouth.
Parker, James, Indian Ocean.
Reporter, Maneckjee Eduljee, Amrolee, Surat.
Smith, James Alexander John, Stornoway.
Smyth, Albert Charles Butler, Dublin.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, August 9:—

Blott, Herbert, Bassingbourne.
Clements, William George, Fernsbury, Kent.
Dingle, William Alfred, Millbrook, Southampton.
Masser, Herbert Charles Pickard, Foleshill, Coventry.
Todd, William, 301, Mile-end-road.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Bartlett, Charles Richard, St. George's Hospital.
Fuller, Leedham Henry, King's College.
Gardner, John Twiname, Guy's Hospital.
Jones, Frederick Felix, Guy's Hospital.
Morgan, Augustus Kinsey, Guy's Hospital.
Stace, Malcolm Vincent, Westminster Hospital.

NAVAL, MILITARY, &c., APPOINTMENTS.

ADMIRALTY.—The following qualified candidates for the Naval Medical Service have been appointed Surgeons in her Majesty's Fleet, with seniority of March 31, 1877:—William Cotter Williamson, M.D., Charles Edward Geoghegan, Michael Joseph M'Carthy, M.D., John Christian, Howard James M'Chleary Todd, Standish Thomas O'Grady, Percy Kinburn Cree, Wingate Kidd Johnston, John Price, Horace Edward Firmin Cross, Alexander Livingston Christie, M.D., Denis Paul O'Farrell, and Charles Anderson. Fleet Surgeon John Elliott has been appointed Deputy Inspector-General of Hospitals and Fleets.

M'CLOSKY, JAMES HUGH, L.R.C.S. and L.M. Edin., L.S.A. Lond., late Colonial Surgeon, Labuan, Colonial Surgeon Malacca Straits Settlements.

WAR OFFICE—MEDICAL DEPARTMENT.—Surgeon-General John H. Kerr-Innes, C.B., to be Honorary Surgeon to her Majesty *vice* Inspector-General of Hospitals (honorary rank) Charles Scott, M.D., C.B., half-pay, deceased; Surgeon-General Robert Bowen retires upon half-pay; Surgeons-Major Daniel Macqueen, M.D., Robert Thornton, and Arthur Jackson Greer, retire upon half-pay; Surgeons Brodie Cruickshank, M.D., and Pierce George Power, M.D., half-pay, resign their commissions. The undermentioned Surgeons-Major to have the honorary rank of Deputy Surgeon-General on retiring upon half-pay:—Daniel Macqueen, M.D., Robert Thornton, and Arthur Jackson Greer.

MILITIA MEDICAL DEPARTMENT.—Surgeon Richard John Magee (Kilkenny), to be Surgeon-Major, under the provisions of Royal Warrant of July 12, 1876. Surgeon-Major John Walter (Kent Artillery) resigns his commission. Assistant-Surgeon Thomas William Spink Locke (West Suffolk), to be Surgeon, under the provisions of the Royal Warrant of July 12, 1876. The Memorandum which appeared in the *Gazette* of June 29, 1877, changing the surname of Surgeon-Major Enright, Royal Limerick County Militia, to Enwright, is cancelled. The date of the Warrant under which Surgeon Munro, 1st Durham Militia, was promoted to Surgeon-Major is July 12, 1876, and not as stated in the *Gazette* of July 20, 1877.

BIRTHS.

ARBUCKLE.—On August 12, at Thorne, near Doncaster, the wife of Hugh W. Arbuckle, M.D., of a son.

BODINGTON.—On July 29, at Ashwood House, Kingswinford, Staffordshire, the wife of G. F. Bodington, M.D., of a daughter.

BOWES.—On August 4, at Herne Bay, Kent, the wife of J. Bowes, L.R.C.P. Lond., of a son.

BLOXAM.—On August 13, at 8, George-street, Hanover-square, W., the wife of J. Astley Bloxam, F.R.C.S. Eng., of a daughter.

DARKE.—On August 13, at Salisbury, the wife of Fitz Roy P. Darke, M.R.C.S. Eng., of a daughter.

DAVSON.—On August 1, at Campden Villa, 203, Maida-vale, the wife of S. Houston Davson, M.D., of a son.

LEAKE.—On August 11, at Rathkeale House, Giraler's-road, Brook-green, the wife of Jonas R. Leake, L.R.C.P., M.R.C.S., late H.M.'s 80th Regiment, of a daughter.

LLOYD.—On August 9, at Wick, Bath, the wife of John Daniel Lloyd, L.R.C.P. Edin., M.R.C.S. Eng., of a daughter.

MILLER.—On August 11, at Blair-Hyrne, Hampstead-hill-gardens, the wife of Andrew Miller, M.D., of a daughter.

PICKERING.—On August 12, at 6, Rue Aguado, Dieppe, the wife of Thomas Henry Pickering, M.D., L.K.Q.C.P., of a son.

STEWART.—On August 10, at 4 Hut, P Lines, North Camp, Aldershot, the wife of Surgeon-Major W. Stewart, M.D., of a daughter.

THORNTON.—On August 8, at 83, Park-street, Grosvenor-square, W., the wife of J. Knowsley Thornton, M.B. Edin., of a daughter.

MARRIAGES.

BATTEN—MAGRATH.—On August 8, at St. Michael's, East Teignmouth, John Maxwell, second son of J. Hallet Batten, Esq., Bengal Civil Service, retired, to Norice Margaret, second daughter of J. A. Magrath, M.D., Teignmouth.

EWART—BURDER.—On August 15, at St. Mary's Church, Crumpsall, Manchester, John Henry Ewart, L.R.C.P. Lond., of Limefield House, Crumpsall, to Josephine Caroline, youngest daughter of John Burder, Esq., of Wilton Polygon, Crumpsall.

GAYE—WILLIS.—On August 7, at the Church of St. Mary, Trimley, near Ipswich, Robert Edward Gaye, B.A., of Downing College, Cambridge, son of Robert Edward Gaye, M.R.C.S.E., L.S.A., of 57, St. Marylandroad, St. Peter's-park, London, to Maria Elizabeth eldest daughter of the Rev. Henry M. Willis, Rector of St. Mary's, Trimley.

LAMB—PHIPPS.—On August 9, at the Church of St. Colombo, Collingtree, William Henry Lamb, M.B. Lond., of 46, Kensington-park-gardens, W., to Agnes Mary, eldest daughter of Pickering Phipps, Esq., M.P., of Collingtree Grange, Northamptonshire.

SCOTT—PIKE.—On August 2, at All Saints Church, Upper Norwood, William Scott, M.D., of Dumfries, N.B., to Maria, widow of James Lee Pike, Esq., of Dumfries, N.B.

SUTTON—MOXHAY.—On August 9, at the Church of St. John the Evangelist, Reading, Herbert, third son of Alfred Sutton, of Greenlands, Reading, to Emma, eldest daughter of Wm. Watkinson Moxhay, M.R.C.S. Eng., of London-street, Reading.

TOWNSEND—AINSWORTH.—On August 7, at the parish church, Cleator, Thomas Suttou Townsend. M.R.C.S. Eng., of Clifton, Warwickshire, and 68, Queen's-gate, London, to Mary Alice, only daughter of Thomas Ainsworth, of the Flosh, Cleator, Cumberland.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

KENT AND CANTERBURY HOSPITAL.—House-Surgeon. "Bye-Law 58. No person shall be eligible for the office of House-Surgeon unless he bring proof that he is registered under the Medical Acts as legally qualified to practise medicine and surgery. He must be unmarried, and not more than forty years of age, and he shall reside in the house." Testimonials of qualification to be sent in on or before August 24.

ROYAL FREE HOSPITAL, GRAY'S INN-ROAD.—Assistant-Physician and Assistant-Surgeon. The Assistant-Physician must be a Member of the College of Physicians of London, and the Assistant-Surgeon a Fellow of the Royal College of Surgeons of England. Testimonials to James S. Blyth, Secretary, before September 1.

WILTS COUNTY LUNATIC ASYLUM.—Assistant Medical Officer. Candidates must be duly qualified and registered medical practitioners. Applications, stating age, and accompanied by not more than six recent testimonials, to "The Clerk to the Committee of Visitors of the Wilts County Lunatic Asylum, Devizes," marked "application," on or before Aug. 21.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The popnlation is computed according to the census of 1871.

RESIGNATIONS.

Chorlton Union.—Mr. W. H. George has resigned the office of Assistant Medical Officer at the Workhouse; salary £140 per annum.

Lincoln Union.—The First District is vacant; population 26,766; salary £120 per annum.

Nantwich Union.—The Wybunbury District is vacant; area 14,641; population 3516; salary £36 per annum.

Southwell Union.—The Farnsfield District is vacant; area 15,128; population 2453; salary £28 per annum.

Sunderland Union.—The Bishopwearmouth West District is vacant; population about 22,000; salary £50 per annum.

APPOINTMENTS.

Coventry Union.—Charles W. Iliffe, M.R.C.S. Eng., L.R.C.P. Edin., to the Workhouse.

Folkestone.—Mr. Sidney Harvey as Analyst for the Borough.

Manchester Township.—James Magill, L.R.C.S. Edin., M.D. Queen's Univ., Ire., as Resident Assistaut at the Crumpsall Workhonse.

Southmolton Union.—Albert Hind, L.R.C.S. Edin., L.S.A. Lond., to the Ninth District.

TREATMENT OF INTUSSUSCEPTION BY ABDOMINAL SECTION.—Prof. Sands, of New York, on the strength of a case of an infant which he successfully treated, and the results of twenty other recorded cases in which the operation was performed, has arrived at the following conclusions:—1. The success which has already been obtained in the operation of abdominal section for intussusception is sufficient to justify its repetition when other means have proved unavailing. 2. There is reason to believe that in intussusception, as in strangulated hernia, the great danger lies in delay, and that in acute cases the operation, to be successful, must be performed at a very early period, probably within twenty-four hours from the invasion of the disease. 3. In chronic cases the operation is indicated when other means have failed, and there is reason to think that the invagination is still reducible. 4. It has been proved by the case herewith related that the operation may succeed in acute cases, if performed during the first eighteen hours. 5. The greater fatality of the operation in infants has been shown to be rather apparent than real, and it remains to be proved whether, in them, the performance of abdominal section may not yet yield gratifying results. 6. In infancy the operation is the more justifiable, because during that period there is hardly any tendency towards spontaneous recovery after sloughing of the intestine.—*New York Medical Journal*, June.

NOTES, QUERIES, AND REPLIES.

"He that questioneth much shall learn much."—*Bacon.*

Studens.—There is no book like Steggall nowadays. The examinations are quite different, and require other training. Read Druitt's "Manual of Surgery," and Guy's or Tanner's "Medicine."

Cosmo.—Cremation has been legalised in the Canton of Zurich, subject to certain restrictions.

Hereditariness.—It is alleged that the children of skilled artisans are, as a rule, more apt at petty manipulations than the children of ordinary labourers, and that hence the population of certain towns—Birmingham, for example—has a great advantage over that of other towns in point of manufacturing industry.

Explorer.—The Norwegian exploring expedition put to sea from Stavenger for this summer's campaign in the *Vöringen* on June 13. The vessel is now lying at Tromsö, refitting. It is intended first to work two more sections north of Tromsö, and then call there to make ready for the voyage to Jan Mayen. From that island the course will be to westward till ice-cold water is reached, then southwards to a point midway between Jan Mayen and Iceland, whence the expedition will return to Bodö and Bergen.

Paul P.—The eminent chemist James P. W. Johnstone died at Durham in 1853. He was chiefly known as an agricultural chemist. His last work was "Chemistry of Common Life," which originally appeared in *Blackwood's Magazine*, and has since gone through two editions.

O.—The Royal College of Physicians, London, was founded in 1518. The reason for forming the incorporation, as set forth in the original charter, is "to check men who profess physic rather from avarice than in good faith, to the damage of the credulous people"; and the King, following the example of other nations, founds "a college of learned men who practise physic in London and within seven miles, in the hope that the ignorant and rash practisers be restrained or punished." The charter further declares that "no one shall exercise the faculty of physic in the said city or within seven miles without the College licence, under a penalty of £5."

Malt Liquors.—"Porter" came into use in London in 1722. According to Leigh, "the malt liquors previously in use were ale, beer, and twopenny, and it was customary to call for a pint or tankard of half-and-half—*i.e.*, half of ale and half of beer, or half of ale and half of twopenny."

Dido.—Humboldt calculated that the same extent of ground which would produce thirty pounds of wheat would produce one thousand pounds of potatoes. But potatoes are not nearly so nutritious as wheat, and the constant employment of them as the chief article of food is not favourable to the development of the physical powers, and is consequently in its protracted influence unfavourable to mental energy.

Caius.—Yes, an Act of Parliament fixed that the fine dust of which hair-powder was composed should be made from starch *alone*, and we learn from the *Gentleman's Magazine* that on November 20, 1746, fifty-one barbers were convicted before the Commissioners of Excise at London, and fined £20 each, for having in their keeping hair-powder not made of starch, contrary to the Act of Parliament; and on the 27th of the same month forty-nine others were fined for the like offence in the same penalty. The tax put upon the use of hair-powder in 1795 had the effect of causing it to fall into general disuse.

A Free Giver.—Dr. Neil Arnott died in 1874. His widow has made in his name, since his death, the additional contribution of £1000, which he had promised, to each of the four Scottish Universities. He had previously given £1000 to each of them, and £2000 to the University of London. Yes; the doctor declined patenting any of his inventions, of which the hydrostatic bed was one.

DE LISLE ALLEN FUND.

The Hon. Treasurer begs to announce the following additional subscriptions to the above-named Fund received since our last notice:—

	£	s.	d.
Coates, C., Esq., M.D., Bath	2	2	0
Hill, Berkeley, Esq., London...	2	2	0
Page, W. B. Esq., Carlisle	2	2	0
Stephens, H., Esq., Finchley	5	5	0
Whitelaw, W., Esq., M.D., Kirkintilloch	0	10	6

Mrs. Allen begs us also to acknowledge with many thanks the following subscriptions sent to her before the formation of the Fund:—

	£	s.	d.
Clark, Andrew, Esq., M.D., London	2	2	0
Critchett, G., Esq., London	1	1	0
Hawkins, Cæsar, Esq., F.R.S., London	2	2	0
Henslow, Rev. G., London	3	0	0
Ogle, J., Esq., M.D., London	1	0	0
Paget, Sir James, Bart., F.R.S., London	2	2	0
Smith, Thomas, Esq., F.R.C.S., London	5	5	0

Further subscriptions to the Fund sent to the Hon. Treasurer, Benjamin W. Richardson, F.R.S., 12, Hinde-street, London, W., or to the De Lisle Fund, Union Bank of London, Argyll-place, Regent-street, W., will be thankfully received.

The Hôtel-Dieu, Paris.—The new Hôtel-Dieu was officially opened on Saturday by Marshal MacMahon. It appears to have cost forty millions of francs, and as it contains only 400 beds, each bed costs £200 a year.

Humphrey S.—As a tribute to his eminence as an ethnologist, Dr. James Cowles Prichard was elected President of the Ethnological Society, while in recognition of his researches into the nature and various forms of insanity he received the Government appointment of Commissioner in Lunacy. This occasioned his removal from Bristol to London. He was the first to raise ethnology to the rank of a science.

Athlete.—Gymnastic games are so old as to be pre-historic. They are alluded to in the second and twenty-third books of the "Iliad." Before the time of Hippocrates, gymnastic exercises had been adopted in Greece as part of the course of medicine intended to counteract increasing luxury and indolence. The various exercises were soon combined into a system, and gymnasia where they should be carried out were formed first by the Lacedæmonians, and subsequently at Athens.

COMMUNICATIONS have been received from—

Messrs. Burgoyne, Burbidge, and Co., London; Dr. Bucknill, Rugby; Dr. E. Sparks, Dorchester; The Registrar of the Apothecaries' Hall, London; Mr. J. Horne, London; Mrs. De Lisle Allen, London; Dr. A. Carpenter, Croydon; Dr. H. Oliver, Boston; Dr. G. E. Dobson, Netley; Dr. V. M. Church, Edinburgh; Dr. G. Wyld, London; Mr. John Ingpen, London; Messrs. Ferris and Co., Bristol; Dr. J. W. Moore, Dublin; Dr. F. Churchill, London; Dr. Pavy, London; Dr. H. Sutherland, London; Dr. I. Burney Yeo, London; Dr. Herman, London; Dr. Barlow, London.

BOOKS AND PAMPHLETS RECEIVED—

The Advantages of Glengarriff as a Winter Resort and Sanatorium—Richard Barwell, F.R.C.S., On Curvatures of the Spine, their Causes and Treatment—V. P. Gibney, M.D., The Strumous Element in the Etiology of Joint-Disease—Oliver Goldsmith, Asem, the Man-Hater—Edward S. Dunster, M.D., The Use of the Obstetric Forceps in Abbreviating the Second Stage of Labour.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—Medical Examiner—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Iron—Home Chronicler—La Province Médicale—Cincinnati Clinic—Boston Journal of Chemistry—Glasgow Medical Journal—Indian Medical Gazette—Western Review of Science and Industry—Proceedings of the Medical Society of the County of Kings—Gaceta Cientifica de Venezuela—Dublin Journal of Medical Science—Nordiskt Medicinskt Arkiv—Richmond and Louisville Medical Journal—American Supplement to the Obstetrical Journal of Great Britain and Ireland.

APPOINTMENTS FOR THE WEEK.

August 18. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

20. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

21. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

22. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

23. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

24. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

Quekett Microscopical Club, 8 p.m. Meeting.

VITAL STATISTICS OF LONDON.

Week ending Saturday, August 11, 1877.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·64 in. The highest reading was 29·91 in. on Sunday morning, and the lowest 29·31 in. on Tuesday and Wednesday afternoons.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

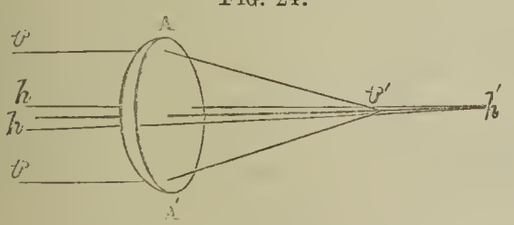
By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

LECTURE V.—ASTIGMATISM.

MR. PRESIDENT,—I have already defined astigmatism to be a state in which the curvature of the cornea is different in two different meridians, which are often vertical and horizontal or nearly so, and always at right angles to one another. It is necessary to amend this definition by saying, further, that astigmatism is probably the normal condition of the human eye, and that it must be present in an unusual degree in order to be disturbing to vision. As contrasted with a portion of a sphere, the most familiar example of an astigmatic surface is furnished by the bowl of a spoon, which is turned upon a shorter radius, in a direction transverse to the line of the handle, than in a direction continuous with it. The former is the meridian of greatest curvature; the latter is the meridian of least curvature. In the human eye, the meridian of greatest curvature is most frequently vertical; the meridian of least curvature is most frequently horizontal. This rule applies not only to the normal or moderate degree of astigmatism, but also to the abnormal degrees; although many instances are upon record in which the ordinary direction of the meridians has been reversed, and the greatest curvature has been in the horizontal direction. As a rule, again, the astigmatic formation is symmetrical or nearly so in the two eyes; but to this rule we find numerous exceptions.

When parallel rays of light are refracted by passing through a medium which presents a convex spherical surface, all the rays of which the light is composed become united in a single focal point, except for some trifling irregularities due to what is called aberration. Disregarding these, and assuming the refracting medium to be of circular outline, the light forms a cone between the medium and the focus, and any section of this cone in a plane perpendicular to its axis is necessarily a circle. Hence, the diffusion patches which are formed on the retina of a hypermetropic or of a myopic patient, from rays of light which have not united or which have united and overcrossed, are ordinarily circular; but those formed in astigmatism are only circular if the retina happens to coincide with one particular point of the refracted bundle. In Fig. 24, AA′ represents a lens which is more

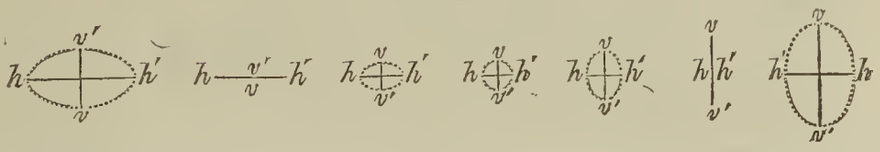
FIG. 24.



strongly curved in the vertical than in the horizontal direction. The result is, that parallel rays *vv*, which fall upon the surface of the lens in a vertical plane, are brought to an earlier focus, at *v′*, than the rays *hh*, which fall upon the lens in a horizontal plane, and are brought to a focus at *h′*. If we suppose AA′ to be the cornea, *v′* will be the focus of the meridian of greatest curvature; *h′* the focus of the meridian of least curvature; and the space between the two, *v′ h′*, is called the focal interval. If we were to intercept the course of the rays by a screen, placed between the cornea AA′, and the focus *v′*, the diffusion patch would not be a circle, but an ellipse with its major axis horizontal. The rays *vv* would have approached each other more nearly than the rays *hh*. At the point *v′*, where the rays *vv* are united, *hh* not being yet united, the diffusion patch would be a horizontal line. A little farther, *vv* having overcrossed, and *hh* approaching each other more nearly, the diffusion patch is a smaller ellipse in the same position as before; and this passes into a circle as soon as the overcrossing of *vv*, and the approach of *hh*, form equal magnitudes. A continuance of the same process of refraction causes the rays to pass into a small upright ellipse beyond the circle, into a vertical line at the point *h′*, and into a larger upright ellipse when both the vertical and the horizontal rays have overcrossed each other. These successive forms of the diffusion patches are represented in the series of diagrams which make up Fig. 25, and which are taken from Professor Donders.

When a cornea is so curved as to bring the rays which fall upon it in one direction to an earlier focus than those which fall upon it in the opposite direction, the resulting astigmatism may assume five different forms, which are governed by the position of the retina with regard to the two foci. In the following figures, *v* is always the focus of the meridian of greatest curvature, and *h* that of the meridian of least curvature. It will be convenient to assume that the former is vertical, and that the latter is horizontal.

FIG. 25.



In the first form, Fig. 26, the focus of the vertical meridian is in front of the retina, and that of the horizontal meridian is upon the retina. In other words, the eye is myopic for parallel rays refracted in a vertical plane, and emmetropic for parallel rays refracted in a horizontal plane. This is called simple myopic astigmatism.

FIG. 26.

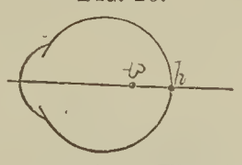


FIG. 27.

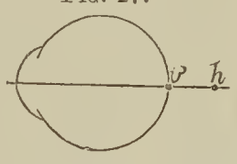

In the second form, Fig. 27, the focus of the vertical meridian is upon the retina, and that of the horizontal meridian is behind it. In other words, the eye is emmetropic for parallel rays refracted in a vertical plane, and hypermetropic for parallel rays refracted in a horizontal plane. This is called simple hypermetropic astigmatism.

In the third form, Fig. 28, the foci of the two meridians are both in front of the retina, but the focus of the vertical meridian is anterior to that of the horizontal. In other words,

FIG. 28.

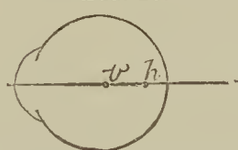

FIG. 29.

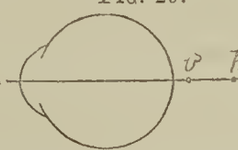

FIG. 30.

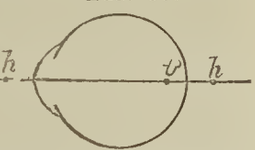

the eye is myopic for parallel rays refracted in both meridians, but in a greater degree for rays refracted in a vertical plane than for those refracted in a horizontal plane. This is called compound myopic astigmatism.

In the fourth form, Fig. 29, the foci of the two meridians are both behind the retina, the focus of the vertical meridian being anterior to that of the horizontal. In other words, the eye is hypermetropic for parallel rays refracted in both meridians, but in a greater degree for rays refracted in a horizontal plane than for rays refracted in a vertical plane. This is called compound hypermetropic astigmatism.

In the fifth form, Fig. 30, the retina is situated in the focal interval, so that the focus of the vertical meridian is in front of the retina, and the focus of the horizontal meridian is behind it. In other words, the eye is myopic for parallel rays which are refracted in a vertical plane, and hypermetropic for parallel rays which are refracted in a horizontal plane. This is called mixed astigmatism.

Besides these, there are no other forms of astigmatism, excepting only that the meridians of least and of greatest curvature may be in any other directions, so long as they are always at right angles to each other.

The degree of astigmatism is the measure of the distance between the foci of the two chief meridians; or, that is, the measure of the difference between the refraction of these meridians, expressed in dioptrics in the usual way. Thus, in a case of simple myopic astigmatism, where the eye is emmetropic for rays refracted in a horizontal plane, with a myopia of two dioptrics for rays refracted in a vertical plane, we say that the astigmatism is equal to two dioptrics. In a case of compound myopic astigmatism, with myopia of two dioptrics for rays in the horizontal plane, and of three dioptrics for rays in the vertical plane, we say that the astigmatism is the difference between the two planes, or one dioptric. The degrees of hypermetropic astigmatism are expressed in a precisely similar way; and those of mixed astigmatism by the sum of the two forms of ametropia. Thus, if the eye shown in Fig. 30 had one dioptric of myopia for rays refracted in a vertical plane, and one dioptric of hypermetropia for rays refracted in a horizontal plane, the resulting astigmatism would be equal to two dioptrics.

The correction of astigmatism, that is to say, the equalisation of the refraction in the two chief meridians, is effected by means of cylindrical lenses. In these, as their name implies, the refracting surface, instead of being a portion of a sphere, as in ordinary lenses, is a portion of a cylinder. In Fig. 31, A A represents a plano-convex cylindrical lens; and the dotted lines show the cylinder of which it forms part. A plano-concave cylindrical lens is of analogous form, only its refracting surface is concave instead of convex.

Fig. 31.

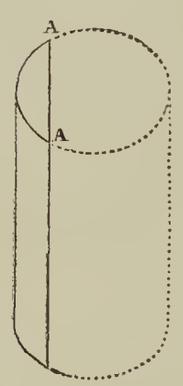

Fig. 32.

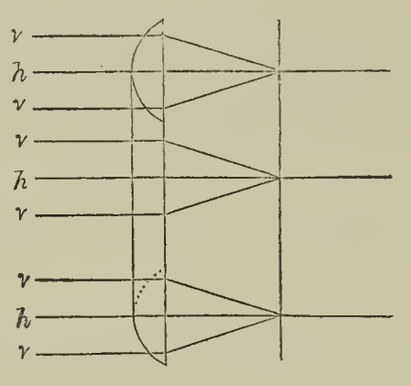


The action of a plano-convex cylindrical lens upon light is shown in Fig. 32. In this figure, the parallel rays of light, *hhh*, which fall upon the convex surface of the lens in a vertical plane, or in a plane coincident with the axis of the cylinder of which it forms part, are not refracted at all. They only encounter and pass through a piece of glass with parallel sides, and this does not change their direction. They enter the lens parallel, and they emerge parallel on the other side. But the rays *vv*, *vv*, *vv*, which fall upon the glass in successive horizontal planes, that is, in planes perpendicular to the axis of the cylinder, encounter a strongly curved refracting surface, and are brought to foci accordingly. We therefore start from the position that a plano-convex cylindrical lens, with its axis in a vertical direction, exerts no influence at all upon the rays of light which fall upon it in a vertical plane, while it strongly refracts the rays which fall upon it in a horizontal plane. In Fig. 27, which illustrates simple hypermetropic astigmatism, we have an eye which exerts a contrary action, bringing rays which fall upon it in a vertical plane to an earlier focus than rays which fall upon it in a horizontal plane. It is manifest that there must be a plano-convex cylindrical lens which will just correct this error of refraction of the eye; and which, if placed in front of it with axis vertical, will increase the total refraction of the rays in the horizontal meridian until their focus coincides with that of the rays which were previously more strongly refracted in the vertical meridian. In other words, there must be a lens which will bring the focus *h*, Fig. 27, back to the retina, and render it coincident with focus *v*, the position of which will be left unchanged. In like manner, there must be a plano-concave cylindrical lens which will postpone the refraction in the vertical plane of the eye shown in Fig. 26, and will therefore put back the focus *v* to the retina, leaving the position of focus *h* unchanged. A plano-convex cylindrical lens of the proper strength both corrects and measures simple hypermetropic astigmatism, and a plano-concave cylindrical lens of the proper strength both corrects and measures simple myopic astigmatism.

If we look again at Figs. 26 to 30, we shall see plainly that the correction of either of the two forms of simple astigmatism leaves the eye emmetropic as far as its two chief meridians are concerned; and although the emmetropia is not absolute, on account of the impossibility of exactly correcting the refraction of the intermediate meridians, it is yet sufficient for all the practical requirements of life. In the compound forms, however, the correction of the astigmatism still leaves the eye ametropic; and the correction of the mixed form may be accomplished in such a manner as to produce the same effect. Thus, in Fig. 28, the astigmatism may be corrected in two ways, either by a plano-convex cylinder which would bring forward the focus *h* to *v*, and leave the eye highly myopic, or by a plano-concave cylinder which would put back the focus *v* to *h*, and leave the eye myopic, but in a less degree. Hence, however the astigmatism is corrected, there must still be a myopic eye; and the myopia will require a concave lens of the ordinary spherical kind. In like manner, the astigmatism of Fig. 29 could be corrected by a plano-convex cylinder, to bring the focus *h* up to *v*; or by a plano-concave cylinder, to put back the focus *v* to *h*. Either course would leave the eye hypermetropic, the former in a much less degree than the latter: and in either case the hypermetropia would require a spherical convex lens for its correction. Both the above-described conditions are of frequent occurrence, and they are met by the so-called spherico-cylindrical lenses, which are ground to be portions of a spherical surface on one side and to be portions of a cylindrical surface on the other. Such lenses are made, of course, of any desired curvature on either side.

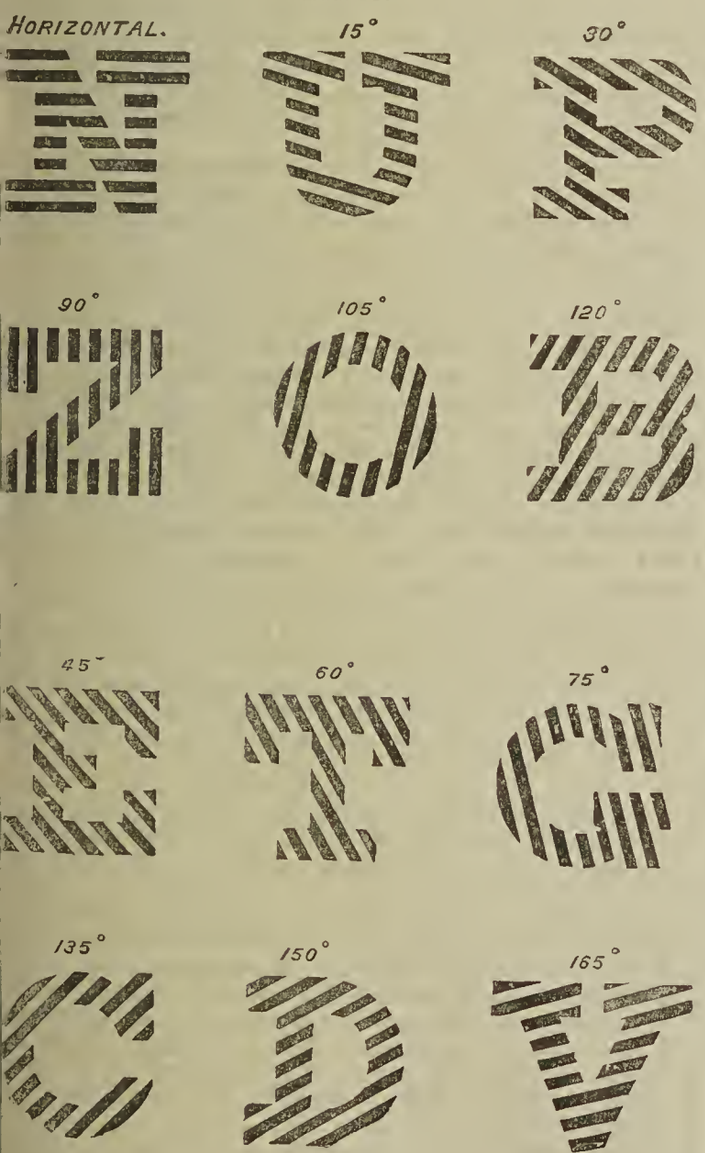
Mixed astigmatism, as shown in Fig. 30, might be corrected either by a plano-concave cylinder, to put back focus *v* to *h*, combined with a spherical convex to correct the resulting hypermetropia, or by a plano-convex cylinder, to bring up focus *h* to *v*, combined with a concave spherical to correct the resulting myopia. Usually, however, the better way is to employ a bi-cylindrical lens; that is, one which has a convex cylindrical surface on one side, and a concave cylindrical surface on the other, the axes of the two being precisely at right angles. In this arrangement, the concave cylinder should be of the power to put back focus *v* to the retina, and the convex side should be of the power to bring up focus *h* to the retina. The two foci will then coincide, and the eye will be left emmetropic or nearly so. There is, however, a difficulty in this mode of correction, arising from the fact that it will not be accurate unless the axes of the two cylindrical surfaces are precisely at right angles. This requirement may be defeated by the smallest rotation of the lens during the process of grinding; and its fulfilment can only be secured by the employment of an optician of adequate skill and carefulness. It may be laid down as a general rule, in the correction of astigmatism, that we should always endeavour to obtain the desired result by the simplest combination, and by means of glasses of the smallest refracting power, which will fulfil the indications in each case; but it is always proper to think over the various ways in which the correction may be accomplished, and it is sometimes desirable to try the possible combinations experimentally, before finally deciding upon any of them. We sometimes find that, with no apparent reason, one combination will give better vision than another which seems to be its optical equivalent.

The influence of astigmatism upon the sight is very considerable, and is exerted in various ways. Its first and most obvious effect is to produce differences in the apparent distinctness of equal lines, which are drawn in different directions; and in this way it produces indistinctness of some of the linear boundaries of figures, leaving others clearly defined. Thus, an astigmatic person, in reading a printed page, may be able to see clearly the vertical lines which enter into the formation of many letters, and so, for example, to distinguish an m from an n. But he would have to place the page at a different distance, or to alter the accommodation of his eyes, in order to distinguish the horizontal lines with equal clearness, and to tell readily an n from a u. The indistinctness of many boundary lines produces a corresponding diminution in the acuity of vision; and the necessity constantly to alter the accommodation in looking at the same object produces great fatigue of the ciliary muscle. Hence, defective sight, coupled with weariness and aching of the eyes, are the symptoms of which astigmatic persons most commonly complain.

The defective vision of astigmatism is primarily for lines

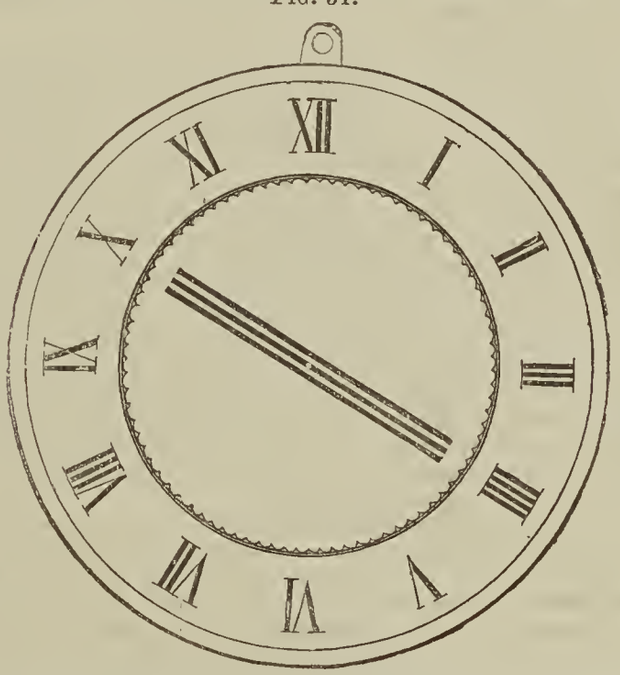
which are at right angles to the meridian of the preponderating ametropia. In the case shown in Fig. 26, for example, there is myopic curvature in the vertical meridian; and in Fig. 27, there is hypermetropic curvature in the horizontal meridian. The effect of the myopia, that is, of the myopic curvature, in the vertical meridian, is to render the eye short-sighted for horizontal lines; and the effect of the hypermetropic curvature in the horizontal meridian is to render the eye dim-sighted for vertical lines. The reason is, that a line is formed, optically speaking, of a succession of points, from each of which light is reflected. In the case of a vertical line, any diffusion circles which may be formed from the rays which diverge from successive points of the line in a vertical plane will overlap one another in that plane, and will not impair the distinctness of the retinal image; but any diffusion circles from the rays which diverge in a horizontal plane will serve to widen out the retinal image in a horizontal direction, and will cause the line to appear diffused or spread. Hence, the eye which has hypermetropic formation in the horizontal meridian has hypermetropic vision for vertical lines; and the eye which has myopic formation in the vertical meridian has myopic vision for horizontal lines. In writing upon this subject, it is necessary to adopt some uniform system of nomenclature in order to avoid confusion; and my own practice is to neglect the formation and to describe the vision. By vertical myopia, therefore, I mean myopic vision for vertical lines; and I disregard the fact that the vertical myopia is a result of faulty curvature in a horizontal direction. This method of description has a farther advantage in the direction of simplicity; because the axis of the correcting cylinder must always be placed in the same direction as the visual defect.

Fig. 33.



Since astigmatism always diminishes the acuity of vision, astigmatism of any appreciable degree is excluded whenever that acuity is normal; and, as astigmatism is often combined with general ametropia, so the acuity of astigmatic vision is often increased by common spherical lenses. But when, in any case of apparent ametropia, common lenses fail to bring the acuity of vision nearly to the normal standard; and especially when the patient does not express any decided preference between two or more lenses of about the same power, astigmatism should be suspected and searched for. The test object for this purpose is furnished by any figure which presents equal lines inclined in different directions; and among the many which have been devised for the purpose I know of none so good, and so generally useful, as the striped letters designed by Dr. Orestes Pray, which are shown in Fig. 33, and which may be obtained, in a size convenient for the consulting-room, from the Autotype Fine Art Company in Rathbone-place. An astigmatic eye, when its ametropia has been as completely as possible corrected by spherical glasses, will see the stripes in Dr. Pray's letters in different degrees of distinctness; and in high degrees of astigmatism the difference will be very marked indeed. The direction of the stripes which are most clearly seen indicates the direction of one of the chief meridians; and the other chief meridian will be at right angles to the former. Thus, if the patient says, "I see the stripes most plainly in the letter N," we know that the chief meridians are vertical and horizontal; and, if he sees them most plainly in E or C, we know that the chief meridians are diagonal. The same applies to any other direction. When once the fact of astigmatism, and the directions of the chief meridians, have been determined, Pray's letters are no longer useful; since their various lines are distracting to the attention when we are about to determine the state of the refraction in each meridian singly. For this purpose, the best object is such a disc

Fig. 34.



as is shown in Fig. 34, which consists of an outer circle, nine inches in diameter, inscribed with the figures of an ordinary clock face, and an inner circle, six inches in diameter, inscribed with three parallel lines, and turning on a central pivot which is concealed from view. The apparatus is of tin, painted white, and was made for me, by Messrs. Carpenter and Westley, of 24, Regent-street. The first disc of the kind which I employed was of home manufacture in cardboard, and was put together thirteen or fourteen years ago; but Dr. Green, of St. Louis, U.S., claims to have been the originator of the contrivance, and it is possible that I may have derived it from him in some indirect fashion. At all events, I am more than willing to concede to him the merit of the invention.

(To be continued.)

Erratum.—In Lecture IV., page 163, column one, eleven lines from bottom, for "nine" read "four."

Contributions amounting to $100 have already been received from American friends of the late Lady Augusta Stanley, to the fund which is being raised for the purpose of perpetuating her memory with the Westminster Training School and Home for Nurses.

FORTY-FIFTH MEETING
OF THE
BRITISH MEDICAL ASSOCIATION,
HELD IN MANCHESTER, AUGUST 7, 8, 9, AND 10, 1877.

THE SECTION OF SURGERY.

OPENING ADDRESS.

By EDWARD LUND, F.R.C.S.,
Surgeon to the Manchester Royal Infirmary; Professor of Surgery in the Owens College, and President of the Section.

THE AFTER-HISTORY OF SURGICAL CASES.

GENTLEMEN,—My first duty in taking the chair as President of the Surgical Section, at this the forty-fifth annual meeting of the British Medical Association, is a very pleasing one; it is to thank, with all sincerity, the Committee of Council for the honour they have done me in selecting me for this office, and to ask your help in carrying out successfully the responsible duties which it involves. I am quite aware that in making this selection the names of many surgeons have been passed over, who are not only my seniors but my superiors in this branch of our profession. I allow myself, nevertheless, to hope and believe that the honour thus conferred upon me is an expression of your conviction of the deep interest I take in the prosperity of our Association, and more particularly in this special department of it, as well as of my readiness at all times to bear my share in all that will tend to increase its general usefulness.

The first of these annual meetings which I had the pleasure to attend was held at Canterbury in the year 1861, and from that time to the present I have rarely missed the yearly gatherings, contributing sometimes to the list of papers, and joining in the discussions arising upon them. I am thoroughly convinced that it is only by such means as these that we can hope to sustain amongst our body a true sentiment of brotherhood, and create a bond whereby the hopes and fears of the few shall be enlarged and dispelled by the many; that knowledge, likewise, shall be diffused amongst us, and the results of experience matured and perfected, so that in our mutual intercommunications we may verify the remark, "Next to the pleasure we derive in the acquisition of knowledge, is the delight which is afforded us by communicating it to others." And I trust, gentlemen, that our discussions during the next few days will show that truth is to be alone reached through freedom of thought and freedom of discussion, in minds unbiassed by unyielding prejudices.

It is my intention to detain you but for a very short time to-day with introductory remarks on the business which we have before us. The list of papers for reading in this section is creditable to their authors, as regards both the number and the nature of the communications. It was part of the scheme suggested by the excellent secretaries of this section, that we should select certain definite subjects for consideration and discussion; and I believe among these, excision of the knee, antiseptic surgery, and urethrotomy were specially named. I do not know how far it will be found practicable to work out this plan; and I will not anticipate what may possibly be done, but will pass on to the few remarks I have to make upon a subject which, I think, you will agree with me is in perfect harmony with the practical character of our meeting, and which in its nature is almost indefinitely expansible. I refer to the one great question from the thoughtful study of which much benefit may accrue, namely, the *after-history of surgical cases*. We know that surgeons engaged in general practice, who are linked, so to speak, to their patients by various ties of personal regard and social intercourse, and who have constant, indeed, I may say, daily opportunities of noting their habits of life, their hereditary and acquired peculiarities, are in many respects better able to form a correct prognosis as to the reparative powers and tenacity of life in individual cases than, all other things being equal, a stranger can be; and if this be true in what I may call the incipient stage of disease, before the climax is obtained, that which justifies direct surgical or operative interference, it is also true that the general practitioner, or the constant surgical attendant in any given case or series of cases, if he will observe for himself and reason out his observations, will be able to testify to the permanent good effect of certain operations or modes of treatment which may have been inaugurated or suggested by a consultant, or practised in a hospital as a brilliant operation startling in its originality, but possibly, as the after-history may show, questionable in its results. I fear that we, who revel in opportunities for operative interference, are too apt to forget the old adage that "the operation is but the beginning of the treatment." Our patient leaves the hospital with a healed stump or a closed cicatrix, but who will tell us what shall be the fashion and utility of the former six or twelve months hence, or whether the tumour removed to-day is but the advance-guard of an enemy of far more deadly import? In excisions of joints, in all their varied forms, with or without permanent mobility,—in the best form of stumps after amputation,—not as they appear when they leave the operating table, nor even when the patient's name is struck off the hospital roll, nor yet at a slightly more advanced stage than this, when consolidation of the new tissue has been fully established, but months and years afterwards, is the proper time at which to say whether due regard was given, and sufficient thought bestowed, on the possible after-effects of muscular retraction and atrophy of tissue; for it is by such changes as these that many a comely stump, on which the operator justly prided himself, has shrunk up and become distorted, until, as far as being suitable for bearing the weight of an artificial limb is concerned, it shall be next to, or even worse than, useless. Now here, the after-history, if honestly scanned, will read its own lesson, and will be far more frequently watched by those in general practice than by surgeons of large hospitals. It is, in fact, in hospital practice a great drawback that we are unable, as a rule, to follow up our cases after they have left our care; for, with superior opportunities for so doing, we could, indeed, learn the best of all lessons, the experience taught by failure rather than by success. The same remarks will apply to the after-history of such surgical subjects as lithotrity *versus* lithotomy, tenotomy in orthopædic surgery, excision *versus* amputation in disease of the knee, and urethrotomy, as the expression of the more modern method of combating the advance of stricture.

In some degree to illustrate and confirm these remarks, I am able to bring before you to-day—at least, before such of my audience as like to examine for themselves, in an adjoining room where they can be seen, half a dozen very interesting surgical cases, all of which have been operated on at distant periods, and in which the permanent benefits or permanent defects are at once apparent. They are these. A case of excision of the knee was performed in the year 1870 on a man then aged about twenty-two years, now, therefore, twenty-nine years old. This case was described by me in the *Manchester Medical and Surgical Reports*, after the publication of which the paper was reprinted. Here you will have an opportunity of noting the condition of the limb and of hearing from the man himself what he can do, and then it will be for you to consider how far his present state and capacity for walking and working may be said to compensate the long illness and treatment, which I am bound to say were very tedious, and which I do not believe could have terminated as successfully as they have done had the patient not been watched with scrupulous care by my old pupil and friend, Mr. John Parks, of Bury. My second case is one which I mention with some diffidence, and to which I am glad to refer to now in the presence of so high an authority in his own speciality as my dear friend, our Vice-President, Mr. William Adams. It is the case of a little boy from whom, in the year 1872, I removed both astragali in order to correct severe double talipes, in the previous treatment of which much patience had been expended, and, as it seemed to me at the time, to a hopeless degree. I am pleased to show this case to-day, if for no other reason than that I may thank my friend for behaving so generously as he did when I read the particulars of the case at our meeting in Birmingham, in not at once condemning the course I had pursued as unjustifiable, but merely hinting, in the most considerate manner, that possibly, in such a case, a less heroic method of treatment might have secured equally good results. The third case is an instance of double section of the neck of the thigh-bone, done in the months of March and May, 1876—Adams's operation, the credit of which is his own, in the special form in which he designed it, *nullo contradicente*. You will now see, reviewing the past and recent history of this case, at a fair interval of time, how far this operation was justifiable, and how far it has been successful.

Next, I would invite your attention to a case of amputation of the hip-joint, performed in 1872, in which an excellent recovery was made. The chief interest in this case consists in the contemplation of the wonderful way in which the patient can walk and get about after so severe a mutilation as that of not less than one-sixth part of his entire body, and of some interesting physiological problems which might be worked out upon it as to the action of the steadying muscles of the hip and loins, whereby the balance of the body is still preserved.

I have also ready for your inspection two cases of partial removal of the ulna, in each of which an excellently useful hand is preserved, with power of rotation by pronation and supination, to a remarkable degree. In one case, which was operated upon about eleven months since, the lower third of the ulna was removed, and all healed well. In the other, only just the extreme end was excised. It is an operation upon which I cannot refrain from dwelling, because it shows that not only in infancy, but even in our student days, early impressions are imprinted indelibly on our memory. I had the good fortune to be one of the first set of dressers for Mr. Hilton when he was appointed one of the surgeons to Guy's Hospital, about the year 1845. No one at that time was more ready or more able to apply correct anatomical knowledge to surgical practice than he. It was his delight, as his *chef d'œuvre* on *Rest and Pain* will fully testify. At this time he had under treatment a young woman with necrosis of the lower part of the ulna, without, as was then thought, any present disease in the carpal joints. Mr. Hilton said, "How would it do to take away the diseased bone, and not destroy the integrity of the carpus, by carefully leaving intact the triangular fibro-cartilage which intervenes between the end of the ulna and the cuneiform bone? This was done, and a perfect recovery resulted. The fact thus presented to my mind was never forgotten. I referred to it from time to time in my anatomical demonstrations, as a possible operation. It was not until quite recently, however, that I had a precisely similar case to treat, one in which, as you will observe, I have removed the lower inch of the ulna without disturbing any of the carpal joints. Recovery has followed, and now, after nearly fifteen months, you may see for yourselves what an useful hand the patient has. But yet there is danger to be averted, as possibly only the after-history of such a surgical case could foreshadow. The two ulnar muscles, the flexor and the extensor, unrestrained by the resistance of the shortened ulna, are now beginning to show a tendency to draw the hand towards the internal side of the fore-arm, and in spite of all I can do, I fear I must admit that, without the use of some mechanical apparatus, the hand will become less serviceable, by permanent fixed adduction.

The lessons to be learnt from the after-history of these cases will, I hope, be as interesting as I believe they might be made instructive; and I trust that the present condition of these patients will convince you that, in many instances of surgical disease and surgical treatment, careful study of the after-history of each individual case will prove an endless source of accumulated experience.

SECTION OF OBSTETRIC MEDICINE.

OPENING ADDRESS.

By W. O. PRIESTLEY, M.D., F.R.C.P.,
President of the Section.

THE HISTORY OF OBSTETRIC MEDICINE IN MANCHESTER.

Gentlemen,—When I was honoured with an invitation to accept the Presidency of the Obstetrical Section at the present meeting of the British Medical Association, it struck me that it would be interesting to look back on the part which Manchester has from time to time taken in the advancement of obstetric science, and to recall some of the great names who have contributed to its literature.

Manchester, indeed, has had its school of obstetric medicine as well as its school of politics. It has made its mark both in the present and preceding century, and it seems to me a happy coincidence that the Address in Obstetric Medicine, which is given once only in three years, should be delivered in Manchester, a town so much identified with the progress of the science and art of midwifery; and the Association may be congratulated that the address is to be delivered by so competent an authority as Dr. Barnes.

So long ago as 1773, Mr. Charles White, a pupil of William Hunter and Surgeon to the Manchester Infirmary, wrote a treatise on the "Management of Pregnant and Lying-in Women," which went through three editions; and, in 1784, he issued a work on the "Nature and Cause of Swelling of the Lower Extremities, which Sometimes Happens in Lying-in Women." This work also appeared in three editions, and was remarkable as one of the first scientific attempts to unravel the pathology of the disease called "phlegmasia dolens" by a careful study of the anatomical changes taking place in the limbs. Mr. White gave a very accurate description of the affection, and adopted the view that it depends on "obstruction, detention, and accumulation of lymph in the limb."

In 1800, Dr. Hull published an extended treatise on the same subject; and, from his introductory remarks, it may be gathered that he first bestowed the term "phlegmasia dolens" on the inflammatory swelling of the legs observed in puerperal women, and assigned it its place in the nosology of Cullen. He expresses a fear lest some of his readers should be puzzled by the new name. He regarded the disease as an inflammatory affection, producing suddenly a considerable effusion of serum and lymph into the cellular membrane of the limb. Whatever may be thought of the pathology of these two authors, in view of the more recent researches of Dr. Robert Lee, Dr. Mackenzie, Professor Virchow, and others, there can be no doubt that both Mr. White and Dr. Hull made most important contributions towards elucidating the nature of phlegmasia dolens, and deserve great credit.

Probably no single locality in the United Kingdom has contributed so much as Manchester and its vicinity to the discussion and elucidation of the subject of Cæsarean section. In 1769, Mr. Wood here performed the operation upon a woman whose pelvis became greatly distorted by mollities ossium after she had previously borne children naturally. This case led to a discussion, in which Mr. Simmons, Mr. Ogden, and Mr. Tomlinson of Manchester, with Dr. Sims of London, took part; and out of this controversy came the excellent treatise by Dr. Hull entitled "A Defence of the Cæsarean Operation," etc. In this work, Dr. Hull entered most intelligently into the nature of the cases requiring the operation, the best method and the proper time for performing it, the sources of danger, and the subsequent treatment of the patient. This book besides gave much information on the subject of pelvic distortions. If, with the light of later experience, exception be taken to some of Dr. Hull's positions, his book may be said to have formed the groundwork of information on Cæsarean section for British practitioners, and to this day it is regarded as containing sound opinions and good practice.

The promulgation of Dr. Hull's views was unfortunately mixed up with a most rancorous controversy between him and Mr. W. Simmons, in which Mr. Simmons charged Dr. Hull with being "little acquainted with the decencies common among authors, and ignorant of the language and manners of a gentleman." The contention in bitter personality inevitably recalled the celebrated combat between Susannah and Dr. Slop, graphically described by Sterne in "Tristram Shandy," and its occurrence is much to be regretted.

In 1801, Dr. Hull translated and published M. Baudelocque's two memoirs on the Cæsarean operation, thus giving English practitioners further information on the subject; and the history of the operation is still further identified with Manchester through the much-respected name of Dr. Radford, who delivered the first Obstetric Address before the Provincial (now named British) Medical Association at Manchester in 1854. Dr. Radford then selected Cæsarean section for the subject of his Address, and subsequently published a more extended memoir with an appendix of cases. From this memoir, it appears that, up to a certain period, the greatest number of cases, relatively speaking, in which Cæsarean section had been performed in Great Britain and Ireland had occurred in this city and neighbouring districts. Of fifty-five cases in England and Wales collected by Dr. Radford up to 1865, no fewer than twenty-five had occurred in Lancashire. The occurrence of this large proportion of Cæsarean operations in Lancashire was, no doubt, in a great measure, due to the pernicious influences surrounding the occupation of young girls and women in factories. Cogent evidence of this is to be found in the fact, which I have on good authority, that, since the introduction of the Factory Act, which prohibits girls being employed in factories before a certain age, and limits the hours of work

both for women and children, such deformities of the pelvis as necessitate the Cæsarean section have become much rarer, and Lancashire is losing its unhappy pre-eminence in this respect. This, one of the indirect ways in which the Factory Act has ameliorated the condition, and lessened danger and suffering for poor working-women in parturition, deserves to be recorded, and must furnish a source of gratification to Lord Shaftesbury and others who were concerned in passing this beneficent measure.

Looking still onward, we learn that to Mr. Kinder Wood, of Manchester, is probably due the first suggestion that the placenta should be detached from the os and cervix uteri in certain embarrassing cases of placenta prævia, where the severity of the hæmorrhage places the patient in peril, and immediate delivery is difficult or impossible. Sir J. Y. Simpson developed this question more fully later, and impressed upon it, as he did on all subjects he handled, the imprint of his genius. Sir James evidently was not aware, when he made his first communication on this subject, that Mr. Kinder Wood had before him adopted this plan of treatment, or had recognised the fact that complete separation of the placenta would arrest hæmorrhage in cases of placental presentation. Becoming informed later, he made a full acknowledgment, and expressed himself as having "great and sincere pleasure in rendering posthumous justice to the memory of a man of distinguished professional attainments."

And here I may remark that some misapprehension still exists concerning Sir James Simpson's teachings as to the treatment of placenta prævia. It is common enough to hear Sir James accredited with recommending separation of the placenta as a general plan of treatment for cases of unavoidable hæmorrhage. Those who have carefully studied his writings are not likely to fall into such an error; but it may be well once more to point out that Sir James Simpson only proposed the separation of the after-birth before delivery in cases where the hæmorrhage had been so great that the patient could not bear the shock of immediate delivery, or where perilous flooding was associated with such an undilated or undilatable state of the passages as to render speedy delivery impracticable.

These doctrines, it is well known, have been still further modified more recently by the obstetric orator at the present meeting—Dr. Barnes.

Tracing further the history of obstetric medicine in Manchester, I approach delicate ground, inasmuch as many of the men identified with its progress are still living, and their names are familiar to all of us. Of the venerable Dr. Radford, whose name I have already mentioned, and whose first medical diplomas date as far back as 1817, everybody must speak with admiration and esteem. A long life, combined with ardent love of his profession, have enabled him to make many substantial contributions to the literature of obstetrics, and to form a very fine collection of instruments. This collection now belongs to the Radford Museum in Manchester, and, by kind favour, was lent for a brief period to the Obstetrical Society of London for exhibition at its *conversazione* last year. Among Dr. Radford's more important writings, I may mention his "Essays on Various Subjects connected with Midwifery"; his "Essays on Cæsarean Section and Deformities of the Pelvis"; "Cases of Torsion, Doubling, and Expulsion of the Fœtus in Shoulder Presentations"; "Cases of Laceration of the Uterus," etc.

Dr. John Roberton, whose first diploma dates as far back as Dr. Radford's, has also, during his lifetime, rendered signal service to his profession. His writings bear the stamp of a genius which has been recognised by many eminent authorities, and his practical suggestions have greatly helped to further a more scientific and precise use of midwifery instruments.

Dr. Charles Clay, besides entering the domains of archæology and general science, has brought renown to the Manchester School by the diversity and extent of his contributions to obstetrics. Without going into the question of priority, I may state that Dr. Clay's name is indisputably associated with the earliest successful cases of ovariotomy in this country, and that he materially aided, by his own work and writings, to establish the propriety of an operation which has led to such wonderful results in the hands of Mr. Spencer Wells, Dr. Thomas Keith, and others. Further, Dr. James Whitehead, both by his writings and practice, has attained more than a local celebrity as an accomplished gynæcologist; and Dr. Renaud, who, I understand, does not engage in obstetric practice, yet has added important material to its literature. I have often heard my late friend Dr. Montgomery, of Dublin, speak of the value of his researches on the corpus luteum, and, in his admirable work on "The Signs and Symptoms of Pregnancy," Dr. Montgomery says of Dr. Renaud's account of the corpus luteum that, "as far as it goes, it is decidedly one of the best and most accurate."

I may add that, within the last day or two, Dr. Lloyd Roberts has informed me that a Mr. Ward, a surgeon in Manchester, was the first to point out that infantile leucorrhœa was an idiopathic affection, and not necessarily produced as the result of carnal intercourse. The importance of this discovery in a medico-legal sense was illustrated by a case occurring at the time. In 1791, Mr. Ward was asked to examine a little girl four years old who was supposed to have been violated. He gave evidence to the effect that there were proofs of such violation, and a man was committed for the capital offence. Immediately afterwards, Mr. Ward saw other cases of infantile leucorrhœa in hospital, which a careful examination convinced him were due to natural causes. He was courageous enough to report this to the authorities, with an avowal that he might have been mistaken as to the evidence he had given in the criminal case. This was explained to the judge of assize at Lancaster, and the man was acquitted.

This brief recital does not at all profess to complete the history of obstetric medicine in Manchester; it merely gives a *résumé* of some of its more salient points up to a given period. In any fuller exposition, one could scarcely omit to mention the names of the present honorary secretaries of this Section. They are the worthy representatives in gynæcology in Manchester at this moment, both as teachers in the medical schools and as pioneers in practice.

Since the last meeting of the British Medical Association in Manchester, considerable strides have been made in perfecting the science and art of midwifery, and in investigating and treating the diseases of women. New light has been thrown on the treatment of difficult and anomalous labours; fresh expedients have been suggested to meet special emergencies. The subjects of uterine hæmorrhage, the use of midwifery instruments, the diversities in the method of turning, and the pathology of puerperal ailments, have each received fresh illustration in this country by such men as Simpson, Matthews, Duncan, Barnes, Braxton Hicks, and others, and by a host of fellow-workers abroad. In the treatment of diseases of women the advance has even been more marked. The wonderful results which have recently attended the operation for ovarian tumours are the marvel of our time, and indicate a courageous and skilful battle with disease and death, crowned with a success which twenty years ago was scarcely hoped for.

The impetus given to the cultivation of uterine pathology not many years since by the writings of Dr. Henry Bennet in London, and by Dr. Simpson in Edinburgh, may be said almost to have created the modern school of gynæcology in this country. The various implements introduced into practice, more especially by Simpson, have made diagnosis much more precise and accurate than before. With these improvements, the danger is lest the physician be merged too much into the mere mechanist, and lest he should look on all derangements of the reproductive organs as having too exclusively a local origin, to be remedied with undue frequency by local expedients.

As we are avowedly met here for mutual discussion and criticism, I trust I may be pardoned if I indicate, in passing, one or two pitfalls into which gynæcologists are prone to stumble in the present phase of our art.

In the first place, out of the mechanical improvements in diagnosis and treatment, there seems to have grown too great a proclivity to trust less to the information afforded by the educated fingers, and more than is desirable to instruments. These mechanical aids are often employed as a mere matter of routine, without regard to the pathological nature of the uterine disturbance, in the vague hope that they may assist to find out something, the nature of which is not well-defined beforehand, and apparently with the idea that full justice is not meted out to the patient if any are dispensed with. These remarks apply both to the speculum and sound, with other instruments, but especially to the uterine sound. The uterine sound is a great addition to our resources, but there are many uterine affections in which it affords no information whatever, and many in which it is positively injurious. My experience convinces me that it is employed with unnecessary frequency both as an instrument of diagnosis and for

restoring the displaced uterus when a finger in the vagina or rectum would equally well answer the purpose. A sound cannot be introduced into an inflamed and tender womb without stirring up more mischief; and it is often forgotten that a preliminary investigation on this point is as needful and desirable before having recourse to the sound as it is to exclude the chances of pregnancy. The result is the infliction of a large amount of avoidable suffering; sometimes it may be an aggravation of the disease for which the patient seeks relief, and an amount of discredit attaching to the practitioner which most men would be glad to escape.

It is of great moment, now that we possess instruments of acknowledged value, to learn the exact limits within which they render actual service, and when they had better be avoided.

Again, as certain remedies have had their fashion for the day, and then have sunk into unmerited oblivion, so, in defiance of sound principles, a single idea in uterine pathology has been raised into a position of undue prominence, and then given place to something else.

At one time, ovarian pathology was in the ascendant; at another time, inflammation of the os and cervix uteri was regarded as the chief ailment from which women suffered; and lately these have given place to the theory that mechanical displacements of the uterus are the root of all evil,—and patients, taking their cue from the doctors, at once jump to the conclusion that all pelvic discomforts come from uterine dislocation. Thus the world is afflicted suddenly with what seems an epidemic of flexions and versions of the womb, and a large amount of time and ingenuity are expended in the invention of pessaries which might be more profitably employed in other directions. Need I point out how important it is that, in all our scientific progress, we should relegate each special subject of study to its proper place in a sound system of pathology, and attach to each morbid condition its true importance? Both in diagnosis and in attempts at cure, while we should have courage enough, when necessary, to face both difficulties and dangers, it comports best with scientific practice to measure as exactly as possible the amount of interference to the needs of the case. All beyond this is not only superfluous; it is apt to be mischievous.

Turning to another subject, I am anxious to draw the attention of members to the subject of transfusion, which has been chosen by our Manchester *confrères* as a topic for discussion in this Section of our meeting. The operation of transfusion has had a chequered career, and, after being forgotten or neglected for long periods, is again attracting much attention.

From a sketch of the history, by the late Mr. Pettigrew and others, we learn that the earliest experiments in transfusion were made in France about 1658 by Hansheau. Lower performed the operation in this country in 1665. M. Denis, satirically described as a physician "plus occupé des jeux de hazards que des jeux de la machine animale," subjected a man to the experiment about the same time. Biva and Manfredi in Italy, and Sinnibaldus in Flanders, repeated the experiment only a few years later. The first four volumes of the *Philosophical Transactions*, which cover the years from 1665 to 1704, contain records of several, but all unsuccessful, cases.

After this time, the practice seems to have fallen into abeyance, although Dr. Harwood of Cambridge published a thesis on the subject in 1785, and endeavoured to rouse attention to its importance. It was not until 1824, when Dr. Blundell of Guy's Hospital re-opened the question, that it gained distinct vitality. Dr. Blundell showed, by a series of experiments, that blood may be transfused with success and safety from one animal to another, provided they are of the same species; but if from one animal to another of different species, the result is fatal. MM. Prévost and Dumas in France, and Bischoff in Germany, believed they had afterwards verified Dr. Blundell's conclusions; but Dr. Brown-Séquard has shown that there were fallacies in these experiments, and that, under certain conditions, the blood of other animals may be injected into the human body without danger, while he holds with Dieffenbach that defibrinated blood answers as well as fibrinated blood.

Dr. Blundell performed the operation of transfusion eleven times with his own hand; in ten of these cases there was pressing danger from loss of blood, and in only four of these did he succeed in restoring the patient.

The sparing results attained by Dr. Blundell did not encourage the adoption of the practice by medical men generally. The operation was regarded as delicate, difficult, and uncertain of success, and it languished, although from time to time new instruments were devised and fresh suggestions were made for perfecting the process. In later days, Dr. Hamilton of Ayr, Dr. Graily Hewitt, and Dr. Aveling have each suggested modifications of apparatus. Dr. Aveling's method of immediate transfusion was at once so simple and practical that its introduction gave a new impetus to the operation in this country.

In limine, it may be said that, as increasing attention is paid to the subject, and apparatus becomes more perfected, greater promise is afforded and favourable results are gradually growing. The late Professor Martin of Berlin recorded fifty-seven cases, in which forty-three were completely successful; Dr. Higginson of Liverpool fifteen cases, in which ten were successful; and Dr. McDonnell of Dublin, de Bellina of Paris, with others, have published interesting cases.

It will be in the recollection of many members that, at the meeting of the British Medical Association in London, there was a discussion on transfusion, and a lively debate took place between the advocates of *mediate* and the supporters of *immediate* injection.

Just now, new life has been imparted to the subject by the appearance of M. Roussel, demonstrating the utility and simplicity of his method for direct transfusion. This subject is obviously a study of deep and increasing interest, as the introduction of the practice in a perfect and simple form may be the means of saving many from the very jaws of death. I commend it to your careful consideration, and, at the appropriate time, to your earnest and dispassionate discussion.

ORIGINAL COMMUNICATIONS.

CHLORATE OF POTASH IN SATURATED SOLUTION A SPECIFIC REMEDY AGAINST DIPHTHERIA.

By Dr. A. SEELIGMÜLLER, of Halle (Prussia).

Dr. Aitken, in his splendid work on Pathology, when treating of the cure of diphtheria, says (page 734):—"We have no specific treatment which can cure the disease (diphtheria) or eliminate the poison."

In the same manner Dr. Isambert, in his "Études Chimiques, Physiologiques, et Cliniques sur l'Emploi thérapeutique du Chlorate de Potasse spécialement dans les Affections Diphthéritiques" (Paris, 1856), summing up what he has experienced from observing the effects of chlorate of potash against diphtheritic affections, propounds (page 102) this question—"Le chlorate de potasse a-t-il une action spécifique sur la cause générale de la diphthérite?" And here is his answer—"L'est ce que les faits ne nous permettent pas d'affirmer. Peut-être des expériences nouvelles pourrait-elles décide la question; celles qui consisteraient à élever les doses pourraient fournir un élément." This prevision has been fulfilled, for large doses, or rather saturated solutions, are indeed a panacea against diphtheritic affections.

Everybody knows that, of all remedies internally made use of against diphtheria, chlorate of potash has figured for a long time as the most useful, and has been constantly recommended anew in compendiums of treatment. But no less it is known to every physician how little, when used in doses and degrees of concentration commonly applied, this remedy can pretend to the name of a successful one against diphtheria, else there would not have been internally and externally tried, recommended, and applied so many other remedies besides chlorate of potash. How did we not—I, as assistant-physician (*Assistentarzt*), and a dozen of students extremely diligent and zealous—during the summer of 1864, in the Newmarket quarter of the University-Policlinic of Halle, torture the poor children and ourselves by scratching off the diphtheritic deposits, and then cauterising! And what did we gain by all this torture? In this quarter, which forms nearly the third part of the policlinical district of Halle (a town at that time of about 40,000 inhabitants), there died of diphtheria in one month twenty-five children,(a) sometimes three in a single family; and those who recovered were

(a) In this number are not comprised the children who died among the better classes under the hands of private physicians.

easily to be numbered, and surely their recovery was not due to our endeavours. It seems hardly necessary to add that, besides the topical treatment, chlorate of potash was ordered in usual doses. And now for the saturated solution—℞. Chlorate of potash grammes 10, aq. dest. grammes 200; every hour or every two hours a spoonful—and nothing else! Gargling, anointing, brushing, and cauterising, all this management, as time-wasting for the physician as tedious for the little patients, *may be omitted*, without the physician accusing himself of neglect. Indeed, one needs not be a homœopathist to feel very comfortable at this quiet *laissez-aller* in cases where one was to be incessantly on the move, and to be worn out with anxiety by the crying and spitting of the children, and all in order to arrive at nothing but the dying of the patients!

During the five years that I have ordered no other remedy against diphtheria besides our saturated solution, this remedy has proved successful in all cases of diphtheria except a few cases that were neglected in the beginning, in which the blood was already profoundly altered and systemic poisoning had occurred when I was consulted.

Method of Administration.—You have to give the above-named saturated solution of chlorate of potash (5 per cent.), as long as there is to be found any relic of diphtheritic deposits, at the commencement every hour; later, if the case progresses favourably, every two or three hours. To children above the age of three years a whole spoonful, and to those under that age a half one; (*mark well!*) *during the beginning, day and night without intermission.* You have not to add to this solution any syrup or any other ingredient to sweeten the savour, because of the risk of diminishing surety of effect. Besides, I have had only a very few children under treatment who would not take it without any forcing. Do not forget that drinks must not be allowed for some minutes after the administration, lest the solution might be washed away too quickly from the fauces. It is not necessary to add that I have ordered sometimes the same solution as a gargle, when the children were capable of using it. I also washed the mouth and fauces with a sponge saturated with the same solution, or I introduced it through the nostrils by means of a nostril-syringe, or by ordering the patient to sniff it in. But all this management is superfluous, and serves only to quiet the parents, lest they may think you have neglected something. Finally, it may be repeated that it is abundantly established by clinical experience *that the internal medication alone is sufficient in all cases.*

Mode of Action.—The symptom you will see disappear first is the fetid breath. I myself have seen the most penetrating odour removed within a few hours. At the same time, the diphtheritic deposits will diminish apparently, the sores that were at first covered with a creamy pus clean quickly, and an ulcer will remain behind which is disposed to rapid cicatrisation. But what is most astonishing is the quick amelioration—not to say recovery—of the general state. Children whom I found in the evening, when I was called in, reduced by exhaustion and fever, the next morning were sitting up in their beds, fresh and without fever, demanding food, and playing. The cases in which I was obliged to employ any other medicament besides the chlorate of potash were extremely rare—namely, when the pulse was becoming extraordinarily weak and intermittent, and the force of the heart was diminishing. In these cases I have ordered a solution of quinine to be taken alternately with the first solution. Then it will not be amiss to administer also some spoonfuls of Hungarian wine, black coffee, tea, or beef-tea. In all other cases I have ordered only the chlorate of potash from the beginning of the diphtheria till its ending, without having to regret any fatal results excepting the above-named neglected cases, and two other cases of which I shall make hereafter a detailed mention.

Theory of Action.—Dr. Isambert, in his observations on the treatment of diphtheria, says (page 65):—"Le chlorate de potasse n'est pas un médicament héroïque, qui guérisse à coup sûr l'angine maligne, son action n'est pas instantanée, bien qu'il apparaisse au bout de quelques minutes dans la salive, il lui faut au moins vingt-quatre heures, et le plus souvent deux ou trois jours, pour agir; aussi faut-il l'administrer de bonne heure. Son action semble être plutôt locale que générale, bien que l'état général s'améliore ordinairement en même temps que l'état local; ce n'est donc pas un remède d'urgence." It is not necessary, after what I have been demonstrating, to say that I cannot adhere to the propositions made by Dr. Isambert. On the contrary, I have experienced in a great number of diphtheritic affections that the action of chlorate of potash is sensible already in the first twelve hours of administration. Particularly it is the last part of his proposition I cannot confirm. My experience, on the contrary, is that the *saturated* solution of chlorate of potash does not only act *in loco effecto*, but has also a general effect on the diphtheritic affections. Its topical action is apparently that of a mild cautery; but perhaps it is acting yet more in separating the diphtheritic pseudo-membrane from its basement-membrane by promoting a very abundant secretion between the two membranes. In favour of this hypothesis you have the experiments of Dr. Laborde, who has found the same quantity of chlorate of potash eliminated on the respiratory surface of the bronchial tubes as by salivation. But as to the mode of general action, and the chemical decomposition, I cannot but propose the following conjectures:—Dr. Bollinger, of Munich, has reduced the chemical action of the anthrax-bacteria within the living animal body principally to this: that these organisms, because of their enormous chemical relation to oxygen, absorb this gas with great avidity and in great quantity by withdrawing it from the red blood-corpuscles. Now, in diphtheria we have similar bacteria, which probably will exert the same withdrawing action. On the other side, Professor Binz, of Bonn, has stated that chlorate of potash is reduced by animal fluids—for instance, by pus. Therefore, if we introduce a saturated solution of chlorate of potash into the blood, we are entitled to expect that it will deliver up there a great quantity of oxygen, supplying that which is withdrawn by bacteria, and having besides a destructive power on those organisms. Therefore, it may happen that the effect of chlorate of potash will not appear if you apply solutions not sufficiently saturated or in too small doses.

Precautions.—Yet some caution is required in administering it, for my clinical observations have given me the conviction that our solution may have a dangerous action—1, on heart; 2, on digestion. As for the first, it is easy to decide in the single cases how much the diphtheria itself was acting on the heart; for many clinical facts have taught us that diphtheria produces very dangerous perturbations of the functions of the heart. Yet in a series of clinical observations I have received the same impression that the concentrated solution has indeed a retarding and debilitating influence on heart-action. In some diphtheritic children I have observed a great weakness of heart-action, with a pulse much retarded and sometimes intermittent, even when the chlorate of potash had been given only during twenty-four hours.

This opinion receives support from the experiments of Dr. Podkopaew and those of Dr. Isambert himself, who has recommenced his investigations. When these physicians injected two grammes of chlorate of potash into the crural vein of a dog, it died in a very short time of heart-paralysis. Probably it is the alkali contained in the chlorate of potash which produces its effects on the heart. Further, our solution may exercise an injurious influence on the organs of digestion. That I have observed particularly in those cases where children affected by diphtheria had acquired in the same time an acute stomachal catarrh. Then the vomiting with which the malady had commenced before the administration of the chlorate increased in such a degree that it was not to be stopped. A complete anorexia supervened, and the patients were in danger of dying from weakness (this last did happen, indeed, in one of my observations); therefore you must cease the administration of our panacea for some hours, as soon as grave gastric symptoms appear, and recommence its administration with cautious doses. Besides, I have observed one case of poisoning by chlorate of potash, which offers a strong confirmation of our proposition that the saturated solution may have a pernicious influence on the organs of digestion. This case was that of a very spoiled boy, aged six, who, seized by a grave diphtheritic affection of the fauces, refused to open his mouth to take medicine. This resistance obliged one of my colleagues, who represented me for that time, to infuse in three doses a whole bottle, so that the boy received, in about twelve hours, fifteen grammes of chlorate of potash. After that forced medication the boy refused at all opening his mouth and taking anything. He became more exhausted every day, vomiting green matter and having diarrhœic evacuations of the same colour. He died of weakness ten days after the forced medication. There is a strong probability in this case that the child did not die of diphtheria, but of poisoning.

Here is the summary of my observations :—

1. The chlorate of potash administered in a saturated solution (5 per cent.) has a specific effect on diphtheria.

2. It must be given in a solution of ten grammes in 200 grains of distilled water without adding any syrup or any other substance to ameliorate the taste.

3. This solution is to be ordered to infants under three years at half a spoonful, to elder ones at a whole spoonful, every two hours (if the malady is very grave, every hour), at first *day and night* without interruption.

4. This internal medication *alone* will suffice in all cases.

5. The saturated solution of chlorate of potash exercises (*a*) a topical action, and (*b*) a general one on the diphtheritic process—(*a*) a topical one, as a mild cautery, and by separating the diphtheritic pseudo-membranes from their basement membranes; (*b*) a general one, supplying the oxygen withdrawn from the blood corpuscles by bacteria and destroying these organisms.

6. Caution is required lest the saturated solution may act dangerously on heart or digestion. When such symptoms occur, the administration must be suspended.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

HEAD INJURIES.

UNIVERSITY COLLEGE HOSPITAL.

Cases under Mr. Marcus Beck.

Case 1.—*Fracture of Parietal and Temporal—Wound of Middle Meningeal Artery—Separation of Dura Mater and Compression of Brain by Blood-clot—Trephining—Removal of Clots—Non-expansion of Brain—Death.*

[Notes by Mr. Neville S. Whitney.]

T. H. R., aged twenty-eight. Patient was a healthy brewer's drayman. He was driving his cart on the evening of January 11, 1877, when he fell from the driving-seat into the road. He mounted the box again and drove some distance; then, feeling giddy, he dismounted, and lay down in the van. His mate, who was a little the worse for drink, drove on, and thought no more of him for half an hour. At the end of this time he was found by a policeman to be in a state of complete insensibility, and was immediately brought to the hospital. He was admitted about 9 p.m., and was seen by Mr. Beck at 10 p.m. On admission he was completely unconscious, pupils widely dilated and fixed; stertorous breathing 18 respirations per minute; complete general paralysis, pulse very full and tense, 32 per minute. Slight bleeding from right nostril. Over the back of the left parietal bone was a slight puffy swelling; no wound anywhere. The head was shaved at once, and it was then seen that the whole of the left temporal fossa was distinctly fuller than the right. At ten o'clock there was no change. The history clearly showed that the coma was due to hæmorrhage, and the absence of insensibility immediately after the accident proved that it was not from lacerated brain substance and pia mater. It was therefore diagnosed to be between the dura mater and the bone, and the fulness of the left temporal fossa pointed out which side it was on. A T-shaped incision was therefore made, exposing the lower and anterior angle of the left parietal bone. The superficial and deep temporal arteries were divided and tied. The pin of the trephine was applied about an inch and a half above the zygoma, and the same distance behind the external angular process of the frontal bone. In this situation a fissured fracture was found from which blood was oozing. The trephine was applied so as to include the point where this fissure was supposed to cross the course of the anterior branch of the middle meningeal artery. On removing the circle of bone it was found to be almost exactly bisected in a direction downwards and forwards by the fissure, and almost vertically by the groove for the artery, so that the two crossed each other in the centre. As soon as the bone was removed fluid blood and soft coagula welled up from the wound. The finger passed in, penetrated to a depth of between one and a half and two inches before it reached the dura mater, and it could not reach the limit of the clot laterally in any direction. The clot was now scooped out with a small lithotomy scoop, and was at once followed by a perfect torrent of blood, dark in colour, and without pulsation, except such as was communicated to it by the brain. The colour of the blood was doubtless due to the state of semi-asphyxia in which the patient was. Its quantity seemed almost greater than could be imagined to come from so small an artery as the middle meningeal. No bleeding artery could be seen or felt. Compression of the carotid seemed to have but little effect. It seemed at first as if the hæmorrhage would have proved fatal, but after a time it ceased spontaneously before the pulse showed any signs of serious loss of blood. The brain showed no tendency whatever to expand. The dura mater remained pulsating slightly, and at the same distance from the surface as it was at first. Consequently, the space between the dura mater and the bone became again filled with soft loose clots. After the operation the pulse rose to 60. It was moderately full and of fair force. The coma remained absolutely unrelieved in any way. The wound was lightly dressed, so as not to resist the exit of the clots in case the brain should begin to expand, and the patient was carried back to bed. At 11.30 the pulse was smaller, irregular, and occasionally intermittent —52. No relief to the coma. No recurrence of the hæmorrhage. At 7 a.m., January 12, he vomited, and at 8 a.m. he died comatose.

Post-mortem.—Head: A little blood under the scalp on the left side and in left temporal muscle. A fissure was found running from just above the left parietal eminence across the trephine-hole, and from the further side of that downwards and forwards ending just below the outer end of the lesser wing of the sphenoid. At one place in the very thin squamous bone it was starred. The centre of the trephine wound was found to be two inches behind the external angular process of the frontal bone, and one inch and a half above the zygoma. Head opened; longitudinal sinus healthy. Surface of brain dry; convolutions everywhere much flattened. A slight bruise of the brain was found on the under surface of the anterior part of the temporo-sphenoidal lobe just opposite the point struck. There was another slight bruise on the under surface of the same lobe on the left side, just beneath the point struck. No blood in the cavity of the arachnoid. A considerable quantity of clear fluid in the ventricles. Veins of Galen distended with blood. The left corpus striatum projected considerably further into the ventricle than the right. No hæmorrhage into or laceration of any part of the brain or medulla. Nothing was found to account for the want of expansion in the brain after the removal of the clot. The dura mater was found to be detached from the skull on the left side for a space several inches in diameter, extending forwards to the small wing of the sphenoid, downwards to the petrous portion of the temporal bone, upwards nearly to the middle line and backwards to the middle of the posterior fossa of the base of the skull. It was separated by some distance from the bone, and the space filled up by a soft black clot about the size of the hand. The middle meningeal artery was found to be torn, but not divided at a point opposite the starred fracture just behind and beneath the small wing of the sphenoid bone. A considerable distance below the trephine-wound, at a point in fact at which it would be impossible to reach it in any way, the lateral sinus was uninjured. No other injury of any kind; viscera healthy.

Case 2.—*Fracture of Parietal and Sphenoid—Separation of Dura Mater and Compression of Brain by Blood Clot—No Arterial Wound subsequently Discovered—Trephining—Relief of Compression—Death from Hyper-pyrexia.*

[For the notes of this case we are indebted to Mr. J. T. Gadsby, House Surgeon.]

J. R., aged seven, was admitted into University College Hospital at 2 p.m., on July 13, 1877. An hour before he had fallen from the top of a wall about eight feet high; had since not been thoroughly sensible, and was very much inclined to sleep. He was brought to the hospital to have his arm set, no complaint being made of his head. When first seen the boy told the dresser what was the matter, but so rapidly became unconscious that, when seen by the House Surgeon some five minutes after, no answer could be got out of him, though the patient cried, and was very irritable when disturbed, or when the injured arm was touched. Right pupil closely contracted, and left somewhat dilated and insensible. Pulse 60, rather soft. In left temporal fossa, just above zygoma, there was a distinct puffy swelling, and the left eye was more prominent than the right. No bruises or depressions could be felt anywhere else. There had been bleeding from the nose; none

from the ear. Bones of left arm fractured about one inch from lower end, with angular deformity; reduction not attempted. 2 p.m.: Ice-bags applied to head. Mr. Beck saw the case, but did not think symptoms sufficiently urgent to require interference, as the child struggled and cried when touched. Orders were given to watch it carefully, and, if the symptoms increased and coma supervened, to send at once for the surgeon. 3 p.m.: Patient breathing more rapidly; almost entirely insensible, but moves his limbs. 3.30: Two or three convulsions noticed by nurse of no definite character. 3.40: Patient is now somewhat cyanosed, and breathes at long intervals, respiration seeming obstructed by mucus. Coma complete, both pupils widely dilated and immovable. There was some delay in finding Mr. Beck, who was in another ward of the hospital; and at 3.55, when he saw the case, breathing had become much more infrequent, patient being once taken for dead, and the sheet thrown over the face. However, he gave a gasp after an interval of quite half a minute, and artificial respiration was immediately resorted to, and he came round. He was immediately picked up, and carried as quickly as possible into the theatre, and the operation commenced. The swelling on the left temporal fossa, which by this time had become much larger, was cut into and the bone bared, when blood was seen issuing from a small hole in it (vein), but no fracture. A crown of trephined bone was taken from over the course of middle meningeal, when the anterior edge of a clot was seen. A piece of bone was removed with the bone forceps from the back of the trephine-hole, more surface of clots being exposed. The finger introduced into the opening now made, discovered a large clot separating dura mater from the bone over whole of parietal lobe. This was scooped up with a small lithotomy scoop, when violent hæmorrhage took place, but no distinct bleeding-point could be discovered. During this time artificial respiration had to be resorted to at intervals; but as the brain filled up the place previously occupied by clot, the breathing became regular and pulse rapid. The patient was now propped up in the sitting posture, and ice applied to the side of the face, neck, and head; and, the bleeding seeming to cease in great measure, two or three stitches were put into lips of incision, a carbolised sponge lightly bandaged on, and patient was removed into private ward, with an ice-bag to the head. Just before leaving the theatre several futile attempts were made to vomit, and the limbs were freely moved. The right pupil was again contracted and movable, the left unaltered. 5 p.m.: Patient has taken feeders of two milk, and has smacked his lips as if conscious of the drink. Movement of limbs frequent, and easily excited by pinching. Once it appeared that patient tried to speak. 7 p.m.: Temperature 100·6°; condition unchanged, except that breathing has become somewhat more rapid. 10 p.m.: Breathing 60 per minute; pulse 170. Both pupils immovable.

July 14, 1 a.m.: Temperature 106° in axilla; profuse perspiration; patient cannot swallow; breathing 78, irregular, not stertorous; no voluntary motion of limbs, but reflex of eyelids good; pulse 180, irregular; right pupil one quarter, left three-fifths, both immovable. 1.45 a.m.: Temperature 105·8°; eyelids still sensible. 3 a.m: Death took place quietly, breathing becoming more and more irregular; temperature at 2.30 was 106·4°, and five minutes after death it had risen to 108·4°.

Autopsy.—Twelve hours after death: On removal of skull cap some remains of clot were found on left side behind trephine-aperture, and the dura mater was separated from skull to level of tentorium, and as far back as occipital bone; no arterial branch wounded. Fissured fracture was found passing vertically downwards, rather behind middle of left parietal bone, and about half an inch behind trephine-hole, then passing forwards separating temporal from parietal bone, it entered great wing of sphenoid, and then across body of sphenoid in front of anterior clinoid processes; no depression anywhere; the brain seemed perfectly healthy; no flattening of convolutions or other sign of pressure; and nothing to account for death found on section. Left ulna was found fractured about two inches from lower end, and the lower epiphysis of left radius was separated.

Case 3.—Fracture of Great Wing of Sphenoid—Wound of Middle Meningeal Artery—Separation of Dura Mater and Compression of Brain—Trephining—Relief, but subsequent Recurrence of Compression—Death.

L. C., female, aged twenty-five. The patient fell from the height of about 8 or 9 feet into a stable yard. She was admitted into this hospital August 15, 1877, about a quarter of an hour after the accident. On admission she was conscious, and related how the accident happened. Both pupils equal and contracted. Pulse 64. She was bleeding freely from a wound on the right side of the head, a little below the parietal eminence. While being examined she complained of being unable to sit up and lay back on the couch. After this she rapidly became unconscious, and the pulse gradually fell to 42. About a quarter of an hour later, the *right* pupil became widely dilated and insensible to light. The left was of moderate size and reacted feebly to light. She was seen by Mr. Beck about two hours after the accident. At 2 a.m. the condition was as follows:—Patient was unconscious, but moved her arms and legs feebly when disturbed. No definite signs of paralysis. If left to herself, she lay absolutely motionless. Breathing stertorous and irregular, occasionally ceasing for an interval of 10 or 15 seconds. In this respect she was rapidly getting worse. Right pupil widely dilated—insensible to light. Left, slightly dilated, acted very feebly, if at all, to light. The right eyeball was prominent, and the lids discoloured. No blood was showing beneath the conjunctiva. A little blood had trickled from the nose. No bleeding from the ear. Just below the right parietal eminence was a small irregular T-shaped wound, greatly contused. A very slight depression could be felt in the bone at this point. No fissure was detected. The wound was not bleeding freely. No particular fulness was to be recognised in the right temporal fossa. The wound was enlarged forwards, and the bone examined. A small dent was found in the bone at the point struck, but a fissure was not found. The wound was then enlarged still more forwards so as to expose the bone rather more in the direction of the branches of the middle miningeal artery. As the patient was evidently dying, a large trephine was applied immediately in front of and below the slight dent. At the time the operation was commenced the pulse was 42, slow and laboured. On removing the piece of bone the dura mater was seen at the upper part; but at the lower part of the opening was a dark mass of clot which bulged up into the wound. The finger passed downwards in the clot as far as it could reach. The clots were then removed, as far as possible, by means of a small lithotomy scoop. This was followed by very profuse hæmorrhage, the source of which could not be seen through the wound nor felt with the finger. The patient was immediately raised into the sitting posture, and an ice-bag applied over the side of the head and face. In a short time the bleeding ceased, but the space from which the clots had been removed with the lithotomy-scoop became rapidly filled again with soft coagulated blood. The immediate effect of the operation was to raise the pulse from 42 to 72, and the breathing improved. The left pupil contracted somewhat, and acted more readily to light. The right pupil did not alter at first. After waiting a little time, the symptoms of compression began slowly to return. The pulse fell to below 60, and the left pupil again became slightly dilated. The lithotomy-scoop was therefore again applied with considerable relief to the symptoms. A piece of lint soaked in carbolised oil was then laid lightly over the wound. The grave symptoms of compression did not again return, and at 4 a.m. the pulse was about 70, and the left pupil moderately contracted and acting to light. The breathing was laboured, but not stertorous. About one hour after, a large mass of clot which protruded from the wound was pulled away, but it was not necessary again to use the lithotomy-scoop. At 10 a.m. she was quite unconscious, very restless, so that she had to be watched to prevent her falling out of bed. Pulse 75. Pupils nearly equal; blood had appeared under the right conjunctiva. Respiration very laboured; much mucus about the pharynx and in the bronchi; occasional moaning; temperature not taken. At 2.45 the pupils were equal and of normal size; pulse 120; temperature 103°; respirations 36. At 5 p.m., temperature 103 6°; respiration worse. At 8 p.m. she died. Temperature at death 103°; shortly after it was 102°. There was no paralysis or dilatation of the pupils before death. She seemed to die rather from asphyxia than coma.

Post-mortem Examination.—On examining the skull the trephine was found to have been applied in the anterior and lower part of the parietal bone. Two large branches of the middle meningeal crossed the piece of bone removed. Owing to the trephine having been applied in the wound produced by the accident slightly enlarged forwards, the piece of the bone removed was rather above and behind the position of

the chief branch of the middle meningeal artery. Immediately behind the trephine-hole was found the commencement of an extensive fissured fracture. The main fissure ran through the great wing of the sphenoid between the foramen ovale and the foramen rotundum, and crossed the sella turcica, terminating a short distance from the groove for the left carotid. The sphenoidal sinus beneath was full of blood. From this a fissure ran at right angles through the orbital surface of the great wing of the sphenoid, and opposite this fissure somewhat abundant hæmorrhage had occurred into the fat of the orbit. Thus the bleeding from the nose and subconjunctival ecchymosis which had been supposed to indicate a fissure running through the orbital plate of the frontal bone and of the cribriform plate of the ethmoid, was in reality due to these two fissures, both belonging to the middle fossa of the skull. From the point struck a short fissure passed downwards and backwards into the squamous portion of the temporal bone, and another connected this with the first fissure, so that a large triangular piece of bone was loose. The coronal, sagittal, and lambdoidal suture were firmly united by bone. The clot between the dura mater and bone was found to have filled the whole middle fossa of the right side of the skull from the sphenoidal fissure in front to the petrous portion of the temporal bone behind. Inwards it extended to the three foramina in the great wing of the sphenoid. The amount of clot found was not great. It was nowhere more than about one-third of an inch in thickness. It was firm and adhered to the dura mater. The large anterior branch of middle meningeal was found to be completely torn across. As is so commonly the case, just before reaching the anterior and inferior angle of the parietal bone it lay in a bony canal. It seemed to have been torn across just at its exit from this, almost one inch below the trephine-hole. The dura mater was uninjured. On the left side exactly opposite the part struck were three small superficial lacerations on the temporo-sphenoidal lobe. From these a very small quantity of blood had escaped into the cavity of the arachnoid. In other respects the brain was perfectly healthy. It scarcely showed any perceptible flattening opposite the seat of the clot. Heart large; post-mortem clot on right side. Lungs distended with air, bulged out of the chest when the sternum was removed. Marked hypostatic congestion of the posterior parts. Bronchial tubes choked with frothy mucus. Kidneys greatly engorged with blood. Other organs healthy.

Remarks.—These three cases illustrate very well the diagnosis and treatment of hæmorrhage between the dura mater and bone. In each case consciousness was not lost immediately after the injury; for in the first the patient attempted to drive his van, in the second the child was brought to the hospital for its broken arm, without suspicion of any serious head injury, and in the third the patient described the nature of the accident after admission. In each case consciousness was lost, and the symptoms of compression set in within a very short time of the accident. This, of course, could only arise from hæmorrhage, as no inflammatory exudation could possibly occur in so short a time. Such abundant hæmorrhage could only arise from laceration of brain substance, or from the vessels of the dura mater. As in none of these cases there was any depressed fracture which could have caused direct laceration of the brain, the hæmorrhage, if from laceration, would have been seated exactly opposite the point struck, and the paralysis would have appeared first on the same side as the external injury. In none of these cases could this fact be used as a means of diagnosis. In two, the pupil became dilated first on the same side as the external injury, but there was no hemiplegia. The post-mortem showed that in both these cases dilatation of the pupil was due to direct pressure of the blood-clot upon the nerves as they enter the sphenoidal fissure. In both these also the same pressure acting on the cavernous sinus led to distension of the veins of the orbit and consequent prominence of the eyeball. In one this was increased by slight hæmorrhage into the orbit. The interval of consciousness would also negative any idea of the hæmorrhage being due to laceration, for such an amount of tearing of the brain-substance as would be required to yield such abundant hæmorrhage must of necessity be accompanied by prolonged loss of consciousness. In these three cases, therefore, hæmorrhage between the dura mater and bone was clearly indicated, and in two it was evident that it extended in the middle fossa to such an extent as to press on the cavernous sinus and the third nerve passing into the sphenoidal fissure; for the dilatation of the pupil was accompanied by projection of the eyeball, and occurred first on the injured side. In two of the cases marked fulness of the temporal fossa also served as a valuable aid to diagnosis. The diagnosis having been made, trephining was evidently the only chance of saving the patient's life. All three patients were on the verge of death when operated on, and the urgency of the symptoms was still increasing. The situation chosen for applying the trephine was over the course of the great anterior branch of the middle meningeal artery. In the case of the woman it was applied a little higher to avoid making a fresh wound. It would doubtless have been better to apply it lower down, as the clot would have been more easily removed. As soon as the operation was completed, the same result followed in each case. The clot was scooped out, and was immediately followed by a deluge of blood—so great as to give rise to a fear that the patient had been relieved of his' coma merely to die of hæmorrhage. In each case the source of this blood could be neither seen nor felt, so that none of the ingenious theoretical plans of arresting it which are recommended in text-books could be employed. In the first it ceased spontaneously after the loss of about half a pint of blood. In the two later cases it was very soon arrested by putting the patient in the sitting posture (of course watching carefully for signs of syncope), and applying a large ice-bag over the whole side of the head, face, and neck. Each case, however, showed that it is perfectly impossible to prevent the re-accumulation of clot to a certain extent, but as there is a large hole in the skull to serve as a sort of safety valve, the pressure is so greatly diminished as not to be incompatible with life. In order to ensure this it is necessary to make use of a large trephine, a small trephine hole would be almost useless. The small lithotomy scoop proved in each a most valuable instrument for removing the clot. It may be questioned, however, whether as the clots always re-form to some extent, it is worth while removing them at all, and whether it would not be enough to trust to the safety-valve action of the trephine hole. Probably it is better to remove the original clot, which from its slow formation and the pressure it has been exposed to is somewhat dense, and the expanding power of the brain seems hardly sufficient alone to expel it. On the other hand, the new formed clot after the operation is much more readily expelled. In all three cases death resulted. In the man, for some unexplained reason, the brain showed no tendency to expand, and the coma was as profound after the clot was removed as before. In this case the pressure had been very great, the clot at the time of operation being at least one inch and a half in thickness, and filling the whole middle fossa of the base of the skull. In the child death seemed to occur from hyperpyrexia. The coma had completely disappeared. It could swallow well, and seemed likely to recover. When the temperature suddenly ran up to 108°, the pulse became uncountable, and the respiration excessively rapid, and death quickly followed. In the same way in the woman there was a marked rise in temperature after the first few hours, and at the same time the pulse rose to 120, and the breathing became more embarrassed. This rise of temperature occurred much too early to be septic or inflammatory in its origin; moreover, there were no signs of inflammation or even of congestion of the membranes in either case. It must therefore have been of purely nervous origin, and its exact nature is difficult to explain. The source of the hæmorrhage in two cases was distinctly ascertained to be from the main branch of the middle meningeal artery. In the child the most careful search failed to show any large vessel wounded, and the hæmorrhage must have come from a multitude of small vessels. The hæmorrhage must, in the first place, have occurred along the line of fracture, and the dura mater have been thus stripped from the bone. As it was stripped off other small vessels were torn, which, in their turn, helped to furnish blood. This process is readily conceivable in the vascular dura mater connected with the growing bones of a child's skull.

Although all these cases terminated fatally, they are no discouragement to a repetition of the operation. The life of two of the three patients was certainly prolonged many hours, and in each case the patient was relieved from a condition absolutely incompatible with life, and given a chance of recovery, small though that chance seems to be. It is to be hoped also that statisticians, when estimating the mortality of the operation of trephining, will remember that in such cases as the above the operation has nothing whatever to do with the death of the patient.

SATURDAY, AUGUST 25, 1877.

ITALIAN HEALTH-RESORTS.

We purpose giving our readers some of the latest information we have been able to obtain about Italian health-resorts, and especially about some of those places on the Riviera, which, while they are well calculated to benefit those who can, and will do well to, go abroad in search of health, are less well known than Mentone and some other places; and we give first a sketch of Bordighera as a health-resort.

No. I.—Bordighera.

The most Western health-station of the Italian Riviera is Bordighera, which lies about three miles and a half from the Italian frontier at Ventimiglia. Its name is familiar to many persons who have never quitted England, for it is there that the novelist Ruffini has laid the scene of part of his admirable romance "Doctor Antonio." During the last seven or eight years Bordighera has been gradually gaining in favour as a winter residence for invalids, and hence a short account of it will not be unacceptable.

The town of Bordighera proper is of the same character, and apparently of much the same age, as most of the other coast towns. It consists of houses closely packed together on an eminence to the east of what may be called the plain of Bordighera. It has the usual narrow streets, rather smelly, and not overclean, here and there arched over, or else buttressed across, so as to weld all the houses more or less into one mass. A church, and a square with a battered marble fountain, comprise its chief objects of interest. If we take our stand just below the old town, where there is a terrace with a quaint wooden cross, with the carriage-road at our feet, we can form a good idea of the general position of the place. To the south and to the left, and within a few minutes' walk, we have the open sea, and as we turn from left to right the eye ranges over palms and olives to the houses of the new town of Bordighera or Borgo Marina (of which more by-and-by) out to sea. Then, as we still turn, there meet us in the distance, if the day is clear, the faint outlines of the coast from Toulon eastward to Cannes, then nearer in the west the bold Tête du Chien, above Monaco; the Mentone hills, the ridge on whose eastern slope Ventimiglia nestles, until at last, in the west-north-west, the eye is lost in the olive slopes which help to shelter New Bordighera from the northern winds. The near coast-line as far as Ventimiglia is clearly visible. The most striking feature of this view, putting the mountains out of consideration, is the enormous expanse of olive woods which lie stretched out between Bordighera and Ventimiglia. The whole plain to the west-north-west is a sea of olives. Nearer Bordighera palms are an occasional feature in the landscape; but the overwhelming mass of vegetation consists of olives. This view is probably almost unique in its way, and to it Bordighera owes much of its charm. It is, unfortunately, far from unlikely that many of these trees will before long be swept away, and their place taken by oranges or vines. The petroleum trade in America has seriously damaged the sale of olive oil; and other causes, such as the failure of the crop on several recent occasions, and the greater profits obtained from vine-culture, are year by year tending to destroy numbers of venerable trees. At Mentone such destruction is in many parts a *fait accompli*; and it is to be feared that the Bordighera district will also suffer.

If we now descend a little to an open space at the southern end of the point on which Old Bordighera stands, and turn with the face to the east, the remainder of the near coast comes into view. From right to left we have the Capo Nero east of San Remo, the Capo Verde to its west, the latter olive-coloured promontory completely protecting the little bay of Ospedaletti, with its village on the shore, from the easterly winds. Then comes a nearer stony ridge, which projects slightly into the sea, and which is thinly studded with stunted pines, and the shore bends round towards the south, the hills retreating, and leaving a broad strip of sandy beach to blend with the promontory on which we stand. Without entering into further detail, we may say that the view on the western side of Bordighera is far more striking than that on the east; and as far as the existence of Bordighera as a health-resort is concerned, it is only the district west of the old town and its cape which has any special interest. Descending among the olives from the old town in a south-south-westerly direction, in less than ten minutes the eastern extremity of the straggling street which forms New Bordighera is reached. It runs from Cape Bordighera (on which stands the old town) at a short distance from the seashore, for about half a mile from south-east to north-west. A sandy beach, the railway (which skirts the shore throughout this part of the coast), and some strips of garden, separate the nearest houses from the sea. There are shops of various kinds, including an English grocer's, to be found in the main street, which it should be noted is also the carriage-road from Bordighera to Ventimiglia; and where the houses get more and more isolated from each other by gardens and open ground, in the direction of Ventimiglia, we have on the sea side of the street the railway-station, and on the land side the two hotels of which at present Bordighera boasts—the south-eastern, opposite the station, the Hôtel de Bordighera; and the south-western, five minutes further on, the Hôtel d'Angleterre. To the north-north-east and east New Bordighera is sheltered by unbroken hills, which rise up about a quarter of a mile from the shore, and which are covered with olives and pines. Their height varies between about 400 and (at most) 1000 feet. At their base runs the remains of the old Roman road or Via Aurelia, which is about to be resuscitated and converted into a boulevard, and dense olive groves fill up the gap between them and New Bordighera. Here and there the red roof of a new villa stands out in strong contrast to the grey-green foliage, but the number of new houses is as yet small. The position of New Bordighera

is not the best that could have been chosen in a health point of view. The land on which the hotels and most of the houses stand is very little raised above the level of the sea, and in fact owes its existence to the gradual retreat of the latter southwards. Hence the ground is flat, and good drainage almost impossible. The present hotels are also too near the sea for persons of a nervous temperament, as the noise of the waves and exciting character of the air prevent their sleeping. The sea breeze, which is at times rather rough, is also much more felt close to the shore than a little way inland; in fact, under the olives it may not be felt at all. For all these reasons it would have been much better to have built close to the foot of the northern hills, or even a little way up their slope; and when the new boulevard is completed, it is probable that most of the future building will be carried out in the above situation. In reality the position of New Bordighera has been dictated rather by convenience than by sanitary considerations, the existence of the carriage-road and of a nucleus of a few old houses near the shore having been the chief inducements to continue to build in the present situation rather than further inland.

Turning now to the climate of Bordighera,(a) we find that it agrees in the main with that of most of the other health-resorts of the Riviera, and that it may be classed among the mildest of these. Old Bordighera is exposed to the east, south, and west; but New Bordighera is to a considerable extent protected from the south-east and easterly winds by its position under the flank of Cape Bordighera. On the north it is completely protected, and the outlines of the Alpes Maritimes to the north-west and west break the force of the winds from those quarters. It may be doubted whether Bordighera does not suffer most from the south-east winds, and Dr. Semeria, the resident Italian doctor of the parish, admits that the south-west winds (which, however, are warm and moist) sometimes blow with considerable violence. The size of the olives and the palms is, however, a sufficient proof that the climate is never severe. The orange and the lemon succeed very well at Bordighera, but at present so much ground is taken up by olives that the former are not cultivated nearly as largely as they might be. The capabilities of the climate will readily be appreciated by anyone who visits the garden of Monsieur Moreno, close to the old town, where a vast number of oriental and tropical plants flourish luxuriantly without any special protection.

The mean temperature of the winter months, according to Dr. Semeria, is nearly as follows:—November, 55° Fahr.; December, 53°; January 52°; February, 52°; March 54°; April, 57·5°. For the year 1876 the following maximum and minimum temperatures were recorded in each month:—

Month.	Maximum.	Minimum.
January	58°	38°
February	59	38
March	61	36
April	68	45
May	74	49
June	79	52
July	83	63
August	85	52
September	85	58
October	81	54
November	68	36
December	65	41

Snow and hail are of extremely rare occurrence, and, as at Mentone, the former melts almost immediately after it falls. The average number of rainy days, according to Dr. Semeria, is forty-five. The drinking-water is excellent, and is partly brought down from the hills by an aqueduct, and partly derived from springs. The soil on which New Bordighera is built is a loose sand; the rocks of which the near hills are formed appear to be chiefly sandstone of various degrees of fineness. Here and there masses of conglomerate are met with. The population of Bordighera with its surrounding hamlets exceeds 2500 inhabitants, and the statistics for the year 1876 give eighty-five as the total number of births, and forty-five as the total number of deaths. The latter figures are very striking, for they indicate an annual death-rate of about one to fifty-six or fifty-seven individuals. As might be expected from this statement, the inhabitants of the Bordighera district are extremely healthy. There are no endemic diseases of any importance, and epidemic diseases are very rare. Small-pox and cholera have never yet reached Bordighera; and a small epidemic of typhoid fever, which occurred some years ago, was clearly traced to pollution of the drinking-water, and ceased on the repair and purification of the aqueduct. According to Dr. Semeria, asthma, gout, and chronic rheumatism are very rare, and he has never met with a case of renal or vesical calculus, although he has the sole medical charge of the poor population. Among the diseases for which the climate of Bordighera is best suited are phthisis in its early stages, chronic bronchitis, laryngeal catarrh, pleurisy with retarded absorption of effusion, and chronic catarrh of the stomach and intestines. According to Dr. Schmitz, of Neuenahr, who practises at Bordighera in the winter, the climate also suits diabetes, chronic gout, and Bright's disease extremely well. It is not adapted to cases of phthisis attended with much fever, or with a tendency to hæmorrhage; in any case such patients must carefully avoid the immediate neighbourhood of the sea. Bordighera suits phthisical patients of a lymphatic temperament the best. Patients of any kind of a nervous or excitable constitution find the air too stimulating.

At present there is only a limited amount of accommodation at Bordighera, and it is calculated that there is only room for about 270 visitors. There are two pensions besides the hotels which have previously been mentioned—the Pension Anglaise, near the old town, and the Pension Victoria in New Bordighera; and about eighteen villas or houses which let apartments. Some of the villas are the property of English people, one of whom, a lady, has not only built, but endowed, a church in her grounds. Of the hotels, the older, Hôtel d'Angleterre, is close to the main street, and not very far from the sea. From all accounts it is well managed, and the proprietor, M. Lozeron, we found extremely obliging. There is a comfortable saloon, and a large dining-room. The only drawback to the hotel is its nearness to the carriage-road, and consequent liability to noise and dust. The Hôtel de Bordighera, which is newer, is exactly opposite the railway-station, and stands much further back from the sea than the Hôtel d'Angleterre, having a good-sized garden between it and the road. It is the larger of the two, and has three storeys, and two side-wings at right angles to the main building, but connected with it by glass passages in which people can walk during bad weather. The "pension" prices at both hotels range between ten and twelve francs per diem for board and room, according to the situation of the latter. There can be very little doubt that before long other hotels will spring up. For those who are unable to walk, carriages are attainable, but driving is only possible *with comfort* along the shore to the west and east of Cape Bordighera.

Nearer Ventimiglia a carriage-road has lately been made for a couple of miles northwards into the valley of Borghetto; but at present a drive along it can only be considered as a species of martyrdom. Still further west a better road, available for strong springs and persons used to bumping, runs up the picturesque valley of Dolce Acqua, and the town of that name is a favourite place for excursions. The pleasantest time for Bordighera is the spring, when the olive-terraces are covered with abundant flowers. At present the flora is a rich

*

(a) For the meteorological and other statistics here quoted we are indebted to a little work recently published, entitled "Bordighera in Gennaio, 1877, compilato da Federigo Hamilton."

one; but, as at Mentone, the advancing tide of foreign colonisation will probably, before many years have elapsed, have exterminated the rarest, and wrought havoc even among the commonest species. The walks about Bordighera at present offer great advantages to invalids. Leaving their hotel or villa, they at once find a shady and level retreat under the olives; or, if able to ascend the hills, they can do so without having to encounter any very steep ascents. For those who can walk well, the country behind Bordighera affords abundant scope for their activity, and the old brown villages nestling in the olives are well worthy of a stranger's visit. On the whole, whether as a passing or a permanent winter residence, Bordighera has many claims to attention. For the class of cases mentioned above there can be little doubt that it is well adapted, as well as for anæmic persons, or convalescents to whom sunlight and healthy air are the chief necessity. Remembering with Dr. Semeria, "*Che climi perfetti non se ne danno*"—that is to say, that "A happy valley of Avilion" has not yet been found,—those who do not expect too much of Bordighera, or any other southern health-resort, will get on the best and be the least disappointed.

A REVIEW OF THE SESSION OF PARLIAMENT.

We have little, if anything, to report as the result of progress made with the much-needed measures of Sanitary Reform. In fact, the past session of Parliament has been unusually barren of any comprehensive measure for ameliorating the condition of towns and villages in respect of drainage, water-supply, etc. The attempt of Mr. Sclater-Booth to consolidate and amend existing Public Health Acts for the better management of the metropolis, and a similar attempt of Sir M. Hicks-Beach on behalf of the Irish Public Health Acts, have both failed in consequence of strong opposition to the proposals of the Government towards the end of the Session. We must not omit to mention the only sanitary measure which has escaped the general "massacre"—viz., the "Canal Boats" Bill. This, having been hurried through both Houses of Parliament with unusual celerity, has now received the Royal assent. It proposes to deal with the migratory population living in boats trafficking our canals, to provide efficient inspection of the cabins used as dwelling apartments for the entire family, to regulate the amount of cubic space thus occupied, and to provide for speedy isolation of all cases of illness of an infectious nature, and proper subsequent disinfection. More stringent regulations will be made to prevent overcrowding in the basins and wharves of the canal when loading and unloading, and to avoid unnecessary detention at the more important termini. This act will come into operation on January 1, but it will not be enforced before January, 1879. All canal boats, barges, or flats will have to be registered, marked, and numbered in a prominent place by their owners, stating to which place the boat is registered as belonging, before they can be used as dwellings. Certificates of registration, fixing the number of persons allowed to dwell in a canal boat, barge, or flat, will be obtainable of the officer of registration. The boats will not be allowed to carry about infectious diseases, and provision will have to be made by the owner for proper ventilation and the separation of the sexes, and the boats will have frequently to be thoroughly cleaned, painted, and rendered habitable. Any person duly authorised by the proper authorities will have power to enter these boats and detain them until all the law requires is carried out, and the master of the boats shall, if requested by the officer, produce to him the certificate of his registry. A child living in a canal boat, barge, or flat is to be subject to the compulsory clauses of the Education Act which are in force at the place at which the boat is registered as belonging to. Power is given to canal companies or associations to appropriate any portion of their funds for the establishment or maintenance of schools wherein the children living in canal boats may be lodged, maintained, and educated. The master, and also the owner of a canal boat, barge, or flat will be liable to a fine of 20s. for each time the boat is used as a dwelling contrary to the act; and fines are specified for breaches of the act, which does not extend to Ireland or Scotland.

In giving a general *resumé* of the session, we must not forget to mention that the medical element in the House of Commons is making itself increasingly felt, although there are still but two or three medical men in Parliament. As an illustration, we may mention the frequent debates at the early part of the session upon the prevalence of scurvy in the Arctic Expedition, and the strong comments of Dr. Lyon Playfair and others upon the grave error of Captain Nares in deciding to set his judgment of the prophylactic virtues (or supposed failings, rather) of lime-juice in scurvy against that of the Director-General of the Navy, the naval medical officers of the Expedition, and the universal experience of all Arctic explorers. A somewhat feeble reprimand of his conduct was at last extorted from the Lords of the Admiralty when a Select Committee appointed to inquire into the subject had given in their report decidedly against him.

At a subsequent period of the session Dr. Playfair endeavoured to extort from the Government a promise that the lesson thus dearly learnt should be productive of practical good in the fitting out of all the vessels of the Navy, whether intended for Arctic regions or elsewhere; but Mr. Ward Hunt briefly replied that, as another Arctic expedition was not at present contemplated, there would be no necessity to issue fresh regulations to the commanders of the Navy.

The status, pay, and retiring allowances of medical officers of the Army have been made the subject of a debate, and fresh regulations have been issued by the War Office making this branch of the service somewhat more attractive.

Numerous cases of repeated prosecutions for non-compliance with the Vaccination Acts have been the subject of comment in the House of Commons. It has been thought undesirable to prosecute the same person frequently and at short intervals—(1) because the fines are paid by the Anti-Vaccination Society; and (2) because the prejudiced opponent being made a martyr of, for the time being, the "fine" remedy is found worse than the disease. Two or three children having died of erysipelas after vaccination, Mr. J. Netten Radcliffe was sent down to the Midland Counties, where the disease was prevalent. He found as the result of his inquiry other conditions quite sufficient to account for the fatal issue apart from the much-abused vaccination.

The spread of cattle plague in Yorkshire, and also in the neighbourhood of London, especially in some of the large suburban dairies, necessitated the reintroduction of stringent measures for effectually stamping out the disease. All movements of cattle have been forbidden in the infected districts, and the disease seems now fully under control. A large number of animals have been slaughtered.

Great alarm was caused by the reported unsanitary condition of the War Office and the new Government offices in Whitehall. An unusual proportion of clerks in these offices was reported as absent on account of illness, and the result of a careful examination proved that the drainage, especially of the new buildings, was not properly constructed. The system of drainage in each case is being carefully remodelled, and we trust that these buildings, in which are congregated so many of the rising generation, will be rendered as sanitarily perfect as science can make them.

This meagre summary is all that we have to report of progress made during the past session of Parliament in matters interesting to the medical profession.

THE THEORY AND PRACTICE OF THE PROPAGATION OF DISEASE.

A report by Dr. Thorne has recently been made to the Local Government Board with respect to the health and sanitary condition of a district of Norfolk not far from King's Lynn. The report shows the district to be unsavoury in the extreme, but the example which it affords of the perversity of certain rural bodies conveys a lesson we cannot well pass by. One or two villages have been for a long time infested by scarlatina, and it was to inquire into the causes leading to this persistence that Dr. Thorne was chiefly sent. The chief site of the epidemic was a village named Great Massingham, and another not far off, both situate in the Freebridge Lynn Union. The former village was supplied by water partly from deep chalk wells, partly from surface wells in the superficial gravel. Drainage, we may say, did not exist. Liquid sewage was disposed of anyhow, and some of the privies, which were only supplied in scanty proportions to the houses, were unapproachable for filth. Was it then to be wondered at that scarlet fever should hang about such a place once it had found admission to such a paradise of filth? But where was the officer of health all this time? men will say; and well may they iterate the question. In 1873 the Local Sanitary Authority appointed a medical officer of health and an inspector of nuisances. The salary of the former was £100 a year; that of the latter the same, only he was to devote his whole time to the work. All this was very well, but, unfortunately, these appointments were only made for one year, and the holders of the offices seem to have done their work so well that by the end of the year the local body thought they might now dispense with these expensive officers, and return to the cheap and nasty style. Accordingly, the medical incumbent was invited to retain the name of medical officer of health, but was only to interfere when called upon to do so, and to be paid for each piece of work as it arose. The inspector of nuisances was dismissed, and his work distributed among the relieving officers, who, however, were carefully left in their native ignorance as to the nature of their new duties. Under the circumstances it would surprise nobody that the medical gentleman has only been thrice employed in as many years, and that he has been invariably called in too late to be of real service. Such savings on the part of small sanitary authorities will in course of time force Government to take measures to have all sanitary work done in an efficient manner. To this end there is nothing more important, as it seems to us, than a more general dissemination of the principle of fairly large united areas, which will ensure comparative independence to the medical authority.

THE WEEK.

TOPICS OF THE DAY.

The Act for the supervision of Canal Boats will come into operation on January 1 next, but it will not be enforced before January, 1879. All canal boats, barges, or flats, will have to be registered, marked, and numbered in a prominent place by their owners, stating to which place the boat is registered as belonging, before they can be used as dwellings. Certificates of registration fixing the number of persons allowed to dwell in a canal boat or barge, will be obtainable of the officer of registration, for which a small fee will be charged. The boats will not be allowed to carry about infectious diseases, and provision will have to be made by the owner for proper ventilation, and the separation of the sexes; and the boats will have to be frequently cleansed thoroughly, painted, and rendered habitable. Any duly authorised person will have power to enter these boats, and detain them until all that the law requires is carried out. A child living in these boats is to be subject to the compulsory clauses of the Education Act which are in force at the place at which the boat is registered. Power is also given to canal companies or associations to appropriate any portion of their funds for the establishment and maintenance of schools, wherein the children living in canal boats may be lodged and educated. When fully in working order this very useful piece of legislation will, in fact, tend greatly to increase the sanitary condition of certain portions of the country traversed by canals.

A rather singular case of suicide was the subject of inquiry before Dr. Diplock, last week. A Mr. Joseph Freeman, aged fifty-seven, who was an inmate of Dr. Stillwell's private lunatic asylum, at Hillingdon, near Uxbridge, recently died from injuries he had inflicted on himself, previous to October 7 last, the date of his admission to the asylum. The evidence showed that deceased's mania was of a somewhat peculiar nature. He was impressed with the idea that he could make incisions in his flesh, and otherwise surgically operate upon himself without receiving any injury, and, following this out, he permanently injured himself in such a serious manner that he was always in great suffering. During his residence at Dr. Stillwell's he underwent several operations, but, as was feared from the first, his case was a hopeless one. The verdict of the jury was that deceased died from injuries inflicted by his own hand while he was of unsound mind.

Professor Wanklyn has just been elected to the chair of chemistry at St. George's Hospital, vacated by the death of Dr. Noad, F.R.S., who has filled the post for the past thirty years. Professor Wanklyn will, it is announced, deliver a course of lectures on physics and chemistry during the ensuing session.

At a recent meeting of the Lambeth Vestry complaints were made as to the quality of the water supplied by the Southwark and Vauxhall Company, and special allusion was made to Dr. Frankland's report as to "moving organisms in the water." The Medical Officer was therefore instructed to make a report, and such report was recently submitted to that Vestry. It states that it must not be inferred that the water is teeming with insect life visible to the naked eye; at the same time if a quantity of water be set aside and allowed to deposit its suspended matter, and some of this be placed under the microscope, low forms of organic life are plainly visible, most of them being so minute as to defy the finest filter. Their presence is significant as being indicative of organic impurity, for without this they could neither be developed nor sustained. So long as the water supply is taken from the Thames, we shall ever be open, at certain seasons, to inconveniences which no amount of caution can prevent, viz., by the winter floods rendering it turbid and undrinkable, and by the development of these microscopic organisms in the summer time. On the other hand, the Thames water, when pure, is so suitable for all purposes that if it were possible to rid it of its organic impurity and to insure its perfect filtration, we should have water even preferable in some respects to that coming from the Kent and Colne Valley. But it has to be borne in mind that, with a rapidly increasing population, there will be a proportionately increased demand, so that the possibility of ever getting purer water from the Thames seems problematical. At certain times the demand is so great that there is not sufficient time to admit of subsidence and filtration before delivery. Large additional reservoirs for subsidence are needed to improve the quality of the water. Little advantage would accrue from seeking a water-supply purer than the present if the plan of storing water in cisterns placed in the most exposed and inaccessible situations were still adhered to. What is really needed is a separate supply of water for drinking and culinary purposes. While our drinking water is drawn from the same source which supplies our baths and washhouses, the wonder

is that the water is as pure as it is. It was decided to defer the discussion of the report until the intention of the Metropolitan Board of Works to purchase the interests of the London Water Companies was more fully known.

Last week a Parliamentary volume of nearly 600 folio pages was issued, containing the evidence given before the Committee on the Lunacy Laws. The Committee report as follows:—"The Committee, having regard to the short time which remains for consideration of their Report during the present session, resolve to report the evidence to the House, and to express an opinion that the Committee should be re-appointed next session for the purpose of agreeing upon a report to be presented to the House."

The Hospital Saturday collection in aid of the metropolitan hospitals has been appointed this year to take place upon September 1 next. The street collections, which have always been a feature of this movement, are again to be resorted to upon the present occasion.

A memorial has been presented from the Metropolitan and National Nursing Association for providing trained nurses for the sick poor, to the Lord Chancellor, who has been directed by the Queen to frame rules for the future administration of the Royal Hospital of St. Katherine by the Tower. The memorialists submit that it would be strictly in accordance with the intention of the founders and with the past history of the Hospital if a nurses' home for the benefit of the sick poor were established in connexion with it in the East of London, and if a portion of its funds were applied to the maintenance of such an institution; and that in the event of his lordship thinking fit to establish one or more nursing homes in connexion with the Hospital, the said memorialists are prepared to undertake the management and supervision of such homes under such rules as might be deemed suitable.

Her Royal Highness the Princess of Wales has, by her own desire, been elected a "Dame Chevalière" of the Order of St. John of Jerusalem, a philanthropic society presided over by the Duke of Manchester.

Evidence of the early practice of cremation in this country was recently discovered at Abergynotwyn, where some workmen in digging a foundation came upon a grave about four feet long, sixteen inches long, and eighteen inches deep. The sides were of the ordinary slate of the neighbourhood. In it were found two vessels containing ashes and burnt bones. Believing the urns contained treasure, the workmen broke them to pieces. From the appearance of the lines and marks upon some of the fragments there is reason to suppose the vases to have been of Roman workmanship, but the roughness of the material and the imperfect baking make it probable that they were relics of the ancient Britons. One of the urns was thicker in formation than the other, and also darker in colour, and perhaps ten inches in diameter when entire.

A life was last week sacrificed to the criminal recklessness of dropping matches and fusees about the public footways. From evidence taken before Mr. Donaldson at the London Hospital, it was shown that the wife of a mechanical engineer living at Gough-square, Poplar, was walking along Stainsby-road on the 14th inst., when she was observed by a woman who was passing to become suddenly enveloped in flames, which consumed nearly the whole of her clothing. She was fearfully burnt all over the body, and was conveyed to the London Hospital, where she died the same evening. Although so seriously injured deceased was able to state that whilst walking on the pavement she trod upon something which ignited her dress.

This week the Countess of Leicester laid the foundation-stone of the new buildings connected with the Hunstanton Convalescent Home for the Eastern Counties, which are to be erected as a memorial of thankfulness for the recovery of the Prince of Wales in 1872.

On Monday last, under arrangements made between the Vestry of St. Luke's and the owners of the property, a most important sanitary improvement was carried out in the metropolis. Acting under the provisions of an Act of George III., which empowers vestries and other local bodies to acquire property for the purposes of sanitary improvements, the Vestry of St. Luke's and the Metropolitan Board of Works decided, at a joint cost of £100,000, to widen Golden-lane from Old-street to the City boundary to a space of fifty feet, and at the same time to construct a new street running at right angles to Golden-lane through Bridgwater-gardens to Aldersgate-street. This scheme involved the destruction of a number of low courts in that neighbourhood described by the sanitary inspector of St. Luke's as "the most infamous den in the metropolis, a hotbed of filth and contagion, consisting almost exclusively of houses of ill-fame of the lowest type, and occupied by the most desperate section of the criminal classes, both male and female." The demolition of this block has now been completed, and irrespective of the social aspect of the question, its removal will enhance the sanitary condition of the neighbourhood, and prove a great saving to the pockets of the ratepayers.

THE HEALTH OF HACKNEY.

The report on the sanitary condition of the Hackney district for the year 1876, by Dr. John W. Tripe, the Medical Officer of Health for the district, as might be expected, treats principally on the chief sanitary event in that neighbourhood, namely, the outbreak of the small-pox epidemic of the past year, which visited the east-end of the metropolis with so much severity. In his history of the outbreak Dr. Tripe observes that the first case report to him occurred in Hackney on July 24, in the person of a servant; in this case the disease was contracted outside the district. The second case happened in Banbury-terrace, nearly a quarter of a mile away from the first. The next was at Upper Clapton, also a servant, on September 16; the next in Mare-street on the 18th; another on the 26th in Brooksby's-walk; and on October 6, when the epidemic fairly commenced, cases occurred in Homerton, South Hackney, and Kingsland. From this time the progress of the disease in the various districts is shown by the following facts:—By the end of the year notice had been received of 506 cases, of which 65 had occurred in Hackney, 61 in Clapton, chiefly near Homerton, 65 in Hackney-wick, 80 in South Hackney, 24 in Dalston, 14 in Kingsland, 7 in De Beauvoir Town, 4 in Stoke Newington, 1 in West Hackney, and 1 in Stamford-hill. In the first week in December the highest number of Hackney patients in the small-pox hospitals was attained, viz., 160, and from this the number gradually decreased to 93. Dr. Tripe advances the proposition that the comparative mortality from zymotic diseases is not a better proof, under existing legislation and practice, of the sanitary condition of a locality than are the deaths from all causes; and he points out the fallacy of terming zymotic diseases "preventable," as though medical officers of health had the power of preventing deaths from these causes. He admits that small-pox is preventable to a great extent by vaccination, and that scarlet-fever, measles, etc., may be reduced by proper sanitary measures, but he objects to the word preventable being applied, as though *every* death from these diseases could be prevented.

LUNACY IN SCOTLAND.

It appears, from the report of the Commissioners of Lunacy in Scotland for the past year, that the increase in the admissions both of private and pauper patients into establishments during 1875 and 1876 has been very large. For 1876 the

admissions show an increase of 31 per cent. on those of 1858, while the increase of population has been slightly more than 16 per cent. Except the last two years, the admissions of private patients have indicated no increase. The Commissioners suggest that, possibly, the large increase in the number of pauper patients admitted in 1875 and 1876 may, to some extent, be accounted for in respect to the grant from Government towards the support of pauper lunatics. No doubt the relief of local taxation in such cases has induced local authorities to include among lunatics persons who should not have been so disposed of. The hypothesis, however, that the large increase of pauper lunatics during the last two years is due to the grant may, or may not, hold good. Evidently, further experience is necessary before any satisfactory conclusion can be arrived at on the matter; nevertheless, the Commissioners have seen fit in a large number of cases to institute inquiries as to the placing persons on the lunatic roll whose insanity was apparently slight, and whose previous treatment was that of an ordinary pauper.

NEW ACT ON WATER SUPPLY.

An important Act on water supply has just been printed, 40 and 41 Vict. c. 31, to give further facilities to landowners of limited interests in England, Wales, and Ireland, to charge their estates with the expenses of constructing reservoirs for the storage of water. It recites that in many places it would greatly conduce to the establishment of a plentiful supply of pure water to the inhabitants of villages and towns, and to the industrial requirements of the locality, if facilities were given to landowners of limited interest to charge their estates, subject to the approval of the Inclosure Commissioners, with sums expended by them in constructing reservoirs and other work for the supply of water. In a number of sections the way the Act is to be adopted is explained, and if carried out a plentiful supply of water may be expected both for villages and towns.

The New Hôtel-Dieu.—This grand edifice is now opened for patients, and even a little too soon after such long delays, as the walls are said to be damp. Built on the most gigantic scale by Baron Hausmann, as an ornament to Paris, the remonstrances of the profession succeeded after it was finished in getting a portion of it removed, and the accommodation reduced to 400 or 450 beds. The building, as it now stands, has cost the municipality nearly 40,000,000 frs., or about 100,000 frs. (£2500) per bed.

Death of M. Conneau.—"We announce with regret the death of Dr. Henry Conneau, who has just succumbed to a prolonged illness in Corsica. Dr. Conneau was born at Milan, of French parents, in 1803, and we may say that the life of our worthy confrère has been a life of affection and devotion for one family—first for Louis, King of Holland, whose secretary he was, then for Queen Hortense, upon whom he lavished the most assiduous care until her death; and lastly for Louis Napoleon, whose bad and good fortune he participated in until the end. His conduct at the prison at Ham, and the part he took in the escape of Louis Napoleon, constitute a historic trait which will always do honour to the medical profession. On the establishment of the second empire, he was appointed Chief Physician to the Emperor. He was elected twice a member of the Corps Legislatif, and afterwards nominated Senator and Grand Croix of the Legion of Honour. During the second empire also, he fulfilled the office of dispenser of the charitable donations from the civil list, and 1,200,000 francs devoted to this object, passed through his honest and pure hands. Dr. Conneau was a modest man, of simple tastes, avoiding all noise and ostentation; good hearted, willing to be of service, and very anxious to be useful to his confrères. He entirely rejected the proposition made by his too zealous and ardent friends to revive an ordinance of the Academy of Medicine, constituting the first physician of the king the honorary president of this learned body. He only accepted the post of free associate, and even that he never filled."—*Union Méd*, August 21.

ADDRESS OF THE PRESIDENT

OF THE

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Delivered at Plymouth, Wednesday, August 15.

By ALLEN THOMSON, M.D., F.R.S., LL.D., etc.

The distinguished President at the beginning of his address alluded to the enormous changes which have come over men's minds since last the Association had visited Plymouth. This was especially notable with regard to the prevalent theories as to the origin of living beings and the fixity of type which was supposed to characterise them as compared with the notions now entertained as to their constant variation—in short, with all the ideas comprehended in the words evolution or development. Closely connected with this were the doctrines commonly entertained as to the origin of life. On this point the speaker's views were adverse to those entertained by Bastian and his followers, maintaining, as he did, that in no instance had it been conclusively proved that an organism originated *de novo* when due care had been taken to exclude all source of error. This view of the origin of living beings has its practical outcome in the germ theory, as seen in the so-called antiseptic system of surgery, to which the speaker alluded. Turning thence to the life history of higher organisms, the President spoke of the development of plants from seed and spore. This led him on to the discussion of the structure and properties of the ovum as seen in the higher animals, which constituted the substance of his address.

The germinal element, from which, when fertilised, the new animal is derived, is contained within the animal ovum or egg—a compact and definite mass of organic matter, in which, notwithstanding great apparent variations, there is maintained throughout all the members of the animal kingdom, excepting the protozoa, which are destitute of true ova, a greater uniformity in some respects than belongs to the germinal product of plants.

Usually more or less spherical in form, the animal ovum presents the essential characters of a "complete cell," in the signification given by Schwann to that term. The germinal substance is enclosed by an external vesicular membrane or *cell-wall*. Within this covering the *cell-substance*, generally named yolk or vitellus, from the analogy of the fowl's egg, consists, to a greater or less extent, of a mass of protoplasm, and imbedded in this mass, in a determinate situation, there is found a smaller internal vesicular body, the *germinal-vesicle* or nucleus, with its more or less constant or variable *macula* or nucleolus.

Now the first thing which strikes us as remarkable connected with the ovum is the very great variation in size as compared with the entire animal, while in all of them the same simple or elementary structure is maintained. The ovum of mammals is, for example, a comparatively small body, of which the average diameter is about the $\frac{1}{150}$th of an inch, and which consequently scarcely weighs more than a very minute fraction of a grain, which may be calculated perhaps only at the $\frac{1}{12000}$th part. And further, in two animals differing so widely in size as the elephant and the mouse, the weights of which may be held to stand towards each other in the proportion of 150,000 to 1, there is scarcely any difference in the size of the mature ovum.

On the other hand, if we compare this small ovum of the mammal with the yolk of the egg in the common fowl, the part to which it most nearly corresponds, it may be estimated that the latter body would contain above three millions of the smaller ova of a mammal.

The attribute of size, however, in natural objects ceases to excite feelings of wonder or surprise as our knowledge of them increases, whether that be by familiar observation or by more scientific research. We need not, at all events, on account of the apparent minuteness of the ovum of the mammifer, or of any other animal, have any doubts as to the presence of a sufficient amount of germinal substance for explaining in the most materialistic fashion the transmission of the organic and other properties and resemblances between the parent and offspring. For we are led to believe by those

who have recently given their attention to the size of molecules composing both living and dead matter that, in such a body as this minute ovum of the mammal, there may be as many as five thousand billions of molecules, and even if we restrict ourselves to the smaller germinal vesicle, and, indeed, to the smallest germinal particle which might be made visible by the highest microscopic enlargement, there are still sufficient molecules for all the requirements of the most exacting material biologist.(a)

This great disparity of size is, however, connected with an important difference in the disposition of the yolk-substance, according to which ova may be distinguished as of two kinds, the large- and the small-yolked ova, between which there are also many intermediate gradations. The larger yolked ova belong to the whole tribe of birds, scaly reptiles, osseous and cartilaginous fishes, and the cephalopods among the invertebrates; and are distinguished by the strictly germinal part or protoplasm being collected into a small disc, known familiarly as the cicatricula of the fowl's egg, and to be seen as a whitish spot on that side of the yolk which naturally floats uppermost; while the rest of the yolk, of a deeper yellow colour, contains a large quantity of vitelline granules or globules of a different chemical nature from the protoplasm.

The phenomena of embryonic development are, in the first instance at least, confined to the germinal disc, and the rest of the yolk serves in a secondary or more remote manner to furnish materials for nourishment of the embryo and its accessory parts. Thus we distinguish the germinal from the nutritive or food-yolk, or, as the younger Van Beneden has named them, the *protoplasm* and the *dutoplasm*.

In the smaller ovum of the mammal, on the other hand, it seems as if the whole, or nearly the whole, of the yolk were protoplasmic or germinal. There may be some admixture of yolk-granules, but there is not the marked separation or limitation of the protoplasmic substance which is so distinct in birds, and the earliest changes of development extend to the whole component substance of the yolk—or, in other words, the yolk is entirely germinal. Hence, some have given the names of *meroblastic* and *holoblastic*, meaning partially and entirely germinal, to these two contrasting forms of ova. There are many of the invertebrate animals of which the ova present the same entirely germinal arrangement as in those of mammals, and the *amphioxus* may be included in the same group.

The amphibia stand, in some measure, between the two extremes; the purely protoplasmic or germinal part occupying one side, and the nutritive or vitelline the other. But among the invertebrates the gradations are often such as to make it difficult to determine under which group the ova should be placed.

The genesis or formation of the ovum itself, if it be considered with reference to its first origin, carries us back to a very early period of the formation of the parent in which it is produced; and it is one of the most interesting problems to determine what is the source of the cells in the parent from which the ova originally spring. All that I can venture to say at present in regard to this point is, that the primordial ova or germs appear in the parental body while still embryonic, at a very early period of its development, and clearly derive their origin from a deeply-seated part of the formative cells which are undergoing transformation into the primitive organs; but the exact seat of the origin of the reproductive cells is still a matter of doubt.

When the ovum attains its full maturity in the ovary, the seat of its formation within the parent, it is separated from that organ, and when perfected proceeds to undergo embryonic development; a marked difference in this respect existing between the germinal product of the higher plants and animals.

The period of maturation of the ovum is marked in the greater number of animals by a series of phenomena which have generally been interpreted as the extrusion or absorption of the germinal vesicle; and various observers have actually traced the steps of the process by which that vesicle appears to leave the yolk and is lost to sight, or has passed into the space between the yolk and its membrane in the shape of the peculiar hyaline bodies named the *polar* or *directing* globules. But recent researches, afterwards to be referred to, tend to show that some part at least of the substance of the germinal vesicle remains to form, when combined with the fertilising element, the newly endowed basis of future development.

Among the earliest changes to which the perfect animal ovum is subject, I have first to refer to the segmentation of the germ, a series of phenomena the observation of which has been productive of most important results in leading to a comprehension of the intimate nature of the formative process, and which is of the deepest interest both in a morphological and histological point of view. This process, which was first distinctly observed by Prevost and Dumas more than fifty years ago, and is now known to occur in all animal ova, consists essentially in the cleavage or splitting up of the protoplasmic substance of the yolk, by which it becomes rapidly subdivided into smaller and more numerous elements, so as at last to give rise to the production of an organised stratum of cells out of which by subsequent changes the embryo is formed.

The process of yolk segmentation may at once be distinguished as of two kinds, according as it affects in the small-yolked ova the whole mass of the yolk simultaneously, or in the large-yolked ova is limited to only one part of it. The cleavage process, in fact, affects the germinal and not the food-yolk; so that to take the two most contrasting instances of the bird and mammal to which I have before referred, it appears that while the mammal's ovum undergoes entire segmentation, this process is confined to the substance of the cicatricula or germinal disc of the bird's egg. This process is essentially one of cell-division, but it is also in some measure one of cell-formation. The best idea of its nature will be obtained from a short description of the total segmentation occurring in the mammal's ovum.

When, as before mentioned, the germinal vesicle has been in part extruded or lost to sight, the whole yolk-substance of the ovum forms a nearly uniform mass of finely granular protoplasm, inclosed within the external cell-membrane. Within a few hours later a clear nucleus has arisen in this mass. To this more definite form of organisation, assumed by the germinal substance of the future animal which is about to be the subject of the segmenting process, the name of the first segment-sphere may be given.

By the process of cleavage, which now begins, the first segment-sphere and its nucleus undergo division into two nucleated spheres of smaller size, the whole substance of the yolk, in a holoblastic ovum, such as that of the mammal, being involved in the segmenting process.

The second stage of division follows after the lapse of a few hours, and results in the formation of four nucleated segment-spheres; and the process of division being repeated in a certain definite order, there result in the succeeding stages, that is, the third, fourth, fifth, and up to the tenth, the numbers of 8, 12, 16, 24, 32, 48, 64, and 96 nucleated yolk-spheres, germ-spheres, or formative cells.

In the rabbit's ovum the tenth stage is reached in less than three days; and as during that time the size of the whole ovum has undergone very little increase, it follows that the spheres of each succeeding set, as they become more numerous, have diminished greatly in size. The segment-spheres are all destitute of external membrane, but are distinctly nucleated; and their protoplasmic substance is more or less granular, presenting the usual histological characters of growing cells.

By the time that segmentation has reached the seventh or eighth stage, when thirty-two or forty-eight spheres have been formed, the ovum has assumed the appearance of a mulberry, in which the outer smaller spheres, closely massed together, project slightly and uniformly over the whole surface; while the interior of the ball is filled with cells of a somewhat larger size and a more opaque granular aspect, also resulting from the process of segmentation.

Already, however, the mutual compression of the spheres or cells on the surface, by their crowding together, has led to the flattening of their adjacent sides; and by the time the tenth stage is reached, when the whole number of the cells is about ninety-six, the more advanced superficial cells having ranged themselves closely together, form a nucleated cellular layer or covering of the yolk, inclosing within them the larger and more opaque cells, derived like the first from segmenting process. In a more advanced stage, the deeper cells now referred to having also taken the form of a layer, there results at last the bilaminar blastoderm or embryonic germinal membrane.

(a) According to a calculation made by Mr. Sorby, the number of molecules in the germinal vesicle of the mammalian ovum is such that if one molecule were to be lost in every second of time the whole would not be exhausted in seventeen years. See Address to the Microscopic Society in *Journal of Microscopical Science*, vol. xv., page 225, and *Nature*, vol. xiii.' page 332. See also Darwin on "Pangenesis," in his work on "Variations," etc. (1868), vol. ii., page 374, and the Review by Ray Lankester of Haeckel's work, "Perigenesis der Blastidule," etc., in *Nature* for 1876, page 235, and Ray Lankester's Essay on "Comparative Longevity," 1870.

The process of partial segmentation, such as occurs in the bird's egg, though perhaps fundamentally the same as that of the mammal previously described, stands in a different relation to the parts of the whole yolk or egg, and consequently differs in its general phenomena. The segmentation is mainly restricted in the meroblastic ova of birds to the germinal disc or cicatricula, and does not immediately involve any part of the larger remainder of the yolk. This takes place during the time of the descent of the yolk through the oviduct, when the yolk is receiving the covering of the white or albumen, the membrane and the shell, previous to being laid—a process which, in the common domestic fowl, usually occupies less than twenty-four hours. Corresponding essentially to the more complete segmentation of the mammal's ovum, the process leads to the same result in the production of two layers of nucleated formative cells in the original seat of a protoplasmic disc; a bilaminar blastoderm resulting as in the mammal's ovum, though in a somewhat different relation to the yolk.

I will not fatigue you with a description of the details of these phenomena, interesting as they may be, but only mention generally that they consist in the formation of deep fissures running from the surface into the substance of the germ-disc. The first of these fissures crosses the disc in a determinate direction, dividing it into two nearly equal semicircular parts. In the next stage another fissure, crossing the first nearly at right angles, produces four angular segments. Then come four intervening radial fissures, which subdivide the four segments into eight; and next afterwards the central angles of these eight radial segments are cut off from their peripheral portions by a different fissure, which may be compared to one of the parallels of lattitude on the globe near the pole where the radial or *longitude* fissures converge. And so thereafter, by the succession and alternation of radial and circular clefts, which, however, as they extend outwards, come soon to lose their regularity, the whole germinal disc is divided into the two layers of nucleated cells, constituting the blastoderma or germinal membrane of Pander and all subsequent embryologists. (b) If a laid egg be subjected to the heat of incubation for eight or ten hours, the cicatricula, now converted into this segmented blastoderm, is found to be considerably expanded by a rapid multiplication of its constituent cells, and in as many more hours, by further changes in its substance, the first lineaments of the chick begin to make their appearance. Similar changes affect the blastoderm of the mammal, and thus it appears that the result of segmentation, in the bird as well as in the mammal and other animals, is the production of an organised laminar substratum, which is the seat of the subsequent embryonic development.

I must still request your attention to some details connected with the process of segmentation, which bear upon the question of the origin of the new cells, and on which recent research has thrown a new and unexpected light.

With respect to the nature of the first segment-sphere of the ovum and the source of its nucleus, as well as of the other segment-spheres or cells which follow each other in the successive steps of germ-subdivison, it appears probable from the researches of several independent observers, and more especially of Edward Van Beneden and Oscar Hertwig, that in the course of the extrusion of the germinal vesicle a small portion of it remains behind in the form of a minute mass of hyaline substance, to which Van Beneden has given the name of *pronucleus*, and that, as the result of the fertilising process, there is formed a second similar hyaline globule or pronucleus, situated near the surface, which gradually travels towards the centre and unites with the first pronucleus, and that these two pronuclei, being fused together, form the true nucleus of the first segment sphere. According to this view, the original germinal vesicle, when it disappears, or is lost to sight, as described by so many embryologists, is not dissipated, but only undergoes changes leading to the formation of the new and more highly endowed nucleus of the first embryonic or segmental sphere. It further appears that the subdivision of each segmenting mass is preceded by a change and division of the nucleus, and that this division of the nucleus is accompanied by the peculiar phenomenon of a double conical or spindle-shaped radial lineation of the protoplasm, which, if we were inclined to speculate as to its nature, seems almost as if it marked out the lines of molecular force acting in the organising process. These lines, however, it will be understood, if visible with the microscope, even of the highest magnifying power yet attained, belong to much larger particles than those of the supposed molecules of the physicist; but considered in connexion with what we know of the movements which frequently precede the act of division of the yolk-spheres, we seem in this phenomenon to have made some near approach to the observation of the direction in which the molecular forces operating in organisation may be supposed to act.(c)

With respect to the nature of the blastoderm, the organised cellular stratum resulting from segmentation, and its relation to the previous condition of the ovum on the one hand, and the future embryo on the other, there is presented to us, by modern research, the interesting view that the blastoderm consists, after completion of the segmenting process, of two layers of cells, an outer or upper, usually composed of smaller, clearer, and more compact nucleated cells, named *ectoderm*, or *epiblast*, and an inner or lower, consisting of cells which are somewhat larger, more opaque, and granular, but also nucleated, and named *endoderm*, or *hypoblast*.

In the meroblastic ova, such as those of birds, the bilaminar blastoderm is discoid and circumscribed, as it lies on the yolk surface, and only comes to envelope the whole of the food-yolk in the progress of later development; while in the holoblastic ova, and more especially in mammals, the blastoderm from the first extends over the whole surface of the yolk, and thus forms an entire covering of the yolk known as the "vesicular blastoderm;" the space within being occupied by fluid.

Huxley long ago presented the interesting view that these two layers are essentially the same in their morphological relations and histological structure with the double wall of the body in the simplest forms of animals above the protozoa; and Haeckel has more recently followed out this view, and supported it by his researches in the "Calcareous Sponges," and has founded upon it his well-known *Gastræa* theory. According to this view all animals take their origin from a form of *Gastrula*. In the simpler tribes, as in the instance of the common fresh-water polype or hydra, they proceed no further than the gastrula stage, unless by mere enlargement and slight differentiation of the two primitive layers of cell, representing the persistent ectoderm and endoderm.(d)

If, pursuing this idea, we take a survey of the whole animal kingdom in its long gradation of increasing complexity of form and structure from the simplest animal up to man himself, we find that all the various modifications of organic structure which present themselves are found, in the history of the

(b) The more exact nature of the process of segmentation was first made known by the interesting researches of Bagge in 1841, and more especially of Kölliker in 1843. The phenomena of complete segmentation were first fully described in the mammal's ovum in Bischoff's "Description of the Development of the Rabbit," 1842, and followed out in his succeeding "Memoirs on the Dog, Guinea-pig and Roe-deer." The phenomena of partial segmentation were first made known, in their more exact form, by Kölliker's "Researches on the Development of the Cephalopoda," published in 1844. In birds the process was first described by Bergmann in 1846, and more fully by Coste in 1848.

(c) The observations referred to above as to the division of the nucleus are so novel and of such deep interest that I am tempted to add here a short abstract of their more important results from a very clear account given of them by Dr. John Priestley, of Owens College, Manchester, in the *Journal of Microscopical Science* for April, 1876.

The researches now referred to are those of Auerbach, Butschli, Strasburger, Hertwig, and Edw. Van Beneden, and the following may be stated as the points in which they mainly agree:—

The nucleus when about to divide elongates into a spindle-shaped body, becomes irregular and indistinct, acquires a granular disc or zone in the plane of its equator; this divides into two, and each half moves towards the pole of the spindle on its own side, there being radiated lines of protoplasm between the poles and the equatorial disc.

The disc segments are the new nuclei, and the subsequent division of the cell takes place in the intermediate space.

Although these observers still differ in opinion upon some of the details of this process, and especially as to the fate of the germinal vesicle, all of them seem to agree that there are two pronuclei or distinct hyaline parts of the yolk protoplasm, a superficial and a deep one, engaged in the formation of the new nucleus, and both Hertwig and Van Beneden are of opinion that the two proceed from different productive elements.

The radiated structure of the nuclei had been previously recognised by Fol and Flemming, and further observed by Oellacher.

1. Butschli's researches are published in the *Nov. Act. Nat. Cur.*, 1873, and in the *Zeitschr. für wissensch. Zool.*, vol. xxv.

2. Auerbach's observations in his *Organolog. Studien*, 1874.

3. Strasburger's observations in his memoir "Ueber Zell-bildung und Zeiltheilung," Jena, 1875.

4. Edward Van Beneden's researches, partly in his memoir "On the Composition and Significance of the Egg," etc., presented to the Belgian Academy in 1868, and more particularly in the extremely interesting preliminary account of "Researches on the Development of Mammalia, etc., 1875; and in a separate paper in the *Journ. of Microscopical Science* for April, 1876.

5. Oscar Hertwig's Memoirs are contained in the *Morpholog. Jahrbuch*, 1875, and his most interesting and novel observations in the same work, 1877.

(d) At this place I will only refer to one of the most recent of Haeckel's works, in which the views alluded to above are fully expose in a series of most interesting memoirs—viz., "Studien zur Gastræ-Theorie," Jena, 1877.

individual or ontological development of the different members of the series, to spring originally from two cellular laminæ, ectoderm and endoderm, the component elements of which may again be traced back to the first segment-sphere and primitive protoplasmic elements of the ovum.

Time does not admit of my conducting you through the chain of observation and reasoning by which Haeckel seeks to convince us of the universal applicability of his theory, but I cannot avoid calling your attention to the extremely interesting relation which has been shown to exist between the primary phases of development of the ovum and the foundation of the blastoderm in very different groups of animals, more especially by the researches of Haeckel himself, of Kowalevsky, Edward van Beneden, and others, and which has received most efficient support from the investigations and writings of E. Ray Lankester in our own country; so that now we may indulge the well-grounded expectation that, notwithstanding the many and great difficulties which doubtless still present themselves in reconciling various forms with the general principle of the theory, we are at least in the track which may lead to a consistent view of the relations subsisting between the ontogenetic, or individual, and the phylogenetic, or race, history of the formation of animals and of man.(e).

In all animals, then, above the protozoa, the ovum presents, in some form or other, the bilaminar structure of ectoderm and endoderm at a certain stage of its development, this structure resulting from a process of segmentation or cell cleavage; and there are three principal modes in which the double condition of the layers is brought about. In one of these it is by inward folding or invagination of a part of the single layer of cells immediately resulting from the process of segmentation that the doubling of the layers is produced; in the second, perhaps resolvable into the first, it may be described rather as a process of inclosure of one set of cells within another; while in the third the segmented cells arranged as a single layer round a central cavity of the ovum, divide themselves later into two layers. But the distinction of ectodermic and endodermic layers of cells is maintained, whether it be primitive and manifested from a very early period, or acquired later by a secondary process of differentiation. Thus, in many invertebrates, and also in *Amphioxus* among the vertebrates, a distinct invagination occurs, while in mammals, as recently shown by Van Beneden's most interesting observations in the rabbit's ovum, and probably also in some invertebrates, the cells of the ectoderm gradually spread over those of the endoderm during the progress of segmentation, and thus the endodermic comes to be enclosed by the ectodermic layer of cells.

From the very novel and unexpected observations of Van Beneden, it further appears that from the earliest period in the process of segmentation in the mammal's ovum it is possible to perceive a distinction of two kinds of segment spheres or cells, and that when this process is traced back to its first stage it is found that the whole of the cells belonging to the ectoderm are the progeny of, or result from the division of the upper of the two first formed segments, and that the whole of the endodermic cells are the descendants of the lower of the two first segmented cells. This, however, is not an isolated fact belonging only to mammalian development, but one which very nearly repeats a process ascertained to occur in a considerable number of the lower animals, and it seems to promise the means of greatly advancing the comprehension of the whole process of blastodermic formation. Thus, ectoderm and endoderm, or the primordial rudiments of the future animal and vegetative systems of the embryo, are traced back as distinct from each other to the first stage of segmentation of the germ.

Accepting these facts as ascertained, they may be regarded as of the deepest significance in the phylogenetic history of animals; for they appear to open up the prospect of our being able to trace transitions between the earliest embryonic forms occurring in the most different kinds of ova, as between the discoid or meroblastic, and the vesicular or holoblastic, through the intermediate series, which may be termed amphiblastic ova.

In the lowest animals, the two layers already mentioned—viz., ectoderm and endoderm—are the only ones known to constitute the basis of developmental organisation; but as we rise in the scale of animals, we find a new feature appearing in their structure which is repeated also in the history of the formation of the blastoderm in the higher animals up to man. This consists in the formation of an intermediate layer or layers constituting the *mesoderm*, with which, in by far the greater number, is connected the formation of some of the most important bodily structures, such as the osseous, muscular, and vascular systems.

I will not stop to discuss the very difficult question of the first origin of the mesoderm, upon which embryologists are not yet entirely agreed, but will only remark that a view originally taken of this subject by the acute von Bäer appears more and more to gain ground; and it is this—that the mesoderm, arising as a secondary structure, that is, later than the two primary layers of ectoderm and endoderm (corresponding to the serous and mucous layers of Pander), is probably connected with or derived from both of these primitive layers, a view which it will afterwards appear is equally important ontogenetically and phylogenetically.

But whatever may be the first origin of the mesoblast, we know that in the vertebrata this layer, separating from between the other two, and acquiring rapidly by its cell multiplication larger proportions and much greater complexity than belongs to either ectoderm or endoderm, speedily undergoes further subdivision and differentiation in connection with the appearance of the embryonic organs which arise from it, and in this respect contrasts greatly with the simplicity of structure which remains in the developed parts of the ectodermic and endodermic layers. Thus, while the ectoderm supplies the formative materials for the external covering or epidermis, together with the rudiments of the central nervous organs and principal sense-organs, and the endoderm by itself only gives rise to the epithelial lining of the alimentary canal and the cellular part of the glands connected with it, the mesoblast is the source of far more numerous and complex parts, viz., the whole of the true skin or corium, the vertebral column and osseous system, the external voluntary muscles and connective tissue, the muscular walls of the alimentary canal, the heart and blood-vessels, the kidneys, and the reproductive organs thus forming much the greatest bulk of the body in the higher animals.(f)

There is, however, a peculiarity in the mode of the earliest development of the mesoblast which is of great importance in connexion with the general history of the disposition of parts in the animal body to which I must now refer. This consists in the division of the mesoblast in all but its central part into two laminæ, an outer or upper and an inner or lower, and the separation of these by an interval or cavity which corresponds to the space existing between the outer wall of our bodies and the deeper viscera; and which from the point of view of the vertebrate animals is called the pleuro-peritoneal cavity, but viewed in the more extended series of animals down to the annuloida, may receive the more general appellation of pleuro-splanchnic or parieta-visceral cavity, or, shortly, the *cœlom*. Thus, from an early period in the vertebrate embryo, and in a considerable number of the invertebrate, a division of the mesoderm takes place into the somato-pleuro or outer lamina, and the splanchno-pleural or inner lamina; the outer being the seat of formation of the dermal, muscular, and osseous systems—the volunto-motory of Remak; and the inner of the muscular wall of the alimentary canal, as well as of the contractile substance of the heart and the vascular system generally.

It is interesting to find that there is a correspondence between the later division of the mesoderm of the higher animals derived from the two primitive blastodermic laminæ, and the original absence of mesodermic structure in the lowest animals, followed by the gradual appearance, first of one layer (the external muscular in the higher cœlonterata), and, soon afterwards, by the two divisions or laminæ with the intermediate cœlom.

(e) I ought here to refer to the elaborate memoirs of Prof. Semper on the morphological relations of the vertebrate and invertebrate animals contained in the "Arbeiten aus dem zoolog. zootom. Institut in Würzburg," 1875 and 1876, in which the conclusions arrived at do not coincide with the views above stated.

(f) If we reserve the words "ectoderm" and "endoderm" to designate the two layers of the primary bilamimar blastoderm, we may apply the terms "epiblast" and "hypoblast" to their derivatives after the formation of the mesoderm, and indicate the relations of the whole to the secondary or quadrilaminar blastoderm, by the accompanying table:—

Primary Blastoderm	Ectoderm ...	.....	Epiblast.....	Secondary Blastoderm.
	Mesoderm...		Sematopleure ... Splanchnopleure	
	Endoderm ..		Hypoblast	

In this account of what may be termed the organised foundation of the new being, I have entered into some detail, because I felt that our conception of any relation subsisting between the ontogenetic history of animals and their phylogenetic evolution can only be formed from the careful study of the earliest phenomena of embryonic organisation. But, notwithstanding the many difficulties which unquestionably still block the way, I am inclined to think that there is great probability in the view of a common bilaminar origin for the embryo of all animals above the protozoa, and that the vertebrate, equally with the invertebrate, animals may be shown to possess in the first stages of their blastodermic or embryonic formation the two primitive layers of ectoderm and entoderm.

To attempt, however, to pursue the history of the development of animals in detail would be equivalent to inflicting upon you a complete system of human and comparative anatomy. But I cannot leave the subject abruptly without an endeavour to point out in the briefest possible manner the bearing of one or two of the leading facts in embryology upon the general relation of ontogeny and phylogeny.

We are here brought into the contemplation of those remarkable changes, all capable of being observed and demonstrated, by which the complex organisation of the body is gradually built up out of the elementary materials furnished by the blastodermic layers—a process which has been looked upon by all those who have engaged in its study with the greatest interest and admiration. And if, by comparing these phenomena as observed in individuals belonging to different classes and orders of animals, it is found not only that they are not different, but, on the contrary, that they present features of the most remarkable resemblance and conformity —we shall be led to conclude that there is a general plan of development proved to extend to the members of considerable groups, and possibly capable of being traced from one group to another. But this is clearly nothing else than another way of stating that there is a similar type of structure pervading the animals of each group, and a probability of a common type being ascertained to belong to them all. The main question, therefore, to be answered is whether there is or is not a general correspondence between the phenomena of development and the gradation of type in animal structure upon which anatomists and zoologists are agreed; and my object will now be to bring rapidly before you one or two of the most marked illustrations of the correspondence, drawn from the early history of development in the higher animals.

As one of the examples of the earlier phenomena of development, I may refer to the change which is perceptible as early as the eighteenth or twentieth hour of incubation in the chick, and which is reproduced in the course of development of every member of the vertebrate sub-kingdom. It consists in the formation of cross clefts on each side of the primitive neural cavity which divide off from each other a number of segments of this wall in the length of the axis of the embryo. At first there are only one or two such clefts, but they rapidly increase in a backward direction in the body of the embryo, and as development proceeds they extend into the tail itself. These are the *protovertebræ* of embryologists, not corresponding, as might at first be supposed, with the true or actual vertebræ which are formed later, but representing in an interesting manner transverse *vertebral segments* of the body, and containing within each the elements of a great part of the structure belonging to the body-wall afterwards to be developed, including the true cartilaginous or osseous vertebral arches and the muscular plates.

This change, however, belongs to the mesodermic lamina, and occurs in an elongated thick portion of it, which makes its appearance on each side of the primitive neural canal between the epiblast and the hypoblast. The transverse cleavage is ascertained to commence near what afterwards forms the first cervical vertebra, but does not extend into the base of the cranium. And it is most interesting to note in this cleavage the formation at so early a period of the succession of *metameres* or series of similar parts, which forms a main characteristic of vertebral organisation.

As intimately connected with the formation of the vertebral column, the appearance of the chorda dorsalis, or *notochord*, presents many points of peculiar interest in embryological inquiries.

The notochord is a continuous median column or thread of cellular structure, running nearly the whole length of the rudimentary body of the embryo, and lying immediately below the cerebro-spinal canal. It occupies in fact the centre of the future bodies of the vertebræ. It exists as a primordial structure in the embryo of all vertebrates, including man himself, and extending down to the amphioxus, and, according to the remarkable discovery of Kowalevsky in 1866, it is to be found among the invertebrates in the larva of the ascidia.(g)

In amphioxus and the cyclostomatous fishes the notochord, growing with the rest of the body into a highly developed form, acts as a substitute for the pillar of the bodies of the vertebræ, no vertebral bodies being developed; but in cartilaginous and osseous fishes various gradations of cartilaginous and osseous structures come to surround the notochord and give rise to the simpler forms of vertebral bodies, which undergo more and more distinct development in the higher vertebrates. In all instances the substance forming the vertebral bodies is deposited on the surface of or outside the notochord and its sheath, so that this body remains for a time as a vestigial structure within the vertebral bodies of the higher animals.

The observations of Kowalevsky with respect to the existence of a notochord in the ascidia, which have been confirmed by Kupfer and others, have produced a change little short of revolutionary in embryological and zoological views, leading as they do to the support of the hypothesis that the ascidia is an earlier stage in the phylogenetic history of the mammal and other vertebrates. The analogy between the amphioxus and ascidian larva is certainly most curious and striking as regards the relation of the notochord to other parts; and it is not difficult to conceive such a change in the form and position of the organs in their passage from the embryonic to the adult state, as is not inconsistent with the supposition that the vertebrates and the ascidia may have had a common ancestral form. Kowalevsky's discovery opens up at least an entirely new path of inquiry; and we must be prepared to modify our views as to the entire separation of the vertebrates from the other groups of animals, if we do not at once adopt the hypothesis that through the ascidian and other forms the origin of the vertebrates may be traced downwards in the series to the lower grades of animal organisation.

The notochord extends a short way forward into the cranial basis, and an interesting question here presents itself, beginning with the speculations of Goethe and Oken, and still forming a subject of discussion, whether the series of cranial or cephalic bones is comparable to that of the vertebræ. On the whole, it appears to me that it is consistent with the most recent views of the development and anatomy of the head to hold the opinion that it is composed of parts which are to some extent homologous with vertebral metameres.(h)

The history of the formation of the vertebral column presents an interesting example of the correspondence in the development of the individual and the race, in that all the stages which have been referred to, as occurring in the gradual evolution of the vertebral column in the series of vertebrates, are repeated in the successive stages of the embryonic development of the higher members of the series.

There is perhaps no part of the history of development in the vertebrates which illustrates in a more striking manner the similarity of plan which runs through the whole of them than that connected with what I may loosely call the region of the face and neck, including the apparatus of the jaws and gills. The embryonic parts I now refer to consist of a series of symmetrical pairs of plates, which are developed at an early period below the cranium, and may therefore, in stricter embryological terms, be styled the *sub-cranial plates*.

Without attempting to follow out the remarkable changes which occur in the development of the nose and mouth in connexion with the anterior set of these plates, which, from being placed before the mouth, are sometimes named *preoral*, I may here refer shortly to the history of the plates situated behind the mouth, which were discovered by Rathke in 1826, and formed the subject of an elaborate investigation by Reichert in 1837.

These plates consist of a series of symmetrical bars, four in number in mammals and birds, placed immediately behind the mouth, separated by clefts passing through the wall of the throat, and each traversed by a division of the great artery

(g) *Mém. de l'Acad. de S'. Pétersbourg*, vol. x.

(h) See the interesting and valuable memoirs of W. K. Parker, "On the Anatomy and Development of the Vertebrate Skull," in *Transactions of the Royal Society*, the researches of Gegenbaur, Mihalkovics, and more particularly the Memoir by F. M. Balfour, "On the Development of the Elasmobranchs," in the *Journal of Anatomy and Physiology*, vols. x. and xi.

from the heart; thus constituting the type of a branchial apparatus, which in fishes and amphibia becomes converted into the well-known gills of these animals, whilst in reptiles, birds and mammals they undergo various changes leading to the formation of very different parts, which could not be recognised as having any relation to gill structure but for the observations of their earlier embryonic condition. The history of this part of development also possesses great interest on account of the extraordinary degree of general resemblance which it gives to the embryos of the most different animals at a certain stage of advancement—so great, indeed, that it requires a practised eye to distinguish between the embryos of very different orders of mammals, and even between some of them and the embryos of birds or reptiles, as well as in connexion with the transformations of the first pair of branchial apertures, which lead to the formation of the passage from the throat to the ear in the higher vertebrata. There is equal interest attached to the history of the development of the first pair of arches, which include the basis of formation of the lower jaw with the so-called *cartilage of Meckel*, and which, while furnishing the bone which suspends the lower jaw in reptiles and birds, is converted in mammals into the hammer-bone of the ear.

The other arches undergo transformations which are hardly less marvellous, and the whole series of changes is such as never fails to impress the embryological inquirer with a forcible idea of the persistence of type and the inexhaustible variety of changes to which simple and fundamental parts may be ubject in the process of their development.

It is also of deep significance in connection with the foregoing phenomena, to observe the increase in the number of the gillbars and apertures as we descend in the scale to the cartilaginous fishes and lampreys, and the still further multiplication of these metameres or repeated parts in the amphioxus; and it is, perhaps, also interesting to note that in the ascidia the arrangement of the gills is exactly similar to that of the amphioxus.

The study of the comparative anatomy of the heart and its mode of formation in the embryo furnishes also most striking illustrations of the relation between ontogenetic and phylogenetic development in the vertebrates, and is not without its applications to some of the invertebrate groups of animals.

I need only recall to your recollection the completely double state of this organ in warm-blooded animals, by which a regular alteration of the systemic and pulmonary circulations is secured, and the series of gradations through the class of reptiles by which we arrive at the undivided ventricle of the amphibian, and the further transition in the latter animals by which we come at last to the single heart of fishes; and to state that in the embryo of the higher animals the changes by which the double heart is ultimately developed out of an extremely simple tabular form into which it is at first moulded from the primitive-formative cells are, in the inverse order, entirely analogous to those which I have just now indicated as traceable in the descending series of vertebrate animals; so that at first the embryonic heart of man and other warm-blooded animals is nothing more than a rhythmically contractile vascular tube. By the inflection of this tube, the constriction of its wall at certain parts, and the dilatation at others, the three chambers are formed which represent the single auricle, the single ventricle, and the aortic bulb of the fish. By later changes a septum is formed to divide the auricles, becoming completed in all the air-breathing animals, but remaining incomplete in the higher animals so long as the conditions of fœtal life prevent the return of arterialised blood to the left auricle. The growth of another septum within the ventricular portion gradually divides that cavity into two ventricles, repeating somewhat in its progress the variations observed in different reptiles, and attaining its complete state in the crocodile and warm-blooded animals.

I must not attempt to pursue this interesting subject further, but I cannot avoid making reference to the instructive view presented by the embryological study of the nature of the malformations to which the heart is subject, which, as in many other instances, are due to the persistence of transitory conditions which belong to different stages of progress in the development of the embryo. Nor can I do more than allude to the interesting series of changes by which the aortic-bulb, remaining single in fishes, and serving as the channel through which the whole stream of blood leaving the heart is passed into the gills, becomes divided in the higher animals into the roots of the two great vessels, the aorta and the pulmonary artery, and the remarkable transformations of the vascular arches which proceed from the aortic-bulb along the several branchial arches, and which, in the gills of fishes and aquatic amphibia undergo that minute subdivision which belongs to the vascular distribution of gills, but which in the higher non-branchiated animals are the subject of very different and various changes in the partial obliteration of some, and the enlargement of others, by which the permanent vessels are produced.

These changes and transformations have for many years been a subject of much interest to comparative anatomists, and will continue to be so, not only from their presenting to us one of the most remarkable examples of conformity in the plan of development and the type of permanent or completed organisation in the whole series of vertebrated animals, but also because of the manifest dependence of the phenomena of their development upon external influences and atmospheric conditions which affect the respiration, nutrition, and modes of life of the animal.

Nor is the correspondence to which I now refer entirely limited to the vertebrata. For here, again, through the amphioxus and the ascidia, we come to see how an affinity may be traced between organs of circulation and respiration which at first appear to belong to very different types. The heart of vertebrates is, as is well known, an essentially concentrated form of vascular development in the ventral aspect of the body; while the heart of the invertebrate, whether in the more concentrated form existing in the articulata and muscula, or in a more subdivided shape prevalent in the annelida, is most frequently dorsal; yet the main aorta of the vertebrates is also dorsal; and it is not impossible through the intermediate form of amphioxus, to understand how the relation between the vertebrate and the invertebrate type of the blood-vascular system may be maintained.

But I am warned by the lapse of time that I must not attempt to pursue these illustrations further. In the statement which I have made of some of the more remarkable phenomena of organic production—too long, I fear, for your endurance, but much too brief to do justice to the subject—it has been my object mainly to show that they are all more or less closely related together by a chain of similarity of a very marked and unmistakable character; that in their simplest forms they are indeed, in so far as our powers of observation enable us to know them, identical; that in the lower grades of animal and vegetable life they are so similar as to pass by insensible gradations into each other; and that in the higher forms, while they diverge most widely in some of their aspects in the bodies belonging to the two great kingdoms of organic nature, and in the larger groups distinguishable within each of them, yet it is still possible, from the fundamental similarity of the phenomena, to trace in the transitional forms of all their varieties one great general plan of organisation.

In its simplest and earliest form that plan comprises a minute mass of the common nitrogenous hydrocarbon compound to which the name of "protoplasm" has been given, exhibiting the vital properties of assimilation, reproduction, and irritability; the second stage in this plan is the nucleated and inclosed condition of the protoplasmic mass in the organised cell. We next recognise the differentiation of two productive elements, and their combination for the formation of a more highly endowed organising element in the embryonic germ-sphere or cell; and the fourth stage of advance in the complexity of the organising phenomena is in the multiplication of the fertilised embryo-cell, and its conversion into continuous organised strata, by further histological changes in which the morphological foundations of the future embryo or new being are laid.

I need not now recur to the further series of complications in the formative process by which the bilaminar blastoderm is developed, and becomes trilaminar or quadrilaminar, but only recall to your recollection that while these several states of the primordial condition of the incipient animal pass insensibly into each other, there is a pervading similarity in the nature of the histological changes by which they are reached, and that in the production of the endless variations of form assumed by the organs and systems of different animals in the course of their development, the process of cell-production, multiplication and differentiation remains identical. The more obvious morphological changes are of so similar a character throughout the whole, and so nearly allied in the different larger groups, that we are led to regard them as placed in some very close and intimate relation to the inherent properties of

the organic substance which is their seat, and the ever-present influence of the vital conditions in which alone these properties manifest themselves.

The formative or organising property, therefore, resides in the living substance of every organised cell and in each of its component molecules, and is a necessary part of the physical and chemical constitution of the organising elements in the conditions of life; and it scarcely needs to be said that these conditions may be as varied as the countless numbers of the molecules which compose the smallest particles of their substance. But, setting aside all speculation of a merely pangenetic kind, it appears to me that no one could have engaged in the study of embryological development for any time without becoming convinced that the phenomena which have been ascertained as to the first origin and formation of textures and organs in any individual animal are of so uniform a character as to indicate forcibly a law of connexion and continuity between them; nor will his study of the phenomena of development in different animals have gone far before he is equally strongly convinced of the similarity of plan in the development of the larger groups, and, to some extent, of the whole. I consider it impossible, therefore, for any one to be a faithful student of embryology, in the present state of science, without at the same time becoming an evolutionist. There may still be many difficulties, some inconsistencies, and much to learn, and there may remain beyond much which we shall never know; but I cannot conceive any doctrine professing to bring the phenomena of embryonic development within a general law which is not, like the theory of Darwin, consistent with their fundamental identity, their endless variability, their subjugation to varying external influences and conditions, and with the possibility of the transmission of the vital conditions and properties, with all their variations, from individual to individual, and, in the long lapse of ages, from race to race.

I regard it, therefore, as no exaggerated representation of the present state of our knowledge to say that the ontogenetic development of the individual in the higher animals repeats in its more general character, and in many of its specific phenomena, the phylogenetic development of the race. If we admit the progressive nature of the changes of development, their similarity in different groups, and their common characters in all animals, nay, even in some respects in both plants and animals, we can scarcely refuse to recognise the possibility of continuous derivation in the history of their origin; and however far we may be, by reason of the imperfection of our knowledge of palæontology, comparative anatomy, and embryology, from realising the precise nature of the chain of connexion by which the actual descent has taken place, still there can be little doubt remaining in the minds of any unprejudiced student of embryology that it is only by the employment of such an hypothesis as that of evolution that further investigation in these several departments will be promoted so as to bring us to a fuller comprehension of the most general law which regulates the adaptation of structure to function in the universe.

The death is announced of Mr. W. Lovett, well known as a Chartist. In 1852 he published some elementary lessons in anatomy and physiology, and was the author of various lectures. His autobiography appeared about twelve months since.

Spina Bifida Treated by the Elastic Ligature.—Dr. Baldassare relates the case of an infant eight months old upon whom he operated for spina bifida situated at the base of the sacrum. The peduncle of the tumour was four centimetres in length. The largest circumference of the tumour measured twenty-two centimetres, its entire length (including the pedicle) being eleven centimetres. Fluctuation and transparency indicated its contents, and these were not influenced by respiration and only slightly so by compression. The tumour became somewhat more tense in the erect posture. Compression was commenced on the pedicle by elastic ligature on November 30, and by the sixteenth day, the tumour being then in a gangrenous condition with the pedicle reduced to a centimetre in circumference, it was removed by the bistoury, leaving a small depressed space almost filled with granulations. On January 7 the child was well and lively. A linear cicatrix occupied the place of the peduncle, and beneath this could be felt a resisting membrane occupying the place where th bone was defective.—*Annali Universali*, May.

ARMY, NAVY, AND INDIAN MEDICAL SERVICES.

The following are the questions which were set at the recent examination of candidates for her Majesty's Army, Navy, and Indian Medical Services:—

Anatomy and Physiology.—1. Write a full description of the superior maxillary bone; its development, connexions, and relations with blood-vessels, nerves, muscles, &c. 2. The arteries on the thigh, from the level of Poupart's ligament in front and behind, to the knee, and including the popliteal space:—State their courses, relations and anastomoses, more particularly around the hip and knee joints. 3. Describe the minute structure of the cerebral substance, and the mode in which you would proceed to demonstrate it, with the reagents you would employ for the purpose. 4. Describe the development of the human embryo, from the entrance of the ovum into the Fallopian tube, to the end of the third month.

Surgery.—1. A patient has obstruction of the bowels. Describe the symptoms which would indicate the probable seat of the obstruction, whether in the small or large intestine; and the conditions which would generally determine the nature of the treatment, medical or operative. 2. What are the causes of incontinence of urine—local, constitutional, or accidental—and the measures to be adopted for its relief? 3. Describe the local and general characteristics of acute inflammation of the knee joint, the result of accident or other cause; the changes which occur in and around the joint when the progress is unfavourable; and the treatment of such a case from the commencement. 4. Describe the symptoms of abscess of bone. What is the more common seat of such an abscess, and the treatment to be adopted in a suspected case? 5. Describe the symptoms of rupture of the intestine—the result of a blow or fall—(without external wound), and state under what conditions such a rupture might possibly not prove fatal. 6. What are the symptoms and causes of ozæna; at what period of life is it most frequently met with, and what local treatment should be adopted, when general measures fail to relieve it?

Medecine.—1. What do you understand by the terms "infectious," "contagious," "epidemic," and "endemic"? Name the diseases which are believed to be contagious, and mention the principal reasons for your belief in the diseases you name being contagious. 2. Describe the morbid anatomy of "sclerosis" as a lesion of the nervous system. Name the diseases in which it is a constant morbid condition, arranging them according to the parts or tracts of the nervous system which are the seat of sclerosis; and state the most characteristic symptoms of such cases during life. 3. What are the symptoms and physical signs of a fatty heart? 4. Describe a case of acute hydrocephalus in a child, and the appropriate treatment. 5. Name the diseases which mostly cause deformities of the female pelvis, and what are the most common varieties of pelvic deformity? How are they diagnosed; what are the standard measurements of the diameters of the true pelvis in the adult female, at the brim, and in the cavity; and what are the external measurements which aid in the diagnosis of deformities of the pelvis? What size would be considered too small for the natural delivery of a full-grown child; and what would you do, in such a case, to meet the existing difficulties; and in the event of the same female becoming again pregnant? 6. What do you understand by an "alterative" medicine? Name the most approved preparations of arsenic, iodine, and mercury used as "alteratives," and the appropriate doses of each preparation you name used as such.

Natural History and Physics.—Zoology: 1. Describe the principal modifications of the respiratory system in the animal kingdom. 2. How does the vertebral column differ in the different classes of mammals? 3. Give the characters of Cephalopods, and state their distribution at the present time and at former periods. 4. Give an account of the chief races of man. 5. What is meant by alternation of generation? In what groups of animals does it occur? 6. Botany: Contrast the characters of Labiatæ, Boragineæ, Scrophulariaceæ, and Solanaceæ. 7. Give the characters of the order Characeæ. 8. What is the area of geographical distribution of Cruciferæ, Dipterocarpeæ, Ericaceæ, Epacrideæ, Proteaceæ, Betulaceæ, Coniferæ, and Orchideæ. 9. Describe the process of germination in exogens and endogens, and in a fern spore. 10.

Describe the structure and junction of a leaf. Physics, etc.: 11. Two travellers start from the same point to make the circuit of the globe, one going easterly, the other westerly. On returning to the point of starting, one will have gained and the other lost a day. Explain the reason of this. 12. Define the terms specific heat, latent heat, radiant heat, and point out the differences in the conduction of heat by different bodies. 13. Give a sketch of the principal geological formations on the earth, in their order of succession. 14. In what forms does carbon occur in nature, free and in combination with other elements? 15. What is meant by specific gravity? How is it ascertained in solids, liquids, and gases?

FROM ABROAD.

Abolition of Coroners.

For a considerable time past a movement has been going on in the chief cities of the United States with a view either of a reform of, or abolition of, the office of Coroner. It seems, in some instances, to have entirely got into the hands of the politicians, who work it for their own purposes, in rewarding their supporters, without any regard for the public good. Unnecessary inquests are held, and these are often conducted in an indecent manner. In some places the coroners have been multiplied to a ridiculous extent, and the sums spent to obtain the office show that other than legitimate sources of emolument must exist somewhere. The Municipal Society of New York has been investigating the subject carefully, and has unanimously adopted the following resolution:—"That the Judiciary Committee take the necessary steps to secure the passage through the Legislature of an amendment of the Constitution, abolishing the office of coroner in cities of upwards of 10,000 inhabitants." In Massachusetts matters have advanced to a much greater extent, as the coronership has actually been abolished; and the *Boston Medical Journal* (June 28) gives an account of the measures which have been substituted. It seems that the Governor of the State has had conferred upon him the power, assisted by his Council, of choosing certain official persons entitled "Medical Examiners," upon whom will fall the duty of examining into all the medical facts connected with suspicious deaths, making autopsies, etc., the juridical part of the proceedings being carried to the ordinary law courts. The competition for these new offices was, it seems, very keen, all sorts of persons, well- and ill-qualified, offering their services. The selection made by the Governor in Council has, however, been highly approved of; and the two Medical Examiners chosen for Suffolk County (which is really Boston), at a salary of $3000 each—or about £600, viz., Drs. F. W. Draper and F. A. Harris, are spoken of as most competent persons. Altogether there are about fifty of these Medical Examiners, and thirty of their number have already formed themselves into the Massachusetts Medico-Legal Association, for the purposes of co-operation and advancing the knowledge of legal medicine.

The experiment is of great importance, the working of which will be watched with great interest, not only in the United States, but in our own country; for although with ourselves the abolition of the office of coroner has been advocated by scarcely anyone, and certainly the coroner's court is not open to the class of objections attaching to it in the United States, yet it stands in need of reforms, which success of the procedure now set on foot in Massachusetts may tend to expedite.

Dr. Fordyce Barker on Uterine Surgery.

At the recent annual meeting of the Gynæcological Society, Dr. Fordyce Barker, its President, made some highly interesting remarks upon the abuses of uterine surgery, which are thus commented upon by the *New York Medical Record* for June 9:—

"Without wishing to ignore the just claims of operative gynæcology, he very properly urged the giving more attention to the medical treatment of uterine disease. There is no doubt that this latter branch of our service has been too much neglected—that many operations have been done more because they were fashionable than for any good conferred by them upon the patient. It is so easy to gain credit by such procedures, that it is no wonder that so many yield to the temptation. Then again the uterus is so non-retaliating that it invites all sorts of inroads upon its textural integrity. The shedding of uterine blood apparently begets an insatiety for gynæcological operations, which, when once established, is sometimes dreadful to contemplate. Cases are on record in which surgeons have timidly begun with incising the os, then with excising the cervix, body, and fundus; and lastly, when ovaries were included in the ablation, have actually mourned that nothing more was left to conquer. The fact that some of these patients got well, may help to prove that, gynæcologically speaking, the uterus and appendages are incumbrances. But the other side of the argument is that women who are not operated upon, whose uteri know not the knife, the scissors, ecraseur, or pessary, also got well. This is certainly a great comfort to the ordinary practitioner, who has a healthy fear of disturbing peritoneal coverings, of poking pessaries into the bladder, of mistaking the uterus for the ovary, and of any of the other trivial accidents which occasionally happen in the higher walks of gynæcology. The fact is that the desire to cut, twist, burn, amputate, electrolyse, and pessarise the uterus has amounted almost to a mania. The aspiring gynæcologist who has been unable to devise a new operation, invent a new speculum or modify an old one, has been compelled to infuse his energies either into a new cautery-iron, a novel back-acting curette, or a manifold self-acting elevator. If perhaps he fails in every other way in encouraging operative procedures, he gives a new and important twist to a pessary, establishes a principle, and makes a reputation. But if the time has come for a change of opinion, if the worst must come to the worst, advocates of the new doctrine can do no more than arrest the study of surgical statistics, and, as a possible consequence, create a corner in uterine pathology. In any event, we are willing to give the uterus one more chance."

"Since 1845," says Dr. Barker in the address referred to, "immortality has been sought by 142 men in the invention of a pessary, when doubtless more would have been accomplished for the relief of suffering and the preservation of the body, had the same energy been displayed in the study of the circulatory, nervous, and digestive apparatuses of the body in their relation to the diseases of the pelvic organs."

New Mode of Radical Cure of Hernia.

At a meeting of the Norfold District Medical Society, Massachusetts, Dr. Davenport described at length (*Boston Med. Journal*, July 5,) the method of treating hernia, which has been for many years employed successfully by Dr. Heaton of Boston. Dr. Heaton considers that Gerdy's, Wützer's, and Wood's operations "now almost discarded" have proved ineffectual, principally on account of the *inflammation* excited by the plug of adjacent integument, or of the invaginated scrotal tissues, or of both, which after a variable interval, in which apparent success has been obtained, is got rid of by nature, and the rupture usually recurs. He therefore lays it down as a principle that all inflammation except of the mildest character must be carefully avoided, and this is best brought about by what he calls the method of *tendinous irritation*, *i.e.*, a mild irritation of those portions of fibrous tissue lying directly in contact with the exterior of the neck of the hernial sac, thickening and consolidating this substance, and effecting a contraction of the openings. This contraction is due not only to the astringent used as an irritant, but also largely to the peculiar normal distribution of the bundles of fibre in the neighbourhood of the abdominal rings. For the performance of the operation, the hernia, together with its sac, must be returned into the abdomen; but when the sac cannot be returned it may be allowed to remain in the canal.

"Next invaginate the right forefinger in the scrotum, and find the external abdominal ring, and with the left forefinger pressed perpendicularly upon the integument directly over the ring, force the skin with the finger directly into the ring, the spermatic cord and the sac, if in the way, being pushed aside, so that nothing may remain between the external pillar of the ring and the finger except the integument and subjacent superficial fasciæ. Keeping the left forefinger thus, the needle of the instrument (which resembles the ordinary subcutaneous syringe) is quickly introduced through the skin and superficial fascia, just passing the external pillar and entering the canal at once. The left forefinger is then removed, and the beak of the instrument insinuated further on, well into

the canal, care being taken to avoid the spermatic cord and the fibrous walls of the canal. To wound any of these parts endangers the success of the operation. The beak of the instrument when thus introduced is in a suitable position for the injection of the liquid irritant, about ten minims of which is introduced drop by drop. The point of the needle should be well swept about while delivering the fluid, which should pass around the exterior of the sac if unreduced, and should wet all the fibrous tissues. After the withdrawal of the needle, which should be done quickly, the previous protrusion should not be allowed to descend, nor the patient be permitted to assume even the sitting posture, until a suitable bandage or other means of support had been properly applied. The irritant consists of Thayer's fluid extract of quercus alba half an ounce, and of solid alcoholic extract of the quercus about fourteen grains. This is to be triturated with the aid of gentle heat for a long time in a mortar until the solution is as perfect as possible. It is as well to add to this mixture sulphate of morphia (about a grain to the ounce), in order to diminish the dull aching that follows the operation. A bandage is preferable to a truss after operating, because it can be more accurately adjusted, and can be worn with comfort while lying down. There is a dull pain in the groin following the operation, but after attaining a moderate degree of acuteness this subsides, and disappears altogether in from six to twelve hours. After this there is no pain, if the patient avoids exercise; no swelling appears, nor any local redness, nor any increase of temperature in the groin. For the first week the patient is not allowed to sit up, as there is more or less tenderness during that time. During the second week moderate exercise may be allowed, and after that time the patients can generally be allowed to return to their avocations. Dr. Heaton usually advises them to wear the bandage until it is worn out, and then to discard all mechanical support."

The numerous details wanting in the above statement will be found in a work on the subject just published by Dr. Heaton, in which he gives a full account of his method as applied to the different varieties of hernia, and derived from the treatment of "many hundreds of cases."

GENERAL CORRESPONDENCE.

ASSOCIATION OF MEN HOLDING IRISH QUALIFICATIONS.

LETTER FROM DR. JAMES THOMPSON.

[To the Editor of the Medical Times and Gazette.]

SIR,—A meeting of Irish qualified men practising in England, was held at Owens College, during the late meeting of the British Medical Association at Manchester, when it was resolved to form an association of those medical men holding Irish qualifications, who were practising in England, and Dr. Balthazar Foster, of Birmingham, was elected President, and Dr. Daniell, 20, Cathcart-road, and myself were elected as Secretaries. As soon as possible a circular will be sent to all those holding qualifications. Any gentleman who wishes to join will oblige by sending his name and address to either of the secretaries. I am, &c.

JAMES THOMPSON, M.D., Hon. Sec.

Avenue-house, Leamington, August 20.

DR. HARDWICKE recently held an inquest at 22, Claremont-square, Clerkenwell, on the body of Mr. James Black, aged seventy-four, a retired baker, who was found dead in the conservatory at the above address. On the left temple was a terrible gash, evidently received immediately before, or or at the point of, death. The evidence was to the effect that the deceased, who seldom ventured out of the house, was perfectly well on the previous Thursday morning, but at dinner refused to partake of any beer. He went upstairs, and remained there some time. He came downstairs, and afterwards went into the conservatory, where he was found lying dead on the stones. Dr. Bolton stated that he was called in, and found the deceased lying as described. He had *not made a post-mortem examination because the nephew objected to it;* and he believed the cause of death was serous apoplexy, the injuries being received while falling, *but he refused to give a certificate of death.* A verdict in accordance with the medical evidence was returned. With respect to the certificate, we think Dr. Bolton acted wisely.

MEDICAL NEWS.

UNIVERSITY OF LONDON.—The following are lists of candidates who have passed the recent examinations:—

FIRST M.B. EXAMINATION FOR HONOURS.

ANATOMY.

First Class.—Richard Gill, St. Bartholomew's Hospital; Tiaeliesin Wilim Owen Pughe, Liverpool Royal Infirmary and Guy's Hospital.

Second Class.—Norman Dalton, King's College; William Banks, University College.

Third Class.—Frank Rushworth, St. Bartholomew's Hospital; Alfred Harvey, Queen's College, Birmingham.

PHYSIOLOGY, HISTOLOGY, AND COMPARATIVE ANATOMY.

Second Class.—Angel Money, University College; Mark Feetham Sayer, University College; Leonard Charles Wooldridge, Guy's Hospital.

Third Class.—Tiaeliesin Wilim Owen Pughe, Liverpool Royal Infirmary and Guy's Hospital; James Isaac Paddle, B.A., B.Sc., University College; Richard Gill, St. Bartholomew's Hospital.

CHEMISTRY.

First Class.—Richard Gill (Exhibition and Gold Medal), St. Bartholomew's Hospital; William Hale White, Guy's Hospital.

Second Class.—Leonard Charles Wooldridge, Guy's Hospital; Alfred Ernest Maylard, Guy's Hospital, and James Isaac Paddle, University College, *equal.*

Third Class.—Arthur Jackson, St. Bartholomew's Hospital.

MATERIA MEDICA AND PHARMACEUTICAL CHEMISTRY.

First Class.—William Banks (Exhibition and Gold Medal), University College; Hutton Castle, St. Thomas's Hospital, John Edward Hine, University College, Bilton Pollard, University College, and Leicester Cuthbertson Ponsford, University College (*equal*), obtained the number of marks qualifying for the Exhibition; Gilbert Harry Barling, St. Bartholomew's Hospital; Mark Feetham Sayer, University College, and Leonard Charles Wooldridge, Guy's Hospital (*equal*), obtained the number of marks qualifying for a Medal.

Second Class.—William Henry Russell Forsbrook, Westminster Hospital, and Greville Matheson MacDonald, King's College, *equal;* James Balls, King's College, and William Outhwaite, St. Bartholomew's Hospital, *equal.*

Third Class.—Thomas Hahnemann Hayle, Owens College, and Arthur Jackson, St. Bartholomew's Hospital, *equal;* James Isaac Paddle, University College; Richard Gill, St. Bartholomew's Hospital.

FIRST B.SC. AND PRELIMINARY M.B. CONJOINTLY.

CHEMISTRY.

First Class.—Charles Frederick Cross (First B.Sc.—Exhibition), King's and Owens Colleges, and William Henry Thomas (First B.Sc.—Disqualified by age for the Exhibition), Royal College of Chemistry, *equal.*

Second Class.—Arthur Hamilton N. Lewers (Prel. Sci.), University College; Alexander Barron (Prel. Sci.), Owens College.

Third Class.—Charles Edward Cassal (Prel. Sci.), University College; Herbert Irving Bell (First B.Sc.), private study; Hyde Marriott (First B.Sc. and Prel. Sci.), Owens College, and Herbert Pearce (First B.Sc.), University College, *equal*; Frederick Wallis Stoddart (First B.Sc. and Prel. Sci.), University College, Bristol.

EXPERIMENTAL PHYSICS.

First Class.—Joseph Larmor (First B.Sc.—Arnott Exhibition and Medal), St. John's College, Cambridge; Moses John Jackson (First B.Sc. —Arnott Medal) University College.

Second Class.—Hugh Erat Harrison (First B.Sc.), University College, and Herbert Pearce (First B.Sc.), University College, *equal.*

Third Class.—Edwin Leonard Adeney (Prel. Sci.), Guy's Hospital; Oswald James Currie (Prel. Sci.), Guy's Hospital.

BOTANY.

First Class.—Pramatha Nath Bose (First B.Sc. and Prel. Sci.), University College.

Second Class.—William Henry Horrocks (Prel. Sci.), Owens College; Henry Edmonds (First B.Sc.), private study; Robert Jones (Prel. Sci.), St. Bartholomew's Hospital; Henry Hoole (Prel. Sci.), Charing-cross Hospital, and George Henry Spencer Pearson (First B.Sc.), private study, *equal.*

Third Class.—Wm. Havelock Hill (First B.Sc. and Prel. Sci.), University College; David John Rygate (Prel. Sci.), London Hospital.

ZOOLOGY.

First Class.—Sydney John Hickson (First B.Sc. and Prel. Sci—Exhibition), University College; Sidney Harris Cox Martin (First B.Sc. and Prel. Sci.), University College.

Second Class.—Donald Douglas Day (Prel. Sci.), St. Bartholomew's Hospital.

Third Class.—Pramatha Nath Bose (First B.Sc. and Prel. Sci.), University College; Henry Edmunds (First B.Sc.), private study; Arthur Guy Salmon (Prel. Sc.), St. Bartholomew's Hospital; George Henry Spencer Pearson (First B.Sc.) private study.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, August 16:—

Battle, William Henry, Potter Hanneth, Lincoln.
Bunting, Robert Obadiah, West Green-road, Tottenham.
Chadwick, John, Milnrow, Rochdale.
Cocksedge, Chas. Ernest, Clapton-park.
Greasley, John, Canterbury.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Ling, Maurice Edward, London Hospital.
Pope, Herbert Francis M., St. Bartholomew's Hospital.
Thomas, Richard Weddale, St. Thomas's Hospital.
Underhill, George, Middlesex Hospital.

At the recent examination for the prizes in Botany, given

by the Society of Apothecaries, the successful candidates were:—

First.—Arthur Henry Shakespere Lucas, London Hospital, a gold medal.

Second.—Sydney Harland Henty, University College, a silver medal and a book.

Third.—Charles Pardy Lukis, St. Bartholomew's Hospital, a bronze medal and a book.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Murdoch, Wm., M.B. and C.M. Edin.—Assistant-Physician, Perth District Asylum.

NAVAL, MILITARY, &c., APPOINTMENTS.

Cumberland Lodge, Windsor-park.—Their Royal Highnesses the Prince and Princess Christian, of Schleswig-Holstein, have been pleased to appoint Thomas Fairbank, M.D., to be Surgeon in Ordinary to their Royal Highnesses' Household.

BIRTHS.

Gallwey.—On August 10, at Ponteland, Northumberland, the wife of J. Hoppner M. Gallwey, M.B., of a son.

Hett.—On August 11, at 1, Ledbury-road, Bayswater, the wife of Geoffrey Hett, M.D., prematurely of a daughter.

Iliffe.—On August 16, at Kendal, the wife of Walter Iliffe, F.R.C.S.E., of a son.

Kesteven.—On August 17, the wife of Wm. Henry Kesteven, M.R.C.S., of 51, Tufnell-park-road, of a daughter.

MacGrath.—On August 20, at 14, Colville-terrace East, Bayswater, the wife of William Michael MacGrath, F.R.C.S.I., &c., of a son.

Miller.—On August 17, at Blackheath, the wife of J. N. Miller, M.D., of a son.

Stokoe.—On August 19, at the Chestnuts, Beddington, the wife of Paul Henry Stokoe, B.A., M.D., of a son.

Tonge.—On August 15, at Harrow-on-the-Hill, the wife of Morris Tonge, M.D., of a son.

MARRIAGES.

Barker—Pennell.—On August 15, at St. Peter's Church, Brighton, R. A. Barker, M.D., Civil Medical Officer, Bengal, to Julia Constance Keith, eldest daughter of the late Rev. George Keith Pennell.

Davidson—Russ.—On August 21, at Holy Trinity Church, Clapham, Charles Davidson, F.R.C.S. Edin., of Hackney, to Gertrude Marian, second daughter of William Russ, C.E., of Cedars-road, Clapham-common.

Heelas—Robinson.—On August 13, at Christ Church, Hampstead, James Heelas, M.B., C.M., of Fellow's-road, Hampstead, son of John Heelas, The Holt, Wokingham, to Lizzie, third daughter of the late S. S. Robinson, of Liverpool.

Jones—Williams.—On August 17, at Moriah Chapel, Carnarvon, Owen Thomas Jones, M.R.C.S. Eng., Port Dinorwic, to Katie Williams, of 5, Uxbridge-square, Carnarvon.

Lewis—Ellison.—On August 14, at St. John's Church, Windsor, Arthur Griffith Power Lewis, of Lincoln's-inn, barrister-at-law, to Annie Wilhelmine, second daughter of James Ellison, M.D., Surgeon to her Majesty's Household in Windsor.

Phillips—Garrett.—On August 16, at Cushendun, co. Antrim, George Arthur Phillips, M.R.C.S. Eng., Walsall, Staffs, to Mary Higginson, younger daughter of the late James R. Garrett.

Pope.—Townsend.—On August 15, at Old Edgbaston Church, Harry Campbell Pope, F.R.C.S., M.B. Lond., of Shepherd's-bush, son of Edward Pope, Surgeon, of Tring, Herts, to Constance Nellie, daughter of the late Charles Townsend, Surgeon, of Birmingham.

Room—Malcolm.—On August 16, at St. John the Evangelist's, Edinburgh, Charles Turner, son of the Rev. Charles Room, of Finchley, London, to Fanny Rolland, youngest daughter of Robert Bowes Malcolm, M.D., F.R.S.E., of George-street, Edinburgh.

DEATHS.

Boot, John Hopkinson, M.D., at Sleaford, Lincs, on August 18, aged 68.

Copland, Maria Annie, eldest daughter of James Charlesworth Copland, M.R.C.S. Eng., at 87, Ladbroke-grove, Notting-hill, on August 18, aged 13.

Grayson, Francis Dorrell, only son of Francis Dorrell Grayson, M.R.C.S., Eng., at Rayleigh, Essex, on August 20, aged 8 months.

Nason, Charles Arthur, M.R.C.S. Eng., at Ashford, Kent, August 13, aged 35.

Shaw, Edward Charles James, M.D., M.R.C.S. Eng., at the Firs, Elstree, Herts, on August 15, aged 69.

Smith, Alexander James, M.R.C.S., eldest son of Alexander Smith, Esq., Deputy Collector, Chetput, Madras, at Ramsgate, on August 15, aged 22.

Willows, Robert George Edward, M.R.C.S., late of Chesterton, Staffs, only son of Major-General J. E. L. Willows, Bengal Staff Corps (Retired), at Oakfield-road, Penge, on August 21, aged 25.

VACANCIES.

Birmingham and Midland Free Hospital for Sick Children.—Resident Medical Officer. Candidates must be unmarried, and registered members of the medical profession. Applications, with certificate of registration, accompanied by references, to be sent to the Medical Committee, Children's Hospital, Shelthouse-lane, Birmingham, not later than September 7.

Charlton Union.—Assistant to the Workhouse Medical Officer. Applicants must be fully qualified and registered. Applications, accompanied by copies of recent testimonials and statement of qualifications, to Wm. N. Edgill, Clerk to the Guardians, not later than September 4, endorsed "Assistant to Medical Officer."

Holbeach Union, Lincolnshire.—Medical Officers for the Lutton and Tydd Districts, and Public Vaccinator for the Lutton District. Applications, stating qualification, accompanied by testimonials and certificate of registration under the Medical Acts, to Richard P. Mossep, Clerk, on or before September 5.

Royal Free Hospital, Gray's Inn-road.—Assistant-Physician and Assistant-Surgeon. The Assistant-Physician must be a Member of the College of Physicians of London, and the Assistant-Surgeon a Fellow of the Royal College of Surgeons of England. Testimonials to James S. Blyth, Secretary, before September 1.

Royal United Hospital, Bath.—House Surgeon. Candidates must be M.R.C.S., and registered. Diplomas and testimonials of professional capacity and moral character to the Secretary, on or before August 30.

Somerset County Lunatic Asylum.—Assistant Medical Officer, unmarried, and duly qualified in both Medicine and Surgery. Only gentlemen who have held the post of either House-Surgeon or House-Physician in some recognised general hospital need apply. Applications, stating age, together with recent testimonials (which must be printed), to be addressed to the Medical Superintendent.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Amersham Union.—Mr. B. Baker has resigned the Missenden District; area 6200; population 2382; salary £50 per annum.

Drayton Union.—The Third District is vacant; area 14,338; population 2650; salary £25 per annum. Mr. E. T. Thompson has resigned the Fifth District; area 11,201; population 2438; salary £21 per annum.

Worksop Union.—Dr. Coutts has resigned the Cuckney District; area 7557; population 1590; salary £20 per annum.

APPOINTMENTS.

Samford Union.—Thos. Pink, M.R.C.S. Eng., L.S.A., to the Stratford District.

Royal College of Surgeons.—The library and museum of this institution will be closed as usual in September for the necessary repairs and cleaning of both departments.

Migraine.—In order to alleviate pain in the course of an attack of migraine, or to cut it short at the commencement, Delioux recommends the juice of a lemon to be squeezed into a cup of coffee without milk or sugar, and drunk off at a draught.—*Union Méd.* Aug. 7.

Morphia Injections in Puerperal Convulsions.—Dr. Dieterich relates two cases with a view of encouraging the more frequent resort to subcutaneous injection of morphia in puerperal convulsions. In these cases recovery rapidly followed the injection of a quarter or one sixth grain of the hydrochlorate, a repetition being required in one of these.—*St. Petersb. Méd. Woch.*, July 28.

Pessaries.—During a discussion at the Gynæcological Society, Dr. Atlee, of Philadelphia, observed that he had had no experience in the introduction of pessaries, but that he had had a large experience in their withdrawal. He had been able to remove the symptoms in most of his patients without the use of pessaries, and when that could be done he was satisfied without their use. With the uterus and pelvic organs in a healthy condition a change in position of the uterus was of no significance whatever, and there was no need of an instrument to keep it in a certain position.—*New York Med. Record*, July 7.

A Transformation following Mumps.—M. Lereboullet presented a soldier, aged twenty-two, before the Société des Hôpitaux who had undergone a very serious transformation as a result of an attack of mumps. When affected by this four months ago, he was in possession of full virile powers, but four days after the origin of the mumps he was seized with double orchitis, the testicles acquiring the size of a fist. Three days later, the orchitis disappeared, the parotidean tumefaction persisting for some time longer, and then also disappearing. In the course of twenty days the testes became so atrophied as not to exceed an almond in size. At the same time the mammary glands underwent considerable development. The man, whose pilous system of the pubis was well developed, also found his beard ceased growing, so that the chin became absolutely smooth. Thus, this young man, who before had presented all signs of virility and no signs of feminism, now found his testicles wasted, his breasts developed, and his venereal desires gone. M. Lereboullet believed these changes were definitive, and that they should (why we cannot imagine) exempt the subject of them from military service.—*Gaz. des Hôp.*, August 14.

OILING THE URETHRA.—M. Desprès has employed, re all other surgeons, various substances for greasing instruents intended to be passed into the bladder, but has often und, in spite of every precaution, that very painful friction produced. Although not a partisan for injecting the bladder ior to lithotrity, experience has taught him that greasing e patient is a far more effectual procedure than greasing the struments. For this purpose he injects, by means of a glass ringe, without any catheter, from seventy to eighty grammes oil, and this renders the passage of the instruments far less ainful, these passing into the bladder, so to say, by their own eight.—*Gaz. des Hôp.*, August 4.

A SENSIBLE ARRANGEMENT.—Dr. Winsor prefa ces is report, June, 1876, of the Middlesex East Medical Society, Massachusetts, with the following statement:—"This society as held a meeting every month on some evening near to full oon, always at the house of some member who volunteers o act as host and furnish a supper for hard-worked physicians, any of whom ride a number of miles to the meeting, and me of whom must come without supper at home, and cannot e held to regular attendance on meetings for medical improvement unless they can be certain to find a pleasant, social eal provided there. The average attendance has been thirteen embers."

AUTOMATIC REDUCTION OF DISLOCATION OF THE EMUR.—At a meeting of the New York Academy of Medine, Dr. Crosby described Dr. Allen's mode of procedure. t consists in flexing both legs at right angles to the thighs, nd both the thighs at right angles to the abdomen. When in his position, the operator, by means of his hands placed eneath the knees, lifts the patient off the bed, and while radually swinging him from side to side the dislocated head lips into the acetabulum. Dr. Allen discovered the method ccidentally, while lifting a patient from one side of the bed to he other. The head slipped into the acetabulum of its own ccord, when he thus held him in order that the bedclothes ight be arranged.—*New York Med. Journ.*, July.

THE BOYLSTON PRIZE QUESTIONS.—The Medical Committee of the Boylston Prize appointed by the President and Fellows of Harvard University proposes the following prize questions:—For 1878 there are two questions, for each of which a prize of $75 is offered—1, "Antiseptic treatment: What are its essential details? How are they best carried out n practical form?" 2. "Diphtheria: Its causes, diagnosis, nd treatment." For 1879, prizes of $200 are offered for successful dissertations on either of the following subjects:—. "The relation of animal contact in the diseases known as ydrophobia." 2. "Evidence showing that so-called 'filth iseases' are not dependent upon 'filth.'" Essays are to be ent in by the first Wednesday in April in the respective ears, addressed to "J. B. S. Jackson, M.D., Boston, Mass." The pages of the essays are to be bound in book form, and preference will be given to those essays which exhibit original work.—*Boston Med. Journ.*, July 5.

EFFECTS OF PILOCARPIN.—Dr. Popow, reporting upon he results derived from the hypodermic injection of pilocarpin n men in health and suffering from fever, and in experiments pon animals made in Prof. Suschtschinsky's laboratory, comes o the following conclusions:—1. Pilocarpin produces the ame effects as an infusion of the leaves of jaborandi; 2. An njection of from 0·01 to 0·02 gramme induces abundant weating, without causing the unpleasant effects (giddiness, omiting, cephalalgia) produced by jaborandi, and is, therefore, etter suited for therapeutical employment; 3. The temperaure diminishes without any prior exaltation, from one hour nd a half to four hours, and reaches its minimum soon after he cessation of the sweating; 4. The increased excretion of aliva is observed alike in the healthy and the sick after doses f from 0·001 to 0·015 gramme. Sweating only occurs in such doses in the healthy—fever patients, *e.g.*, typhus, requiring 0·02 gramme; 5. The quickening of the heart's action produced by the pilocarpin continues a pretty long time after small doses, but when large ones are employed this is soon replaced by retardation; 6. On the direct introduction of pilocarpin into the veins a retardation of the heart's action takes place suddenly without any prior acceleration; 7. Doses not exceeding 0·03 gramme do not exert any particular effect on the alimentary canal; but large doses (0·05 to 0·10 gramme) induce purging or even bloody stools, with intestinal movements and the development of gases.—*St Petersburg Méd. Woch.*, Aug. 4.

PROFESSIONAL SWALLOWING OF FOREIGN BODIES.—The *Australia Medical Journal*, January, gives an account of a mountebank undergoing imprisonment for being unable to restore a gold ring which he had swallowed, belonging to the prosecutor. He is being treated by the visiting surgeon of the gaol with the view of making him disgorge a large steel albert chain and a common brass ring. The chain can be distinctly felt at the bottom of the stomach, and the prisoner states that it is now nine months since he swallowed it, and it is the only one he has had any difficulty about. He says that he has had 2lb. weight of jewellery in his stomach, and has had watches there as long as twenty-four hours. The gaoler has a collection of objects, such as albert chains, penknives and rings, which he has procured by making him vomit by emetics. The prisoner is an intelligent young man of twenty-three.

REMOVING FOREIGN BODIES FROM THE ŒSOPHAGUS.—Dr. Reeves says:—"The plan is exceedingly simple, and it may be said to be the same as that adopted for extracting pieces of cork from bottles, the only difference being that the ends of the wire are bent outwards and upwards instead of inwards, and in place of a wire ring to compress the prongs, a large-sized catheter is passed down to their extremities, which, when the wires are passed beyond the obstruction, is drawn up to allow the prongs to expand. The instrument is made in the following manner:—Three or four pieces of elastic wire, from twenty to twenty-four inches long, are twisted together down to within half an inch of their extremities, the extreme ends of which are curved outwards and upwards, and carefully filed down to prevent their injuring the coats of the canal. A piece of large-sized catheter of the same length is passed down, to prevent the prongs expanding, the extremities fitting well over the ends of the catheter, to admit of the instrument readily passing beyond the obstruction, without driving it deeper into the canal. The instrument, with the prongs closed, is passed down the gullet, well beyond the piece of bone or money, and the tube is then drawn up, the prongs expanding, bringing with it the foreign body. Some difficulty may be experienced with fine long fish-bones, from the extremities of the prongs not being able to obtain sufficient hold upon them to loosen them from their attachment to the mucous membrane; but if a little floss-silk is passed loosely from the extremity of one prong to the other, this will be overcome."—*Melbourne Medical Record*, May 23.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. R. Young.—Received with thanks.

Nestor.—A Parliamentary Committee in 1815 struck the *first* blow against the system of mechanical restraint of the insane; but it was not before the early years of the present reign, that the old system was superseded by the benevolent treatment set on foot by Drs. Gardiner Hill and Conolly.

Silas.—Paley's remark, was in all "instances wherein the mind feels itself in danger of being confounded by variety, it is sure to rest upon a few strong points, or perhaps upon a single instance. Amongst a multitude of proofs it is *one* that does the business." "If we observe in any argument," he continues, "that hardly two minds fix upon the same instance, the diversity of choice shows the strength of the argument, because it shows the number and competition of the examples."

Ignoramus.—No doubt, in ancient times, water was believed to be an element, or simple substance in nature. As is well known, it is now ascertained by experiment that water is not an elementary body, but is a substance composed chiefly of two gases—oxygen and hydrogen—in a state of chemical union.

David G.—The Belgian general census, which terminated on December 31 last, shows that Belgium now numbers 5,336,185 inhabitants.

Scientific.—Dr. Gilbert, an English physician, made the first step towards a generalisation of facts on "Electricity," in the year 1600. He published a valuable treatise on the subject. Boyle, Guericke, Newton, and some other philosophers of that period, also contributed to extend knowledge on it; but the real science of electricity took its rise in a later age. About the middle of the eighteenth century very remarkable facts were ascertained, particularly by Benjamin Franklin; but the extensive relations which connect it with so many other departments of physical science were not discovered till the present century, nor was their importance until then appreciated.

Val.—A curious case of injury to the brain is recently recorded:—A farm labourer was thrown from a horse, and sustained a fracture of the skull, portions of the cranium near the left temple being driven into the substance of the brain. Forty-eight hours elapsed after the accident before the examination was made, and it was found that some spicules of bone, still attached by their bases, were piercing the brain with their free ends. These being removed, it was discovered that there must be a piece of bone still lodged in the man's brain. By a careful search made with the probe and a finger, a piece of bone about an inch and three-eighths long, by three-quarters of an inch broad, was withdrawn. During the operation, performed under chloroform, a considerable quantity of blood and brain-substance escaped. While the brain was exposed to view, it was seen to rise and fall with the pulsations of the arteries, but no movement was perceived synchronous with expiration or inspiration. When the patient vomited, brain-matter bulged out of the open wound, but receded again when vomiting ceased. The man made a rapid recovery. In this instance not only were the membranes severely lacerated, but large quantities of brain-matter escaped. The most noticeable feature in the case is the recovery of the man, for at no period was there any inflammation, nor were the senses or faculties of the patient in any way affected. The recovery was due to the constitution of the patient, who had youth, health, and strength on his side.

COMMUNICATIONS have been received from—

Mr. R. Brudenell Carter, London; Dr. Barlow, London; Dr. Herman, London; Mr. John Chatto, London; Mr. Warrington Haward, London; Dr. F. Churchill, Tunbridge Wells; Dr. Boustead, Ryde; Mr. T. APPOINTMENTS FOR THE WEEK.

August 25. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

27. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

28. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

29. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

30. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

31. *Friday*.

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, August 18, 1877.

BIRTHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·77 in. The highest reading was 29·90 in. on Sunday morning, and the lowest 29·61 in. on Tuesday afternoon.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

THE HUNTERIAN LECTURES FOR 1877.

ON DEFECTS OF VISION WHICH ARE REMEDIABLE BY OPTICAL APPLIANCES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By ROBERT BRUDENELL CARTER, F.R.C.S.,
Late Professor of Surgery and Pathology to the College; and Ophthalmic Surgeon to St. George's Hospital.

LECTURE V.—ASTIGMATISM.

(*Concluded from page* 193.)

HAVING approximately determined the chief meridians, and the eye being fully under the influence of atropine, the inner disc should be so turned as to make its three lines coincide in direction with one of the meridians; and then the ametropia for these lines, in that position, should be tested with the greatest possible care by spherical lenses. When the best lens is found, the inner disc should be moved a little in both directions, in order to discover, by the position in which the best vision is obtained, the precise direction of the meridian under examination; and then the lines should be placed in a position at right angles to the former one, and the ametropia tested again. When a definite result is obtained, the astigmatism, and the lenses required for its correction, may be ascertained by a very simple calculation. In order to make this clear, it may be well to take examples from each of the five possible varieties of the condition. For this purpose I will select actual cases from my note-books.

Case 1. *Simple Myopic Astigmatism.*—On looking at Pray's letters, the patient said that the stripes in the top line were clearer than the others, and those in N and U were the clearest. Her attention was then directed to the lines on the disc, which were placed from IX to III, or in a horizontal direction, and she counted them readily. No glass improved her vision for them. Her answers about the letters had left the *precise* direction of the chief meridians uncertain; but on moving the disc a little, she declared that the lines were most distinct when their right hand extremities were depressed about 10° below the horizontal position—that is, to one-third of the distance between III and IV on the clock face. For lines so placed she was emmetropic. On turning them to be at right angles to this position, or with their upper extremities one-third of the distance from XII to I on the dial, they became extremely dim, but were rendered clearly visible by a concave lens of one dioptric and a half. Here, then, was the condition shown in Fig. 26, with the difference that the greatest corneal curvature was nearly horizontal, thus producing myopia for vertical lines. A plano-concave cylinder of a dioptric and a half, with its axis corresponding with the direction of the visual defect, that is, with its upper extremity inclined 10° to the right of a vertical line, restored vision nearly to the normal standard, and relieved all the inconvenience which the patient had previously suffered.

Case 2. *Simple Hypermetropic Astigmatism.*—On looking at Pray's letters, the patient said that the lines in D were quite clear, and, on placing those of the disc in the corresponding position, that is, from II to VIII on the dial, no glass rendered them more distinct. They also became less clear by any change of position. On placing them in the reverse direction, from XI to V, they were obscurely seen, but were rendered distinct by a convex lens of two dioptrics. Hence, there was the condition shown in Fig. 27, with the difference that the chief meridians were inclined 30° from the horizontal and vertical positions. A convex plano-cylinder of two dioptrics, with the upper extremity of its axis 30° to the left of the vertical line, corrected the defect.

Case 3. *Compound Myopic Astigmatism.*—Pray's types showed that the chief meridians were horizontal and vertical. For the right eye, for horizontal lines, there was a myopia of eight dioptrics; and for vertical lines a myopia of five and a half dioptrics. For the left eye there was myopia for horizontal lines of seven and a half dioptrics, and for vertical lines a myopia of four and a half dioptrics. Both eyes, therefore, resembled Fig. 28, the preponderance of myopic curvature being in the vertical meridian, and the preponderance of myopic vision being for horizontal lines. Taking the right eye, a plano-concave cylinder of two and a half dioptrics—the difference between the myopia of the two meridians—equalised this difference, put back focus v to coincide with focus h, corrected the astigmatism, but left five and a half dioptrics of myopia in all meridians. The case required therefore, for complete correction, a spherico-cylindrical lens, one side of which was a concave spherical lens of five and a half dioptrics, the other side a concave cylinder of two and a half dioptrics. The cylindrical side of this lens corrected the astigmatism, the spherical side corrected the residual myopia; and the axis of the cylinder was so placed as to correspond with the direction of the highest degree of myopic vision—that is, it was horizontal. The defect of the left eye was corrected in a similar manner; and the patient has now worn the glasses with comfort for nearly four years.

Case 4. *Compound Hypermetropic Astigmatism.*—In the right eye Pray's types showed that the meridians were vertical and horizontal; in the left they corresponded with the lines in letters P and B. In the right eye there was hypermetropia of half a dioptric for horizontal lines, and hypermetropia of three dioptrics for vertical lines. In the left eye there was half a dioptric of hypermetropia in the direction of the lines in P; and there were two dioptrics in the direction of the lines in B. The right eye precisely resembled Fig. 29: the preponderance of hypermetropic formation being in the horizontal plane, and the preponderance of hypermetropic vision being for vertical lines. The left eye differed from Fig. 29 in that its chief meridians were inclined thirty degrees from the horizontal and vertical positions. Taking the right eye, a convex plano-cylinder of two and a half dioptrics, with its axis vertical, corrected the astigmatism, and left half a dioptric of uncorrected hypermetropia. This small amount of hypermetropia might in many cases be neglected without harm; but the patient in this instance was past forty, her accommodation was very limited, and so I prescribed a spherico-cylindrical glass, by which both the hypermetropia and the astigmatism were corrected. The left eye was treated on the same principle.

Case 5. *Mixed Astigmatism.*—A girl of eighteen, with simple hypermetropic astigmatism of her left eye, had the chief meridians of the right in the directions of the lines in the letters E and C of Pray's types. For the lines in C she had myopia of one dioptric; and for the lines in E she had hypermetropia of half a dioptric, making a dioptric and a half of astigmatism. Her eye differed from Fig. 30, in that its chief meridians were diagonal. Three forms of correction were possible. A concave cylinder of a dioptric and a half would have carried back focus v to h, leaving the eye hypermetropic to half a dioptric; and this plan might have answered very well. A convex cylinder of a dioptric and a half would have brought up focus h to v, leaving the eye with a myopia of one dioptric, which would have required correction, at least for distant vision, by a concave spherical surface on the other side of the lens. A lens having two cylindrical surfaces, at right angles to each other, one a convex of half a dioptric, the other a concave of one dioptric, served by the former surface to bring forward focus h to the retina, and by the other to put back focus v to the same position. The visual result of this combination left nothing to be desired.

In considering the possible methods of correcting any particular case of astigmatism, it is necessary to think about the way in which the eye is to be used, with especial reference to its accommodation. Like all others, astigmatic eyes become presbyopic; and, if we so correct astigmatism as to leave them emmetropic—or, still more, if we leave them hypermetropic—they will need convex spectacles in addition to the correction, for reading and other close occupations, as soon as the presbyopia begins to assert itself. This requirement may sometimes be fulfilled by the original manner of correction, sometimes by an addition to the plane (or to the spherical, as the case may be) side of the correcting lens. Thus, in Case 2, where the correction of a simple hypermetropic astigmatism of two dioptrics left the eye approximately emmetropic, this emmetropic eye will have its near-point receding as life goes on. It will then be easy to correct the presbyopia, without interfering with the astigmatism, by grinding on the other side of the cylindrical lens whatever convex power is required; remembering that the compound lens so made will only be needed for near work, and that the original must still be used for all distant objects. Sometimes the requirements of presbyopia may be met in a different manner. I was

consulted by a gentleman forty years of age, upon whom an iridectomy had been performed in the treatment of iritis. The eye had recovered from the operation, but was the subject of an acquired astigmatism, due to alteration of curvature consequent upon the wound. I found it emmetropic for horizontal lines, and with two dioptrics of myopia for vertical lines. A concave cylinder of two dioptrics, with its axis vertical, gave perfect vision for distance; but the eye thus furnished had but small power of accommodation, and, being rendered emmetropic, required convex spectacles for reading. By giving a convex plano-cylinder of two dioptrics, with its axis horizontal, the eye was rendered as myopic in the horizontal as it was previously in the vertical meridian, the astigmatism being corrected in the direction of rendering the eye as a whole myopic, and not in the direction of rendering it emmetropic. The result was that the patient read perfectly with the plano-cylinder alone; and this, as it subjected the rays of light to simpler conditions of refraction than a spherico-cylindrical lens would have done, afforded the best, because the simplest, means of correcting the defect. In many analogous cases the surgeon will find ample opportunity for the exercise of ingenuity and resource; always bearing in mind that the office of the cylindrical lens is to equalise the refraction of the chief meridians, and so to correct astigmatism, leaving any ametropia which may be residual to the astigmatism to be dealt with, if necessary, by a spherical lens with which the cylindrical one may be combined. The conditions which are to be fulfilled are of the most extreme simplicity, and nothing but the perverted ingenuity of authors has appeared to deprive them of this character.

The method of testing astigmatism which I have described, although it seems to me the best which can be used, has many rivals. Dr. Green, of St. Louis, has invented a most elaborate series of test-objects; and so many others have been devised by various persons that it would exceed my limits even to enumerate them. The optometer of Hirschberg, mentioned in the first lecture, is fitted with metal caps, each pierced by a narrow slit, for the testing of astigmatism, the *rationale* of this arrangement being that looking through a slit produces effects analogous to those of looking at a line. The slit is turned first in the direction of one chief meridian, and then in that of the other, and the ametropia is ascertained for both. From the data thus obtained the astigmatism is deduced in the ordinary way.

The only other method which requires notice is that by means of the direct ophthalmoscopic image—and I have deferred until now what I have to say upon this method as applied not only to astigmatism, but also to ametropia generally. The method is based upon the principle that the rays of light which are returned from the retina of an emmetropic eye leave the cornea parallel; while those which are reflected from the retina of a myopic eye leave the cornea convergent, and those which are reflected from the retina of a hypermetropic eye leave the cornea divergent; the degree of convergence or of divergence, in either case, being the measure of the degree of ametropia. The passive emmetropic eye can only obtain a clear image from parallel rays; and hence an emmetropic observer, looking into an ametropic eye with his own accommodation absolutely at rest, would require to add to his ophthalmoscope a lens sufficient to correct the ametropia, as a condition of seeing the retina clearly. In other words, the passive emmetropic eye, in order to look into the ametropic one, requires the same lens which the ametropic eye itself requires for distant objects. Again, if the observer himself is not emmetropic, but ametropic, his own ametropia will be a known quantity for which allowance can be made. If he be myopic, his myopia must be added to the convex lens required for a hypermetropic eye, and must be deducted from the concave lens required for a myopic eye. Thus, suppose an observer with two dioptrics of myopia. In examining another eye, he requires a concave lens of four dioptrics to give him a clear image. It is manifest that two of the four dioptrics will be the correction of the observer's myopia; and that only the other two dioptrics represent the myopia of the observed. In examining an emmetropic eye, the same observer would require a concave of two dioptrics; and, hence, an eye for which he required no lens would be hypermetropic to two dioptrics; the defects of the observer and of the observed precisely neutralising each other. In the same way, if we suppose the observer to be hypermetropic, his hypermetropia would increase by its own amount the apparent hypermetropia of another eye, and would decrease to the same extent the apparent myopia. In a case of astigmatism, it is said to be easy to determine with the ophthalmoscope, by the different degrees of clearness of the retinal vessels which course in different directions, not only the directions of the chief meridians, but also the degree and kind of ametropia in each. In order to facilitate such observations, ophthalmoscopes are now made with an abundant supply of concave and convex lenses, so placed upon a disc behind the mirror that they may be brought in rapid succession over the sight-hole; and the latest and best of these ophthalmoscopes, that of Dr. Loring, of New York, has its mirror hung in such a manner that it can be inclined to the angle required for illumination independently of the disc, so that the observer may look always through the axis of the auxiliary lens, and may thus avoid distortion of the retinal image from looking obliquely. We are told that it is quite possible to determine ametropia and astigmatism in this way, and to prescribe spectacles for their correction, without putting a single question to the patient. While admitting some of the premises, I must express my dissent from the conclusion.

It is obvious, and therefore undeniable, that an experienced observer, looking into the eye of another with an ophthalmoscope so arranged as to give the erect or virtual image of the fundus, will see at a glance whether the eye so examined is in any marked degree ametropic, and the form of the ametropia. He will also see whether it is astigmatic; in which case vessels running in some one direction will be more clearly defined than any others.

In order to do more than this, to determine with precision the degree of the ametropia, or the degree and nature of the astigmatism, conditions would be required which I believe can never, or scarcely ever, be fulfilled.

In the first place, there is no object in the fundus of the eye which is of such a nature as to show plainly when the best definition of it is obtained. Ametropia depends upon the distance between the yellow spot and the apex of the cornea, and the optic disc will not serve as the required object, because it is situated at a variable distance from the yellow spot, and sometimes, especially in myopic eyes, is distinctly anterior to it. At the yellow spot itself there are no bloodvessels to serve as test objects, and there is nothing to be seen in a normal eye but the somewhat granulated looking surface of the pigmented epithelium, seen through the transparent layers of the retina, and more or less obscured, in this position, by the image of the flame which affords the necessary illumination. The appearance of this surface may vary a little, when a change is made in the power of the lens through which it is seen; but there is nothing to show which variation should be accepted as the best representation. The observer must carry his eye a little way from the yellow spot, to a region where there are small retinal bloodvessels, which, if he knew their diameter, might answer his purpose. But he does not know their diameter in any given case, and they are upon a background of a colour only slightly different from their own. The observer cannot tell whether he is looking at a vessel of the smallest calibre, a little out of focus and so made to appear broader by diffusion, or at a vessel of the next degree of magnitude seen clearly. The examination does, in fact, test the vision of the observer instead of that of the patient; and the first essentials of accurate testing—objects of known aspect, known distance, and known magnitude—are wanting and cannot be supplied. On this ground alone, I believe it is impossible to arrive within a dioptric of trustworthy results.

In the next place, the refraction of both the eyes concerned is liable to be continually, and in an unknown degree, disturbed by variations in their accommodation. The eye of the patient may, indeed, be atropinised; and this is often essential. The ophthalmoscopic mode of testing has been recommended, however, upon the ground, among others, that it renders atropine unnecessary, because the observed eye, having no definite object of vision, will completely relax its accommodation. I am quite sure that this idea is a delusion; and that neither in hypermetropia nor in myopic spasm will the accommodation be completely relaxed by the absence of an object of vision. In these cases, if the test were otherwise fine enough, the observer would get the refraction of the observed eye, *plus* the unknown amount of accommodation which it was at the moment exerting. The application of atropine to the eye of the observer would be impossible in ordinary practice; but some tell us that this is immaterial, for that they have acquired by training the power of knowing how much accommodation they are exerting at any given

time. I have not the smallest doubt that all who thus profess do so in perfectly good faith; but none the less I find it impossible to yield assent to their professions. I know of no parallel instance in which the muscular sense of any other organ has been trained to anything like equal delicacy. Even that of the fingers is clumsy by comparison. We are asked to believe, it must further be remembered, that this extraordinary degree of muscular sense is exercised at a time when the attention is occupied by something else—namely, by the aspect of the retinal image. To me it seems certain that the observer, looking at the retina of the observed eye, would have his attention concentrated upon the object of vision, and that he would exert, quite unconsciously, whatever accommodation within his range might be needed in order to give him a clear view. His conjectural estimate of the amount of this accommodation could only be an afterthought, coming at a time when the effort itself had been discontinued

On these grounds, then, from the uncertain character and position of the only available objects of vision, and from the further uncertainty due to unknown and unknowable variations in the accommodation of the observer, I regard the ophthalmoscope as affording only a rough test of ametropia or astigmatism—trustworthy, perhaps, within a dioptric or two, but having no valid claim to greater accuracy. I have been confirmed in this opinion by some cases in which spectacles, especially for astigmatism, have been prescribed as the result of ophthalmoscopic investigation, and in which they have entirely failed to meet the requirements of the patient. I remember one such instance particularly, in which the patient was himself a medical man. He had mixed astigmatism, and came to me wearing plano-concave cylindrical glasses. The myopia of one meridian had been discovered, but the hypermetropia of the other had been wholly overlooked. The only case in which I can imagine accuracy being attained by the ophthalmoscope is when the observer is myopic in so high a degree as to have little or no use for his accommodation, and to be accustomed to work at a perfectly definite far-point. Given these conditions, he might be able to keep his accommodation passive during the act of looking; but eyes which are highly myopic are so often defective, from choroidal or other changes, that it seems scarcely desirable to rely upon them for the conduct of fine and accurate observations.

As a cylindrical lens corrects astigmatism, so, of course, it renders a normal eye astigmatic; and by wearing cylindrical lenses it is easy to feel and realise the conditions of vision which astigmatism produces. It has been said, and is often supposed, that astigmatism produces distortion of the shape of objects; but, as a matter of fact, it has no such effect. If we place a cylindrical lens in the dioptric apparatus of a magic lantern, we shall obtain distortion of the images cast upon the screen; but this is due to the fact that the rays of light, after their refraction, travel a sufficient distance to allow the distortion to take place. The distance between the cornea and the retina is not sufficient for this purpose; and the only effect of astigmatism is to obscure certain boundary lines, rendering them hazy and ill-defined. If we place cylindrical glasses, with their axes vertical, close to the eyes, and look at any well-known object, such as a postage-stamp, we shall see no alteration in its shape; but its lateral boundaries, and the lateral boundaries of the Queen's head, will look fuzzy and diffused. If we remove the lenses a little way from the eyes, so as to give the distance necessary for distortion, distortion will take place, the object appearing extended in a vertical direction if the lenses are concave, and extended horizontally if they are convex. It is unimportant whether the object looked at is near or distant. As long as the cylindrical lenses are close to the eye, an obscuration of the boundary lines of the object, in a direction transverse to the axes of the cylinders, is the only effect observed; but, as soon as the lenses are held at a distance, alteration of shape becomes apparent. As the seat of ordinary astigmatism is in the cornea, what is true of the lens held close must be true, *à fortiori*, of the astigmatic eye itself; and hence the suggestion that the correctness of figure drawing can be disturbed by astigmatism is one which appears to me to have no sort of foundation in the facts of the case.

Although, in testing for astigmatism, cylindrical glasses are not required, it is nevertheless useful to be provided with them, as means of demonstrating to the patient how much his vision will be improved by their use. Whatever may be the variety of the affection, the examination should always be conducted under atropine, since in no other way can perfect accuracy be attained. Even in the myopic forms, we constantly find that we do not obtain the same answer to a question about the effect of a given lens after a short interval of time; the accommodation undergoing frequent variations, consequent upon efforts to see now this and now that boundary line of some neighbouring object. The use of atropine involves a few days of inconvenience, but this time may be curtailed by the occasional instillation of a drop of a solution of sulphate of eserine after the examination has been concluded; and, even if the atropine action is left to run its course, the eyes will only be better for the rest afforded them. The examination, if complete and accurate, need only be made once in a lifetime; and hence no pains should be spared in order to arrive at full knowledge of the truth. An additional reason for the use of atropine is furnished by the fact, of which my experience leaves me in no doubt, that the astigmatism of an eye in its natural state is sometimes apparent only, and is due to the circumstance that the accommodation-change is greater in some one meridian than in others. This applies chiefly, I think, to hypermetropia; and I have seen many instances in which, with a marked degree of apparent astigmatism before atropine was employed, complete paralysis of accommodation has removed the astigmatism, and has left only hypermetropia to be corrected. The temporary inconvenience which attends upon the use of atropine is a very small matter when the future comfort of vision is at stake. An effect sufficient for all practical purposes may be obtained by three applications of a drop of a four-grain solution of the neutral sulphate. One of these applications should be at bedtime on the night preceding the examination; the others in the morning, at intervals of two hours, and the last of them two hours before the examination is commenced. If this method leaves some shred of accommodation remaining, the amount will not be sufficient to vitiate the conclusions which will be reached. In some instances it will be better to atropinise the eyes singly, allowing one to recover before the other is examined; but this is a matter which in astigmatism, as in other forms of ametropia, may depend solely upon the arrangements and the convenience of the patient.

The efficacy of the glasses, however accurately they may be prescribed, will depend upon the positions of their axes; since a position at right angles to the correct one will double the defect. Hence it is usual to make cylindrical spectacle lenses circular, so that any slight deviation from correct position may be rectified by turning them a little in the rings of the frame. In prescribing, the surgeon should not only specify the position of each axis in writing, but he should also use a diagram of a frame, and should draw a line across this diagram to show the position. When the spectacles are otherwise ready, the patient should himself give the lenses their final adjustment before they are fixed; and in this way the most precise accuracy may be attained.

Inasmuch as almost all eyes are to some extent astigmatic, it is manifest that the defective curvature must reach a certain degree before it calls for optical assistance. It may perhaps be assumed that a small amount of astigmatism is useful in giving to the eyes some amount of that quality which is called penetration in microscopic object-glasses; and that, if the curvatures of the chief meridians were identical, accurate vision would be too closely limited to objects lying in a single plane. According to Donders, astigmatism of less than a dioptric is seldom disturbing to vision; but there are great individual differences in this respect. As a general rule, we may parody the legal maxim, and may say, "*De minimis non curat oculus;*" but we shall nevertheless see, in treating of asthenopia, that under some circumstances even very small defects of refraction will require to be carefully estimated and corrected.

Religious Insanity in the United States.—Dr. Fisher, after relating (*Boston Medical Journal*, July 19) some cases of insanity which he regards as mainly produced by a recent revival at Boston, furnishes the result of an examination which he has made of the reports for 1876 of about sixty of the lunatic asylums of the United States. From these he finds that in the New England States 4·97 per cent. of the total cases are set down to religious excitement; 2·78 per cent. in the Middle States; 7·43 per cent. in the Southern States; and 8·37 per cent. in the Western States. The total number of cases dealt with was 36,983, of which 2144, or 5·79 per cent., were referred to religious excitement.

FORTY-FIFTH MEETING
OF THE
BRITISH MEDICAL ASSOCIATION,

HELD IN MANCHESTER, AUGUST 7, 8, 9, AND 10, 1877.

THE SECTION OF PHYSIOLOGY.

ABSTRACT OF THE OPENING ADDRESS.

By ARTHUR GAMGEE, M.D., F.R.S.,
Brackenbury Professor of Physiology in Owens College; President of the Section.

AN annual address, such as the one I have the honour to deliver to-day, affords a favourable opportunity, if not for casting a retrospect on all the work done during the year in our special department, at least of drawing attention to some of the more evident advances which have been made. I therefore purpose laying before you an account of some of the work which has been done of late, and which, I believe, is destined to leave its impress on science. Whilst the attention of scientific men generally has been devoted more keenly than ever before to those ferment actions which are associated with the life of minute organisms, our knowledge of the remarkable class of unorganised or unformed ferments has undergone, of late, very great development. "Unorganised" or "unformed" is the term applied to such ferments as those which occur in the animal body, to distinguish them from certain elementary organisms which, possessing the power of setting up certain decompositions (fermentations) in bodies with which they are in contact, are termed *organised ferments*. Unorganised ferments are chiefly distinguished from organised —(1) by the fact that they may be dissolved in certain menstrua without any impairment of their ferment action, thus the ferments of the animal body are probably without exception all soluble in glycerine and in water; (2) by the fact that their action is not prevented by many agents, such as chloroform and salicylic acid, which at once arrest the action of organised ferments. The ferments of this class which have been longest known to us as belonging to the animal body are ptyalin and pepsine—the former, the amylolytic ferment of the saliva; the latter, the proteolytic ferment of the gastric juice. With regard to the former, we know that its physiological importance is very secondary to that of the latter, in that it is absent from the saliva of the great majority of animals (its presence being, indeed, a rare exception); that fluid serving primarily mechanical functions, dissolving certain of the constituents of food, moistening the whole mass, and thus co-operating in a most important manner in the acts of gustation, mastication, and deglutition. With regard to the gastric jnice, it has long been known that its function is a purely chemical one, that it depends upon a ferment, pepsine, which, in the presence of dilute acids and at the temperature of the body, possesses the power of dissolving insoluble proteids, and converting them into bodies termed *peptones*, which, whilst not differing sensibly in chemical composition from the bodies whence they are derived, possess the power of diffusing readily through animal membranes—bodies which, being absorbed, are capable, as direct experiments have lately positively shown us, of being reconverted into the various proteids occurring in the tissues and organs of the body.

The researches of Corvisart, of Bernard, and of Kühne, showed that the gastric juice is not the only alimentary secretion possessed of proteolytic action, for the pancreatic gland secretes a fluid which is capable of acting on all the three chief groups of organic constituents of food—upon the proteids, the starches, and the fats—in virtue of three distinct ferments: one proteolytic, capable of converting proteids into peptones; one amylolytic, like ptyalin; and a third capable of decomposing fats into fatty acids and glycerine. The proteolytic action of the pancreas had been positively ascertained by Corvisart, but comparatively little importance was paid to it until the researches of Kühne showed that not only are the conditions of the activity of this ferment different from those of pepsine, but that the results of its activity differ also. Kühne showed that, when proteids are dissolved by the pancreatic juice, not only are peptones formed, but considerable quantities of leucine and tyrosine; these bodies, of which the former is closely related to the fatty acids, and the latter to the group of aromatic bodies, prove by their presence that not only is the action of the pancreatic juice upon certain proteids more powerful than that of the gastric juice, weight for weight, but that the former attacks the proteid molecule in a more profound manner. These facts are already old to science, but they have lately been added to in many particulars. First of all, Heidenhain has shown us that in the pancreas, as also in the salivary glands and stomach, there are structural differences to be observed which correspond with the various states of functional activity of these organs. During rest, the secretory cells of the pancreas enlarge, and there accumulates within them granular matter, which disappears when the gland enters into activity and the gland-cell shrinks. Further, he has pointed out that the secretory cell of the pancreas at the time of secretion does not contain ready-formed ferment, but a body which, under suitable circumstances, yields the ferment, and which he terms *zymogen*, ferment-generator. Heidenhain has shown that the zymogen yields the ferment when it is present in a watery solution, more rapidly still when it is treated with weak acids; he has studied more carefully than had ever been done before the conditions of the activity of the fully formed ferment, and has shown that alkalies are as essential to its activity as are acids to the activity of pepsine, a watery solution of sodium carbonate of 1 per cent. being as favourable to the activity of the proteolytic ferment of the pancreatic juice as is a watery solution of hydrochloric acid containing 0·2 per cent. to that of the proteolytic ferment of the stomach. To these discoveries, partly anatomical and partly chemical, of Heidenhain, Kühne has added others, however, which throw great light, not only on the functions of the pancreas in digestion, but likewise on the mutual relations of gastric juice, bile, and pancreatic juice. To the proteolytic ferment of the pancreas, Kühne applies the distinctive name of *trypsin* (presumedly derived from *θρύπτω ψω*, break up, crush). He has shown that trypsine differs from pepsine in that it appears to be proteid in nature. Its activity is increased by alkalies and alkaline fluids, such as the bile; but it is prevented by acid fluids. Trypsine has no power of digesting pepsine, but pepsine in acid solutions has the power of destroying trypsine. Here we have one important explanation of the function which the bile serves in digestion. The bile, as has long been known, helps to neutralise the acid chyme, and brings peptic digestion proper to a close; initiating, in this way, the conditions which are favourable to pancreatic digestion at the very time when this digestion should commence.

I shall leave the researches of Kühne without referring in detail to his views on the different action of pepsine and trypsine upon the proteid bodies, because these appear to me to be, to a certain extent, hypothetical, and shall now speak of the ferments of the intestinal juice. This fluid appears, by the researches of Thiry and others, to contain a ferment which possesses the power of dissolving certain of the proteids, as boiled fibrine; the ferment which is chiefly characteristic of it is, however, one which possesses in a singularly high degree the power of converting cane-sugar and milk-sugar into grape-sugar. This ferment, which had long been surmised to exist, has lately been re-investigated by Claude Bernard, who finds that it can be dissolved and precipitated by the reagents which dissolve and precipitate the other unorganised ferments of the body; to it he gives the name of the *inverting ferment* (ferment inversifi). Great light has thus lately been thrown upon those functions of the alimentary canal whereby proteids, starches, and sugars are modified. Is our knowledge concerning the digestion and absorption of fats progressing? It has long been known that both the bile and pancreatic juice possess the power of emulsionising fats, and, as I previously stated, it has also been known that the pancreatic juice possesses, to a certain extent, the power of splitting up fats into glycerine and fatty acids. The result of such a decomposition in the alkaline intestinal fluid would be the formation of soaps, which would aid by their presence the emulsionising of the remaining fat. That this decomposition of fat goes on to a large extent is scarcely probable, and it has always been considered one of the unsolved riddles of physiology how fat makes its way from the intestines into the lacteals. In a very thorough research on the anatomy of the intestinal canal, Dr. Herbert Watney appears to offer a solution. He believes that the finely divided, *i.e.*, emulsionised, fat makes its way into the interior of the villus by passing through the intercellular substance of the epithelium covering the villus.

Perhaps one of the most startling discoveries made in physiology of late years is that of the so-called *vision-purple*. It had been pointed out long ago by Heinrich Müller that the rods of the frog's retina are of a red colour, which, he thought, might be due to the imbibition of blood-colouring matter. Leydig afterwards again drew attention to the fact that the retina of the frog presents to the naked eye a lively red satiny gloss; and Max Schultze, in the second of his classical memoirs on the retina, makes the same observation for the retina of the owl and of the rat; stating, in the case of the latter, that it exhibits a strikingly distinct satin-lustre with a red glimmer. On November 23 last, Professor Du Bois Reymond presented to the Berlin Academy a communication from Professor Boll, of Rome, announcing what he then believed to be an absolutely new fact—viz., that the external layer of the retina possesses in all living animals a purple colour. During life, according to Boll, the peculiar colour of the retina is perpetually being destroyed by the light which penetrates the eye. Darkness, however, restores the colour, which vanishes for ever immediately after death. In this paper, Boll pointed out that the red colouration which the fundus of the eye exhibits when examined ophthalmoscopically does not depend upon the illumination of the choroidal vessels, but upon the proper colour of the retina—a conclusion which he afterwards modified, as being too sweeping. The wonderfully suggestive nature of Professor Boll's discovery led Professor Kühne, of Heidelberg, to repeat Boll's observations; and in doing so, whilst he confirmed the fundamental statement of Boll, he ascertained a large number of facts which added great interest to the discovery.

Kühne's observations were made on the retinæ of frogs and rabbits. In the first place, implicitly relying upon the statements of Boll, he examined, as soon as possible after death, the retinæ of animals which had been kept for some time in darkness. He soon found that the beautiful purple colour persists after death if the retina be not exposed to light; that the bleaching takes place so slowly in gas-light, that by its aid the retina can be prepared and the changes in its tint deliberately watched; that, when illuminated with monochromatic sodium light, the purple colour does not disappear in from twenty-four to twenty-eight hours, even though decomposition have set in. These first observations of Kühne on the vision-purple, as he terms it, whilst they showed that the disappearance of the colour is not, as Boll had asserted, a necessary concomitant of death, removed many of the difficulties which stood in the way of a careful investigation. Carrying out his preparations in a dark chamber illuminated by a sodium-flame, Kühne was able to discover the conditions necessary to the destruction of the vision-purple, as well as some facts relating to its restoration or renewal. As long as the purple retina is kept in the dark, or is illuminated only by yellow rays, it may be dried on a glass plate without the tint changing; the colour is not destroyed by strong solution of ammonia, by saturated solution of common salt, or by saturation in glycerine for twenty-four hours. On the other hand, a temperature of 100° Cent. destroys the colour; and alcohol, glacial acetic acid, and strong solution of sodium hydrate produce the same effect. It is not true, as Boll asserted, that the retina of the living eye exposed to ordinary daylight does not exhibit the vision-purple; for, on preparing the eyes of animals which had just been exposed to light as quickly as possible, in the chamber illuminated by sodium-light, Kühne found the retina to be of a beautiful purple. It is only when eyes are exposed for a considerable time to the direct action of the sun's rays, that a fading of the purple colour is perceived.

A most suggestive experiment now threw some light upon the circumstances which retard the decolorisation, and which restore the vision-purple. The two recently extirpated eyes of a frog were taken; from one the retina was removed, whilst an equatorial section was made through the other eye, so as to expose the retina, and still leave it *in situ*. Both preparations were exposed to diffuse daylight until the isolated retina had lost its purple colour. On now taking the other preparation into the yellow chamber, and removing the retina, Kühne found that its colour yet remained; it was *dark red*, but was bleached when exposed in its naked condition to daylight.

The most curious and remarkable of Kühne's discoveries consisted, however, in finding that, as long as the retinal epithelium is alive, it possesses the power of restoring the faded vision-purple. If an equatorial section be made through a recently extirpated eye, and a flap of the retina be lifted up from the underlying choroid to which the retinal epithelium adheres, and exposed to light, the purple colour of the flap will be destroyed, whilst the colour of the rest of the retina persists. If, however, the bleached portion of the flap be carefully replaced, so that it is again in contact with the inner surface of the choroid, complete restoration of the vision-purple occurs. This restoration is a function of the living choroid, or rather of the living retinal epithelium which adheres to it—*i.e.*, of the hexagonal pigment-cells which, until Max Schultze showed their true relations, were looked upon as part of the choroid; and it is independent of the black pigment which the retinal epithelium normally contains. As it is absolutely dependent upon the life of the structures which overlie the layers of rods and cones, it is natural that it should be observed to occur for a longer time after somatic death in the frog than in the rabbit.

The discoveries of Boll and Kühne must, as the latter remarked, have called back to the memory stories which we all have heard of images of things seen at the moment of death being left imprinted on the eye. After his first researches, Kühne endeavoured over and over again to observe on the retina of rabbits bleached spots corresponding to the images of external objects; but his endeavours failed. As Kühne remarks, and as all who have followed my accounts of his experiments will allow, in order to obtain an obvious picture, or, as he terms it, optogram, upon the retina, the effect of light would have to be so prolonged or so intense as to destroy the balance between the destruction of the vision-purple and the power of the retinal epithelium to restore it. If the image of a luminous object were to fall upon the retina at the time of death, and were maintained there until the death of the retinal epithelium, then a picture ought to be visible after death, appearing of a white colour with purple borders.

Kühne took a rabbit and fixed its head and one of its eyeballs at a distance of a metre and a half from an opening thirty metres square in a window-shutter. The head was covered for five minutes with a black cloth, and then exposed for three minutes to a somewhat cloudy midday sky. The animal was then instantly decapitated; the eyeball which had been exposed was rapidly extirpated by the aid of yellow light, then opened, and instantly plunged into a 5 per cent. solution of alum. Two minutes after death, the second eyeball, without removal from the head, was subjected to exactly the same processes as the first—viz., to a similar exposure to the same object, then extirpation, etc. On the following morning the milk-white and now toughened retinæ of both eyes were carefully isolated, separated from the optic nerve, and turned. They then exhibited, on a beautiful rose-red ground, a nearly square sharp image with sharply defined edges. The image on the first eye was somewhat roseate in hue, and less sharply defined than that on the second, which was perfectly white. The size of the images was somewhat greater than one square millimetre.

Since these most striking phenomena were described by Boll and Kühne, both these observers have pursued their inquiries, which have besides been confirmed by a number of independent inquirers. Kühne has studied with great care the chemical characters of the vision-purple, which, though exceedingly sensitive to light, is a body which resists very violent means of attack. From the yet living retina the vision-purple may be extracted by a colourless solution of crystallised bile, which then becomes of a beautiful purple colour, which is destroyed by light. The purple of dead retinæ cannot be extracted by such a solution; it has become insoluble. Indeed, such a retina may be extracted successively with solution of bile, with weak acetic acid; then be subjected to pancreatic digestion; be afterwards dried, treated with alcohol and with benzol; after drying, washed with concentrated solution of ammonia; and yet the vision-purple remains (mixed with neuro-keratin). It preserves its colour throughout all these operations, provided they are carried on in monochromatic yellow light; but exposure to white light bleaches it for ever.

What interpretation are we to give to these remarkable facts of Boll and Kühne, which teach us that the living retina contains a substance which, under the influence of light, undergoes constant changes, which vary in intensity according to the intensity and character of the luminous rays, and which teach us, moreover, that the internal epithelium is to be looked upon (to use Kühne's expression) as a purple generating gland?

They enable us to realise how probably light acts as a stimulus of the end-organs of the optic nerve, by inducing a chemical decomposition of matters connected with these end-

organs. Still, as has been most philosophically shown by Kühne, the vision-purple does not yet explain all the physical changes in the retina which are the precursors of luminous impressions, for the following reasons:—1. The cones of the retina possess no purple colour in the frog. 2. In the monkey Kühne has found that the fovea centralis is destitute of vision-purple: the same is, doubtless, true of man. 3. In some animals, as in snakes, the retina possesses only cones and no rods, and is therefore destitute of vision-purple.

We need no further facts than the one afforded by the absence of vision-purple in the fovea centralis, to prove to us that the vision-purple is not essential to the perception of light. Still, how interesting are the facts which I have brought under your notice, and how pregnant with thoughts and suggestions alike to the physiologist and the psychologist.

The interest which was aroused by the beautiful discoveries to which I have just directed your attention is scarcely greater than that which we have experienced in becoming acquainted with Engelmann's confirmation of the truth of Hermann's views on the "muscular current," and by the splendid investigation in which Hermann supports the position which he took up some years ago.

Let me remind those of my hearers who are not physiologically expert that, when any point in an artificial transverse section of a muscle is connected by means of non-polarisable electrodes to a galvanometer with any point on a natural or artificial longitudinal surface of the muscle, an electrical current passes through the galvanometer from the longitudinal to the transverse surface; in other words, the former is electrically positive in reference to the latter.

This so-called muscular current bears, in the case of voluntary muscles, a direct relation to the irritability of the muscle, and only lasts as long as the muscle remains irritable. Du Bois Reymond, to whom we owe all the methods of observing the electrical phenomena of the tissues, and to whom we owe, moreover, our knowledge of the laws which govern the muscular current, showed that, whenever the muscle passes from the state of rest into that of activity, there is a diminution of the intensity of the muscular current, technically known as its "negative variation."

Du Bois Reymond maintained that the tendinous end of a muscle bears the same electrical relations to its external longitudinal surface as an artificial transverse section, and he therefore called the tendon the natural transverse surface of the muscle. He himself admitted, however, that occasionally there is but a very feeble current to be observed passing between the tendinous and longitudinal surfaces; in some cases, indeed, the tendon being positive in reference to the natural longitudinal surface. To this condition Du Bois Reymond gave the name of the parelectronomic condition, and stated that it was observed most frequently in frogs which had been subjected to cold. I have not time to refer to the *molecular hypothesis* of Du Bois Reymond, by which he sought to explain both the normal muscular current and the parelectronomic condition, as these are well known to all.

Professor Hermann, however, some years ago, asserted that, *in a perfectly uninjured unskinned animal, the muscles which are in a state of rest are entirely free from electrical currents.* According to Hermann, muscles which have been removed from the body without any injury being inflicted upon them are the seat of feeble currents of very varying intensity and direction.

Any injury inflicted upon the muscle—as, for instance, the contact of the external surface of the frog's skin with it, or the tearing of muscular fibres,—at once sets up a muscular current by giving rise to an artificial transverse section.

Hermann's explanation of these phenomena is the following:—Muscle which is passing into a state of rigor (dying), or which is passing into the state of activity, is, in relation to living muscle at rest, with which it is brought into contact, electrically negative. The negativity of the artificial transverse section is to be explained by the section having at once initiated the process of rigor in the injured muscle-fibres.

I need scarcely refer to the animated discussion which has been proceeding for several years, and which has, on the part of the school of Du Bois Reymond, had for its object the demonstration of the truth of what may be termed the pre-existence theory of the muscular current, in opposition to the contact theory of Hermann, which, it appears to me, received its death-blow by the researches of Engelmann. This observer has shown that the absolutely uninjured heart is altogether currentless; moreover, that *not only the heart as a whole, but each individual muscle-cell contained in the heart, whilst in an uninjured state and at rest, is almost or quite free from electrical currents.*

The principal fact in Engelmann's most recent researches which merits attention is his discovery of the very rapid diminution of the electro-motive force of the current observed when a cross section through the base of the ventricle is in connexion with one electrode, and the apex of the heart with the other. Within five minutes, according to Engelmann, the electro-motive force sank to 64 per cent. of its original value; in fifteen minutes, to 32·9 per cent.; in one hour to 4·7 per cent.; in twenty-four hours, to 1·1 per cent. The extraordinary nature of this result will be better appreciated when we contrast the influence of time on the electro-motive force in the case of the sartorius of a frog. In one hour, the electro-motive force had sunk to 86·1 per cent. of the original; in twenty-four hours, to 43·6 per cent.; in forty-eight hours, to 30·8 per cent.; or, to summarise, the electro-motive force of the heart, through which a section dividing the base of the ventricle has been made, diminishes as much in ten minutes as that of the sartorius in twenty-four hours, the heart, after twenty-four hours, being practically currentless.

Now, these facts are to be taken in connexion with the undoubted fact that the heart preserves its irritability, *i.e.*, its vitality, for a singularly long period of time. How, then, are these facts to be explained? Engelmann has done so in the sense of Hermann's theory. If the heart may remain irritable and be currentless, then that relation between the electro-motive properties and the irritability of muscles, which formerly was maintained to exist, cannot hold.

The muscular substance of the heart differs from that of voluntary muscle chiefly in its being composed of cellular contractile elements, which are many hundred times shorter than the muscle-tubes of voluntary muscle. When a section is made through the heart-substance, the process of rigor or death is initiated in the muscular fibre-cells which are injured, and the section becomes negative in respect to any uninjured part of the heart's surface; the process of death does not, however, extend to neighbouring cells, it is confined to the cell first injured; when the latter is dead, we then have it behaving as an indifferent conductor. On the other hand, in the case of the muscle-tube, the process of rigor proceeds from one end to the other, being unarrested, until the whole is rigid and dead. Both physiological and anatomical facts support Englemann's beautiful explanation. For instance, microscopically, it may be shown that the cells adjacent to those which have died remain normal and contractile; again, a new section made parallel to the first one will, in the case of the heart of which the current, once strong, has become very weak, cause it to return to its original intensity—a result which does not occur with voluntary muscle.

And now we come to Hermann's great research, published only a few weeks since. The idea which served as the basis of this research was the following:—To prepare a muscle (the gastrocnemius) so as to injure it as little as possible, to place it in contact with non-polarisable electrodes, and to determine the electro-motive force of the current of the whole muscle; then, having compensated this, to inflict a sudden injury upon the tendinous end, and, after an interval, which could be varied at will, to determine again the electro-motive force of the muscle. Professor Hermann used in this research an instrument which he calls the "fall rheotome." A falling weight is made to inflict an injury upon the tendon of the gastrocnemius by rubbing a piece of fish-skin, and then, after an interval, which can be varied, to close a circuit between non-polarisable electrodes connected with the muscle and the galvanometer.

The long and interesting account must be read in the original in order to appreciate the value of the results, which may, however, shortly be stated as follows. When an injury is inflicted upon a muscle, or upon the tendon of a muscle, which is not the seat of electrical currents, or of which the electrical currents have been compensated, there is, as a result of the injury, developed a powerful muscular current; this does not set in at once, but requires at least one-four-hundredth of a second for its full development.

If those muscles when at rest are not, as was held by Du Bois Reymond, the seat of electrical currents, are there any changes in the electro-motive properties to be observed when muscle passes from the state of rest into that of activity? Certainly, as I previously stated, according to the contact

theory of Hermann, any part of a muscle which is passing into the state of activity is negative in reference to any other point in the same muscle which is at rest; and the uninjured muscle does show this negative deflection. In the case of uninjured gastrocnemius, it has been shown by T. Meyer, and fully confirmed by Hermann, that there is a double variation, portions of which become at first negative, and then positive.

The following numbers express the mean duration of the negative variation, and of the succeeding positive variation, deduced from fifteen experiments:—

Commencement of negative variation ...	0·0049 sec.	after excitation.
Change in direction of current	0·0098 ,,	,,
End of positive variation	0·0147 ,,	,,

We can quite conceive that some, who are inclined to disparage science, would be inclined to quote the changes in our views of the distinct relations of muscle as proving the uncertainty—nay, the unsatisfactory nature—of researches which have been conducted with the greatest care, and in which we have all placed the greatest reliance. But to the scientific man, who weighs the matter carefully, there will appear nothing in any sense disparaging either to the dignity of science on the one hand, or to the merit of the distinguished man who has hitherto done more than anyone else in the department of muscle- and nerve-electricity, if his views as to the pre-existence of the muscular current must now be abandoned. But for the facts which he discovered, but for the methods with which he enriched physiology, we can scarcely doubt that we should be much farther from the truth than at present. His facts, indeed, have nearly all been confirmed, though the interpretation of some appears to require some modification, in order to bring them into unison with more recent discoveries.

We have passed, or rather we are passing, through a period of great anxiety to English physiology. A popular clamour, unfortunately too well known to all of you, has imperilled the studies which we all have so greatly at heart. An Act of Parliament is now in force which, if interpreted in a spirit of hostility to science, might put a stop to these studies. But I trust that the spirit of the time, the spirit of justice too, which, we think, characterises our countrymen, will render such hostility impossible; and, relying upon the justice and enlightenment of the Minister of the Crown to whom the enormous responsibility of carrying out this Act has been entrusted, we venture to predict that the interests of science will not ultimately suffer.

Gentlemen, I cannot close this address without expressing the gratification and pride with which I see amongst us the eminent man who to-day honours us by his presence. In Carl Ludwig we see one of the three or four men who, more than all others, have helped to build up the present edifice of physiology; a man to whom those of our science will refer in ages yet to come as having, perhaps more than anyone else, introduced methods of precision into physiology, and, by numerous conquests in nearly all its departments, proved their utility. We welcome him amongst us, and beg to assure him that the influence of his teaching extends not only to every university of Germany, but even tous. All of us have, more or less directly, learned from him, and all of us are, I trust, inspired by his intense devotion to science, and would, at any rate, emulate, to the extent of their power, the example of the great head of the Leipzig Physiological School, who, in unselfishly contributing to win successes for his pupils, for the furtherance of the science which he loves, has seen the fullest realisation of his proudest hopes.

THE SECTION OF PSYCHOLOGY.

OPENING ADDRESS.

By JOHN CHARLES BUCKNILL, M.D., F.R.S.,
Late Lord Chancellor's Visitor; President of the Section.

CONFESSION: THE PHYSICIAN AND THE PRIEST.

Gentlemen,—This occasion seems opportune for speaking on a subject of great and general importance to us as specialists—namely, whether the customary practice of our specialty does not frequently tend to impair our usefulness, by limiting our field of observation and by narrowing our views of men and of society. Certainly, we are not unfrequently accused of the prejudices born of narrowness and one-sidedness; and quite recently I have heard it asserted by the highest and most revered authority among laymen, whose judgment upon us is as kindly as it is conscientious, that the power of certifying insanity ought not to be exclusively entrusted to those who have deeply studied the subject, because they would be most inclined to find half mankind of unsound mind. "I confess I should be very much alarmed," said Lord Shaftesbury to the Select Committee on the Lunacy Laws (Question 11,347), "if there were persons who kept themselves exclusively to that (giving certificates of lunacy) without knowing all the special circumstances which beset lunacy; all the social and ten thousand other circumstances; and all the eccentricities which are developed by men who are not mad, and who yet, under the discrimination of science, would be put down as being in the way of being mad."

There can be no doubt that all special employment leads to narrowness of mind, and that the learned professions suffer from this tendency most notably. This, indeed, was long ago pointed out by Archbishop Whateley in his work on "Rhetoric"; and there can be no doubt that there is a legist's narrowness, and a priest's narrowness, and a physician's narrowness. It will be very useful to ask ourselves whether, within the latter, there is not also a mental physician's narrowness, tending to explain natural varieties of character and natural courses of conduct upon the assumption of morbid deviations from an unknown standard of sanity. For, like the old king, who, when he heard of crime or misfortune among men, always asked "Who is she?" are we not somewhat disposed, in all human follies and miseries, to ask "What is the insanity?" and are we not often tempted to parody Carlyle's cynical description of this realm, as a fair country, containing thirty millions of men, mostly lunatics? If this criticism be too wide and general, it is surely not wholly without foundation, and may well be taken by us as a warning voice against a danger incident to our very peculiar calling in life; for, if you think of it, the study and care of men with diseased minds is a very peculiar calling, distinguishing us from all the rest of the world, which carries on all the business of life on the assumption that men are reasonable beings. Society rubs along, believing in the rule of reason as it does in the law of gravitation; and although we may enjoy vastly more credit than the levitating spiritualists, we scarcely stand on a less distinct foothold from the common faith which actuates the daily conduct of our fellow-men; and the greatest caution is needful that, as the companions of the insane, we do not become too much associated with them in their modes of thought. The learned author of the "History of Civilisation" maintained that the characters of men are developed from their objective surroundings, so that the men of the mountain, of the plain, of the forest or the desert, differ from each other in consequence of the great features of nature by which their character is fashioned, and which they reflect in mental and bodily peculiarities. This, no doubt, is in great measure true; but it is even a more weighty truth that the individual man reflects his fellow-men, and that man is the creature of his social surroundings, and the due consideration of this most important factor of mind is the great addition which Mr. Herbert Spencer and his followers have contributed to modern philosophy. Mind as subject and nature as object does not explain, as used to be said, the whole field of thought and things to be thought of, of feelings and things to be felt. There is a supplement to this: the minds of other men, the manifestations of which are objects, but which in themselves are not objects, but what Professor Clifford, with his keenest insight and appreciation, proposes to call ejects; and these minds of other men it is which really and effectually mould us to what we are. To be moulded by the best minds is the greatest happiness, to be fashioned by the worst is the greatest misfortune which a human being can endure. To be warped by the dishonesty or to be soiled by the impurity of other minds, is bad enough; but, if it be possible that the sound mind can be made to vibrate the discords of unreason by association with the unsound, that, indeed, would be a misery worse than any which the imagination of Dante dared to invent. And who shall say that it is not possible, and even probable? Nay, who shall say that it is not a dreadful fact, dimly revealed in the traditions of our specialty? It is not, however, from any complete fall, but of those touches of imperfection from that contagium of surroundings, the danger of which is imminent and perhaps unavoidable, against which I most desire to exhort you to employ the antiseptics of frequent recreation of mind and body, combined

with the tonics of sane companionship and sound-minded occupation and study. I wish to insist upon the great need of the mental physician to breathe much of the pure air of rational life, for the sake both of himself and of his patients; and of the greater need the more he is of a true mental physician, understanding incoherence and delusion, and sympathising with morbid feeling. If the oculist were to abide long in his dark room, he would soon be worth little as an oculist; and if there be one man more than another ought to be a man of the world, it is the physician who has the care of the insane; for if he allow himself to become ignorant of the outside world, he will be able to make no comparisons of the sane with the insane; and, therefore, liable to consider opinions and conduct morbid which are only strange, a danger of which I could give you amusing examples. An instance of it was, I think, given by Lord Shaftesbury, in certain physicians who considered a lady insane because she carried a small dagger in her dress; carrying such daggers at that time being a common freak of fashionable dressmaking, unknown to those innocent doctors. Other instances I have myself met with in men, who have been certified and treated as lunatics on account of certain habits which are unnatural and portentous to Englishmen, but which these miserable men had acquired in climes and countries where such habits are common, causing no abomination and little remark. Consequently, these denationalised Englishmen who had contracted them were simply vicious and not insane. Even among different classes of our own community, it is difficult for any man who has only observed the habits, opinions, and sentiments of the poor, the rude, and the uneducated, to appreciate and sympathise with those of the wealthy, the refined, and the cultured. The man who could blow hot and cold was not more strange to the Satyr, than the infinite diversity of human nature is to the man of limited education and narrow experience. Therefore, the man of wide culture and broad training must be best able to understand all kinds and conditions of insane people, and to compare them with all kinds and conditions of the sane; to appreciate vehement feeling and strange conduct which does not transgress the bounds of health; and to influence devious and morbid character of all kinds and wayward spirits of every variety; while the work of the narrow specialist must needs become ever more injurious to himself and ever less helpful to his patients.

But, if the psychologist can derive so much instruction and guidance for his own work from knowledge of the outside world, so also he can reflect light upon some of the most important, and yet the most obscure, problems of human life. If the physiology of mind be the key to its pathology, so also does this pathology illustrate mental physiology; and, if sociology strengthen the hand of the psychologist, the latter repays the debt by the aid which his special training and knowledge enables him to give in the investigation of great social questions.

It was said by Descartes that, "If it be possible to perfect mankind, the means of doing so will be found in the medical sciences." But, whether or not perfection be ever attained for a subject so vast and variable as mankind, human progress may at least be hoped for through the means indicated by this great philosopher; and, of all the medical sciences by which human progress towards perfection may be promoted, it would seem certain that the science which studies the greatest function of the human organism is the one from which aid and guidance in the march forward may most surely be expected. Men are too selfish and passionate to listen to our teachings, otherwise (not only from the cradle to the grave, but in regard to that obscure and awful time, weighted with fate, which precedes infant life) we could give counsel which, if followed, would prevent fools and madmen from being born into the world. The concepts of conception, treated with such pleasant ridicule in "Tristram Shandy," are weighty factors in the history of the race, and the right principles of sound-minded heredity, of healthy fecundity and fœtality (if I may coin a word), can only be acquired by means of the progressing study of neuro-physiology and neuro-pathology. The aid which the psychologist may hope in future times to lend the State in the great civic duty of building the brains of the young citizens has hitherto been scarcely considered except in the instructive and delightful book of my friend Dr. Edward Clark, of Boston, U.S. The psychologist has indeed been imperatively called upon to labour in those repairing docks, the schools for idiots, for deaf-mutes, and the blind; but in laying down the lines of new vessels he has never yet been consulted. Yet there is small doubt that we could give most valuable advice as to the better methods of ordinary education for healthy children so as to avoid the evils of physical and moral insanitation, of excessive or ill-directed brain-work, of ill-directed or neglected moral guidance, of onanism and athletism, of tunding and suicide. The psychological aspect of crime has not been so much neglected as that of education, and, apart from the important *rôle* played by specialists in courts of justice, the psychological study of the criminal mind has been earnestly pursued by Dr. Nicholson and other inquirers in a manner which promises at least to enlighten the law-making classes as to the genesis and real characteristics of the law-breaking classes. But whether our Society will ever have the courage to repress the generation of criminals is more than doubtful. Rather it would seem that society loses courage as it gains knowledge; and perhaps at some future time the curious spectacle may have to be regarded of a nation composed entirely of philanthropists and criminals, unless indeed it be a law of the race that from time to time the world must be reorganised by an energetic barbarism. Meanwhile the legislator, policeman, and judge, as well as the schoolmaster and the psychologist, are all working at the same task of the building or repairing of brains, and, if all these fellow-labourers could but recognise the fact that their common aim is the right direction of cerebral nutrition, the world would be spared much inanity both of counsel and action.
