Mud-volcanoes.—Though probably seldom if ever strictly volcanic in the proper sense of that term, certain remarkable orifices of eruption may be noticed here to which the names of mud-volcanoes, salses, air-volcanoes, and macalubas have been applied. These are conical hills formed by the accumulation of fine and usually saline mud, which, with various gases, is continuously or intermittently given out from the orifice or crater in the centre. They occur in groups, each hillock being sometimes less than a yard in height, but ranging up to elevations of 100 feet, or even sometimes, as in the plains of the lower Indus, to 400 feet. Like true volcanoes, they have their periods of repose, when either no discharge takes place at all, or mud oozes out tranquilly from the crater, and their epochs of activity, when large volumes of gas, and sometimes columns of flame, rush out with considerable violence and explosion, and throw up mud and stones to a height of several hundred feet.

The gases play much the same part therefore in these phenomena that steam does in those of true volcanoes. They consist of carbonic acid gas, carburetted hydrogen, sulphuretted hydrogen, and nitrogen. The mud is usually cold. In the water occur various saline ingredients, among which common salt generally appears. Naphtha is likewise frequently present. Large pieces of stone, differing from those in the neighbourhood, have been observed among the ejections, indicative doubtless of a somewhat deeper source than in ordinary cases. Heavy rains may wash down the minor mud cones and spread out the material over the ground, but gas-bubbles again appear through the sheet of mud, and by degrees a new series of mounds is once more thrown up.

There can be little doubt that these phenomena are to be traced to chemical changes in progress underneath. Dr Daubeny explained them in Sicily by the slow combustion of beds of sulphur. The frequent occurrence of naphtha and of inflammable gas points, in other cases, to the disengagement of hydrocarbons from subterranean strata.

Mud volcanoes occur in Iceland, in Sicily (Macaluba), in many districts of northern Italy, at Tamar and Kertch, at Baku on the Caspian, over an area of about 1000 square miles near the mouth of the Indus, and in other parts of the globe.

Gaseous Discharges.—Some of these belong to true volcanic phenomena, others are closely associated with the mud-volcanoes. To the former class we may assign the copious emanations of carbonic acid which so frequently take place in districts where volcanic activity has been long dormant or extinct. The gas either comes out directly from fissures of the rock, or rises dissolved in the water of springs. The old volcanic districts of Europe furnish many examples. Thus on the shores of the Laacher See—an ancient crater lake of the Eifel—carbonic acid gas issues from numerous openings called *moffette*, round which dead insects, and occasionally mice and birds may be found. In the same region occur hundreds of springs more or less charged with the gas. The famous Valley of Death in Java contains one of the most remarkable gas-springs in the world. It is a deep, bosky hollow, from one small space on the bottom of which carbonic acid issues so copiously as to form the lower stratum of the atmosphere. Tigers, deer, and wild-boar, enticed by the shelter of the spot, descend and are speedily suffocated. Many of their skeletons, together with those of man himself, have been observed.

In the second class of gas-springs we may group the emanations of carburetted hydrogen, which, when they take fire, are known as Fire-wells. They occur in many of the districts where mud-volcanoes appear, as in northern Italy, on the Caspian, in Mesopotomia, in southern Kurdistan, and in many parts of the United States. It has been observed that they rise especially in regions where beds of rock-salt lie underneath, and as that rock has been ascertained often to contain compressed carburetted hydrogen, the solution of the rock by subterranean water, and the consequent liberation of the gas, has been offered as an explanation of these fire-wells.

Geysers.—In various regions where volcanic action still continues, or where it has long been dormant, there occur eruptive fountains of hot water and steam, to which the general name of geysers is given, from the well-known examples in Iceland, which were the first to be seen and described. Besides the Great and Little Geysers, the Strokkr, and other minor springs of hot water in Iceland, other, perhaps still more striking, examples have in recent years been brought to light in that tract of the western territories of the United States set aside as the "Yellowstone National Park," and good illustrations are also found in New Zealand. A geyser possesses a vertical pipe in the ground, terminating at the surface in a basin which is formed of siliceous sinter, and may rise some feet or yards above the general level. At more or less regular intervals rumblings and sharp detonations occur underneath, followed by an agitation of the water in the basin, and then by the violent expulsion of a column of water and steam to a considerable height in the air. The hot water contains silica in solution, which, on cooling and evaporating, is deposited at the surface; and thus the geyser builds up its basin, sometimes raising it into a long, solitary, finger-like pillar.

Bunsen and Descloiseaux spent some days experimenting at the Icelandic geysers, and ascertained that in the Great Geyser, while the surface temperature is about 212° Fahr, that of the lower portions of the tube is much higher—a thermometer giving as high a reading as 266° Fahr. The water there must consequently be 48° above the normal boiling-point, but is kept in the fluid state by the pressure of the overlying column. At the basin, however, the water cools quickly. After an explosion it accumulates there, and eventually begins to boil. The pressure on the column below being thus relieved, a portion of the superheated water flashes into steam, and as the change passes down the pipe, the whole column of water and steam rushes out with great violence. The water thereafter gradually collects again in the pipe, and after an interval of some hours the operation is renewed. The experiments made by Bunsen proved the cause of the eruption to lie in the high temperature of a portion of the pipe. He hung stones by strings to different depths in the funnel of the geyser, and found that only those in the higher part were cast out by the rush of water, sometimes to a height of 100 feet, while at the same time the water at the bottom was hardly disturbed at all.[1]

These observations give an additional interest and importance to the phenomena of geysers in relation to those of volcanic action. They show that the eruptive force is steam; that the water column, even at a comparatively small depth, has a temperature considerably above 212°; that this high temperature is local; and that the eruptions of steam and water take place periodically, and with such vigour as to eject large stones to a height of 100 feet.

§ 3. *Structure of Volcanoes.*

It is now admitted that a volcano is due to the accumulation of material round the vent of eruption, and not to any blister-like expansion of the ground. The structure of a volcanic cone necessarily depends in great measure upon the nature of the substances ejected. The following are the more important and interesting types of this kind of structure:—

(1.) *Cones of Non-volcanic Materials.*—These are due to the discharge of steam or other aeriform product through the solid crust without the emission of any true ashes or lava. The materials ejected from the cavity are wholly, or almost wholly, parts of the surrounding rocks through which the volcanic pipe has been drilled. Some of the cones surrounding the crater-lakes or *maare* of the Eifel consist chiefly of fragments of the underlying Devonian slates.

(2.) *Tuff-Cones, Cinder-Cones.*—Successive eruptions of fine dust and stones, often rendered pasty by getting mixed with the water so copiously condensed during an eruption, form a cone in which the materials are solidified by pressure into tuff. Sometimes the cones are made up only of loose cinders, like Monte Nuovo in the Bay of Baiæ. Cones consisting entirely of loose volcanic materials often arise on the flanks or round the roots of a great volcano, as happens to a small extent on Vesuvius, and on a larger scale upon Etna. They likewise occur by themselves apart from any lava-producing volcano, though usually they afford indications that columns of lava have risen in their funnels, and even now and then that this lava has reached the surface. Admirable examples are furnished by the cones of the Phlegræan fields near Naples. Ancient cones of a similar character occur among the Carboniferous rocks of Scotland. The materials of the cone are arranged in more or less regular beds which dip away from the funnel, their inclination corresponding with that of the cone. Inside the crater they slope steeply inward towards the crater-bottom.

(3.) *Mud-Cones* or *Salses* are formed by the accumulation and consolidation of mud round the vents of mud-volcanoes. They sometimes reach a height of 400 feet.

(4.) *Lava-Cones.*—These are comparatively rare, since, in most cases, the emission of lava is accompanied by the discharge of ashes. Owing to its liquidity, the lava flows off quickly, and the cones have very gentle slopes. The most remarkable examples are those in the Hawaii Islands described by Professor Dana. They attain a great height, but so small is their angle of inclination, that they may be described as only gently-sloping mounds, and their craters have been compared to vast open quarries on a hill or moor.

[1] Bunsen, *Ann. der Chemie und Pharmacie*, lxii. (1847), p. 1.

(5.) *Cones of Tuff and Lava.*—These are by far the most frequent. They may be taken, indeed, as the typical form of volcanoes. Around the central vent the successive showers of scoriæ and ashes gather, with occasional streams of lava, which from time to time descend different sides of the growing cone. The component strata have thus the usual inclination outwards, though, when seen in section along the crater-walls, they look approximately horizontal. By continued explosions fissures are formed in the sides of the cone. These are injected with lava, producing a network of dykes which strengthen the cone, or they serve as channels of escape for lava, and give rise to lateral eruptions and minor or parasitic cones. As the main cone increases in diameter by the accumulation of fragmentary and molten ejections, it rises also in height, until at last few or no eruptions take place from its summit, but only from openings on its flanks.

(6.) *Submarine Volcanoes.*—It is not only on the surface of the land that volcanic action shows itself. It takes place likewise under the sea, and as the geological records of the earth's past history are chiefly marine formations, the characteristics of submarine volcanic action have no small interest to the geologist. Unfortunately, the phenomena of recent volcanic eruptions under the sea are for the most part inaccessible. Here and there, as among the islands of the Greek Archipelago and at Tahiti, elevation of the sea-bed has taken place, and brought to the surface beds of lava, which had been erupted and had consolidated under water. There does not appear to be any appreciable difference either in external aspect or in internal structure between such submarine lavas and those erupted on the land. Some of them are highly scoriaceous. There is no reason indeed why slaggy lava and loose scoriæ should not accumulate under the pressure of a deep column of the ocean. At the Hawaii Islands, on 25th February 1877, masses of pumice, during a submarine volcanic explosion, were ejected to the surface, one of which struck the bottom of a boat with considerable violence and then floated. At the same time, when we reflect to what a considerable extent the bottom of the great ocean basins is dotted over with volcanic cones, rising often solitary from profound depths, we can understand how large a proportion of the actual eruptions may take place under the sea. The foundations of these volcanic islands doubtless consist of submarine lavas and fragmentary materials, which, in each case, continued to accumulate to a height of two or three miles, until the pile reached the surface of the water and the phenomena became subaerial. The immense abundance and wide diffusion of volcanic detritus over the bottom of the Pacific and Atlantic Oceans, even at distances remote from land, as has been made known by the voyage of the "Challenger," may indicate the prevalence and persistence of submarine volcanic action, though, at the same time, it must be admitted that an extensive diffusion of volcanic debris from the islands is effected by winds and ocean-currents.

4. *Geographical Distribution of Volcanoes.*

The chief facts under this head may thus be summarized. (1.) Volcanoes occur along the margins of the ocean basins, particularly along lines of dominant mountain ranges. The vast hollow of the Pacific is girdled with a wide ring of volcanic foci. (2.) They rise as a striking feature in the heart of the ocean basins. Most of the oceanic islands are volcanic. Even the coral islands have in all likelihood been built upon the tops of submarine volcanic cones. (3.) Volcanoes are thus situated, as a rule, close to the sea. When they occur inland they sometimes appear in the neighbourhood of a large sheet of water. Yet so many instances have been observed where volcanoes have appeared at great distances from any sheet of water that the proximity of a lake or of the sea cannot be regarded as necessary for the evolution of volcanic phenomena. (4.) The dominant arrangement of volcanoes is in lines along subterranean lines of weakness, as in the chain of the Andes, the Aleutian Islands, and the Malay Archipelago. (5.) Where the linear arrangement does not hold, it gives place to one in groups, as in Italy, Iceland, and the volcanic islands of the great oceans.

§ 5. *Distribution of Volcanic Action in Time.*

Besides the existence of what are called extinct volcanoes, the geologist can adduce proofs of the former presence of active volcanoes in many countries where cones and craters and all ordinary aspects of volcanic mountains have long disappeared. Sheets of lava, beds of tuff, dykes, and necks representing the sites of volcanic vents have been recognized abundantly. These manifestations of volcanic action, moreover, have as wide a range in geological time as they have in geographical area. Every great geological period, back at least as far as the Lower Silurian, has had its volcanoes. In Britain, for instance, there were active volcanic vents in the Lower Silurian period, whence the lavas and tuffs of Snowdon, Aran Mowddwy, and Cader Idris were ejected. The Lower Old Red Sandstone epoch was one of prolonged volcanic activity in central Scotland. The earlier half of the Carboniferous period likewise witnessed the outburst of innumerable small volcanoes over the same region. During the Permian period a few scattered vents existed in the south-west of Scotland, and in the time of the New Red Sandstone some similar points of eruption appeared in the south of England. The older Tertiary ages were distinguished by the outpouring of the enormous basaltic plateaus of Antrim and the Inner Hebrides.

Thus it can be shown that, within the same comparatively limited geographical space, volcanic action has been rife at intervals during a long succession of geological ages. The existing active volcanoes of Iceland rise from amid Tertiary lavas and tuffs, which form part of a great volcanic ridge, extending down through the Faroe Islands into the west of Britain. Volcanic action, which now manifests itself so conspicuously along certain lines, seems to have continued in that linear development for protracted periods of time. The actual vents have changed, dying in one place and breaking out in another, yet keeping on the whole along the same lines.

§ 6. *Causes of Volcanic Action.*

Volcanoes depend, of course, upon the internal heat of the planet as their prime source of energy. But the *modus operandi* whereby that internal heat manifests itself in volcanic action is a problem by no means of easy solution. Were this action merely an expression of the intensity of the heat, we might expect it to have manifested itself in a far more powerful manner in former periods, and to exhibit a regularity and continuity commensurate with the exceedingly slow diminution of the earth's temperature. But there is no geological evidence in favour of greater volcanic intensity in ancient times than in more recent periods; on the contrary, it may be doubted whether any of the Palæozoic volcanoes equalled in magnitude those of the Tertiary period, or whether any of the latter ever produced such stupendous changes as have been effected by modern volcanoes still active. On the other hand, no feature of volcanic action is more conspicuous than its spasmodic fitfulness.

The mere presence of a high internal temperature, therefore, would probably not of itself produce the phenomena of volcanoes, at least in the present condition of the planet. There can be no doubt that one essential exciting cause of volcanic action is the descent of water from the surface. It has already been pointed out how invariably steam plays a chief part in volcanic eruptions, how it issues in vast clouds from the crater, and continues to rise copiously from the lava even after the molten rock has travelled for some miles, and has assumed a solid surface. The quantity of water which descends into the interior must be enormous. The floor of the sea, the beds of rivers and lakes, are all leaky. Of the annual rain which sinks beneath the surface of the land, we cannot tell what proportion is detained and prevented from rising again in springs. Not only does this subterranean water percolate down cracks and joints, it infiltrates through the very pores of the rocks, and can do so even against the pressure of steam on the further side.

Accordingly, there has arisen a very prevalent belief among geologists, that it is to the enormous expansive force of perhaps white-hot water finding access to, and imprisoned in, some of the heated empty spaces at the roots of volcanoes that the explosions of a crater and the subsequent rise of a lava-column are due. It has been supposed that, somewhat like the reservoirs in which the hot water and steam accumulate under the Icelandic geysers, these volcanic spaces receive a constant influx of water from the surface, which cannot escape by other channels, but is in great part converted into vapour or retained in the fluid state at an enormously high temperature and under vast pressure. In the course of time, the materials filling up the chimney are unable to withstand the upward expansion of this imprisoned vapour and water, so that, after some premonitory rumblings, the whole opposing mass is blown out, and the vapour rushes up in the well-known masses of cloud. Meanwhile, the removal of the overlying column relieves some of the pressure from the water-charged lava, which therefore begins to rise in the funnel until it forces its way through some weak part of the cone, or pours over the top of the crater. After a time the vapour is expended, the energy of the volcano ceases, and there comes a variable period of repose, until a renewal of the same phenomena brings on another eruption. By such successive paroxysms it is supposed that the form of the internal reservoirs and tunnels become changed; new spaces for the accumulation of superheated water are formed, whence in time new volcanic vents issue, while the old ones gradually die out.

As physical considerations negative the idea of a comparatively thin crust surmounting a molten interior whence volcanic energy might be derived, geologists have found themselves involved in great perplexity to explain volcanic phenomena for the production of which a source of no great depth would seem to be necessary. They have supposed the existence of pools or lakes of liquid lava lying beneath the crust, and at an inconsiderable depth from the surface. They have sometimes appealed to the influence of the contraction of the earth's mass, assuming that the contraction is greater in the outer than in the inner portions, and that the effect of this must be to squeeze out some of the internal molten matter through weak parts of the crust. Cordier, for example, calculated that a contraction of only a single millimetre (about $\frac{1}{25}$th of an inch) would suffice to force out to the surface lava enough for 500 eruptions, allowing 1 cubic kilometre (about 1300 million cubic yards) for each eruption.

The influence of contraction as the grand source of volcanic energy has recently been insisted upon on quite different grounds by Mr Mallet, who has developed the theory that all the present manifestations of hypogene action are due directly to the more rapid contraction of the hotter internal mass of the earth, and the consequent crushing in of the outer cooler shell. He points to the admitted difficulties in the way of connecting volcanic phenomena with the existence of internal lakes of liquid matter, or of a central ocean of molten rock. Observations made by him, on the effects of the earthquake shocks accompanying the volcanic eruptions of Vesuvius and of Etna, showed that the focus of disturbance could not be more than a few miles deep,—that, in relation to the general mass of the globe, it was quite superficial, and could not possibly have lain under a crust of 800 miles or upwards in thickness. The occurrence of volcanoes in lines, and especially along some of the great mountain-chains of the planet, is likewise dwelt upon by him as a fact not satisfactorily explicable on any previous hypothesis of volcanic energy. But he contends that all these difficulties disappear when once the simple idea of cooling and contraction is adequately realized. "The secular cooling of the globe," he remarks, "is always going on, though in a very slowly descending ratio. Contraction is therefore constantly providing a store of energy to be expended in crushing parts of the crust, and through that providing for the volcanic heat. But the crushing itself does not take place with uniformity; it necessarily acts *per saltum* after accumulated pressure has reached the necessary amount at a given point, where some of the pressed mass, unequally pressed as we must assume it, gives way, and is succeeded perhaps by a time of repose, or by the transfer of the crushing action elsewhere to some weaker point. Hence, though the magazine of volcanic energy is being constantly and steadily replenished by secular cooling, the effects are intermittent." He offers an experimental proof of the sufficiency of the store of heat produced by this internal crushing to cause all the phenomena of existing volcanoes. The slight comparative depth of the volcanic foci, their linear arrangement, and their occurrence along lines of dominant elevation become, he contends, intelligible under this hypothesis. For, since the crushing in of the crust may occur at any depth, the volcanic sources may vary in depth indefinitely; and as the crushing will take place chiefly along lines of weakness in the crust, it is precisely in such lines that crumpled mountain-ridges and volcanic funnels should appear. Moreover, by this explanation it is sought to harmonize the discordant observations regarding the variations in the rate of increase of temperature downward within the earth. In some parts of the crust the crushing must be much greater than in other parts; and since the heat "is directly proportionate to the local tangential pressure which produces the crushing and the resistance thereto," it may vary indefinitely up to actual fusion. So long as the crushed rock remains out of reach of a sufficient access of subterranean water, there would, of course, be no disturbance. But if, through the weaker parts, water enough should descend and be absorbed by the intensely hot crushed mass, it would be raised to a very high temperature, and, on sufficient diminution of pressure, would flash into steam and produce the commotion of a volcanic eruption.

This ingenious theory requires the operation of sudden and violent movements, or at least that the heat generated by the crushing should be more than can be immediately conducted away through the crust. Were the crushing slow and equable, the heat developed by it would doubtless be tranquilly dissipated through the crust, the temperature of which might not be sensibly affected in the process, or not to such an extent as to cause any appreciable molecular rearrangement of the particles of the rock. Moreover, as the action is general throughout the whole mass of the outer shell, there does not seem in the theory any valid reason why volcanic action should be limited to particular lines, and why it should continue so long persistently on these lines. The existence of weak parts of the crust is postulated; but the successive crushings and consequent fusions might be expected to strengthen these weaker parts and to make volcanic conditions less easy.

It cannot indeed be denied that there exists the most convincing geological evidence in favour of the secular contraction of the globe, that during the process masses of sedimentary strata, many thousands of feet in thickness, have been crumpled and crushed, and that the crumpling has often been accompanied by such an amount of heat and evolution of chemical activity as to produce a movement and rearrangement of the elements of the rocks,—this change sometimes advancing to the point of actual fusion. There is reason to believe that some at least of these periods of intense terrestrial disturbance have been followed by periods of prolonged volcanic action in the disturbed areas. Mr Mallet's theory is thus, to some extent, supported by independent geological testimony. The existence, however, of large reservoirs of fused rock, at a comparatively small depth beneath the surface, may be conceived as probable, apart altogether from the effects of the subsidence of the outer shell upon the inner nucleus. The connexion of volcanoes with lines of elevation, and consequent weakness in the earth's crust, is precisely what might have been anticipated on the view that the nucleus, though practically solid, is at such a temperature and pressure that any diminution of the pressure, by corrugation of the crust or otherwise, will cause the subjacent portion of the nucleus to melt. It is along the lines of elevation that the pressure must be relieved, and it is there that the consequent melting will take place. On these lines of tension and weakness, therefore, the conditions for volcanic excitement must be best developed. Water is there able soonest to reach the intensely-heated materials underneath the crust, and to give rise to the volcanic explosions. The periodicity of eruptions will thus depend upon the length of time required for the storing up of sufficient steam, and on the amount of resistance in the crust to be overcome. In some cases the intervals of activity, like those of the geysers, return with considerable regularity. In other cases, the shattering of the crust, or the upwelling of vast masses of lava, or the closing of subterranean passages for the descending water, or other causes may vary the conditions so much, from time to time, that the eruptions may follow each other at very unequal periods, and with very discrepant energy. Each great outburst exhausts for a while the vigour of the volcano, and an interval is needed for the renewed accumulation of vapour.

Section II.—Earthquakes.

The phenomena of earthquake-motion having been discussed in the article EARTHQUAKES, we shall notice here only those which have a marked geological importance from the way in which they affect the crust or surface of the earth, briefly describing the effects of earthquakes upon the surface of the land, and upon terrestrial and oceanic waters, the permanent changes of level occasioned by them, their distribution and geological relations, and their causes.

1. *Effects upon the Soil and General Surface of a Country.*—The earth-wave or wave of shock underneath a country may traverse a wide region and affect it violently at the time without leaving any trace of its passage. Loose objects, however, are apt to be displaced. Thus blocks of rock, already disengaged from their parent masses, may be rolled down into the valleys below. Large landslips are thus produced, and these may give rise to very considerable subsequent changes in the drainage of the localities where they take place. It has often been observed that the soil is rent by the passage of the earthquake. Fissures appear, varying in size from mere cracks, like those due to desiccation, up to deep and wide chasms. Where these cracks are numerous, and where, consequently, the ground has been much disturbed, permanent modifications of the landscape may be produced. Trees are thrown down and buried, wholly or in part, in the rents. These superficial effects may, in a few years, be effaced by the gradual levelling power of the atmosphere. Where, however, the chasms are wide and deep enough to intercept any rivulets, or to serve as channels for heavy rain-torrents, they are sometimes further excavated, so as to become gradually enlarged into ravines and valleys. As a rule, each rent is only a few yards long. Sometimes it may extend for half a mile or even more. In the earthquake which shook the South Island of New Zealand in 1848, a fissure was formed averaging 18 inches in width and traceable for a distance of 60 miles parallel to the adjacent axis of the mountain-chain. The subsequent earthquake of 1855, in the same region, gave rise to a fracture which could be traced along the base of a line of cliff for a distance of about 90 miles.

Remarkable circular cavities are sometimes formed in the ground during the passage of the earth-wave. In many cases these holes serve as funnels of escape for an abundant discharge of water, so that when the disturbance ceases they appear as pools. They are believed to be caused by the sudden collapse of subterranean water-channels and the consequent forcible ejection of the water to the surface.

2. *Effects upon Terrestrial Waters.*—Springs are temporarily affected by earthquake movements, becoming greater or smaller in volume, sometimes muddy or discoloured, and sometimes increasing in temperature. Brooks and rivers have been observed to flow with an interrupted course, increasing or diminishing in size, stopping in their flow so as to leave their channels dry, and rolling forward with increased rapidity. Lakes are still more sensitive to the tremors of the ground beneath. Their waters occasionally rise and fall for several hours, even at a distance of many hundred miles from the centre of disturbance. Thus, on the day of the great Lisbon earthquake, many of the lakes of central and north-western Europe were so affected as to maintain a succession of waves rising to a height of 2 or 3 feet above their usual level. Cases, however, have been observed where, owing to excessive subterranean movement, lakes have been emptied of their contents and their beds left permanently dry. On the other hand, areas of dry ground have been depressed, and have become the sites of new lakes.

Some of the most important changes in the fresh water of a region, however, are produced by the fall of masses of rock and earth. Landslips, by damming up a stream, may so arrest its water as to form a lake. The barrier, if of sufficient strength, may be permanent, and the lake will then remain. Owing, however, to the usually loose, incoherent character of its materials, the dam thrown across the pathway of a stream runs a great risk of being undermined by the percolating water. When this is the case, a sudden giving way of the barrier will allow the confined water to rush with great violence down the valley, and produce perhaps tenfold more havoc there than may have been caused by the original earthquake. When the landslip is of sufficient dimensions to divert the stream from its previous course, the new channel thus taken may become permanent, and a valley may be cut out or widened.

3. *Effects upon the Sea.*—The great sea-wave propagated outward from the centre of a sub-oceanic earthquake, and reaching the land after the earth-wave has arrived there, gives rise to much destruction along the maritime parts of the disturbed region. As it approaches the shore, the littoral waters retreat seawards, sucked up, as it were, by the advancing wall of water, which, reaching a height of sometimes 60 feet, rushes over the bare beach and sweeps inland, carrying with it everything which it can dislodge and bear away. Loose blocks of rock are thus lifted to a considerable distance from their former position, and left at a higher level. Deposits of sand, gravel, and other superficial

accumulations are torn up and swept away, while the surface of the country, as far as the limit reached by the wave, is strewn with debris. If the district has been already shattered by the passage of the earth-wave, the advent of the great sea-wave augments and completes the devastation.

4. *Permanent Changes of Level.*—It has been observed, after the passage of an earthquake, that the level of the disturbed country has been changed. Thus after the terrible earthquake of 19th November 1822 the coast of Chili for a long distance was found to have risen from 3 to 4 feet, so that along the shore the littoral shells were exposed adhering still to the rocks amid multitudes of dead fish. The same coast-line has since been further upraised by subsequent earthquake shocks. On the other hand, many instances have been observed where the effect of the earthquake has been to depress permanently the disturbed ground. For example, by the Bengal earthquake of 1762 an area of 60 square miles on the coast, near Chittagong, suddenly went down beneath the sea, leaving only the top of the higher eminences above water. The succession of earthquakes which in the years 1811 and 1812 devastated the basin of the Mississippi gave rise to widespread depressions of the ground, over some of which the river spread so as to form new lakes, with the tops of the trees still standing above the surface of the water.

5. *Distribution and Geological Relations of Earthquakes.*—While no large space of the earth's surface seems to be free from at least some degree of earthquake-movement, there are regions more especially liable to the visitation. As a rule, earthquakes are most frequent in volcanic districts, the explosions of a volcano being very generally preceded or accompanied by tremors of greater or less intensity. In the Old World the great belt of earthquake disturbance stretches in an east and west direction, along that tract of remarkable depressions and elevations lying between the Alps and the mountains of northern Africa, and spreading eastward so as to enclose the basins of the Mediterranean, Black Sea, Caspian, and Sea of Aral, and to rise into the great mountain-ridges of Central Asia. In this zone lie numerous volcanic vents, both active and extinct or dormant, from the Azores on the west to the basaltic plateaus of India on the east. The Pacific Ocean is surrounded with a vast ring of volcanic vents, and its borders are likewise subject to frequent earthquake shocks. Some of the most terrible earthquakes within human experience have been those which have affected the western seaboard of South America.

6. *Causes of Earthquakes.*—An earthquake shock has been defined by Mr Mallett as the transit of a wave of elastic compression through the crust and surface of the earth, generated by some sudden impulse within the crust. The passage of such a wave has been imitated experimentally, and some of its characteristic features have been illustrated by accidental explosions at powder-works. But though the phenomena point to some sudden and violent blow inflicted upon the solid crust, it is impossible to do more than speculate on the probable nature of this blow. In some cases it may arise from the sudden flashing into steam of water in the spheroidal state, from the sudden condensation of steam, from the explosions of a volcanic orifice, from the falling in of the roof of a subterranean cavity, or from the sudden snap of subterranean rocks subjected to prolonged and intense strain. But we are still in ignorance as to the actual immediate cause of any earthquake in regions remote from active volcanoes. So much, at least, is certain, that the shock must arise from some sudden and violent impulse, whereby a wave or undulation is propagated in all directions through the solid substance of the crust.

Section III.—Secular Upheaval and Depression.

Besides the sudden movements due to earthquake-shocks, the crust of the earth undergoes in many places oscillations of an extremely quiet and uniform character, sometimes of an elevatory, sometimes of a subsiding nature. So tranquil are these changes that they produce from day to day no appreciable alteration in the aspect of the ground affected. Only after the lapse of several generations, and by means of careful measurements, can they really be proved. Indeed, in the interior of a country nothing but a series of accurate levellings from some unchanged datum-line might detect the change of level, unless the effects of this terrestrial movement showed themselves in altering the drainage. It is only along the sea-coast that a ready measure is afforded of any such movement. In popular language it is usual to speak of the sea as rising or sinking relatively to the land. But so long as the volume of the ocean remains the same, the general sea-level can neither rise nor fall, unless by some movement of the solid globe underneath it. And, as we cannot conceive of any possible augmentation of the oceanic waters, nor of any diminution save what may be due to the extremely slow process of abstraction by the hydration of minerals, or absorption into the earth's interior, we are compelled to regard the sea-level as practically a constant datum-line, any deviation from which, in the apparent heights of sea and land, must be due to movement of the land and not of the sea.

There are indeed certain cosmical causes which may affect the relative levels of sea and land. Thus the accumulation of large masses of snow and ice as an ice-cap at one of the poles would, as has been above pointed out (*ante*, p. 217), tend to displace the earth's centre of gravity, and as a consequence to raise the level of the ocean in the hemisphere so affected, and to diminish it in a corresponding measure elsewhere. The return of the ice into the state of water would produce an opposite effect. Dr Croll has also drawn attention to the fact that, as a consequence of the diminution of centrifugal force owing to the retardation of the earth's rotation caused by the tidal wave, the sea-level must have a tendency to subside at the equator and rise at the poles. A larger amount of land need not ultimately be laid bare at the equator, for the change of level resulting from this cause would be so slow that the general degradation of the surface of the land might keep pace with it, and diminish the terrestrial area as much as the retreat of the ocean tended to increase it. Dr Croll has further pointed out that the waste of the equatorial land, and the deposition of the detritus in higher latitudes, must still further counteract the effects of retardation and the consequent change of ocean-level.[1]

Such widespread general causes of change must produce equally far-reaching effects. But in examining the changes of level between land and sea, we find them to be eminently local and variable in character, pointing to some local and unequally acting cause,—so that, while admitting these cosmical and widespread influences to be part of the general system of geological change, we must yet hold the sea-level, for all practical purposes, to be invariable, any apparent oscillations of that level upon the land being due to terrestrial movements.

§ 1. *Movements of Upheaval.*

Various maritime tracts of the land have been ascertained to have undergone in recent times, or to be still undergoing, a gradual elevation above the sea. Thus, the coast of Siberia, for 600 miles to the east of the river Lena, the western tracts of South America, and the Scandinavian peninsula, with the exception of a small area at its southern

[1] Croll, *Phil. Mag.*, 1868, p. 382; Sir W. Thomson, *Trans. Geol. Soc. Glasgow*, iii. 223.

apex, have been proved to have been recently upheaved. The proofs of this change of level chiefly to be relied on are the following[1]:—

(1.) The position of rocks covered with barnacles or other littoral adherent animals, or pierced by lithodomous shells. A single stone with these creatures on its surface would not necessarily prove anything, for it might be cast up by a storm; but a line of large boulders, which had evidently not been moved since the cirripedes and molluscs lived upon them, and still more a solid cliff with these marks of littoral or sub-littoral life upon its base, now raised above high-water mark, would be sufficient to demonstrate a rise of land. The amount of the upheaval might be pretty accurately determined by measuring the vertical distance between the upper edge of the barnacle zone upon the upraised rock, and the limit of the same zone on the present shore.

(2.) A line of sea-caves, now standing at a distance above high water-mark beyond the reach of the sea, would afford evidence of recent uprise, since caves of this kind are only hollowed out by the waves between tide-marks.

(3.) One of the most striking proofs of upheaval is furnished by what are termed *raised beaches.* A beach is the space between tide-marks, where the sea is constantly busy producing sand and gravel, mingling with them the remains of shells and other organisms, sometimes piling the deposits up, sometimes sweeping them away out into opener water. The terrace or platform thus formed is a well-marked feature of coast-lines skirting tidal seas. When the land rises with sufficient rapidity to carry up the line of littoral deposits above the reach of the waves, the flat terrace thus elevated is known as a raised beach. The former high-water mark then lies inland, and while its sea-worn caves are in time hung with ferns and mosses, it furnishes itself an admirable platform, on which meadows, fields, and gardens, roads, houses, villages, and towns spring up, while a new beach is made below the margin of the uplifted one. Raised beaches abound round many parts of the coast-line of Britain. Some excellent examples occur in Cornwall and Devon. The coast-line on both sides of Scotland is fringed with raised beaches, sometimes four or five occurring above each other, at heights of 25, 40, 60, 75 and 100 feet above the present high-water mark. Each terrace marks a former lower level of the land with regard to the sea, and probably a lengthened stay of the land at that level, while the intervals between them represent the vertical amount of each successive uplift of the land, and show that the land in its upward movement did not remain long enough at intermediate points for the formation of terraces. A succession of raised beaches, rising above the present sea-level, may therefore be taken as pointing to a former prolonged upheaval of the country, interrupted by long pauses, during which the general level did not materially change.

(4.) Any stratum of rock containing marine organisms, which have manifestly lived and died where their remains now lie, must be held to prove upheaval of the land. In this way it can be shown that most of the solid land now visible to us has once been under the sea. Even high on the peaks of the cliffs and the flanks of the Himalaya mountains, undoubted marine shells occur in the solid rocks.

(5.) In countries which have been long settled by a human population, it is sometimes possible to prove, or at least to render probable, the fact of recent uprise of the land by reference to tradition, to local names, and to works of human construction. Piers and harbours, if now found to stand above the upper limit of high-water, furnish indeed indisputable evidence of a rise of land since their erection.

[1] "Earthquakes and Volcanoes," by A. Geikie, Chambers's *Miscellany of Tracts.*

§ 2. *Movements of Subsidence.*

It is more difficult to trace the downward movement of the land, for the evidence of each successive sea-margin is carried down and washed away or covered up. Nevertheless, the fact of subsidence can be satisfactorily established by the following kinds of proof[2]:—

(1.) The results of mere erosion by the sea and those of actual depression of the level of the land cannot always be distinguished without some care. The encroachment of the sea upon the land, involving, it may be, the disappearance of successive fields, roads, houses, villages, and even whole parishes, does not necessarily indicate a sinking of the land. Such destruction of the coast-line may, indeed, be in progress without any actual change of level. Should the sea, however, rise to the level of roads and buildings which it never used to touch, should former half-tide rocks cease to show even at low water, and should rocks, previously above the reach of the highest tide, be turned first into shore reefs, then into skerries and islets, we infer that the coast-line is sinking. Such kind of evidence is found in Scania, the most southerly part of Sweden. Streets, built of course above high-water mark, now lie below it, with older streets lying beneath them, so that the subsidence is of some antiquity. A stone, the position of which had been exactly determined by Linnæus in 1749, was found after 87 years to be 100 feet nearer the water's edge. The west coast of Greenland, for a space of more than 600 miles, is perceptibly sinking. It has there been noticed that over ancient buildings on low shores, as well as over entire islets, the sea has risen. The Moravian settlers have been more than once driven to shift their boat-poles inland, some of the old poles remaining visible under water.

(2.) As the land is brought down within reach of the waves, its characteristic surface-features are, of course, apt to be effaced, so that the submerged area which passes down beneath the sea may retain little or no evidence of its having been a land-surface. It will be covered, as a rule, with sea-worn sand or silt. Hence, no doubt, the reason why, among the marine strata which form so large a part of the stratified portion of the earth's crust, and where there are many proofs of depression, actual traces of land-surfaces are comparatively rare. It is only under very favourable circumstances, as, for instance, where the area is sheltered from prevalent winds and waves, and where, therefore, the surface of the land can sink tranquilly under the sea, that fragments of that surface may be completely preserved under overlying marine accumulations. It is in such places that "submerged forests" occur. These are stumps or roots of trees still in their positions of growth in their native soil. Beds of peat, full of tree-stumps, hazel-nuts, branches, leaves, and other indications of a terrestrial surface, are often found in similar situations. Sir Henry de la Beche has described, round the shores of Devon, Cornwall, and western Somerset, a vegetable accumulation, consisting of plants of the same species as those which now grow freely on the adjoining land, and occurring as a bed at the mouths of valleys, at the bottoms of sheltered bays, and in front of and under low tracts of land, the seaward side of which dips beneath the present level of the sea. Over this submerged land-surface sand and silt containing estuarine shells have generally been deposited, whence we may infer that in the submergence the valleys first became estuaries, and then sea-bays. If now, in the course of ages, a series of such submerged forests should be formed one over the other, and if, finally, they should, by upheaval of the sea-bottom, be once more laid dry, so as to be capable of examination by boring, well sinking, or otherwise, they

[2] *Ibid.*

would prove a former long-continued depression, with intervals of rest. In such a case, the intervals of pause would be marked by the buried forests, and the progress of the depression by the strata of sand and mud lying between them. In short, the evidence would be strictly on a parallel with that furnished by a succession of raised beaches as to a former protracted elevation with long pauses.

(3.) An interesting kind of proof of an extensive depression of the north-west of Europe is furnished by the deep fjords or sea-lochs by which that region is indented. A fjord is a long, narrow, and often singularly deep inlet of the sea, which terminates inland at the mouth of a glen or valley. The word is Norwegian, and in Norway fjords are characteristically developed. The English word "firth," however, is the same, and the western coasts of the British Isles furnish many excellent examples of fjords. In Scotland they are usually called lochs, as Loch Hourn, Loch Nevis, Loch Fyne, Gareloch; in Ireland they are sometimes known by the name of loughs, as Lough Foyle, but more commonly by that of bays, as Dingle Bay, Bantry Bay. There can be little doubt that, though now filled with salt water, fjords have been originally land valleys. The long inlet was first excavated as a land-valley or glen. This valley exactly corresponds in form and character with the hollow of the fjord, and must be regarded as merely its inland prolongation. That the glens have been excavated by subaerial agents is a conclusion borne out by a great weight of evidence. If, therefore, we admit the subaerial origin of the glen, we must also grant a similar origin to its seaward prolongation. Every fjord will thus mark the site of a submerged valley. This inference is confirmed by the fact that fjords do not, as a rule, occur singly. Like the glens on the land they lie in groups; so that when they are found intersecting a long line of coast like that of the west of Norway, or the west of Scotland, we conclude that the land has there sunk down so as to permit the sea to run far up and fill the submerged glens.

(4.) Evidence of widespread depression over the area of the Pacific Ocean is furnished by the numerous atolls or coral islands scattered throughout that vast expanse of water. Mr Darwin ascertained that the reef-building corals do not live at a greater depth than about 15 or 20 fathoms. Yet reefs and circular islets of coral rise with nearly perpendicular sides from a depth of 2000 feet and upwards, until they reach the surface of the sea. As the corals could not have begun to grow upward from such vast depths, Mr Darwin first suggested that the sites of these coral reefs had undergone a progressive subsidence, the rate of upward growth of the reefs keeping pace, on the whole, with the depression. A fringing reef would first be formed fronting the land within the limit of the 20 fathom line. Growing upward until it reached the surface of the water, it would be exposed to the dash of the waves, which would break off pieces of the coral and heap them upon the reef. In this way islets would be formed which, by successive accumulations of materials thrown up by the breakers or brought by winds, would remain permanently above water. On these islets palms and other plants, whose seeds might be drifted from the adjoining land, would take root and flourish. Inside the reef, there would be a shallow channel of water, communicating, through gaps in the reef, with the main ocean outside. Fringing reefs of this character are of common occurrence at the present time. In the case of a continent they front its coast for a long distance, but they may entirely surround an island. If the site of a fringing reef undergoes depression at a rate sufficiently slow to allow the corals to keep pace with it, the reef will grow upward as the bottom sinks downward. The lagoon channel inside will become deeper and wider, while, at the same time, the depth of the water outside will increase. In this way a barrier reef will be formed. Continued slow depression must continually diminish the area of the land enclosed within one of these rings of coral-reef, while the reef itself retains much the same size and position. At last the final peak of the original island disappears under the lagoon, and an atoll or true coral island is formed. Should any more rapid or sudden downward movement take place, it might carry the atoll down beneath the surface, as seems to have happened at the Great Chagos bank in the Indian Ocean, which is a submerged atoll. It has recently been suggested that barrier reefs do not necessarily prove subsidence, seeing that they may grow outward from the land upon the top of a talus of their own debris broken down by the waves, and may thus appear to consist of solid coral which had grown upward from the bottom during depression, although only the upper layer, 20 fathoms or thereabouts in thickness, is composed of solid, unbroken, coral growth. The explanation may doubtless account for some barrier-reefs, and for the way in which the steep seaward face of all such reefs is formed and maintained. But it does not elucidate the existence of submerged atolls, the presence of gaps in atolls answering to gaps in the fringing reefs opposite to the mouths of rivers; and the difficulty of supposing that, in a coral archipelago, there should have been scores of submerged peaks so nearly of the same height as to rise within 20 fathoms of the surface, and yet so seldom actually to tower above it. According to the simple and luminous theory of Mr Darwin, every stage in the progress of the changes is open to observation, from the incipient fringing reef to the completed and submerged atoll. Every observed fact fits in harmoniously with the others, and we reach the impressive conclusion that a vast area of the Pacific Ocean, fully 6000 geographical miles from east to west, has undergone a recent subsidence, and may be slowly sinking still.

It by no means follows, however, as some writers have imagined, that the present Pacific Ocean occupies the site of a vast submerged continent. All the coral islands seem to have been built on volcanic peaks. Wherever any non-calcareous rock appears it is of volcanic origin. We must therefore conceive of these oceanic islands as detached volcanic eminences rising out of a wide area of subsidence, and doubtless as deriving their existence from the results of that subterranean movement.

§ 3. *Causes of Secular Upheaval and Depression.*

These movements, without question, we must again trace back to consequences of the original internal heat of the earth. There are various ways in which the heat may have acted. Thus a considerable accession of heat expands rocks, and, on the other hand, a loss of heat causes them to contract. We may suppose therefore that, during the subterranean changes, a great extent of the crust underneath a tract of land may have its temperature slowly raised. The effect of this increment would be to cause a slow uprise of the ground above. The gradual transference of the heat to another quarter might produce a steady subsidence. Such variations in subterranean temperature, however, could give rise at the most to but very insignificant elevations or depressions.

A far more important and generally effective cause is to be sought in the secular contraction of the globe. If our planet has been steadily losing heat by radiation into space, it must have progressively diminished in volume. The cooling implies contraction. According to Mr Mallet, the diameter of the earth is less by at least 189 miles since the time when the planet was a mass of liquid.[1] But the contraction has not manifested itself uniformly over the whole

[1] *Phil. Trans.*, 1873, p. 250.

surface of the planet. The crust varies much in structure, in thermal resistance, and in the position of its isogeothermal lines. As the hotter nucleus contracts more rapidly by cooling than the cooled and hardened crust, the latter must sink down by its own weight, and in so doing requires to accommodate itself to a continually diminishing diameter. The descent of the crust gives rise to enormous tangential pressures. The rocks are crushed, crumpled, and broken in many places. Subsidence must have been the general rule, but every subsidence would doubtless be accompanied with upheavals of a more limited kind. The direction of these upheaved tracts would largely depend upon the original structure of the crust. It would be apt to occur in lines which, once taken as lines of weakness or relief from the intense strain, would probably be made use of again and again at successive paroxysms or more tranquil periods of contraction. Mr Mallet, in the paper already cited, has ingeniously connected these movements with the linear direction of mountain chains, volcanic vents, and earthquake shocks.

Though the origin of the present surface configuration of the land will be more conveniently discussed in a subsequent part of this article, after the structure of the earth's crust has been described, a few words may be inserted here, where some allusion to the subject might be looked for. Mountains may arise from three causes—(1) from the corrugation of the earth's crust due to the effects of secular contraction; (2) from the accumulation of materials poured out of volcanic orifices; and (3) from the isolation of elevated masses of ground, owing to the removal, by denudation, of the materials originally connecting them, and to the consequent formation of valleys. Mountains formed in the volcanic way are almost always conical, and are either solitary, as Etna, or occur in linear groups, like the volcanoes of Java. Those formed by denudation are of minor dimensions, and rather deserve the name of hills. Mountain-chains, on the other hand, which are the dominant features of the earth's surface, though they may have lines of volcanic vents along their crests, are not formed essentially of volcanic materials, but of the sedimentary and crystalline rocks of the crust which have been ridged up into vast folds. If the continental lands may be compared to great undulations of the solid surface of the globe, the mountain-chains may be likened to the breaking crests of such wave-like undulations. In their internal structure mountain-chains bear witness to the intense crumpling of the rocks during the process of upheaval. As a consequence of the uprise of two or more parallel ranges of mountain, lines of longitudinal valley must be produced. But no sooner is a mass of land raised above the sea than it is exposed to the attacks of air, rain, frost, springs, glaciers, or other meteoric agents of disintegration. Its surface is then worn down, the flow of water down its slopes cuts out gulleys, ravines, and valleys, so that eventually a very rugged surface is produced, on which, probably, no portion of the original surface of upheaval may remain, but where new lines of minor ridge and valley may appear as the combined result of internal geological structure and atmospheric denudation. The reader, however, is referred to part vii. of this article for a fuller treatment of this interesting subject.

During the movements by which mountain masses have been upheaved, the stratified rocks have been so compressed as to occupy, in many cases, but a small proportion of the horizontal extent over which they originally extended. They have adjusted themselves to this diminished area by undergoing intense plication, and thus acquiring a much greater vertical depth. On the other hand, they have been abundantly fractured, some portions of their mass being pushed up, others being let down, so that the crust is traversed with a kind of complicated network of fissures. The discussion of these features of geological structure, however, must likewise be postponed to part iv., where the facts regarding their occurrence will be described.

Section IV.—Hypogene Causes of Changes in the Texture, Structure, and Composition of Rocks.

The phenomena of hypogene action hitherto under consideration have related almost wholly to the effects produced at the surface. It is evident, however, that these phenomena must be accompanied by very considerable changes in the rocks which form the earth's outer crust. These rocks, as just stated, have been subjected to enormous pressure; they have been contorted, crumpled, and folded back upon themselves, as if thousands of feet of solid limestones, sandstones, and shales had been merely a few layers of carpet; they have been shattered and fractured everywhere; they have in one place been pushed far above their original position, in another depressed far beneath it: so great has been the compression which they have undergone that their component particles have in many places been rearranged, and even crystallized. They have here and there actually been reduced to fusion, and have been abundantly invaded by masses of molten rock from below.

In the present section of this article we shall consider chiefly the nature of the agencies by which such changes have been effected; the results achieved, in so far as they constitute part of the architecture or structure of the earth's crust, will be discussed in part iv. At the outset, it is evident that we can hardly hope to detect many of these processes of subterranean change actually in progress and watch their effects. The very vastness of some of them places them beyond our direct reach, and we can only reason regarding them from the changes which we see them to have produced. But a good number are of a kind which we can in some measure imitate in our laboratories and furnaces. It is not requisite, therefore, to speculate wholly in the dark on this subject. Since the original and classic researches of Sir James Hall, the founder of experimental geology, great progress has been made in the investigation of hypogene processes by experiment. The conditions of nature have been imitated as closely as possible, and varied in different ways, with the result of giving us an increasingly clear insight into the physics and chemistry of subterranean geological changes. The succeeding portions of this section of the article will therefore be chiefly devoted to an illustration of the nature of hypogene action, in so far as that can be inferred from the results of actual experiment. The subject may be conveniently treated under three heads—(1) the effects of heat; (2) the effects of pressure and contraction; (3) the influence of water in effecting changes in minerals and rocks.

§ 1. *Effects of Heat.*

The importance of heat among the transformations of the rocks has been fully admitted by geologists, since it used to be the watchword of the Huttonian or Vulcanist school at the end of last century. Two sources of subterranean heat may have at different times and in different degrees co-operated in the production of hypogene changes—(1) the internal heat of the globe, of which some account has already been given, and (2) the heat due to the transformation of mechanical energy in the crumpling, fracturing, and crushing of the rocks of the crust, as these have been from time to time compelled to adjust themselves to the diminishing diameter of the more rapidly cooling and contracting interior. From which of these two sources, or from what combination of them, the heat was derived by which any given change in the rocks was produced, is a problem which admits in the meantime of only very partial solution. Leaving this question for the present, let us examine the effects which are clearly referable to the influence of heat. It is evident that the conditions under which these effects are produced must vary almost infinitely. We have to consider (1) the temperature, from the lowest at which any change is possible up to that of complete fusion; (2) the nature of the rock operated upon, some materials being much more susceptible of change from heat than others; (3) the pressure under which the heat acts, the potency of this agency being much increased with increase of pressure; (4) the presence of water, whereby chemical changes take place which would not be possible in dry heat.

In an interesting series of experiments the illustrious De Saussure (1779) fused some of the rocks of Switzerland and France, and inferred from them, contrary to the opinion previously expressed by Desmarest,[1] that basalt and lava have not been produced from granite, but from hornstone (pierre de corne), varieties of "schorl," calcareous clays, marls, and micaceous earths, and the cellular varieties from different kinds of slate.[2] He observed, however, that the artificial products obtained by fusion were glassy and enamel-like, and did not always recall volcanic rocks, though some exactly resembled porous lavas.

Sir James Hall, about the year 1790, began an important investigation, in which he succeeded in reducing various ancient and modern volcanic rocks to the condition of glass, and in restoring them, by slow cooling, to a stony state. Since that time many other researches of a more complicated kind have been undertaken, especially by Delesse, Daubrée, Deville, Bunsen, Bischof, H. and W. Rogers. By these observations it has been abundantly proved that all rocks undergo molecular changes when exposed to high temperature, that when the heat is sufficiently raised they become fluid, that if the glass thus obtained is rapidly cooled it remains vitreous, and that, if allowed to cool slowly, a more or less distinct crystallization sets in, the glass is devitrified, and a lithoid product is the result.

Illustrations of the influence of different degrees of heat upon rocks of different kinds may often be very instructively observed at lime-kilns, especially those roughly-built kilns or pits which may still be met with in outlying districts. Some of the stones lining such cavities will be found with no sensible change, others show a somewhat cellular texture, others have acquired a rudely prismatic structure, while some have had their surfaces fused into a rough glaze or enamel. The bricks or stones used for lining furnaces present similar illustrations, the columnar or prismatic structure being occasionally very perfectly developed in these materials. Mere contact with a highly-heated surface, and subsequent gradual cooling, have often produced this prismatic arrangement in rocks of the most diverse kinds. Thus, in Scotland, beds of sandstone and seams of coal have acquired the most perfect prismatic structure from the intrusion of basalt dykes or sheets through them. To these and other effects of intruded igneous rocks reference will be made in the sequel. In these cases the alteration is merely local, and has obviously been produced by contact with a highly heated surface. But, besides such minor effects due merely to contact, others of a more general kind affect large masses of rock or whole districts of country.

When rocks are exposed to temperatures as high as their melting-points, they fuse into glass which, in the great majority of cases, is of a bottle-green or black colour, the depth of the tint depending mainly on the proportion of iron. In this respect they resemble the natural glasses—pitchstones and obsidians. They almost always contain minute cells or bubbles, arising probably from the disengagement of water or of oxygen during the fusion. But after the most thorough fusion which has been found possible, minute granules usually appear in the solidified glass. Sometimes these consist of specks of quartz, which is especially apt to remain unmelted when the rock is very siliceous, or of other minerals of the original rock. But a microscopic investigation of fused rocks shows that, even in what seems to be a tolerably homogeneous glass, there are abundant minute hair-like, feathered, needle-shaped, or irregularly-aggregated bodies diffused through the glassy paste. These *crystallites* are in some cases colourless silicates, in others they are opaque metallic oxides, particularly oxides of iron. They precisely resemble the crystallites which are observed in many volcanic rocks, such as obsidian, pitchstone, and basalt. They may be obtained even from the fusion of a granitic or granitoid rock, as in the well-known case of the Mount Sorrel syenite near Leicester, which, being fused and slowly cooled, yielded abundant crystallites, including exquisitely grouped octohedra of magnetite.

According to the observations of Delesse, volcanic rocks, when reduced to a molten condition, attack briskly the sides of the Hessian crucibles in which they are contained, and even eat them through. This is an interesting fact, for it helps to explain how some intrusive igneous rocks have come to occupy positions previously filled by sedimentary strata, and why, under such circumstances, the composition of the same mass of rock should be found to vary considerably from place to place.[3]

It would appear that, in passing from a crystalline into a vitreous condition, rocks undergo a diminution of density, which, on the whole, is greater the more silica and alkali are present, and is less as the proportion of iron, lime, and alumina increases. According to Delesse, granites, quartziferous porphyries, and such highly silicated rocks lose from 8 to 11 per cent. of their density when they are reduced to the condition of glass, basalts lose from 3 to 5 per cent., and lavas, including the vitreous varieties, from 0 to 4 per cent. This diminution of density (and consequent increase of volume) may account for minor oscillations of the ground so often observed in volcanic regions. If we suppose a subterranean mass of lava 500 feet thick to pass from the fluid to the crystalline condition, this might cause a subsidence of the ground above to the extent of about 20 or 25 feet. The transition of a similar mass of rock from the solid to the fluid condition would cause an uprise to a like amount.

So far as experiments have yet been conducted, it has been found impossible to obtain from a piece of fused rock a crystalline substance exactly resembling the original mass. Externally it may appear quite stony, but its internal structure, as revealed by the microscope, shows it to be essentially a slag or glass, and not a truly crystalline rock. There is another fundamental difference between the natural and artificial products. When a compound containing substances of different fusibilities is artificially melted, and allowed thereafter to cool in such a way that the various ingredients may separate from each other, they appear in their order of fusibility, the most refractory coming first, and the most fusible being the last to take a solid form. But in rocks which have crystallized naturally from a fluid condition, it is often to be observed that the component minerals have been far from obeying what might have been supposed to be their invariable law. Thus, in all parts of the world, granite presents the very striking fact that its quartz, which we call an infusible mineral, has actually solidified after the more fusible felspar. In the Vesuvian lavas the

[1] *Mem. Acad. Scien.*, 1771, p. 273.
[2] De Saussure, *Voyages dans les Alps*, edit. 1803, tome i. p. 178.
[3] *Bull. Soc. Géol. France*, 2d ser., iv. 1382.

difficultly fusible leucite may be seen to have enclosed crystals already formed of the fusible augite. In many ancient crystalline rocks the pyroxenic constituents, which offer a less resistance to fusion, have assumed a crystalline form before the more refractory triclinic felspars. From these facts it is clear that, in the fusion of rocks and in their subsequent consolidation, there must have been conditions under which the normal order of appearance of the minerals was disturbed or reversed. Yet another fact may be mentioned to show further the difference between the kind of fusion which has frequently obtained in nature and that of the ordinary operations of a glass-work or iron-furnace. As far back as the year 1846 Scheerer showed that there exist in granite various minerals which could not have consolidated save at a comparatively low temperature. He instanced especially several gadolinites, orthites, and allanites, which cannot endure a higher temperature than a dull-red heat without altering their physical characters; and he concluded that granite, though it may have possessed a high temperature, cannot have solidified from simple igneous fusion.

We may conclude, therefore, that the manner in which rocks have been melted within the crust is not that mere simple fusion which we can accomplish artificially, but that it has involved conditions which have not been successfully imitated in any laboratory or furnace. Two obvious differences must occur to the reader between the natural and artificial operations. In the first place, rocks which have undoubtedly once been in a fluid or at least pasty condition, and which have been injected as veins and dykes into previously consolidated masses, contain water imprisoned within their component crystals. This is not water which has been subsequently introduced. It is contained in minute cells, which it usually does not now completely fill, but which it no doubt did occupy completely at the time and temperature at which the rock was consolidated. We have seen (*ante*, p. 250) how abundant are the discharges of water-vapour from volcanic fires, how the molten lava-streams issue from their vents, saturated, as it were, with steam, and how the steam continues to rise from them long after they have congealed and come to rest. In the solid crystals of lava which were erupted only recently, as well as in those of early geological periods, the presence of water in minute cavities may be readily detected. It is in the quartz of such rocks, and still more in that of granite, that the detection of water-cavities is most easily made. The quartz of granite is usually full of them. "A thousand millions," says Mr J. Clifton Ward, "might easily be contained within a cubic inch of quartz, and sometimes the contained water must make up at least 5 per cent. of the whole volume of the containing quartz." Thus microscopic investigation confirms the conclusion arrived at by Scheerer in the memoir already cited, that at the time of its eruption granite must have been a kind of pasty mass containing a considerable proportion of water. It is common now to speak of the "aquo-igneous" origin of some eruptive rocks, and to treat their production as a part of what is termed the "hydro-thermal" operations of geology. We may conclude that, while some rocks, like obsidian and pitchstone, which so closely resemble artificial glasses, may have been derived from a simple igneous fusion such as can be imitated in a furnace (though even in these the presence and influence of water may be traced), the great majority of rocks have had a more complex origin, and in a great number of cases can be proved to have been mingled with more or less water while they were still fluid.

In the second place, there can be no question that, in the great hypogene laboratory of nature, rocks have been softened and fused under enormous pressure. Besides the pressure due to their varying depth from the surface, they must have been subject to the enormous expansion of the superheated water or vapour which filled all their cavities. Mr Sorby has ingeniously estimated the probable pressure under which granite consolidated by taking the ratio between the size of the liquid cavities in the quartz and that of the contained bubble or vacuity. Assuming the temperature of consolidation to have been 680° Fahr. (360° Cent.), or a dull-red heat, he inferred that in many cases the pressure under which the granite consolidates must have been equal to that of an overlying mass of rock 50,000 feet, or more than 9 miles, in thickness. It is not probable that any such thick overlying mass ever did cover the granite; the pressure, even if it be allowed to have been so great, must have been due partly to other causes, such as the compression due to secular contraction.

It would appear therefore that perfect anhydrous fusion, or the reduction of a rock to the state of a completely homogeneous glass, has been a comparatively rare process in nature, or at least that such glasses, if originally formed, have in the vast majority of cases undergone devitrification and crystallization, until the glassy base has been reduced to a smaller or larger fraction of the total mass of the rock, or has entirely passed into a stony condition. In many volcanic rocks the original vitreous base or ground-mass can be readily observed with the microscope between the definitely-formed crystals. Crystallites, or arrested stages in the crystallization of iron oxides and of silicates, can often be detected in these rocks, more especially where it is evident that they must have cooled with comparative rapidity, as where they have been thrust into narrow fissures to form dykes. But in rocks such as granite, where no glass exists, but where the mineral constituents are all crystalline, no trace of the crystallites occurs. Doubtless such differences point to original distinctions in the kind and degree of fusion of the rocks. It seems reasonable to suppose that those rocks which show a glassy ground-mass, and the presence of crystallites, have been fused under conditions more nearly resembling those of the simple igneous fusion of experiment.

It has long been known that many mineral substances can be obtained in a crystalline form from the condensation of vapours. This process, called sublimation, may be the result of the mere cooling and reappearance of bodies which have been vaporized by heat and solidify on cooling, or from the solution of these bodies in other vapours or gases, or from the reaction of different vapours upon each other. These operations are of common occurrence at volcanic vents, and in the crevices of recently erupted and still hot lava-streams. They have been successfully imitated by experiment. In the early researches of Sir James Hall on the effects of heat modified by compression, he obtained by sublimation "transparent and well-defined crystals," lining the unoccupied portion of a hermetically-sealed iron tube, in which he had placed and exposed to a high temperature some fragments of limestone (*Trans. Roy. Soc. Edin.*, vi. 110). Numerous experiments have been made by Messrs Delesse, Daubrée, and others, in the production of minerals by sublimation. Thus many of the metallic sulphides found in mineral veins have been produced by exposing to a comparatively low temperature (between that of boiling water and a dull-red heat) tubes containing metallic chlorides and sulphide of hydrogen. By varying the materials employed, corundum, quartz, apatite, and other minerals have been obtained. It is not difficult, therefore, to understand how, in the crevices of lava-streams and volcanic cones, as well as in some mineral veins, sulphides and oxides of iron and ther minerals may have been formed by the ascent of heated vapours. Superheated steam is endowed with a remarkable power of dissolving that intractable substance, silica; artificially heated to the temperature of the melting point of cast-iron, it rapidly attacks silica, and deposits the mineral in snow-white crystals as it cools.

§ 2. *Effects of Pressure and Contraction.*

Besides the influence of pressure in raising the melting point of subterranean rocks, and in permitting water to remain fluid among them at temperatures far above the boiling-point, even at a red or perhaps a white heat, we have to consider the effects produced by the same cause upon rocks already solidified. The simplest and most obvious result of pressure upon such rocks is their consolidation, as where a mass of loose sand is gradually compacted into a more or less coherent stone, or where a layer of vegetation is compressed into peat, lignite, or coal. In many cases the cohesion of a sedimentary rock is due merely to the pressure of the superincumbent strata. But it usually happens that some cementing material has contributed to bind the component particles together. Of these natural cements the most frequent are peroxide of iron, silica, and carbonate of lime.

Pressure equally distributed over a rock presenting everywhere nearly the same amount of resistance will promote consolidation, but may produce no further internal change. If, however, the pressure becomes extremely unequal, or if the rock subjected to it can find escape from the influence in one or more directions, there will be a disturbance or rearrangement of the particles, which by this means are made to move upon each other. Five consequences of these movements may be noticed here.

(1.) *Cleavage.*—When a mass of rock, owing to subsidence or any other cause, is subjected to powerful lateral compression, its innate particles, which in all rocks have almost invariably a longer and shorter axis, tend, under the intense strain, to rearrange themselves in the line of least resistance, that is, with their long axes perpendicular to the direction of the pressure. The result of this readjustment is that the rock affected by it acquires a facility for splitting along the lines in which its component particles have placed themselves. Fine-grained argillaceous rocks show most characteristically this internal change; but in coarse materials it becomes less conspicuous, or even disappears. Rocks which have been thus acted on, and have acquired this superinduced fissility, are said to be *cleaved*, and the fissile structure is termed *cleavage*. This has been proved experimentally by Sorby, who produced perfect cleavage in pipeclay through which scales of oxide of iron had previously been mixed. Dr Tyndall superinduced cleavage on bees-wax and other substances by subjecting them to severe pressure. Cleavage among rocks occurs on a great scale in countries where the strata have been greatly plicated, that is, where they now occupy much less horizontal surface than they once did, and consequently where, in accommodating themselves to their diminished area, they have had to undergo much powerful lateral compression. The structure of districts with cleaved rocks is described in part iv.

(2.) Further evidence of the compression to which rocks have been subjected is furnished by the way in which contiguous pebbles in a conglomerate may be found to have been squeezed into each other, and even sometimes to have been elongated in a certain general direction. It is doubtless the coarseness of the grain of such rocks which permits the effects of compression to be so readily seen. Similar effects must take place in fine-grained rocks, though they escape observation. Organic remains both of plants and animals may often be found to have undergone considerable distortion from this cause. M. Daubrée has imitated experimentally the indentations produced by the contiguous portions of conglomerate pebbles.[1]

[1] *Comptes Rendus*, xliv. 823.

(3.) The ingenious experiments of M. Tresca on the flow of solids have proved that, even at ordinary atmospheric temperatures, solid resisting bodies like lead, cast-iron, and ice, may be so compressed as to undergo an internal motion of their parts which is closely analogous to that of fluids. Thus, a solid jet of lead has been produced by placing a piece of the metal in a cavity between the jaws of a powerful compressing machine. Iron, in like manner, has been forced to flow in the solid state into cavities and take their shape. On cutting sections of the metals so compressed, their particles or crystals are found to have ranged themselves in lines of flow which follow the contour of the space into which they have been squeezed. Such experiments are of considerable geological interest, for they show that in certain circumstances, under great pressure, the unequally mixed particles of rocks within the earth's crust may have been forced to move upon each other, and thus to acquire a "fluid-structure" resembling that which is seen in rocks which have possessed true liquidity. No large sheet of rock can be expected, however, to have undergone this internal change; the effects could only be produced exceptionally at places where there was an escape from the pressure as, for instance, along the sides of fissures, or in other cavities of rocks. The explanation cannot be applied to the case of rocks like schists, which display a kind of rude foliation or fluid-structure over areas many thousands of square miles in extent.

(4.) *Plication.*—Reference has already been made to the fact that, owing to the more rapid contraction of the inner portion of the globe, the outer layer or crust is from time to time forced to adjust itself to this change by subsiding. As a consequence of the subsidence, the descending area requires to occupy less horizontal space, and must therefore suffer powerful lateral compression. The rocks are thus crumpled up, as, in the classic experiment of Sir James Hall, folds of cloth are folded when a weight is placed upon them and they are squeezed from either side. The mere subsidence of such a curved surface as that of our globe must thus necessarily produce much lateral compression. Mr J. M. Wilson has calculated that, if a tract of the earth's surface, 345 miles in breadth, be depressed one mile, it will undergo compression to the extent of 121 yards; at two miles the compression will be 189 yards; at eight miles 598 yards. The observed amount of compression in districts of contorted rocks, however, far exceeds these figures. Another cause of the compression and contortion of rocks is the injection into them of igneous masses from below, but this is probably a minor source of disturbance. The character of plicated rocks is described in part iv. p. 300.

(5.) *Faults.*—Closely connected with the disturbances which have produced contortions come those by which the crust of the earth has been fractured. But in this case the movement is one of elevation rather than of subsidence; for, instead of having to occupy a diminished diameter, the rocks get more room by being pushed up, and as they cannot occupy the additional space by any elastic expansion of their mass, they can only accommodate themselves to the new position by a series of dislocations. Some portions will be pushed up farther than others, and this will happen more particularly to those which have a broad base. These will rise more than those with narrow bottoms, or the latter will seem to sink relatively to the former. Each broad-bottomed segment will thus be bounded by two sides sloping towards the upper part of the block. This is found to be almost invariably the case in nature. A fault or dislocation is nearly always inclined from the vertical, and the side to which the inclination rises, and from which it "hades," is the upthrow side. The details of these features of geological structure are discussed in part iv., section v.

§ 3. *Influence of Water.*

In the great geological contest fought at the beginning of the century between the Neptunists and the Plutonists, the two great battle-cries were, on the one side, Water, on the other, Fire. The progress of the science since that time has shown that each of the parties had truth on its side, and had seized one aspect of the problems touching the origin of rocks. If subterranean heat has played a large part in the construction of the materials of the earth's crust, water, on the other hand, has performed a hardly less important share of the task. They have often co-operated together, and in such a way that the result must be regarded as their joint achievement, wherein the respective share of each can hardly be exactly apportioned. In the following brief *résumé* of this subject we shall consider the changes produced by pure water, by water charged with substances in solution, and by water raised above ordinary temperatures.

By numerous observations it has been proved that all rocks within the accessible portion of the earth's crust contain interstitial water, or, as it is sometimes called, quarry-water (*eau-de-carrière*). This is not chemically combined with their mineral constituents, but merely retained in their pores. Most of it evaporates when the stone is taken out of the parent rock and freely exposed to the atmosphere. The absorbent powers of rocks vary greatly, and chiefly in proportion to their degree of porosity. Gypsum absorbs from about 0·50 to 1·50 per cent. of water by weight; granite, about 0·37 per cent.; quartz from a vein in granite, 0·08; chalk, about 20·0; plastic clay, from 19·5 to 24·5. These amounts may be increased by exhausting the air from the specimens and then immersing them in water.

The water enclosed within the interstices and crystals of igneous rocks may be either an original constituent, deriving its origin, like any of the component minerals, from molten reservoirs within the earth's crust, or it may have descended from the surface to the incandescent rocks. Many facts may be adduced in support of the greater probability of the second view. Besides the general proximity of volcanic orifices to large sheets of water, we have abundant evidence of the actual descent of water from the surface, both through fissures, and also by permeation through the solid substance of rocks. All surface rocks contain water, and no mineral substance is strictly impervious to the passage of liquid. The well-known artificial colouring of agates proves that even the mineral substances apparently most homogeneous and impervious can be traversed by liquids. M. Daubrée has instituted a series of experiments to illustrate the power possessed by water of penetrating rocks, in virtue of their porosity and capillarity, even against a considerable counter-pressure of vapour; and, without denying the presence of original water, he concludes that the interstitial water of igneous rocks may all have been derived by descent from the surface.

The presence of interstitial water must affect the chemical constitution of rocks. It is now well understood that there is probably no terrestrial substance which, under proper conditions, is not to some extent soluble in water. By an interesting series of experiments, made many years ago by Messrs Rogers, it was ascertained that many of the ordinary mineral constituents of rocks could be dissolved to an appreciable extent even by pure water, and that the change was accelerated and augmented by the presence of carbonic acid.[1] Silica, alkaliferous silicates, and iron oxides can be taken up and held in solution by pure water, even at ordinary temperatures, in considerable quantities. The mere presence of pure water therefore within the pores in subterranean rocks cannot but give rise to changes in the combustion of these rocks. Some of the more soluble materials must be dissolved, and, as the water evaporates, must be redeposited in a new form.

But water in a natural state is never chemically pure. In its descent through the air it absorbs oxygen and carbonic acid, besides other impurities (see p. 267), and as it filters through the soil it abstracts more carbonic acid, as well as other results of decomposing organic matter. It is thus enabled to effect numerous decompositions of the rocks underneath. The nature of these changes may be inferred from the composition of spring water, to which reference will subsequently be made (p. 270). For the present it will be sufficient to remark that two important kinds of chemical decomposition must evidently arise from the action of such infiltrating water. (1.) The presence of the organic matter must exercise a reducing power on oxides. This will be more especially the case with those of iron, the nearly insoluble hæmatite being reduced to the protoxide, which, converted into carbonate, is readily removable in solution. There can be little doubt that by this means a vast amount of ferruginous matter is extracted from subterranean rocks and carried to the surface. (2.) The presence of carbonic acid enables the water to attack vigorously the mineral constituents of rocks. Alkaline carbonates, with carbonates of lime and magnesia, and protoxides of iron and manganese, are produced, and these substances borne onward in solution give rise to further reactions among the rocks through which they are carried. "In the decomposition of rocks," says Bischof, "carbonic acid, bicarbonate of lime, and the alkaline carbonates bring about most of the decompositions and changes in the mineral kingdom."

The microscopic study of rocks has thrown much light upon the mineralogical alterations in rocks due to the influence of percolating water. Even the most solid-looking, unweathered rocks, are found to have been affected by such metamorphism. Their hydrous magnesian silicates, for example, are partially or wholly converted into such hydrous forms as serpentine, chlorite, or delessite. The process of conversion may often be watched. It can be seen to have advanced along the fissures or cleavage-planes of the minerals leaving the intervening sections still fresh; or it may be observed to have proceeded in such a way that diffused alteration-products are dispersed in filaments or irregular patches through the base of the rock, or gathered together and even re-crystallized in cavities; or the whole rock, as in many serpentines, has undergone an entire transformation. Much information regarding such internal alterations of rocks may be obtained from the study of *pseudomorphs*, that is, crystals having the external form of the mineral of which they originally consisted, with the internal structure and composition of the mineral which has replaced it. Serpentine representing olivine, clay taking the place of rock-salt, silica that of wood, and marcasite that of molluscan shell, are familiar examples. There is no reason to doubt that these changes may, in the course of ages, have been effected at ordinary temperatures by water descending from the surface of the ground.

But two other considerations require to be taken into account in the discussion of the internal transformations of rocks by subterranean water. (1.) In the first place, the water has often been at a high temperature. Mere descent into the crust of the earth will raise the temperature of the water until, if this descent be prolonged, a point far above 212° Fahr. may be reached. Experiments have shown that the chemical action of water is vastly increased by heat. Thus M. Daubrée exposed a glass tube containing about half

[1] *American Journ. Science* (2), v. 401.

its weight of water to a temperature of about 400° C. At the end of a week he found the tube so entirely changed into a white, opaque, powdery mass as to present not the least resemblance to glass. The remaining water was highly charged with an alkaline silicate containing 63 per cent. of soda and 37 per cent. of silica, with traces of potash and lime. The white solid substance was ascertained to be composed almost entirely of crystalline materials. These consisted partly of minute perfectly limpid bipyramidal crystals of quartz, but chiefly of very small acicular prisms of wollastonite. It was found, moreover, that the portion of the tube which had not been directly in contact with the water was as much altered as the rest, whence it was inferred that at these high temperatures and pressures the vapour of water acts chemically like the water itself. (2.) In the second place, the effect of pressure must be recognized as most important in enabling water, especially when heated, to dissolve and retain in solution a larger quantity of mineral matter than it could otherwise do. In M. Daubrée's experiments just cited, the tubes were hermetically sealed and secured against fracture, so that the pressure of the greatly super-heated vapour had full effect. By this means, with alkaline water, he not only produced the two minerals above mentioned, but also felspar and diopside.

It is important to observe that the three conditions required for these changes—the presence of alkaline water, a high temperature, and considerable pressure—are precisely those which it can be affirmed must exist abundantly within the crust of the earth. We must admit the possibility of rocks originally at the surface being depressed so as to come within the influence of internal heat, and to contain within their pores abundant interstitial water more or less charged with alkaline carbonates. Rocks under these conditions, so far as we can judge, can hardly escape internal decomposition and recomposition. Mere descent to a great depth beneath the surface will not necessarily result in metamorphism, as has been shown in the case of the Nova Scotian and of the South Welsh coal-field, where sandstones, shales, clays, and coal-seams can be proved to have been once depressed 14,000 to 17,000 feet below the sea-level, under an overlying mass of rock, and yet to have sustained no serious alteration. Perhaps the failure of change may be explicable on the supposition that these Carboniferous strata were comparatively dry. But where rocks possess sufficient interstitial water, and are depressed within the crust so as to be exposed to a considerable temperature and to great pressure, they must be metamorphosed,—the extent of the metamorphism depending partly upon the vigour of the attack made upon them by the water, partly on their own composition and proneness to chemical change, and partly upon the length of time during which the process is continued.

A metamorphosed rock must thus be one which has suffered a mineralogical rearrangement of its substance. It may or may not have been a crystalline rock originally. Any rock capable of alteration (and all rocks must be so in some degree) will, when subjected to the required conditions, become a metamorphic rock. The resulting structure, however, will, in most cases, bear witness to the original character of the mass. A sedimentary rock, for example, consisting of alternate layers of different texture and composition, will doubtless retain, even in its metamorphosed condition, traces of that fundamental structure. The water will travel more easily along certain layers than along others; some laminæ will be more readily affected, or will give rise to a set of reactions different from those of contiguous layers. Hence the rearrangement and recrystallization due to metamorphism will take pace along the predetermined lines of stratification, so long as these lines have not been effaced or rendered inoperative by any other geological structure. It is doubtless to this cause that the foliated character of gneiss, mica-schist, and so many other metamorphic rocks is to be ascribed.

In the process of metamorphism, therefore, as well as in that of fusion, to which reference has already been made, the influence of water would seem to have been always conspicuous. Indeed, as will be shown in part iv., it is extremely difficult in many cases to draw a line between the results of metamorphism and igneous fusion, or to decide whether a rock should be called igneous or metamorphic. It has been pointed out above, for example, that in many rocks which have undoubtedly been in a fluid condition, as proved by their injected veins and dykes, the constituent minerals have not appeared in the order of their respective fusibilities. Scheerer, Élie de Beaumont, and Daubrée have shown how the presence of a comparatively small quantity of water in such rocks has contributed to suspend their solidification, and to promote the crystallization of their silicates at temperatures considerably below the point of fusion. In this way the solidification of quartz in granite after the crystallization of the silicates, which would be unintelligible on the supposition of mere dry fusion, becomes explicable. The phenomena of metamorphism in the architecture of the earth's crust are discussed in part iv.

DIVISION II.—EPIGENE OR SURFACE ACTION.

It is on the surface of the globe and by the operation of agents working there that at present the chief amount of visible geological change is effected. In considering this branch of inquiry, we are not involved in the same preliminary difficulty regarding the very nature of the agencies as we found to be the case in the investigation of plutonic action. On the contrary, the surface agents are carrying on their work under our very eyes. We can watch it in all its stages, measure its progress, and mark in many ways how accurately it represents similar changes which for long ages previously must have been effected by the same means. But in the systematic treatment of this subject we encounter a difficulty of another kind. We discover that while the operations to be discussed are numerous and often complex, they are so interwoven into one great network that any separation of them under different subdivisions is sure to be more or less artificial, and to convey an erroneous impression. While, therefore, under the unavoidable necessity of making use of such a classification of subjects, we must bear always in mind that it is employed merely for convenience, and that in nature superficial geological action must be continually viewed as a whole, since the work of each agent has constant reference to that of the others, and is not properly intelligible unless that connexion be kept in view.

The movements of the air; the evaporation from land and sea; the fall of rain, hail, and snow; the flow of rivers and glaciers; the tides, currents, and waves of the ocean; the growth and decay of organized existence, alike on land and in the depths of the sea;—in short, the whole circle of movement, which is continually in progress upon the surface of our planet, are the subjects now to be examined. It would be desirable to adopt some general term to embrace the whole of this range of inquiry. For this end the word *epigene* may be suggested as a convenient term, and antithetical to hypogene or subterranean action.

The simplest arrangement of this part of Geological Dynamics will be into three sections:—

I. AIR.—The influence of the atmosphere in destroying and forming rocks.

II. WATER.—The geological functions of the circulation of water through the air and between sea and land, and the action of the sea.

III. Life.—The part taken by plants and animals in preserving, destroying, or reproducing geological formations.

The words destructive, reproductive, and conservative, employed in describing the operations of the epigene agents, do not necessarily imply that anything useful to man is destroyed, reproduced, or preserved. On the contrary, the destructive action of the atmosphere may turn barren rock into rich soil, while its reproductive effects sometimes turn rich land into barren desert. Again, the conservative influence of vegetation has sometimes for centuries retained as barren morass what might otherwise have become rich meadow or luxuriant woodland. The terms, therefore, are used in a strictly geological sense, to denote the removal and re-deposition of material, and its agency in preserving what lies beneath it.

Section I.—Air.

Its composition having been already treated of (*ante*, p. 220), we shall consider here (1) the motions, and (2) the geological action of the air, which arises partly from its composition, and partly from its movements.

I. Movements of the Air.

These are due to differences in the pressure or density of the atmosphere, the law being that the air always moves from where the pressure is high to where it is low. Atmospheric pressure is understood to be determined by two causes, temperature and aqueous vapour.

1. *Temperature.*—Warm air, being less dense than cold air, ascends, while the latter flows in to take its place. The unequal heating of the earth's surface, by causing upward currents from the warmed portions, produces horizontal currents from the surrounding cooler regions inwards to the central ascending mass of heated air. To this cause the trade winds and the familiar land and sea breezes are due.

2. *Aqueous Vapour.*—In proportion as the quantity of watery vapour increases, the density of the air lessens. Consequently moist air tends to rise as warmed air does, with a corresponding but often very violent inflow of the drier and consequently heavier air from the surrounding tracts. The ascent of the moist air lessens the atmospheric pressure, which is indicated by the fall of the barometer. When the up-streaming vapour rises into the higher regions of the atmosphere, it expands and cools, condensing into visible form, and descending in copious showers to the earth. Unequal and rapid heating of the air, or accumulation of aqueous vapour in the air, and possibly some other influences not yet properly understood, give rise to extreme disturbances of pressure, and consequently to storms and hurricanes. For instance, the barometer sometimes indicates in tropical storms a fall of an inch and a half in an hour, showing that somewhere about a twentieth part of the whole mass of the atmosphere has in that short space of time been displaced over a certain area of the earth's surface. No such sudden change can occur without resulting in the most destructive tempest or tornado. In Britain the tenth of an inch of barometric fall in an hour is regarded as a large amount, such as only accompanies great storms.[1] When the pressure of the air at one place is shown by the barometer to differ from that at a neighbouring locality at the same time, the wind will be observed to move on the whole from the area of high to the area of low pressure; and if the difference be great or sudden, the movement of the air may rise to the force of a hurricane until the equilibrium of pressure is restored.

The meteorological conditions of the atmosphere do not belong to the scope of this article (see Atmosphere, Climate, Meteorology). The reader, however, may note as of interest from a geological point of view the ascertained velocity and pressure exercised by the air in motion across the surface of the earth as expressed in the subjoined table:—

	Velocity in miles per hour.	Pressure in pounds per square foot.
Calm	0	0
Light breeze	14	1
Strong breeze	42	9
Strong gale	70	25
Hurricane	84	36

II. Geological Influences of the Air.

The paramount importance of the atmosphere as the vehicle for the circulation of temperature and moisture over the globe, and consequently as powerfully influencing the distribution of climate and the growth of plants and animals, must be fully recognized by the geologist. Attention will be confined at present to the direct changes produced on the surface of the earth by the air—(1) on land, and (2) on water.

1. *Its Influence on Land.*

I. Destructive Influences.—These are either (α) chemical or (β) mechanical, though in nature the two kinds of action are often inseparably interwoven.

(α) Under the denomination of *chemical* changes we include the oxidation of those minerals which can contain more oxygen, as in the peroxidation and precipitation of protosalts of iron; likewise the absorption of carbonic acid by rocks, and the production of alkaline and earthy carbonates and bicarbonates, which still further promote the process of decomposition. In the one case the active agent of change is the oxygen of the air, or rather of the aqueous vapour in the air, for perfectly dry air seems to have little or no oxidizing effect. A familiar illustration is afforded by the rust, or oxide, which forms on iron when exposed to moisture, though this iron may be kept long bright if allowed to remain screened from moist air. In the other case, the active agent is the carbonic acid of the air, though here again it appears to be requisite that moisture should intervene as the medium of introducing the acid to the substance which is to be altered by it. The occurrence of sulphuric and nitric acids in the air, especially noticeable in large towns, likewise leads to considerable corrosion of metallic surfaces, as well as of stones and lime. The mortar of walls may often be observed to be slowly swelling out and dropping off, owing to the conversion of the lime into sulphate. Great injury is likewise done from a similar cause to marble monuments in exposed graveyards.

As a rule, the changes effected by the air lead to many subsequent transformations. For example, the oxidation of the bisulphide of iron produces sulphuric acid, which decomposes silicates, carbonates, and other compounds with which it comes in contact. These changes, however, are more appropriately noticed under the head of rain (p. 267).

(β) Among the more recognizable *mechanical* changes of a destructive kind, brought about by the atmosphere, we may notice the following influences:—

1. *Expansion and Contraction.*—The effect of heat is to expand rocks, of cold to contract them. Strictly speaking, these results on the surface of the earth are due, not to the air, but to the heat-rays of the sun which reach the rocks through the air. In countries with a great annual range of temperature considerable difficulty is sometimes experienced in selecting building materials liable to be little affected by the alternate expansion and contraction which prevents the joints of masonry from remaining close and

[1] Buchan's *Meteorology*, p. 266.

tight. In the United States, for example, with an annual thermometric range of more than 90° Fahr. this difficulty led to some experiments by Colonel Totten on the amount of expansion and contraction in different kinds of building-stones, caused by variations of temperature. It was found that in fine-grained granite the rate of expansion was ·000004825 for every degree Fahr. of increment of heat; in white crystalline marble it was ·000005668; and in red sandstone ·000009532, or about twice as much as in granite. If the daily variations in temperature are large, the effects are still more striking. In tropical climates with intensely hot days and extremely cold nights, the rapid nocturnal contraction produces sometimes a strain so great as to rival frost in its influence upon the surface of exposed rocks, disintegrating them into sand, or causing them to crack or peel off in skins or irregular pieces. Dr Livingstone found in Africa (12° S. lat., 34° E. long.) that surfaces of rock which during the day were heated up to 137° Fahr. cooled so rapidly by radiation at night that, unable to sustain the strain of contraction, they split and threw off sharp angular fragments from a few ounces to 100 or 200 ℔ in weight.[1]

2. *Frost.*—Though properly belonging to the subject of the geological behaviour of water to be afterwards described in more detail, the disintegrating action of frost may be noticed here. In freezing water expands, and thereby exerts an enormous strain upon any enclosed cavities or walls which may confine it. The consequence of this action is that in countries exposed to frost a continual disintegration of the surface of rocks goes on. This superficial decay combines with the chemical and mechanical operations of the atmosphere to produce considerable modifications in the forms of rocks and cliffs.

3. *Wind.*—By driving loose sand over rocks, prevalent winds produce on them a scratched and polished surface, as has happened with ancient monuments buried in the sands of the African deserts.[2] It is said that at Cape Cod holes have even been drilled in window glass by the same agency.[3] Cavities are now and then hollowed out of rocks by the gyration in them of little fragments of stone or grains of sand kept in motion by the wind. Hurricanes form important geological agents upon land in uprooting trees, and thus sometimes impeding the drainage of a country, and giving rise to the formation of peat mosses.

Weathering of Rocks.—Under the term "weathering" are included all the superficial changes which rocks undergo in consequence of the action of atmospheric processes upon them. The nature and rapidity of the disintegration depend partly on the one hand upon the climate, and partly on the other upon the composition, texture, and exposure of the rocks. In very dry countries, where the range of temperature is not extreme, weathering is reduced to a minimum. But even if the climate be dry, considerable disintegration may be caused, as has been already explained, by rapid changes of temperature between day and night. It is where moisture prevails, however, that weathering chiefly takes place The nature of the changes will be more properly considered in the section which is devoted to the action of rain.

II. Reproductive Influences.—These arise partly from the result of the chemical and mechanical disintegration involved in weathering, and partly from the transporting power of winds and aerial currents. Under the former head is the formation of soil; under the latter may be noticed the production of sand-hills, the fall of dust-showers and coloured rain, and the transport of seeds.

[2] For an account of this action of drifting sand in North America see Blake in *Pacific Railroad Report*, v. 92, 230.

[3] Dana's *Manual*, p. 631.

Soil.—Of the detritus produced by the action of the air on rocks, and washed away by rains and streams, part remains on the land and forms soil. All soil may be considered as the result of the decomposition of rocks, mingled with decayed vegetable and animal matter. Were it not for the action of rain in washing the loose materials to a greater or less distance from their source, the soil of every locality ought to be merely the decayed upper surface of the rocks underneath. But wherever rain falls, the soil is moved from higher to lower levels. Hence in some cases a good soil is laid down upon rocks which of themselves would only produce a poor one. This action of rain in the formation of soil is further alluded to on p. 270, and the co-operative influence of plant and animal life on p. 289.

Sand-hills or Dunes.—Winds blowing continuously upon loose materials, such as sand, drive them onward, and pile them into irregular heaps and ridges, called "dunes." This takes place more especially on windward coasts either of the sea or of large inland lakes, where the shores are sandy; but similar effects may be seen even in the heart of a continent, as in the sandy deserts of the Sahara and of Arabia. The dunes travel inland in parallel, irregular, and often confluent ridges, between which rain-water is sometimes arrested to form pools (*étangs* of the French coasts), where formations of peat occasionally take place. On the coast of Gascony the sea for 100 miles is so barred by sand-dunes that in all that distance only two outlets exist for the discharge of the drainage of the interior. As fast as one ridge is driven away from a beach another forms in its place, so that a series of huge sandy billows, as it were, is continually on the move from the sea margin towards the interior. A stream or river may temporarily arrest their progress, but eventually they push the obstacle aside or in front of them. In this way the river Adour, on the west coast of France, has had its mouth shifted two or three miles. Occasionally, as at the mouths of estuaries, the sand is blown across so as gradually to exclude the sea, and thus to aid the fluviatile deposits in adding to the breadth of the land.[4] The coast of Norfolk is fringed with sand-hills 50 to 60 feet high. On parts of the coast of Cornwall, the sand consists mainly of fragments of shells and corallines, and through the action of rain becomes sometimes indurated into a compact stone by carbonate of lime or oxide of iron. Long tracts of blown sand are likewise found along many parts of the Scottish and Irish coast-lines.

On the western border of the European continent extensive sand-dunes exist. They extend for many leagues along the French coast, and thence, by Flanders and Holland, round to the shores of Courland and Pomerania. In Denmark they are said to cover an area of 260 square miles. On the coast of Holland they are sometimes, though rarely, 260 feet high,—a common average height being 50 to 60 feet. The breadth of this maritime belt of sand varies considerably. On the east coast of Scotland it ranges from a few yards to 3 miles; on the opposite side of the North Sea it attains on the Dutch coast sometimes to as much as 5 miles. The rate of progress of the dunes towards the interior depends upon the wind, the direction of the coast, and the nature of the ground over which they have to move. On the low and exposed shores of the Bay of Biscay, when not fixed by vegetation, they travel inland at a rate of about 16½ feet; in Denmark at from 3 to 24 feet per annum. In the course of their march they envelop

[4] For accounts of sand-dunes, their extent, progress, structure, and the means employed to arrest their progress, the reader may consult Andersen's *Klitformationem*, 1 vol. 8vo, Copenhagen, 1861; Laval in *Annales des Ponts et Chaussées*, 1847, 2me sem.; and Marsh's *Man and Nature*, 1864, and the works cited by him. See also Élie de Beaumont, *Leçons de Géologie*, vol. i.

houses and fields; even whole parishes and districts once populous have been overwhelmed by them.[1]

Along the margins of large lakes and inland seas many of the phenomena of an exposed sea-coast are repeated, and on no inferior scale. Among these must be included sand-dunes, such as occur at the south-eastern end of Lake Michigan and on the eastern borders of the Caspian Sea. The shifting of vast waves of sand by the wind is exemplified on the grandest scale in the sandy deserts of Africa, Arabia, and Central Asia. Such arid wastes of loose sand, situated far inland and far distant from any sheet of fresh water, suggest curious problems in physical geography. Their sites may have been at a comparatively recent geological period covered by the sea; or, lying in rainless climates and having their surfaces exposed to the disintegrating effects of great extremes of temperature, the tracts may have become sandy and barren through atmospheric disintegration. The desert of the Sahara furnishes a good illustration of a dried-up sea-bed. In the rainless tract to the east of the Red Sea lie the great sandy deserts and hills of Arabia, of which Mr Palgrave has given so graphic a narrative. Captain Sturt found vast deserts of sand in the interior of Australia, with long lines of dunes 200 feet high, united at the base and stretching in straight lines as far as the eye could reach. In the south-east of Europe great tracts of sandy desert occur in Poland, and run through the southern provinces of Russia.

Dust-showers, Blood-rain.—In tropical countries, where great droughts are succeeded by violent hurricanes, the dust or sand of dried lakes or river-beds is sometimes borne away into the upper regions of the atmosphere, where, meeting with strong aerial currents which transport it for hundreds and even thousands of miles, it may descend again to the surface, in the form of "red-fog," "sea-dust," or "sirocco-dust." This transported material, usually of a brick-dust or cinnamon colour, is occasionally so abundant as to darken the air and obscure the sun, and to cover the decks, sails, and rigging of vessels which may even be hundreds of miles from land. Rain falling through such a dust-cloud mixes with it, and descends either on sea or land as what is popularly called "blood-rain." This is frequent on the north-west of Africa, about the Cape Verd Islands, in the Mediterranean, and over the bordering countries. A microscopic examination of this dust by Ehrenberg led him to the belief that it contains numerous diatoms of South American species; and he inferred that a dust-cloud must be swimming in the atmosphere, carried forward by continuous currents of air in the region of the trade-winds and anti-trades, but suffering partial and periodical deviations. But much of the dust must come from the sandy plains and desiccated pools of the north of Africa. Daubrée recognized in 1865 some of the Sahara sand which fell in the Canary Islands. On the coast of Italy a film of sandy clay, identical with that in parts of the Libyan desert, is occasionally found on windows after rain. In the middle of last century an area of northern Italy, estimated at about 200 square leagues, was covered with a layer of dust which in some places reached a depth of one inch. Should the travelling dust encounter a cooler temperature, it may be brought to the ground by snow, as has happened in the north of Italy, and more notably in the east and south-east of Russia, where the snows are sometimes rendered dirty by the dust raised by the winds on the Caspian steppes. It is easy to see that a prolonged continuance of this action must give rise to widespread deposits of dust, mingled with the soil of the land, and with the silt and sand of lakes, rivers, and the sea; and that the minuter organisms of tropical regions may thus come to be preserved in the same formations with the terrestrial or marine organisms of temperate latitudes.[2]

Transportation of Seeds.—Besides the transport of dust and minute organisms for distances of many thousands of miles, the same agency may come into play also in the transport of living seeds, which, finally reaching a congenial climate and soil, may take root and spread. We are yet, however, very ignorant as to what extent this cause has actually operated in the establishment of any given local flora. With regard to the minute forms of vegetable life, indeed, there can be no doubt as to the efficacy of the wind to transport them across vast distances on the surface of the globe. Upwards of 300 species of diatoms have been found in the deposits left by dust-showers. Among the millions of organisms thus transported it is hardly conceivable that some should not fall into a fitting locality for their continued existence and the perpetuation of their species.

2. *Influence of the Air on Water.*

The action of the air upon water will be more fitly noticed in the section devoted to water (p. 285). It will be enough to notice here—

1. *Ocean Currents.*—The in-streaming of air from cooler latitudes towards the equator causes a drift of the sea-water in the same direction. Owing to the rotation of the earth, these aerial currents tend to take a more and more westerly trend as they approach the equator. This they communicate to the marine currents, which, likewise moving into regions having a greater velocity of rotation than their own, are all the more impelled in the same westerly direction. Hence the westerly belt or equatorial current, which flows across the great ocean. Owing to the position of the continents across its path, this great current cannot move uninterruptedly round the earth. It is split into branches which turn to right and left, and, bathing the shores of the land, carry some of the warmth of the tropics into more temperate latitudes.

2. *Waves.*—The impulse of the wind upon a surface of water throws that surface into pulsations which range in size from mere ripples to huge billows. Long-continued gales from the seaward upon an exposed coast indirectly effect much destruction, by the formidable battery of billows which they bring to bear upon the land. Wave-action is likewise seen in a marked manner when wind blows strongly across a broad inland sheet of water, such as Lake Superior. (See p. 279.)

3. *Alteration of the Water-level.*—When the wind blows freshly for a time down a lake or into a bay or arm of the sea, it drives the water before it, and keeps it temporarily at a higher level, at the further or windward side. In a tidal sea, such as that which surrounds Great Britain, and which sends abundant long arms into the land, this action can often be studied. It is no infrequent occurrence that a high tide and a gale should happen at the same time. Whenever that takes place, then at those bays or firths which look windward the high tide rises to a greater height than elsewhere. With this conjunction of wind and tide, considerable damage to property has sometimes been done by the flooding of warehouses and stores, while even a sensible destruction of cliffs and sweeping away of loose materials may be chronicled by the geologist. On the other hand, a wind from the opposite quarter will drive the water out of the inlet, and thus make the water-level lower than it should otherwise be.

[1] This destruction has been, during the last quarter of a century, averted to a great extent by the planting of pine forests, the turpentine of which has become the source of a large revenue.

Section II.—Water.

Of all the terrestrial agents by which the surface of the earth is geologically modified, by far the most important is water. When following hypogene changes in a foregoing part of this article, we found how large a share is taken by water in the phenomena of volcanoes and other subterranean movements. When we returned to the surface of the earth and began to watch the operations of the atmosphere, we saw how impossible it is to consider these apart from the action of the aqueous vapour by which the atmosphere is pervaded. We must now study in detail the working of this wonderful geological agent itself.

The substance which we term water exists on the earth in three well-known forms — (1) gaseous, as invisible vapour; (2) liquid, as water; and (3) solid, as ice. The gaseous form has already been noticed in our inquiry into the geological characteristics of the air. It is in the air that this condition of the water-substance prevails. By the sun's heat vast quantities of vapour are continually raised from the surface of the seas, rivers, lakes, snow-fields, and glaciers of the world. This vapour remains invisible until the air containing it is cooled down to below its dew-point, or point of saturation,—a result which follows upon the union or collision of two aerial currents of different temperatures, or the rise of the air into the upper cold regions of the atmosphere, where it is chilled by expansion, by radiation, and by contact with cold mountains. At first minute particles appear, which either remain in the liquid condition, or, if the temperature is sufficiently low, are at once frozen into ice. As these changes take place over considerable spaces of the sky, they give rise to the phenomena of clouds. Further condensation augments the size of the cloud-particles, and at last they fall to the surface of the earth, if still liquid, as rain; if solid, as snow or hail; and if partly solid and partly liquid, as sleet. As the vapour is largely raised from the ocean surface, so in great measure it falls back again directly into the ocean. A considerable proportion, however, descends upon the land, and it is this part of the condensed vapour which we have now to follow. Upon the higher elevations it falls as snow, and gathers there into snow-fields, which, by means of glaciers, send their drainage down towards the valleys and plains. Elsewhere it falls chiefly as rain, some of which sinks underground to gush forth again in springs, while the rest pours down the slopes of the land, feeding brooks and torrents, which, swollen further by the springs, gather into broader and yet broader rivers, whereby the drainage of the land is carried out to sea. Thence once more the vapour rises to reappear in clouds, and feed the innumerable water-channels by which the land is furrowed from mountain-top to sea-shore.

Here then is a vast system of circulation, ceaselessly renewed. And in that system there is not a drop of water which is not busy with its allotted task of changing the face of the earth. When the vapour ascends into the air it is almost chemically pure. But when, after being condensed into visible form, and working its way over or under the surface of the land, it once more enters the sea, it is no longer pure, but more or less loaded with material taken by it out of the air, rocks, or soils through which it has travelled. Day by day the process is advancing. So far as we can tell, it has never ceased since the first shower of rain fell upon the earth. We may well believe, therefore, that it must have worked marvels upon the surface of our planet in past time, and that it may effect vast transformations in the future. As a foundation for such a belief let us now inquire what it can be proved to be doing at the present time.

The subject of the geological operation of water upon the globe may be conveniently studied under the following subdivisions:—

A. Terrestrial Waters.—Under this head are to be considered—(1) the liquid state, including rain, underground water, brooks, rivers, and lakes; and (2) the solid state—frost, river-ice, snow, hail, glaciers.

B. Oceanic Waters.—Including the influence of marine currents, tides, and waves, and the part taken by the sea in the general geological *régime* of the earth.

A. Terrestrial Waters.

I. In the Liquid State.

§ 1. *Rain.*

Rain effects two kinds of changes upon the surface of the land. (1.) It acts *chemically* upon soils and stones, and sinking under ground continues, as we shall find, a great series of similar reactions there. (2.) It acts *mechanically*, by washing away loose materials, and thus powerfully affecting the contours of the land.

I. Chemical Action.—This depends mainly upon the nature and proportion of the substances abstracted by rain from the air in its descent to the earth. Rain always absorbs a little air, and as we have already seen (p. 220) air always contains carbonic acid as well as other ingredients, in addition to its nitrogen and oxygen. If rain be regarded as an agent washing the air and taking impurities out of it, we may the better realize how by means of these it is enabled to work many chemical changes which, were it to reach the earth as pure water, it could not accomplish.

Composition of Rain-Water.—Numerous analyses of rain-water show that it contains in solution about 25 cubic centimetres of gases per litre. An average proportional percentage is by measure—nitrogen, 66·4; oxygen, 31·2; carbonic acid, 2·4,—the oxygen being in greater proportion than in air, owing to its greater solubility in water. Common salt, ammonia, sulphates, nitric acid, inorganic dust, and organic matter are usually present in minute quantities in rain water. So far as we know at present, the three ingredients which are chiefly effective in the chemical reactions due to rain are the oxygen, carbonic acid, and organic matter.[1]

Permeability of all Rocks by Water.—Though minerals and rocks differ vastly in their degree of porousness, there is none known which is not in some degree permeable by water. Even such hard and apparently impenetrable substances as flint and agate are found to be permeable. For, in fact, rocks and minerals when examined with the microscope are seen to be made up of variously-shaped grains, crystals, or particles, and it is in the minute channels and interstices between these particles, or even through the particles themselves, that the water works its way. Evidently, the smaller the interstices the less easily will the water force a passage into or through the stone. This permeability, though well marked upon the surface of the land, becomes still more so underground, where the rocks are sometimes quite saturated with water.

Liability of all Rocks to alteration by Water.—There is probably no known substance which is not, under some condition, soluble in water containing carbonic acid or other natural reagent. Rain-water, descending with the gases, acids, and organic matter it has abstracted from the air and soil, effects a chemical disintegration of the rocks. This action was referred to in the description of the air as

[1] The organic matter is revealed by the putrid smell which long-kept rain water gives out. The reader who wishes to pursue this subject may consult the elaborate tables of analyses in Dr Angus Smith's *Air and Rain.* See also the section on air, *ante*, p. 220.

partly due to atmospheric moisture, but it is chiefly carried on by rain. And as rain is so widely and almost universally distributed over the globe, this chemical action must be of very general occurrence.

Nature of the Changes effected.—Confining our attention to its three chiefly active ingredients, we find that rain water reacts chemically upon rocks by—1. *Oxidation.*—The prominence of oxygen in rain-water, and its readiness to unite with any substance which can contain more of it, render this a marked feature of the passage of rain over rocks. A thin oxidized pellicle is formed on the surface, and this, if not at once washed off by the rain, sinks deeper until a crust is formed over the stone. As already remarked, this process is simply a rusting of those minerals which, like metallic iron, have no oxygen, or have not their full complement of it. 2. *Deoxidation.*—Organic matter having an affinity for more oxygen decomposes peroxides by depriving them of some part of their share of that element, and reducing them to protoxides. These changes are especially noticeable among the iron oxides so abundantly diffused among rocks. Hence rain-water, in sinking through soil and obtaining such organic matter, becomes thereby a reducing agent. 3. *Solution.*—This may take place either by the simple action of the water, as in the solution of rock-salt, or by the influence of the carbonic acid present in the rain. Of the latter (*Carbonation*) a familiar example is the corrosion of marble slabs down which rain has trickled for a time. The carbonic acid dissolves some of the lime, which as a bicarbonate is held in solution in the carbonated water, but is deposited again when the water loses its carbonic acid or evaporates. It is not merely carbonates, however, which are liable to this kind of destruction. Even silicates of lime, potash, and soda, combinations existing abundantly as constituents of rocks, are attacked; their silica is liberated, and their alkalies or alkaline earths, becoming carbonates, are removed in solution. 4. *Hydration.*—Some minerals, containing little or no water, and therefore called anhydrous, when exposed to the action of the atmosphere, absorb water, or become hydrous, and are then usually more prone to further change. Hence the rocks of which they form part become disintegrated.

Weathering.—The weathering of rocks is dependent upon two sets of conditions—(1) meteorological, as the range of temperature, abundance of moisture, height above the sea, and exposure, and (2) lithological,—the composition and texture of the rocks themselves. As regards the composition of rocks, those which consist of particles liable to little chemical change from the influence of moisture are best fitted to resist weathering, provided their particles have sufficient cohesion to withstand the mechanical processes of disintegration. Siliceous sandstones are excellent examples of this permanence. Consisting wholly or mainly of the durable mineral quartz, they are sometimes able so to withstand decay that buildings made of them still retain, after the lapse of centuries, the chisel-marks of the builders. Some rocks which yield with comparative rapidity to the chemical attacks of moisture show no marks of disintegration on their surface, which remains clean and fresh. This is particularly the case with limestones. The reason lies obviously in the fact that limestone when pure is wholly soluble in acidulous water. Rain falling on this rock removes some of it in solution, and will continue to do so until the rock is dissolved away. It is only where the limestone contains impurities that a weathered crust of more or less insoluble particles remains behind. Hence the relative purity of limestones may be roughly determined by comparing their weathered surfaces, where, if they contain much sand, the grains will be seen projecting from the calcareous matrix, and where should the rock be very ferruginous, the yellow hydrous peroxide or ochre will be found as a powdery crust. In limestones containing abundant encrinites, shells, or other organic remains, the weathered surface commonly presents the fossils standing out in relief. This seems to arise from the crystalline arrangement of the lime in the organic structures, whereby they are enabled to resist disintegration better than the general mechanically aggregated matrix of the rock. An experienced fossil collector will always search well those weathered surfaces, for he often finds there, delicately picked out by the weather, minute and frail fossils which are wholly invisible on a freshly broken surface of the stone. Many rocks weather with a thick crust or even decay inwards for many feet or yards. Basalt, for example, often shows a yellowish-brown ferruginous layer on its surface, formed by the conversion of its felspar into kaolin and the removal of its silicate of lime as carbonate, by the hydration of its olivine and augite and their conversion into serpentine, saponite, or some other hydrous magnesian silicate, and by the conversion of its magnetite into limonite. Granite sometimes shows in a most remarkable way the distance to which weathering can reach. It may often be dug into for a depth of 20 or 30 feet, the quartz crystals and veins retaining their original positions, while the felspar is completely kaolinized.

It is to the effects of weathering that the abundant fantastic shapes assumed by crags and other rocky masses are due. Most varieties of rock have their own characteristic modes of weathering, whereby they may be recognized even from a distance. To some of these features reference will be made in a subsequent section.

II. Mechanical Action.—When a rock has been so corroded by weathering that the cohesion of the particles on its exposed surface is destroyed, these particles are washed off by rain. This detritus is either held in suspension in the little runnels into which the rain-drops gather as they begin to flow over the land, or is pushed by them along the surface. In this way the rain carries off by mechanical movement what it has already loosened by chemical action.

III. Results of Rain-Action.—It is evident that the general result of the fall of rain upon a land-surface must be a disintegration and consequent lowering of that surface. At first we may be inclined to imagine that this waste must be so slow and slight as to be hardly appreciable. But a little observation will suffice to furnish many proofs of its existence and comparatively rapid progress in some places. We are familiar, for example, with the pitted channelled surface of the ground lying immediately under the drip of the eaves of a house. We know that the fragments of stone and gravel are left sticking up prominently because the earth around and above them has been washed away, and because, being hard, they resist the action of the falling drops and screen the earth below them. On a far larger scale we may notice the same kind of operation in districts of conglomerate, where the larger blocks, serving as a protection to the rock underneath, come to form as it were the capitals of slowly-deepening columns of rock. In the same way in certain valleys of the Alps a stony clay is cut by the rain into pillars, each of which is protected by, and indeed owes its existence to, a large block of stone which lay originally in the heart of the mass. These columns are of all heights, according to the positions in which the stones may have originally lain. There are instances, however, where the disintegration has been so complete that only a few scattered fragments remain of a once extensive stratum, and where it may not be easy to realize that these fragments are not transported boulders. In Dorsetshire and Wiltshire, for example, the surface of the country is in some parts so thickly strewn with fragments of sandstone and conglomerate "that a person may almost leap from one stone to another without touching the ground. The stones are frequently of considerable size, many being four or five yards across, and about four feet thick."[1] They have been used for the huge blocks of which Stonehenge and other of the so-called druidical circles have been constructed, hence they have been termed Druid Stones. Other names are Sarsen Stones (supposed to indicate that their accumulation has been popularly ascribed to the Saracens), and Grey Wethers, from their resemblance in the distance to flocks of (wether) sheep. They are found lying abundantly on the chalk, suggestive at first of some former agent of transport by which they were brought from a distance. It is now, however, generally admitted that they are simply fragments of some of the sandy Tertiary strata which once covered the districts where they occur, and that while the softer portions of these strata have been carried away, the harder parts (their hardness perhaps increasing by exposure) have remained behind as Grey Wethers, and have subsequently suffered from the inevitable splitting and crumbling action of the weather.

But it is not from any single example, however striking, that the real importance of rain as a geological agent can be adequately realized. To form a true conception of this momentous action, we need to watch what takes place over a wide region. The whole land-surface over which rain falls is exposed to waste. As Hutton long ago insisted, the superficial covering of decayed rock or soil is constantly, though slowly, travelling outward and downward to the sea. In this ceaseless transport rain acts as the great carrying agent. The particles of rock loosened by atmospheric waste, by frost or the chemical disintegration of the rain itself, are washed off to form new soil. But they as well as the particles of the soil are step by step moved downward over the face of the land till they reach the nearest brook or river, whence their seaward progress may be rapid. A heavy rain discolours the water-courses of a country, because it loads them with the fine debris which it removes from the general surface of the land. In this way rain serves as the means whereby the work of the other disintegrating forces is made conducive to the general degradation of the land. The decomposed crust produced by weathering, which would otherwise accumulate over the solid rock and protect it from further decay, is removed by rain so as to expose a fresh surface to further decomposition. This decay is general and constant, but not uniform. In some places, from the nature of the rock, from the flatness of the ground, or from other causes, rain works under great difficulties. There the rate of waste must consequently be extremely slow. In other places, again, the rate may be rapid enough to be readily appreciable from year to year. A survey of this department of geological activity shows how the unequal wasting by rain has helped to produce the details of the present relief of the land, those tracts where the destruction has been greatest forming hollows and valleys, others, where it has been less, rising into ridges and hills.

Rain-action is not always merely destructive. Usually it is accompanied by reproductive effects, and, as already remarked, the mouldered rock which it washes off furnishes materials for the formation of soil. In favourable situations it has gathered together accumulations of loam and earth from neighbouring higher ground—the "brick-earth," "head," and "rain-wash" of the south of England—earthy deposits, sometimes full of angular stones, derived from the subaerial waste of the rocks of the neighbourhood.[2]

§ 2. *Underground Water.*

When rain falls upon the land its further progress becomes twofold. The greater part of it sinks into the ground and apparently disappears; the rest flows off into runnels, brooks, and rivers, and in this way moves downward to the sea. It is most convenient to follow first the course of the subterranean water.

We have seen that all rocks are more or less porous. They are moreover traversed by abundant joints and cracks. Hence, from the bed of the ocean, from the bottoms of lakes and rivers, as well as from the surface of the land on which rain falls, water is continually filtering downward into the rocks beneath. To what depth this descent of the surface water may go is not known. It may reach as far as the intensely heated interior of the planet, for, as the researches of M. Daubrée have shown, capillary water has the capacity of penetrating rocks even against a high counter-pressure of vapour. The water at extreme depths may be under such pressure as to retain its liquid condition at a red or even at a white heat. Probably the depth to which the water descends varies indefinitely according to the varying nature of the rocky crust. Some shallow mines are practically quite dry, while others of great depth require large pumping engines to keep them from being flooded by the water which pours into them from the surrounding rocks. As a rule, however, the upper layers of rock are fuller of moisture than those deeper down.

The water which in this way sinks into the earth is not permanently removed from the surface, though there may perhaps be a slight loss due to absorption and chemical alteration of the rocks. It accumulates underneath, until by the pressure of the descending column it is forced to find a passage through joints or fissures upward to the surface. The points at which it issues are termed *springs*. In most districts the rocks underneath are permeated with water below a certain limit which is termed the *water-level*. This line is not a strictly horizontal one like that of the surface of a lake. Moreover, it is liable to rise and fall according as the seasons are wet or dry. In some places it lies quite near, in others far below, the surface. A well is an artificial hole dug down below the water-level, into which the water percolates. Hence, when the water-level happens to be at a small depth the wells are shallow, when at a great depth they require to be deep.

Since the rocks underneath the surface vary greatly in porosity, some contain far more water than others. It often happens that, percolating along some porous bed, the subterranean water finds its way downward until it passes under some more impervious[3] rock. Hindered in its progress, it accumulates in the porous bed, from which it may be able to find its way up to the surface again only by a tedious circuitous passage. If, however, a bore-hole be sunk through the upper impervious bed down to the water-charged stratum below, the water will eagerly avail itself of this artificial channel of escape, and will rise in the hole, or even rush up and gush out as a *jet d'eau* above ground. Wells of this kind are now largely employed. They bear the name of *Artesian*, from the old province of Artois in France, where they have long been in use.

That the water really circulates underground, and passes

[1] See *Descriptive Catalogue of Rock Specimens in Jermyn Street Museum*, 3d ed.; Prestwich, *Quart. Journ. Geol. Soc.*, x. p. 123; Whitaker, *Geological Survey Memoir on parts of Middlesex*, &c., p. 71.

[2] See Austen, *Quart. Journ. Geol. Soc.*, vi. 94, vii. 121; Foster and Topley, *Quart. Journ. Geol. Soc.*, xxi. 446.

[3] This term *impervious* must evidently be used in a relative and not in an absolute sense. A stiff clay is practically impervious to the trickle of underground water; hence its employment as a material for puddling (that is, making water-tight) canals and reservoirs. But it contains abundant interstitial water, on which indeed its characteristic plasticity depends.

not merely between the pores of the rocks but in crevices and tunnels which it has no doubt to a large extent opened for itself along numerous natural joints and fissures, is proved by the occasional rise of leaves, twigs, and even live fish, in the shaft of an Artesian well. Such evidences are particularly striking when found in districts without surface waters, and even perhaps with little or no rain. They have been met with, for instance, in sinking wells in some of the sandy deserts on the southern borders of Algeria. In these and similar cases it is clear that the water may, and sometimes does, travel for many leagues underground away from the district where it fell as rain or snow, or where it leaked from the bed of a river or lake.

The temperature of springs affords a convenient but not always quite reliable indication of the relative depth from which they have risen. Some springs are just one degree or less above the temperature of ice. Others in volcanic districts issue with the temperature of boiling water. Between these two extremes every degree may be registered. Very cold springs may be regarded as probably deriving their supply from cold or even snow-covered mountains. Certain exceptional cases, however, occur where ice forms in caverns (*glacières*) even in warm and comparatively low districts. Water issuing from these ice caves is of course cold.[1] On the other hand, springs whose temperature is much higher than the mean temperature of the places at which they emerge must have descended far enough to be warmed by the internal heat of the earth. The hottest springs are found in volcanic districts. But even at a great distance from any active volcano, *thermal springs*, as they are called, appear with a temperature of 120° Fahr. (which is that of the Bath springs) or even more. These have probably risen from a great depth. If we could assume a progressive increase of 1° Fahr. of subterranean heat for every 60 feet of descent, the water at 120° issuing at a locality whose ordinary temperature is 50°, should have been down at least 4200 feet below the surface. But from what has been stated in a previous section (p. 224) regarding the irregular stratification of temperature within the earth's crust, such estimates of the probable depth of the sources of springs are liable to various errors.

Apart from its vast importance in a social point of view, the underground circulation of water has a profound interest for the geologist, from the light which it affords as to the changes that rocks undergo, and the manner in which these changes are effected. For, like all the other geological agents, it does not move on its course without doing work. We have now to inquire what is the nature of that work. A convenient arrangement will be to group its study under two heads—(1) chemical action, and (2) mechanical action.

(1.) Every spring, even the most clear and sparkling, contains mineral matter in chemical solution, obtained from the rocks through which the water travels in its journey from the surface into the interior, and back to the surface again. The nature of the mineral ingredients depends partly upon the composition of the rocks traversed, partly upon the gases, acids, or other reagents which may have been present in the rain, or may have been obtained by the water in its subterranean journey, and partly upon the depth to which the water may have reached and the temperature to which it may have been raised.

We have already (*ante*, p. 267) considered the substances extracted by rain from the air and used by it in the disintegration of rocks. The same reagents are of course carried underneath the ground, when the rain-water sinks out of sight, and continue there the processes of decomposition and alteration which they are seen to effect at the surface. But other sources are open to the subterranean water for the augmentation of its chemical reagents. (1.) In descending through the soil the meteoric water encounters abundant organic matter, which abstracts its oxygen and replaces it by carbonic acid. This interchange probably in many cases far more than compensates for the expenditure of these gases employed in subaerial disintegration. In so far as the water carries down from the soil any oxidizable organic substance, its action must be to reduce the oxides it encounters among rocks. It is remarkable that ordinary vegetable soil possesses the power of removing from the water which permeates it potash, silica, phosphoric acid, ammonia, and organic matter, elements which had been already in great measure abstracted from it by living vegetation, and which are again taken up by the same organic agents. (2.) Carbonic acid gas is sometimes largely evolved within the earth's crust, especially in regions of extinct or dormant volcanoes. Subterranean water coming in the way of this gas greedily dissolves it, and thereby obtains an enormously increased power of attacking even the most obdurate rocks. (3.) Whenever the water has its temperature considerably raised, its solvent capacity, especially for silica, is largely augmented Hot springs often contain a large proportion of that substance in solution. (4.) The production of some of the compounds which are due to decompositions effected by the water, and are carried along with it in solution, increases its ability to accomplish further decompositions. Thus the alkaline carbonates, which are among the earliest products of the action of the water, enable it to dissolve silica and decompose silicates.

The study of these alterations belongs to the subject of Metamorphism, of which some account has already been given (*ante*, p. 262). Let us look at the results achieved by them, as shown in the composition of the water which issues from different springs. Considered from this point of view, springs may be treated as (1) common or ordinary springs, that is, those which contain only such average proportions of mineral matter as occur in ordinary potable water, and (2) mineral springs, or those where the proportion of foreign ingredients is large enough to give a marked character to the water. These two groups, however, merge insensibly into each other.

Common Springs.—The materials ordinarily present in common spring water are, besides atmospheric air and its gases, carbonate and sulphate of lime, common salt, with chlorides of calcium and magnesium, and sometimes organic matter. The amount of dissolved contents in ordinary drinking water does not exceed ·5 or at most 1·0 gramme per litre; the best waters contain even less.

Mineral Springs.—These may be roughly but conveniently classified according to the prevailing mineral substance contained in them, which may range in amount from 1 to 300 grammes per litre.[2]

Calcareous—containing so much lime that it is deposited as a white crust as the water evaporates. Spring water when saturated with carbonate of lime contains about 105 parts in 100,000. Springs of this kind are common in limestone countries. As the water flows away from its point of exit, it throws down a deposit of calcareous tufa or travertine, which, as it encrusts moss, twigs, and other objects, gives them the appearance of having been turned into stone, whence the springs are popularly termed "petrifying." Enormous accumulations of this kind have been formed in some parts of Italy, where the rock so produced is extensively quarried as a building material.

Ferruginous or *Chalybeate*—containing a large proportion of iron in the total mineral ingredients. Such waters have an inky taste, and often deposit along their course a yellow, brown, or red ochry

[1] The most remarkable example of a glacière yet observed is that of Dobschau, in Hungary, of which an account, with a series of interesting drawings, was published in 1874 by Dr J. A. Krenner, keeper of the national museum in Buda-Pesth.

[2] Paul, in Watt's *Chem. Dict.*, v., 1016.

deposit, consisting mainly of hydrated peroxide of iron. They may be frequently observed in those districts where beds or veins of ironstone occur, or where the rocks contain much iron in combination.

Siliceous—depositing silica or flint. Although silica may be dissolved and retained in solution even in cold water, it is in the hot water issuing in volcanic countries that it occurs most abundantly, and where true siliceous springs exist. The geysers of Iceland, New Zealand, the Yellowstone region, and other districts are illustrations. When the heated water of these thermal springs cools and evaporates, the silica is deposited as siliceous sinter round their basins, or in picturesque mounds at the point of escape. One of the sinter beds in the geyser region of Iceland is said to be two leagues long, a quarter of a league wide, and a hundred feet thick. As already stated (*ante*, p.263), the effect of pressure is to enable water at great depths to retain a larger amount of mineral matter in solution. Hence, when the water ascends, it deposits its mineral contents, not only because it cools, but because the pressure is removed. There must in many cases be a copious deposit along the walls of the fissures up which the water flows on its way to the surface. Doubtless in this way many mineral veins have received their successive coatings of quartz, jasper, gypsum, calcite, and other minerals.

Brine—bringing to the surface a solution, more or less nearly saturated, of chloride of sodium. Springs of this kind appear where beds of solid rock-salt exist underneath. The water in its passage encounters the salt, dissolves it, and brings it to the surface. The brine springs of Cheshire in England, the Salzkammergut in Austria, Bex in Switzerland, &c., have long been well known. Some of the English brines contain about one per cent. of salts, of which the chloride of sodium may range from a half to three-fourths or more. Other brines, however, yield a far larger amount; one at Clemenshall, Würtemburg, gave upwards of 26 per cent. of salts, of which almost the whole was chloride of sodium. The other substances contained in solution in the water of brine springs are usually such as exist also in sea-water, such as sulphate and carbonate of lime, chlorides of magnesium and potassium, &c.

Medicinal—a vague term applied to mineral springs which have or are believed to have curative effects in different diseases. Medical men recognize various qualities, distinguished by the particular substance most conspicuous in each—as *Alkaline Waters*, containing lime or soda and carbonic acid, as those of Vichy or Saratoga; *Bitter Waters*, with sulphate of magnesia and soda—Sedlitz, Kissingen; *Salt* or *Muriated Waters*, with common salt as the leading mineral constituent—Wiesbaden, Cheltenham; *Earthy Waters*, lime, either a sulphate or carbonate, being the most marked ingredient—Bath, Lucca; *Sulphurous Waters*, with sulphur as sulphuretted hydrogen and in sulphides—Aix-la-Chapelle, Harrogate.

Oil.—Mineral oil is carried up by some ordinary springs, and floats in dark drops on the surface of the water. But in some parts of the world, as in a wide region in the Northern States of the American Union and in Canada, the oil ascends with little or no water, and forms the oil-springs which in recent years have become so remarkable and abundant a source of illuminating oils, paraffin, and other hydrocarbon compounds.

Results of Chemical Action of Underground Water.—Since every spring is busily engaged in bringing mineral substances from below ground to the surface, there must evidently be a vast amount of subterranean waste, and many tunnels, channels, and caverns must in consequence be formed. To take one illustration: the warm springs of Bath, with a mean temperature of 120° Fahr., are impregnated with sulphates of lime and soda, and chlorides of sodium and magnesium. Professor Ramsay has estimated their annual discharge of mineral matter to be equal to a square column 9 feet in diameter and 140 feet in height. It is in calcareous regions that the extent of the subterranean loss can be most strikingly seen. Sometimes a district of limestone is drilled with vertical cavities (*swallow-holes* or *sinks*) formed by the solution of the rock by the descent of carbonated rain-water. Surface-drainage is there intercepted, and passes at once under ground, where, in course of time, an elaborate system of channels may be dissolved out of the solid rock. Such has been the origin of the Peak caverns of Derbyshire, the intricate grottoes of Antiparos and Adelsberg, and the vast labyrinths of the Mammoth Cave of Kentucky. In the course of time the underground rivers open out new courses, and leave their old ones dry. By the falling in of the roofs of caverns near the surface, brooks and rivers are occasionally engulphed, which, after a long subterranean course, may issue to the surface again in a totally different surface area of drainage to that in which they took their rise, and sometimes, as in Florida, with volume enough to be navigable almost up to their outflow. In such circumstances lakes may be formed over the sites of the broken-in caverns; and valleys may thus be deepened, or perhaps even formed. Mud, sand, and gravel, with the remains of plants and animals, are swept below ground, and sometimes accumulate in deposits there. This has been the origin of ossiferous caverns, and of the loam and breccia so often found in them.

These wonderful results of the subterranean circulation of water appeal to the imagination, and are those usually most dwelt upon as evincing the potency of this kind of geological agency. And yet the thoughtful observer who reflects upon this subject will perhaps be led to perceive that even more important than these visible caverns and grottoes are the silent unobtrusive changes so constantly in progress in the solid heart of rocks. As far down as percolating water reaches there is not a particle of mineral matter safe from its attacks. And as we have seen, it is hardly possible to find any rock which does not bear throughout its minute grains and pores evidence that water has filtered through it, removing some substances and putting others in their place.

(2.) *Results of Mechanical Action.*—In its passage along fissures and channels of the rocks, the underground water not merely dissolves materials chemically and removes them in solution, it likewise loosens some of the finer particles from the sides of these subterranean conduits and carries them along in mechanical suspension. We may occasionally observe, where a spring gushes forth at the surface, that grains of sand are brought up in the clear sparkling water. This removal of material sometimes produces remarkable surface changes when it takes place along the side of a steep slope or cliff, such as occur in river valleys, or by the sea-coast. Let us suppose a thin layer of some porous material, like loose sand or ill-compacted sandstone to lie between two more impervious rocks such as masses of clay or limestone, and that this porous stratum sloping down from higher ground comes out to the surface near the base of a line of abrupt cliff. The water which finds its way down into this layer will use it as its channel of escape, and travelling along its course will issue in springs or in a more general oozing forth along its outcrop at the foot of the declivity. Under these circumstances the support of the overlying mass of rock is apt to be loosened. The water not only removes piece-meal the sandy layer on which that overlying mass rests, but as it were lubricates the rock underneath. Consequently at intervals portions of the upper rock may break off and slide down into the valley or plain below. Such dislocations are known as *landslips*. Many illustrative examples might be cited. Thus in the year 1839 a mass of chalk on the Dorsetshire coast slipped over a bed of clay into the sea, leaving a rent three-quarters of a mile long, 150 feet deep, and 240 feet wide. The shifted mass, bearing with it houses, roads, and fields, was cracked, broken, and tilted in various directions, and was thus prepared for further attack and removal by the waves. On many parts of the coasts of Britain there are landslips on a large scale which doubtless took place many centuries ago, or even in some cases beyond the times of human history. The undercliff of the Isle of Wight, the cliffs west of Brandon Head, county Kerry, the basalt escarpments of Antrim, and the edges of the great volcanic plateaus of Mull, Skye, and Raasay furnish illustrations of such prehistoric landslips. Of Continental examples, the well-known fall of the Rossberg, behind the Righi in Switzerland, is one of the most memorable. After a rainy summer in 1806 a large part of one side of the mountain, consisting of sloping beds of hard red sandstone and conglomerate, resting upon soft sandy layers, gave way. Thousands of tons of solid rock suddenly swept across the valley of Goldau, burying four villages, with about 500 of their inhabitants. In 1855 a mass of debris, 3500 feet long, 1000 feet wide, and 600 feet high, slid into the valley of the Tiber, which, dammed back by the obstruction, overflowed the village of San Stefano to a depth of 50 feet, until drained off by a tunnel.

§ 3. *Brooks and Rivers.*

These will be considered under four aspects:—(1) their sources of supply, (2) their discharge, (3) their flow, and (4) their geological action.

I. Sources of Supply.—Rivers are the natural drains of a land surface. They carry out to sea the surplus water after evaporation, and not water only, but a vast and almost incredible amount of material annually worn off the land. Their contents are derived partly from rain (including mist and dew) and melted snow, partly from springs. In a vast river system like that of the Mississippi, the area of drainage is so extensive as to embrace many different climates and varieties of rainfall, so that on the whole the amount of discharge, being in a great measure independent of local variations in the weather, remains tolerably uniform. But in smaller rivers, such as those of Britain, whose basins lie in a region having the same general features of climate, the quantity of water is regulated by the local rainfall. A wet season swells the streams, a dry one diminishes them. Were rivers entirely dependent, however, upon direct supplies of rain, they would only flow in rainy seasons, and disappear in dry weather. This does not happen, because they derive a great deal of their water not directly from rain, but indirectly through the intermediate agency of springs. Hence they continue to flow even in very dry weather, because, though the superficial supplies have failed, the underground sources still continue available. In a long drought, however, the latter begin to fail, the surface springs ceasing first, and gradually drying up in their order of depth, until at last only deep-seated springs furnish a perhaps daily diminishing quantity of water. It is a matter of great economic as well as scientific interest to know how long any river would continue to yield a certain amount of water during a prolonged drought. So far as we can tell, no rule could possibly be laid down for a generally applicable calculation, every area having its own peculiarities of underground drainage. Mr Joseph Lucas gives some particulars which show what may happen in a chalk district. The river Wandle drains an area of 51 square miles of the chalk downs in the south-east of England. For eighteen months, from May 1858 to October 1859, as tested by gauging, there was very little absorption of rainfall over the drainage basin, and yet the minimum recorded flow of the Wandle was 10,000,000 gallons a-day, which, Mr Lucas says, represents not more than ·4090 inch of rain absorbed on the 51 square miles of chalk. The rock is so saturated that it can continue to supply a large yield of water for eighteen months after it has ceased to receive supplies from the surface, or at least has received only very much diminished supplies.[1]

II. Discharge.—As the natural drains of the land, rivers carry the surplus moisture out to sea. What proportion of the total rainfall is thus discharged by them is a question of great geological and industrial interest. From the very moment that water takes visible form as mist, cloud, dew, rain, snow, or hail, it is subject to evaporation. When it reaches the ground, or flows off into brooks, rivers, lakes, or the sea, it undergoes continual diminution from this cause. Hence in regions where rivers receive no tributaries, they grow smaller in volume as they move onward, till they sometimes even disappear. Apart from temperature, the amount of evaporation is very largely regulated by the nature of the surface from which it takes place, one soil or rock differing from another, and all of them probably from a surface of water. There is no question in meteorology where full and detailed observations are more wanting than in the determination of the relation of evaporation to rainfall and river discharge.[2] During severe storms of rain, the water discharged over the land of course to a very large extent finds its way at once into brooks and rivers, where it causes floods, and whence it reaches the sea. Mr David Stevenson remarks that, according to different observations, the amount carried off in floods varies from 1 to 100 cubic feet per minute per acre.[3] But though floods cannot be deemed exceptional phenomena, forming as they do a part of the regular system of water circulation over the land, they do not represent the ordinary proportions between rainfall and river discharge in such a climate as that of Britain, where the rainfall is not crowded into one season, but is spread more or less equally throughout the year. According to Beardmore's table,[4] the Thames at Staines has a mean annual discharge of 32·40 cubic inches per minute per square mile, equal to a depth of 7·31 inches of rainfall run off, or less than a third of the total rainfall. The most carefully collected data at present available are probably those given by Humphreys and Abbot for the basin of the Mississippi and its tributaries as shown in the subjoined table:—

	Ratio of Drainage to Rainfall.
Ohio River	0·24
Missouri River	0·15
Upper Mississippi River	0·24
Small tributaries	0·90
Arkansas and White River	0·15
Red River	0·20
Yazoo River	0·90
St Francis River	0·90
Entire Mississippi, exclusive of Red River	0·25

Perhaps in Great Britain not more than a fourth part of the total moisture deposited on the land from the atmosphere is carried out to sea by streams.[5] But this is a point on which, until far more facts have been gathered, no definite statement can be accepted as at all trustworthy.

III. Flow.—Rivers, in obedience to the law of gravitation, always move from a higher to a lower level. Where the channel of a river becomes vertical, or nearly so, a water-

[1] Lucas, *Horizontal Wells*, London, 1874, pp. 40, 41. See also Braithwaite, "On the Rise and Fall of the Wandle," *Minutes Proc. Inst. C. E.*, xx.

[2] In the present state of our information it seems almost useless to state any of the results already obtained, so widely discrepant and irreconcilable are they. In some cases the evaporation is given as usually three times the rainfall! and that the evaporation always exceeded the rainfall was for many years the belief among the French hydraulic engineers. (See *Annales des Ponts et Chaussées*, 1850, p. 383.) Observations on a larger scale, and with greater precautions against the undue heating of the evaporator, have since shown, as might have been anticipated, that as a rule, save in exceptionally dry years, the evaporation is lower than the rainfall. As the average of ten years from 1860 to 1869 Mr Greaves found that at Lea Bridge the evaporation from a surface of water was 20·916, while the rainfall was 25·534 (Symons's *British Rainfall* for 1869, p. 162). But we need a vast accumulation of observations, taken in many different situations and exposures, in different rocks and soils, and at various heights above the sea. (For a notice of a method of trying the evaporation from soil, see *British Rainfall*, 1872, p. 206.)

[3] *Reclamation and Protection of Agricultural Land*, Edin., 1874, p. 15.

[4] *Hydrology*, p. 201

[5] In mountainous tracts having a large rainfall and a short descent to the sea, the proportion of water returned to the sea must be very much greater than this. Mr Bateman's observations for seven years in the Loch Katrine district gave a mean annual rainfall of 87½ inches at the head of the lake, with an outflow equivalent to a depth of 81·70 inches of rain removed from the drainage basin of 71½ square miles.

fall is formed; a steep rocky declivity in the channel gives rise to rapids; a flat plain allows the stream to linger with a scarcely perceptible current; while a lake renders the flow nearly or altogether imperceptible. Thus the rate of flow is regulated in the main by the angle of inclination and form of the channel, but partly also by the volume of water, an increase of volume in a narrow channel increasing the rate of motion even without an increase of slope.

The course of a great river may be divided into three parts:—1. *The Mountain Track*,—where, amidst the clouds and snows it takes its rise as a mere brook, and, fed by innumerable similar torrents, dashes rapidly down the steep sides of the mountains, leaping from crag to crag in endless cascades, growing every moment in volume, until it enters lower ground. 2. *The Valley Track.*—It now flows through the lower hills or undulations which traverse or flank a great mountain chain, and is found at one time in a wide fertile valley, then in a dark gorge, now falling headlong in a cataract, now expanding into a broad lake. This is the part of its career where it assumes the most varied aspects, receives the largest tributaries, and fulfils most characteristically the various conditions which are present to our minds in the idea of a river. 3. *The Plain Track.*—Having quitted the undulating region, it finally emerges upon broad plains, probably wholly, or in great part, made by itself. Here it winds sluggishly in wide curves, perhaps divides so as to enclose tracts of flat meadow or marsh, and finally, amid banks of mud and sand, passes out into the great ocean. In Europe the Rhine, Rhone, and Danube, in Asia the Ganges and Indus, in America the Mississippi and Amazon, in Africa the Nile, more or less fully illustrate this typical course of a great river.

If we draw a longitudinal section of the course of any such river from its source, or from the highest peaks around that source to its mouth at the sea, we find that the line forms a concave curve. Steep at first, where it slopes from the mountain crests down into the valleys, the curve grows less and less through the middle portion, until it finally can hardly be distinguished from a horizontal line. Though characteristic of great rivers, this feature is not confined to their courses, but belongs to the architecture of the continents.

It is evident that a river must flow, on the whole, fastest in the first portion of its course, and slowest in the last. The common method of comparing the fall or slope of rivers is to divide the difference of height between their source and the sea-level by their length, so as to give the declivity per mile. This mode, however, often fails to bring out the real resemblances and differences of rivers, even in regard to their angle of slope. For example, two streams rising at a height of 1000 feet, and flowing 100 miles, would each have an average slope of 10 feet per mile; yet they might be wholly unlike each other, one making its descent almost entirely in the first or mountain part of its course, and lazily winding for most of its way through a vast low plain, the other toiling through the mountains, then keeping among hills and table-lands, so as to form on the whole a tolerably equable and rapid flow. The great rivers of the globe have probably a less average slope than 2 feet per mile. The Missouri has a descent of 28 inches per mile. The average slope of the channel of the Thames is 21 inches per mile; of the Shannon about 11 inches per mile, but between Killaloe and Limerick about 6½ feet per mile; of the Nile, below Cairo, 3·25 to 5·5 inches per mile; of the Doubs and Rhone, from Besançon to the Mediterranean, 24·18 inches per mile; of the Volga, from its source to the sea, a little more than 3 inches per mile. Higher angles of descent are those of torrents, as the Arve, with a slope of 1 in 616 at Chamounix, and the Durance, whose angle varies from 1 in 467 to 1 in 208. The slope of a navigable river ought not, if possible, to exceed 10 inches per mile, or 1 in 6336.[1]

But not only does the rate of flow of a river vary at different parts of its course, it is not the same in every part of the cross section of the river taken at any given point. The sides and bottom, being retarded by friction against the channel, move less rapidly than the centre. The central piers of a bridge have thus a greater velocity of river current to bear than those at the banks. It follows that whatever tends to diminish the friction of the moving current will increase its rate of flow. The same body of water, other conditions being equal, will move faster through a narrow gorge with steep smooth walls than over a broad rough rocky bed. For the same reason, when two streams join, their united current, having in many cases a channel not much larger than that of one of the single streams, flows faster, because the water encounters now the friction of only one channel. The average rate of flow of rivers is much less than might be supposed, even in what are termed swift rivers. A moderate rate is about 1¼ mile in the hour; even that of a torrent does not exceed 18 or 20 miles in the hour.[2] Mr D. Stevenson states that the velocity of such rivers as the Thames, the Tay, or the Clyde may be found to vary from about one mile per hour as a minimum to about three miles per hour as a maximum velocity.[3]

It may be remarked, in concluding this part of the subject, that elevations and depressions of the land must have a powerful influence upon the slope of rivers. The upraising of the axis of a country must increase the slope, and consequently the rate of flow which, on the contrary, will be diminished by a depression of the axis or by an elevation of the maritime regions.

IV. Geological Action.—Like all the other forms of moving water, the streams which traverse a country have both a *chemical* and *mechanical* action. The latter receives most attention, as it undoubtedly is the more important; but the former ought not to be omitted in any survey of the general waste of the earth's surface.

i. *Chemical.*—The water of rivers must possess the powers of a chemical solvent like rain and springs, though its actual work in this respect can be less easily measured, seeing that river water is directly derived from rain and springs, and necessarily contains in solution mineral substances supplied to it by them and not by its own operation. Nevertheless, it is sometimes easy to prove that streams dissolve chemically the rocks of their channels. Thus in limestone districts the base of the cliffs of river ravines may be found eaten away into tunnels, arches, and overhanging projections, presenting in their smooth surfaces a great contrast to the angular jointed faces of the same rock where exposed to the influence only of the weather on the higher parts of the cliff.

The composition of the river waters of western Europe is well shown by numerous analyses. The substances held in solution include variable proportions of the carbonates of lime, magnesia, and soda; silica; peroxides of iron and manganese; alumina; sulphates of lime, magnesia, potash, and soda; chlorides of sodium, potassium, calcium, and magnesium; silicate of potash; nitrates; and organic matter. The minimum proportion of mineral matter among the analyses collected by Bischof was 2·61 in 100,000 parts of water in a mountain stream 3800 feet above the sea. On the other hand as much as 54·5 parts in the 100,000 were obtained in the waters of the Beuvronne, a tributary of the Loire above Tours. The average of the whole of these analyses is about 21 parts of mineral matter in 100,000 of water, whereof carbonate of lime usually forms the half, its mean quantity

[1] D. Stevenson, *Canal and River Engineering* p. 224.
[2] Contjean, *Géologie*, p. 225.
[3] *Reclamation of Land*, p. 18.

being 11·34. Bischof calculated that, assuming the mean quantity of carbonate of lime in the Rhine to be 9·46 in 100,000 of water, which is the proportion ascertained at Bonn, enough carbonate of lime is carried into the sea by this river for the annual formation of three hundred and thirty-two thousand millions of oyster shells of the usual size. The mineral next in abundance is sulphate of lime, which in some rivers constitutes nearly half of the dissolved mineral matter. Silica amounting to 4·88 parts in 100,000 of water has been found in the Rhine, near Strasburg. The largest amount of alumina was 0·71 in the Loire, near Orleans. The proportion of mineral matter in the Thames, near London, amounts to about 33 in 100,000 parts of water, 15 of which (nearly half of the whole) consist of carbonate of lime.

It requires some reflection properly to appreciate the amount of solid mineral matter which is every year carried in solution from the rocks of the land and diffused by rivers into the sea. According to recent calculations by Mr T. Mellard Reade, C.E., a total of 8,370,630 tons of solids in solution is every year removed by running water from the rocks of England and Wales, which is equivalent to a general lowering of the surface of the country from that cause alone at the rate of ·0077 of a foot in a century or one foot in 12,978 years. The same writer computes the annual discharge of solids in solution by the Rhine to be equal to 92·3 tons per square mile, that of the Rhone at Avignon 232 tons per square mile, and that of the Danube at 72·7 tons per square mile; and he supposes that on an average over the whole world there may be every year dissolved by rain about 100 tons rocky matter per English square mile of surface.[1]

ii. *Mechanical*.—The mechanical work of rivers is threefold:—(1) to transport mud, sand, gravel, or blocks of stone from higher to lower levels; (2) to use these loose materials in eroding their channels; and (3) to deposit these materials where possible, and thus to make new geological formations.

1. Transporting Power.—It is one of the distinctions of river water, as compared with that of springs, that, as a rule, it is less transparent, that is, it contains more or less mineral matter in suspension. The same stream differs much at successive intervals in the amount of material thus transported. In dry weather when the water is low it may be tolerably clear; but a sudden heavy shower or a season of wet weather will render it turbid. The mud thus so frequently noticeable in rivers is partly derived from the surface of the ground on either side, whence it is washed into the main streams by rain and brooks, but partly also by the abrasion of the water-channels through the operations of the streams themselves. In the mountain tributaries of a river we find the channels choked with large fragments of rock disengaged from the cliffs and crags on either side. Traced downwards the blocks are seen to become gradually smaller and more rounded. They are ground against each other and upon the rocky sides and bottom of the channel, getting more and more reduced as they descend, and at the same time abrading the rocks over or against which they are driven. Hence a great deal of debris is produced, and is swept along by the onward and downward movement of the brooks and rivers. The finer portions, such as mud and fine sand, are carried in suspension, and impart the characteristic turbidity to rivers; the coarser sand and gravel are driven along the river bottom.

The transporting capacity of a stream depends (*a*) on the the volume and velocity of the current, and (*b*) on the size, shape, and specific gravity of the sediment. (*a*) According to the calculations of Hopkins, the capacity of transport increases as the sixth power of the velocity of the current; thus the motive power of the current is increased 64 times by the doubling of the velocity, 729 times by trebling, and 4096 times by quadrupling it. It has been found by experiment that "ordinary sandy soil is moved by a current having a velocity of about half a mile an hour, and that a current of about one mile per hour will move fine gravel, while heavy gravel resists a current of upwards of two miles per hour." Mr David Stevenson[2] gives the subjoined table of the power of transport of different velocities of river currents.

In. per Second.		Mile per Hour.	
3	=	0·170	will just begin to work on fine clay.
6	=	0·340	will lift fine sand.
8	=	0·4545	will lift sand as coarse as linseed.
12	=	0·6819	will sweep along fine gravel.
24	=	1·3638	will roll along rounded pebbles 1 inch in diameter.
36	=	2·045	will sweep along slippery angular stones of the size of an egg.

We must never lose sight, however, of the fact that it is not the surface velocity, nor even the mean velocity, of a river which can be taken as the measure of its power of transport, but the bottom velocity—that is, the rate at which the stream overcomes the friction of its channel. (*b*) The average specific gravity of the stones in a river ranges between two and three times that of pure fresh water; hence these stones lose from a half to a third of their weight in air when borne along by the river. Huge blocks which could not be moved by the same amount of energy applied to them on dry ground are swept along with ease when they have found their way into a strong river current. The shape of the fragments greatly affects their portability, when they are too large and heavy to be carried in mechanical suspension. Rounded stones are of course most easily moved; flat and angular ones are moved with comparative difficulty.

Besides their ordinary powers of transport, rivers gain at times considerable additional force from several causes. Those liable to sudden and heavy falls of rain acquire by flooding an enormous increase of transporting and excavating power. More work may thus be done by a stream in a day than could be accomplished by it during years of its ordinary condition.[3] Another source of increase to the action of rivers is provided when, from landslips, formed by earthquakes, by the undermining influence of springs, or otherwise, a stream is temporarily dammed back, and the barrier subsequently gives way. The bursting out of the arrested waters produces great destruction in the valley. Blocks as big as houses may be set in motion, and carried down for considerable distances. Again, the transporting power of rivers is greatly augmented in countries where they freeze in winter. As the ice gathers along the banks it encloses gravel, sand, and even large blocks of rock, which, when thaw comes, are lifted up by the ice and carried down the stream. Ground-ice likewise appears in cold latitudes on the bottoms of the rivers, whence, rising in cakes to the surface, it carries with it sand, mud, or stones lying on the bottom, which are then swept seaward. When rivers such as those of northern Russia and Siberia, flowing from south to north, have the ice thawed in their higher courses before it breaks up farther down, much disaster is sometimes caused by the piling up of the ice, and then by the bursting of the impeded river through the temporary ice-barrier. In another way ice sometimes vastly increases the destructive

[3] The extent to which heavy rains can alter the usual characters of rivers is forcibly exemplified in the graphic account of *The Morayshire Floods*, by the late Sir T. Dick Lauder. In the year 1829 the rivers of that region rose 10, 18, and in one case even 50 feet above their common summer level, producing almost incredible havoc.

powers of small streams where avalanches or an advancing glacier cross a valley and pond back its drainage. The valley of the Dranse, in Switzerland, has several times suffered from this cause. In 1818 the glacier barrier extended across the valley for more than half a mile, with a breadth of 600 and a height of 400 feet. The waters above the ice-dam accumulated into a lake containing 800,000,000 cubic feet. By a tunnel driven through the ice, the water was drawn off without desolating the plains below.

That rivers differ vastly from each other in the amount of material they transport is made evident by the great diversities in their relative muddiness. It should be borne in mind that the actual amount of sediment borne downwards by a river is not necessarily determined by the carrying power of the current. The swiftest streams are not always the muddiest. The proportion of sediment is partly dependent upon the hardness or softness of the rocks of the channel, the number of tributaries, the nature and slope of the ground forming the drainage basin, the amount and distribution of the rainfall, the size of the glaciers (where such exist) at the sources of the river, &c. A rainfall spread with some uniformity throughout the year may not sensibly darken the rivers with mud, but the same amount of fall crowded into a few weeks or months may be the means of sweeping a vast amount of earth into the rivers, and sending them down in a greatly discoloured state to the sea. Thus the rivers of India during the rainy season become rolling currents of mud.

In his journeys through equatorial Africa Livingstone came upon rivers which appear usually to consist more of sand than of water. He describes the Zingesi as "a sand rivulet in flood, 60 or 70 yards wide, and waist-deep. Like all these sand-rivers it is for the most part dry; but, by digging down a few feet, water is to be found, which is percolating along the bed on a stratum of clay. In trying to ford it," he remarks, "I felt thousands of particles of coarse sand striking my legs, which gave me the idea that the amount of matter removed by every freshet must be very great. . . . These sand rivers remove vast masses of disintegrated rock before it is fine enough to form soil. In most rivers where much wearing is going on, a person diving to the bottom may hear literally thousands of stones knocking against each other. This attrition, being carried on for hundreds of miles in different rivers, must have an effect greater than if all the pestles and mortars and mills of the world were grinding and wearing away the rocks."

The amount of mineral matter transported by rivers can be estimated by examining their waters at different periods and places, and determining their solid contents. A complete analysis should take into account what is chemically dissolved, what is mechanically suspended, and what is driven or pushed along the bottom. We have already dealt with the chemically dissolved ingredients. In determinations of the mechanically mixed constituents of river water, it is most advantageous to obtain the proportion first by weight, and then from its average specific gravity to estimate its bulk as an ingredient in the water. The Ganges, according to Everest, contains during the four months of flood earthy matter in the proportion of $\frac{1}{428}$ by weight or $\frac{1}{856}$ by volume,—the mean average for the year being $\frac{1}{510}$ by weight or $\frac{1}{1020}$ by volume. According to Mr Login, the waters of the Irrawaddy contain $\frac{1}{1700}$ by weight of sediment during floods, and $\frac{1}{5725}$ during a low state of the river. The most elaborate measurements and calculations yet made regarding this aspect of the operations of a river are those by Messrs Humphreys and Abbot on the Mississippi, who found, as the mean of many observations carried on continuously at different parts of the river for months together, that the average proportion of sediment contained in the water of the Mississippi is $\frac{1}{1500}$ by weight, or $\frac{1}{2900}$ by volume. But besides the matter held in suspension, they observed that a large amount of coarse detritus is constantly being pushed along the bottom of the river. They estimated that this moving stratum carries every year into the Gulf of Mexico about 750 million cubic feet of sand, earth, and gravel. Their observations led them to conclude that the annual discharge of water by the Mississippi is 19,500,000 million cubic feet, and consequently that the weight of mud annually carried into the sea by this river must reach the sum of 813,500 million ℔. Taking the total annual contributions of earthy matter, whether in suspension or moving along the bottom, they found them to equal a prism 268 feet in height, with a base of one square mile.

2. Excavating Power.—In transporting its freight of sediment a river performs a vast amount of abrasion. In the first place it rubs the loose stones against each other, breaks them into smaller pieces, rounds off their edges, reduces them to rounded pebbles and finally to sand or mud. In the next place by driving these loose materials over the rocks it wears down the sides and bottom of its channel which is thereby widened and deepened.

The familiar effect of running water upon fragments of rock, in reducing them to smoothed rounded pebbles, is expressed by the common phrase "water-worn." Every stream which descends from high rocky ground may be compared to a grinding mill; large boulders and angular blocks of rocks, disengaged by frosts, springs, and general atmospheric waste, fall into the upper end, and only fine sand and silt are discharged into the sea. M. Daubrée has instituted some ingenious experiments for ascertaining the circumstances under which angular fragments are converted into rounded pebbles with the production of sand and mud. Using fragments of granite and quartz, he caused them to slide over each other in a hollow cylinder partially filled with water, and rotating on its axis with a mean velocity of 0·80 to 1 metre in a second. He found that after the first 25 kilometres (about 15½ English miles) the angular fragments of granite had lost $\frac{4}{10}$ of their weight, while in the same distance fragments already well-rounded had not lost more than $\frac{1}{100}$ to $\frac{1}{400}$. The fragments rounded by this journey of 25 kilometres in a cylinder could not be distinguished either in form or in general aspect from the natural detritus of a river bed. A second product of these experiments was an extremely fine impalpable mud, which remained suspended in the water several days after the cessation of the movement. During the production of this fine sediment the water acted chemically upon the granite fragments, for after a day or two it was found, even though cold, to have dissolved a very sensible proportion of silicate of potash. After a journey of 160 kilometres, 3 kilogrammes (about 6½ ℔ avoirdupois) had yielded 3·3 grammes (about 50 grains) of soluble salts consisting chiefly of silicate of potash. A third product was an extremely fine angular sand consisting almost wholly of quartz, with scarcely any felspar, almost the whole of the latter mineral having passed into the state of clay. The sand grains, as they are continually pushed onward over each other upon the bottom of a river, become rounded as the larger pebbles do. But, as M. Daubrée points out, a limit is placed to this attrition by the size and specific gravity of the grains. So long as they are carried in suspension they will not abrade each other, but remain angular; for he found that the milky tint of the Rhine at Strasburg in the months of July and August was due not to mud but to a fine angular sand (with grains about $\frac{1}{20}$ millimetre in diameter) which constitutes $\frac{2}{100000}$ of the total weight of water. Yet this sand had travelled in a rapidly flowing tumultuous river from the Swiss mountains, and had been tossed over waterfalls and rapids in its journey. He ascertained also that sand with a mean diameter of grain of $\frac{1}{10}$ mm. will float in feebly agitated water; so that all sand of finer grain must remain angular. The same observer has noticed that sand composed of grains with a mean diameter of $\frac{1}{2}$ mm., and carried along by water moving at a rate of 1 metre per second, gets rounded, and loses about $\frac{1}{10000}$ of its weight in every kilometre travelled.

The effects of abrasion upon the loose materials on a river bed are only a portion of the erosive work performed by the stream. Where the bottom is covered with a layer of debris only the upper portion of which is pushed onward by the current, the solid rock of the river channel is there protected from waste. But this protection is only local, and is apt to be swept away from time to time by violent floods. In those parts of a river channel where the current is strong enough to keep gravel and boulders moving along, these loose materials rub down the rocky bottom over which they are driven. As the shape and declivity of the channel vary constantly from point to point, with at the same time frequent changes in the nature of its rocks, this erosive action is liable to continual modifications. While there is a general abrasion of the whole bottom over which loose detritus is rolled, the erosion goes on most briskly in the numerous hollows and grooves along which chiefly these loose materials travel. Wherever an eddy occurs in which gravel is kept in gyration, erosion is much increased. The stones in their movement excavate a hole in the channel, while, as they themselves are reduced to sand and mud, or are swept out by the force of the current, their places are taken by fresh stones brought down by the stream. Such *pot-holes*, as they are termed, vary in size from mere cup-like depressions to huge cauldrons or pools. As they often coalesce by the giving way of the intervening walls between two or more of them they materially increase the deepening of the river bed.

The shape of a river channel at any given point in its course depends mainly upon the nature and structure of the material out of which it has been eroded. One of the most characteristic features of streams, whether large or small, is the tendency to wind in serpentine curves when the angle of declivity is low and the general surface of the country tolerably level. This peculiarity may be observed in every stream which traverses a flat alluvial plain. Some slight weakness in one of its banks enables the current to cut away a portion of the bank at that point. By degrees a concavity is formed, whence the water is deflected to the opposite side, there to break with increased force against the bank. Gradually a similar concavity is cut out on that side, and so, bending alternately from one side to the other, the stream is led to describe a most sinuous course across the plain. By this process, however, while the course is greatly lengthened, the velocity of the current proportionately diminishes, until it may, before quitting the plain, become a lazy, creeping stream, which in England is bordered perhaps with sedges and willows. Such meandering courses are most frequent in soft alluvial plains, but they may also be found in solid rock if the original form of the surface was tolerably flat. The windings of the gorges of the Moselle and Rhine through the table-land between Treves, Mainz, and the Siebengebirge form a notable illustration.

Abrupt changes in the geological structure or lithological character of the rocks of a river-channel may give rise to waterfalls. In many cases waterfalls have originated in lines of escarpment over which the water at first found its way, or in the same geological arrangement of hard and soft rocks by which the escarpments themselves have been produced. In the case of the falls of Niagara, for example, the stream may have fallen over the Queenstown cliff when the river first sought its way to the sea. But much more probably the escarpment and waterfall began to arise simultaneously and from the same geological structure. As the escarpment grew in height, it receded from its starting point. The river-ravine likewise crept backward, but at a more rapid rate, and the result has been that at present the cliff worn down by atmospheric causes stands at Queenstown, while the ravine extends 7 miles further inland, with a width of from 200 to 400 yards, and a depth of from 200 to 300 feet. In this as in other cases the waterfall has cut its way backward up the course of its stream, and will continue to do so as long as the structure of the gorge continues as it is now—a thick bed or beds of limestone resting horizontally upon soft shales. The softer strata at the base are undermined, and slice after slice is cut off from the cliff over which the cataract pours. It has been estimated that at their present rate of recession the Niagara Falls must have taken about 35,000 years to cut their way backward and excavate the gorge between their present position and Queenstown. In other cases waterfalls have been produced by the existence of a harder and more resisting band or barrier of rock crossing the course of the stream, as, for instance, where the rocks have been cut by an intrusive dyke or mass of basalt. In these and all other cases the removal of the harder mass destroys the waterfall, which, after passing into a series of rapids, is finally lost in the general abrasion of the river-channel. The most marvellous river gorges in the world are those of the Colorado region in North America. The rivers there flow in ravines thousands of feet deep and hundreds of miles long, through vast table-lands of nearly horizontal strata. The Grand Cañon (ravine) of the Colorado river is 300 miles long, and in some places more than 6000 feet in perpendicular depth. The country is hardly to be crossed except by birds, so profoundly has it been trenched by these numerous gorges. Yet the whole of this excavation has been effected by the erosive action of the streams themselves.

In the excavation of a ravine, whether by the recession of a waterfall or of a series of rapids, the action of the river is more rapid than that of the atmospheric agents. The sides of the ravine consequently retain their vertical character. But where, from the nature of the ground, the denuding action of rain, frost, and general weathering is more rapid than that of the river, a wider and opener valley is hollowed out, through which the river flows, and from which it carries away the materials discharged into it from the surrounding slopes by the rain and brooks.

3. Reproductive Power.—Every body of water which when in motion carries along sediment drops it when at rest. The moment a current has its rapidity checked it is deprived of some of its carrying power, and begins to lose hold upon its sediment, which tends more and more to sink and halt on the bottom the slower the motion of the water. In the course of every brook and river there are frequent checks to the current. If these are examined, they will usually be found to be each marked by a more or less conspicuous deposit of sediment. We may notice seven different situations in which stream deposits or *alluvium* may be accumulated.

(*a.*) *At the foot of Mountain Slopes.*—When a runnel or torrent descends a steep declivity it tears down the soil and rocks, cutting a deep gash out of the side of the mountain. On reaching the level ground at the base of the slope the water, abruptly checked in its velocity, at once drops its coarser sediment, which gathers in a fan-shaped pile or cone, with the apex pointing up the water course. Huge accumulations of boulders and shingle may thus be seen at the foot of such torrents,—the water flowing through them often in several channels which re-unite in the plain beyond.

(*b.*) *In River-beds.*—This is characteristically shown in many of the rivers of Britain, by the accumulation of a bed of sand or shingle at the concave side of each sharp bend of the river course. While the main current is making a great sweep round the opposite bank, the water lingers along the inner side of the curve and drops there its freight of loose detritus, which, when laid bare in dry weather, forms the familiar sand-bank or shingle beach. Again, when a river, well supplied with sediment, leaves rough ground where its course has been rapid, and enters a region of level plain, it begins to drop its burden on its bed, which is thereby heightened, till sometimes, as in parts of the courses of the Po, Adige, and Brenta across the plains of Lombardy, it is higher than the surrounding level region. This could not happen were it not that in floods a river deposits sediment along its banks, which are thus also heightened so as to retain the river in its ordinary state. But in such cases, if man lives along the margin of the river, he needs all his skill and labour to keep the banks secure. And even with his utmost efforts the river will now and then break through, sweeping down the barrier which it has itself made, as well as any additional embankments constructed by him, and carrying its flood far and wide over the plain. Left to itself, the river would incessantly shift its course, until in turn every part of the plain had been again and again traversed. It is indeed in this way that a great alluvial plain is gradually levelled and heightened.[1]

(*c.*) *On River-banks and Flood-plains.*—This deposit is partly implied in the action described in the foregoing paragraph. It is laid down on the level tracts or flood-plain over which a river spreads in flood, and consists usually of fine silt, mud, earth, or sand, though close to the river it may be partly made up of much coarser materials. When a flooded river overflows, the portions of water which spread out on the plains, by losing velocity and consequently power of transport, are compelled to let fall some or all of their mud and sand. If the plains happen to be covered with woods, bushes, scrub, or even tall grass, the vegetation acts the part of a sieve, and filters the muddy water, which may rejoin the main stream comparatively clear. Every flood increases the height of the plain, until, partly from this cause and partly, in the case of a rapid stream, from the erosion of its bed, the river can no longer overspread it. As the channel is more and more deepened, the river continues, as before, to be liable from inequalities in the material of its banks, sometimes of the most trifling kind, to be turned from side to side in wide curves and loops, and cuts into its old alluvium, making eventually a newer plain at a lower level. Continued erosion carries the channel to a still lower level, where the stream can attack the later alluvial deposit, and form a still lower and newer one. The river comes by this means to be fringed with a series of terraces, each of which represents a former flood-level of the stream. In Britain it is common to find three such terraces, but sometimes as many as six or seven or even more may occur. In North America the river terraces exist on so grand a scale that the geologists of that country have named one of the later periods of geological history, during which those deposits were formed, the Terrace Epoch. In the attempt to reconstruct the history of the old river-terraces of a country, we have to consider whether they have been entirely cut out of older alluvium (in which case, of course, the valleys must have been as deep as now before the formation of the terraces); whether they afford any indications of having been formed during a period of greater rainfall, when the rivers were larger than at present; whether they point to any upheaval of the interior of the country which would accelerate the erosive action of the streams, or to any depression of the interior or rise of the seaward tracts, which would diminish that action and increase the deposition of alluvium. Professor Dana has connected those of America with the elevation of the axis of that continent.

(*d.*) *In Lakes.*—When a river enters a lake its current is at once checked, and its sediment begins to gather over the lake bottom. If the lake be long enough in proportion to the volume of the river, the whole of the detritus may be deposited, so that, at its outflow, the river becomes as clear as when its infant waters began their course from the springs, snows, and mists of the far mountains. Thus the Rhone enters the Lake of Geneva turbid and impetuous, but it escapes at Geneva as blue translucent water. Its sediment is laid down on the floor of the lake, and chiefly at the upper end. Hence, lakes act as filters or sieves to intercept the sediment which is travelling in the rivers from the high grounds to the sea. If we look down from a height even upon a small lake among mountains, we observe that at the mouth of each torrent or brook which enters it there lies a little tongue of flat land (a true *delta*), through which the streamlet winds in one or more branches before mingling its waters with those of the lake. Each of these tongues consists of alluvium, laid down in obedience to the same law which governs the formation of river alluvium elsewhere, and continually creeping further out from the land as the deposit of sediment advances. Two streams entering a lake from opposite sides may join their alluvia so as to divide the lake into two, like the once united lakes of Thun and Brienz at Interlaken. Or the lake may be finally filled up altogether, as has happened in innumerable cases in all mountainous countries; the hilly tracts of Britain, for example, furnish abundant illustrations of every stage in this process. Where a large river with abundant sediment enters an important lake (as the Rhone at the head of the Lake of Geneva), the accumulation of its alluvium or delta may quite rival that of a great river in the sea, as described in paragraph (*f.*) below.

(*e.*) *Bars and Lagoon-Barriers.*—If we take a broad view of the degradation of the land, we must admit that the deposit of any sediment on the land is only temporary; the inevitable destination of all this material is the ocean. Most rivers which enter the sea have their mouths crossed by a bar of gravel, sand, or mud. The formation of this barrier results from the conflict between the river and the ocean. Although the muddy fresh water floats on the heavier salt water, its current is lessened, and it can no longer push along the mass of detritus on its bed. It has been ascertained, moreover, that, though fresh water can retain for a long while fine mud in suspension, this sediment is rapidly thrown down when the fresh is mixed with saline water. Hence, apart from the necessary loss of transporting power by the checking of the river current at the mouth, the mere mingling of a river with the sea must of itself be a cause of the deposit of sediment. But a large body of fresh water may float for a long distance before it is thoroughly mingled with the heavier water of the ocean. Ultimately, however, the fine detritus dropped by a river, together with the coarser materials on the bottom, are arrested by the sea. Moreover, in many cases the sea itself piles up great part of the sand and gravel of the bar. Heavy river-floods push the bar farther to sea, or even temporarily destroy it; storms from the sea, on the other hand, drive the bar farther up the stream. Another remarkable illustration of the contest between the alluvium-carrying streams and the land-eroding ocean is shown by the vast lines of bar or bank which, both in the Old World and the New stretch along the coast. The streams do not flow straight into the sea, but run sometimes for many miles parallel to the coast, accumulating behind the barriers into broad

[1] It is in the north of Italy that the struggle between man and nature in this department has been most persistently waged. See on this subject Lombardini in *Ann. des Ponts et Chaussées*, 1847.

and long lagoons, but eventually breaking through the barriers of alluvium and entering the sea. The lagoons of the Italian coast and of the Baltic near Dantzic are familiar examples. A conspicuous series of these alluvial bars fronts the American mainland for many hundred miles round the Gulf of Mexico and the shores of Florida, Georgia, and North Carolina. A space of several hundred miles on the east coast of India is similarly bordered. M. E. de Beaumont, indeed, has estimated that about a third of the whole of the coast-lines of the continents is fringed with such alluvial bars.

(*f.*) *Deltas in the Sea.*—The tendency of sediment to accumulate in a tongue of flat land when a river loses itself in a lake is exhibited on a far vaster scale where the great rivers of the continents enter the sea. It was to one of these maritime accumulations, that of the Nile, that the Greeks gave the name Delta, from its resemblance to their letter Δ, with the apex pointing up the river, and the base fronting the sea. This shape being the common one in all such alluvial deposits at river mouths, the term delta has come to be always applied to them. A delta therefore consists of successive layers of detritus, brought down from the land and spread out in the sea at the mouth of a river until they reach the surface, and then, partly by growth of vegetation and partly by flooding of the river, form a plain, of which the inner and higher portion comes eventually to be above the reach of the floods. Large quantities of drift-wood are often carried down, and bodies of animals are swept off to be buried in the delta, or even to be floated out to sea. Hence, in deposits formed at the mouths of rivers, we may always expect to find terrestrial organic remains.

When a river enters upon the delta-portion of its course it assumes a new character. In the previous parts of its journey it is always being augmented by tributaries; but now it begins to split up into branches, which wind to and fro through the flat alluvial land, often coalescing and thus enclosing insular spaces of all dimensions. The feeble current, no longer able to bear along all its weight of sediment, allows much of it to sink to the bottom and to gather over the tracts which are from time to time submerged. Hence many of the channels get choked up, while others are opened out in the plain, to be in turn abandoned, and thus the river restlessly shifts its channels. The seaward ends of at least the main channels grow outwards by the constant accumulation of detritus pushed into the sea, unless this growth chances to be checked by any marine current sweeping past the delta.

The European rivers furnish many excellent illustrations of delta-growth. Thus the Rhine, Meuse, Sambre, Scheldt, and other rivers have formed the wide maritime plain of Holland and the Netherlands. The Rhone has deposited an important delta in the Mediterranean Sea. The upper reaches of the Adriatic Sea are being rapidly shallowed and filled up by the Po, Adige, and other streams. Thus Ravenna, originally built in a lagoon like Venice, is now 4 miles from the sea. The port of Adria, so well known in ancient times as to have given its name to the Adriatic, is now 14 miles inland, while in other parts of that coast-line the breadth of land gained within the last 1800 years has been as much as 20 miles. On the opposite side, also, of the Italian peninsula, great additions have been made to the coast-line within the historical period. It is computed that the Tuscan rivers lay down as much as 12 million cubic yards of sediment every year within the marshes of the Maremma. The "yellow" Tiber, as it was aptly termed by the Romans, owes its colour to the abundance of the sediment which it carries to sea. It has long been adding to the coast-line at its mouth at the rate of from 12 to 13 feet per annum. Hence the ancient harbour of Ostia is now more than 3 miles inland. Its ruins are at present (1879) being excavated, but every flood of the river leaves a thick deposit of mud on the streets and on the floors of the uncovered houses. Whence it would seem that the Tiber has not only advanced its coast-line, but has raised its bed on the plains by the deposit of alluvium, so that it now overflows places which, 2000 years ago, could not have been so frequently under water.[1] In the Black Sea a great delta is rapidly growing at the mouths of the Danube. At the Kilia outlets the water is shallowing so fast that the lines of soundings of 6 feet and 30 feet are advancing into the sea at the rate of between 300 and 400 feet per annum.[2]

The typical delta of the Nile has a seaward border 180 miles in length, the distance from which to the apex of the plain where the river bifurcates is 90 miles. That of the Mississippi contains an area of 40,000 square miles. The united delta of the Ganges and Brahmaputra covers a space of between 50,000 and 60,000 square miles, and has been bored through to a depth of 481 feet.

(*g.*) *Sea-borne Sediment.*—Although more properly to be noticed under the section on the sea, the final course of the materials worn by rains and rivers from the surface of the land may be referred to here. By far the larger part of these materials sinks to the bottom close to the land. It is only the fine mud carried in suspension in the water which is carried out to sea, the distance depending on the velocity of the stream, the specific gravity and shape of the particles of the mud, and the help or hindrance given by marine currents. The sea fronting the Amazon is discoloured for 300 miles by the mud of that river. The soundings taken by the "Challenger" brought up land-derived detritus from depths of 1500 fathoms,—several hundreds of miles distant from the nearest shores.

The amount of material carried by a river into the sea may be taken as the measure or gauge of the general lowering of the surface of the basin drained by the river. If we ascertain the annual quantity of mineral matter thus delivered into the sea, and know the superficial extent of ground from which it has been derived, the one sum divided by the other gives the extent by which the mean level of the country is reduced in one year. Both the fine mud mechanically suspended in the water and the salts dissolved in it should be taken into account, as well as the coarser detritus pushed along the bottom. It is the mechanically suspended mud which has generally been measured. According to the data of Messrs Humphreys and Abbot, already cited, the proportion of sediment in the Mississippi is $\frac{1}{1500}$ by weight, or $\frac{1}{2900}$ by volume. The annual discharge of sediment is 7,459,267,200 cubic feet, and the drainage basin 1,147,000 square miles. This is equal to a loss of $\frac{1}{6000}$ of a foot of rock from the general surface of the drainage basin in 1 year, or 1 foot in 6000 years. Other rivers work faster than this rate. The Ganges has been estimated to remove 1 foot of rock from its drainage area in 2358 years, and the Po 1 foot in 729 years. Such computations are at the best only approximations to the truth, but they are useful in showing how great an amount of change must be effected even within comparatively short geological periods by the various agents which are disintegrating the surface of the land.

---

[1] See an interesting article by Professor Charles Martins on the Aigues-Mortes, in *Revue des Deux Mondes*, 1874, p. 780. The present writer accompanied the distinguished French geologist on the occasion of his visit to Ostia in the spring of 1873, and was much struck with the proofs of the rapidity of deposit in favourable situations. In the article just cited some valuable information is given regarding the progress of the delta of the Rhone in the Mediterranean.

§ 4. *Lakes.*

Depressions filled with water on the surface of the land, and known as lakes, occur abundantly in the northern parts of both hemispheres, and more sparingly, but often of large size, in warmer latitudes. They do not belong to the normal system of erosion in which running water is the prime agent, and to which the excavation of valleys and ravines must be attributed. On the contrary, they are exceptional to that system, and the constant tendency of running water is to fill them up. Their origin, therefore, must be sought among some of the other geological processes. See part vii.

Lakes are conveniently classed as fresh or salt. Those which possess an outlet contain in almost all cases fresh water; those which have none are usually salt.

1. *Fresh-water Lakes.*—These, in a vast number of cases, are simply depressions or expansions of the valleys in which they lie. They receive a river at the upper end, together probably with many minor tributaries from the sides, and let the accumulated waters overflow at the lower end. In all these cases, they act as filters for the river water, allowing its sediment to settle, and discharging it purified at the outflow, to continue its course of erosion and mud-making down the valley. A river which flows through a succession of lakes cannot carry much sediment to the sea, unless it has a long course to run after it has passed the lowest lake, and receives one or more muddy tributaries. But the sediment which would have reached the sea and gone to form a delta or deposit on the sea-bed serves its purpose in contributing to fill up the lakes. Hence it is rare to find any lake with an inflowing and outflowing river, where proofs of the gradual encroachment of the land upon the water may not be gathered.

In other cases lakes do not lie in the natural drainage lines of a country, but are scattered apparently at random over the surface, fed by springs, rains, and streamlets from the slopes, or, if of large size, lying as great basins, receiving the collected waters of a wide region, and forming in this way the source out of which full-formed rivers emerge. From the little tarns of Wales and the lochans of Scotland a series may be traced, through innumerable grades of size and form, in Scandinavia, Finland, and Canada, till we reach such vast sheets of inland water as Lakes Huron, Erie, and Superior, and the great equatorial lakes of Africa. In lakes of this kind also the process of filling up may often be traced. Each tributary stream pushes its delta into the water. Where the lakes are shallow, and lie in temperate countries, vegetation comes in to aid in the conversion of the water, first into marsh, then into peat-bog, and finally into dry ground. In Scotland during the last few centuries great changes of this kind have been going on.

On large lakes the wind throws the water into waves which almost rival those of the ocean in size and destructive power. Beaches, sand-dunes, shore-cliffs, and the other familiar features of the meeting line between land and sea reappear along the margins of such great fresh-water seas as Lake Superior.

Three geological functions of lakes are (1) to arrest and equalize the drainage by regulating the outflow and preventing or lessening the destructive effects of floods[1]; (2) to filter river water and permit of the undisturbed accumulation of new deposits, which in some modern cases may cover thousands of square miles of surface, and might attain a thickness of nearly 3000 feet (Lake Superior has an area of 32,000 square miles; Lago Maggiore is 2800 feet deep); (3) to furnish an abode for a lacustrine fauna and flora, to receive the remains of the plants and animals washed down from the surrounding country, and to entomb all these organisms in the growing deposits, so as to preserve a record of the terrestrial life of the period. The deposits in lakes consist of alternations of sand, silt, mud, and gravel, with occasional irregular seams of vegetable matter, and layers of calcareous marl formed from the accumulation of lacustrine shells, *Entomostraca*, &c. In a lake receiving much sediment there will be little or no marl formed, at least not during the time when the sediment is being deposited. In clear lakes, on the other hand, where there is very little sediment or where it only comes occasionally at wide intervals of flood, beds of white marl, formed entirely of organic remains, may gather on the bottom to a depth of many yards.

2. *Salt Lakes* may be divided into two classes—(*a*) those which owe their saltness to the evaporation and concentration of the fresh water poured into them by their feeders; and (*b*) those which were originally parts of the ocean. Salt lakes of the first kind are abundantly scattered over the inland areas of drainage in the heart of continents, as in the great Lake of Utah, and numerous other minor lakes in North America, and the abundant salt lakes of the great plateau of Central Asia. These sheets of water were doubtless fresh at first, but they have progressively increased in salinity, because though the water is evaporated as fast as it is received, there is no escape for the dissolved salts, which consequently remain in the increasingly concentrated liquid. Salt lakes of the second class are comparatively few in number. In their case portions of the sea have been isolated by movements of the earth's crust, and these detached areas, exposed to evaporation, which is only partially compensated by inflowing rivers, have shrunk in level, and at the same time have sometimes grown much salter than the parent ocean. The Caspian Sea, 180,000 square miles in extent, and with a maximum depth of from 2000 to 3000 feet, is a magnificent example. The shells are chiefly the same as those still living in the Black Sea. Banks of them may be traced between the two seas, with salt lakes and marshes and other evidence to prove, not only that the Caspian was once joined to the main ocean, but that a great firth ran up between Europe and Asia, and possibly stretched completely across what are now the steppes and plains of the Tundras till it merged into the Arctic Sea. Even at present, by means of canals connecting the rivers Volga and Dwina, vessels can pass from the Caspian into the White Sea. But the surface of the Caspian is now more than 80 feet below that of the Black Sea. At present the amount of water supplied by rivers to the Caspian just balances that removed by evaporation, so that the level appears to be no longer sinking. But though, owing to the enormous volume of fresh water poured into it by these rivers, the Caspian is not as a whole so salt as the main ocean, and still less so than the Mediterranean, nevertheless the inevitable result of evaporation is there manifested. Along the shallow pools which border this sea a constant deposition of salt is taking place, forming sometimes a pan or layer of rose-coloured crystals on the bottom, or gradually getting dry, and covered with drift sand. This concentration of the water is still more marked in the great offshoot called the Karaboghaz, which is connected with the middle basin of the Caspian by a channel 150 yards wide and 5 feet deep. Through this narrow mouth there flows from the main sea a constant current, which Von Baer estimated to carry daily into the Karaboghaz 350,000 tons of salt. An appreciable increase of the saltness of that gulf has been noticed: seals, which once frequented it, have forsaken its barren shores. Layers of salt are gathering on the mud at

[1] Winds, by blowing strongly down the length of a lake, sometimes considerably increase for the time being the volume of the outflow. If this takes place coincidently with a heavy rainfall, the flood of the river is greatly augmented. These features are noticed in Loch Tay (D. Stevenson, *Reclamation of Land*, p. 14). Hence, though, on the whole, lakes tend to moderate floods in the outflowing rivers, they may by a combination of circumstances sometimes increase them.

the bottom, and the sounding-line, when scarcely out of the water, is covered with saline crystals.[1] These facts furnish an illustration of the circumstances under which the rock-salt deposits in the New Red Sandstone and other geological formations were probably accumulated.

The following table shows the proportion of the saline materials in the waters of some salt lakes:—

	Elton Lake, Kirghis Steppe, in Summer. (Erdmann.)	Indertsch Lake. (Göbel.)	Dead Sea. (C. G. Gmelin.)	Caspian Sea. (Göbel.)

II. FRESH WATER IN THE SOLID STATE—ICE.

Fresh water under ordinary circumstances, when it reaches a temperature of 32° Fahr., passes into the solid state by crystallizing into ice. In this condition it performs a series of important geological operations before being again melted and relegated to the general mass of liquid terrestrial waters. Five conditions under which ice occurs on the land deserve notice, viz., frost, frozen rivers and lakes, hail, snow, and glaciers.

1. *Frost.*—Water in freezing expands. If it be confined in such a way that expansion is impossible, it remains liquid even at temperatures far below the freezing point; but the instant that the pressure is removed this chilled water becomes solid ice. There is a constant effort on the part of the water to become solid, and very considerable pressure is needed to counterbalance its expansive power. The lower the temperature the greater this exerted pressure becomes. At a temperature of 30° Fahr. the pressure must amount to 146 atmospheres, or the weight of a column of ice a mile high, or 138 tons on the square foot. Consequently when the water freezes at a lower temperature its pressure on the walls of its enclosing cavity must exceed 138 tons on the square foot. Bomb-shells and cannon filled with water and hermetically sealed have been burst in strong frosts by the expansion of the freezing water within them. It is easy to see, therefore, that we have here a geological agent of great potency. It is true that in nature the enormous pressures which can be obtained artificially occur rarely or not at all, because the spaces into which water penetrates can hardly ever be so securely closed as to permit the water to be cooled down very considerably below 32° Fahr. before freezing. Still ice forming at even two or three degrees below the freezing point exerts an enormous disruptive force.

Soils and rocks are all porous, and usually contain a good deal of moisture. When frost congeals this interstitial water, the particles of the soil or rock are pushed asunder by the expanding ice; their cohesion is loosened or destroyed, so that when a thaw comes, they seem as if they have been ground down in a mortar. Water lodges also in the numerous joints and crevices of rocks. Freezing there, it exerts great pressure upon the walls between which it lies, pushing them asunder as if a wedge were driven between them. When this ice melts, the separated masses do not return to their original position. Their centre of gravity in successive winters becomes more and more displaced, until the sundered masses fall apart. In mountainous districts, where the winters are severe, and in high latitudes, a great deal of waste is thus produced on exposed cliffs and loose blocks of rock. Some measure of its magnitude may be seen in the heaps of angular rubbish which in these regions are so frequently to be met with at the foot of crags and steep slopes. At Spitzbergen and on the coast of Greenland the amount of destruction caused by frost is enormous. The short and warm summer, melting the snow, fills the pores and joints of the rocks with water, which when it freezes splits off large blocks of rock from the hills, and sends them to the base of the declivities. where they are further broken up by the same cause.

2. *Frozen Rivers and Lakes.*—In countries where the winter temperature falls considerably below 32° Fahr., the lakes and rivers become solidly frozen over. The amount of geological change effected during the process is probably hardly appreciable. But when the ice breaks up in spring its power as a geological agent becomes apparent. In lakes, such as Lake Superior, the ice in forming encloses beach-pebbles and boulders, and when thaw sets in, floats these off, so as either to drop them in deeper water or to strand them on some other part of the coast. Should a gale arise during the breaking up of the ice, vast piles of the latter, with mingled gravel and boulders, may be driven ashore and pushed up the beach. By this means blocks of stone, even of considerable size, are sometimes forced to a great height inland on some of the Canadian lakes, tearing up the soil on their way, and helping to form a bank above the water level. It has been observed that during a severe frost ice occasionally forms on the bottoms of rivers where it encloses stones and large boulders. These are borne up to the surface in cakes of ground-ice to join the rest of the superficial ice-borne detritus. Great damage is frequently done to quays and bridges in Canada by masses of river-ice driven against them on the arrival of spring. Reference has already been made to the increased power of transport and erosion acquired by rivers liable to be frozen over, and especially when their ice is broken up in the higher parts of their courses, before it gives way in the lower.

3. *Hail.*—When rain or aqueous vapour is cooled down in the atmosphere to the freezing point of water, it is frozen, and falls to the earth as hail or snow. The formation of hail is not yet well understood. It is chiefly in summer and during thunderstorms that hail falls. When the pellets of ice are frozen together so as to reach the ground in lumps as large as a pigeon's egg, or larger, great damage is often done to cattle, flying birds, and vegetation. Trees have their leaves and fruit torn off. and farm crops are beaten down.

4. *Snow.*—In those parts of the earth's surface where, either from geographical position or from elevation into the upper cold regions of the atmosphere, the mean annual temperature is below the freezing point, the condensed moisture falls chiefly as snow, and remains in great measure unmelted throughout the year. A line can be traced below which the summer heat suffices to cause the disappearance of the snow, but above which the snow continues to cover the whole or great part of the surface. This line has received the name of the snow-line, or line of perpetual snow. It comes down to the sea within the polar circles. Between these limits it rises gradually in level till it reaches its highest elevation in tropical latitudes. In northern Scandinavia it is less than 3000 feet above the sea. None of the British mountains quite reach it. In the Alps it stands at 8500 feet, on the Andes at 18,000 feet, and on the northern slopes of the Himalayas at 19,000 feet.

[1] Carpenter, *Journ. Geog. Soc.*, vol. xviii., No. 4, quoting from Von Baer's "Kaspische Studien," in *Bull. Acad. Sci. St Petersburg*, 1855–6.

Snow exhibits two different kinds of geological behaviour, one conservative, the other destructive. Lying stationary and unmelted it exercises a protective influence on the face of the land, shielding rocks, soils, and vegetation from the effects of frost. On low grounds this is doubtless its chief function. When snow falls in a partially melted state it is apt to accumulate on branches and leaves, until by its weight it breaks them off, or even bears down entire trees. Snow which falls thickly on steep mountain slopes is frequently during spring and summer detached in large sheets. These rush down the declivities as *avalanches*, and often create much destruction of trees, soil, crops, and houses in their course. Another indirect effect of snow is seen in the sudden rise of the rivers when warm weather rapidly melts the mountain snows. Many summer floods are caused in this way in Switzerland.

5. *Glaciers.*—(1.) Nature and Origin.—A glacier is a river of ice formed by the slow movement and compression of the snow which by gravitation creeps downward into a valley descending from a snow-field. The structure and physics of glaciers are described elsewhere (see GLACIERS). From a geological point of view these ice-rivers may be regarded as the drainage of the snow-fall above the snow-line, as rivers are the drainage of the rainfall. In a mountainous region, such as the Alps, or a table-land like Scandinavia, where a considerable mass of ground lies above the snow-line, three varieties of glaciers have been observed. (*a.*) Glaciers of the first order, where the ice-river comes down well below the snow and extends into the valley, even it may be far below the upper limits of cultivation, or in northern regions approaches or even reaches the sea. In the Alps such glaciers may be 20 or 30 miles long, by a mile or more wide, and 600 feet or more deep. (*b.*) Glaciers of the second order, which hardly creep beyond the high recesses wherein they are formed, and do not therefore reach as far as the nearest valley. Many beautiful examples of this type may be seen along the steep declivities which intervene between the snow-covered plateau of Arctic Norway and the sea. (*c.*) Re-cemented glaciers, consisting of fragments which fall from an ice-cliff crowning precipices of rock, and are re-frozen at the bottom into a solid mass, creeping downward as a glacier usually of the second order. Probably the best illustrations in Europe are furnished by the Nus Fjord, and other parts of the north of Norway. In some cases a cliff of blue ice appears at the top of the precipice,—the edge of the great "snee-fond," or snow-field,—while several hundred feet below, in the corrie or cwm at the bottom, lies the re-cemented glacier (*glacier remanié* of the Swiss), white at its upper edge, but acquiring somewhat of the characteristic blue gleam of compact ice as it moves towards its lower margin.

But it is in high Arctic, and still more in Antarctic, latitudes that land-ice, formed from the drainage of a great snow-field, attains its greatest dimensions. The land in these regions is completely buried under an ice-cap, which ranges in thickness up to a depth (in the South Polar circle) of 10,000 feet (2 miles) or even more. Greenland lies under such a pall of snow that all its inequalities, save the mere steep mountain peaks, are concealed. The snow creeping down the slopes, and mounting over the minor hills, passes beneath by pressure into compact ice. From the main valleys great glaciers like vast tongues of ice, 2000 or 3000 feet thick, and sometimes 50 miles or more in breadth, push out to sea, where they break off in huge fragments, which float away as icebergs.

A glacier, like a river, is always in motion, though so slowly that it seems to be solid and stationary. The motion also, like that of a river, and for the same reason, is unequal in the different parts, the centre moving faster than the sides and bottom. This important fact was first ascertained through accurate measurement by J. D. Forbes, who found that in the Mer de Glace of Chamouni, the mean daily rate of motion in the summer and autumn was from 20 to 27 inches in the centre, and from 13 to 19½ near the side. The consequence of this differential motion is seen in the arrangement of the lines of rubbish thrown down at the end of a glacier, which often present a horse-shoe shape, corresponding to that of the end of the ice by which they were discharged.

There are some features of geological importance also in the behaviour of the ice as it descends its valley. When it has to travel over a very uneven floor, some portions may get embayed, while overlying parts slide over them. A massive ice-sheet may thus have many local eddies in its lower portions, the ice there even travelling for various distances, according to the nature of the ground, obliquely to the general flow of the main mass. In descending by a steep slope from an upper to a lower and more level part of its course, a glacier becomes a mass of fissured ice in great confusion. It descends by a slowly creeping ice-fall, where a river would shoot over in a rushing waterfall. A little below the fall the fractured ice is pressed together again into a solid mass as before. The body of the glacier throughout its length is traversed by a set of fissures called *crevasses*, which, though at first as close-fitting as cracks in a sheet of glass, widen by degrees as the glacier moves on, till they form wide yawning chasms, reaching, it may be, to the bottom of the ice, and travelling down with the glacier, but apt to be effaced by the pressing of their walls together again as the glacier winds down its valley. The glacier continues to descend until it reaches that point where the supply of ice is just equalled by the liquefaction. There it ends, and its place down the rest of the valley is taken by the tumultuous river of muddy water which escapes from under the melting extremity of the ice. A prolonged augmentation of the snow-fall will send the foot of the glacier further down the valley; a diminution of the snowfall with a general rise of temperature will cause it to retreat farther up.

(2.) Work done by Glaciers.—Glaciers have two important geological tasks to perform,—(1) to carry the debris of the mountains down to lower levels; and (2) to erode their beds.

a. Transport.—This takes place chiefly on the surface of the glacier. Descending its valley, the glacier receives and bears along on its margin the earth, stones, and rubbish which, loosened by frost, or washed down by rain and rills, slip from the cliffs and slopes to the level of the ice. In this part of its work the glacier resembles a river which carries down branches and leaves from the woods on its banks. Most of the detritus rests on the surface of the ice. It includes huge masses of rock, sometimes as big as a large cottage, all which, though seemingly at rest, are slowly travelling down the valley with the ice, and liable at any moment to slip into the crevasses which may open below them. When they thus disappear they may descend to the bottom of the ice, and move with it along the rocky floor, which is no doubt the fate of the smaller stones and sand. But the large stones seem sometimes at least to be cast up again by the ice to the surface of the glacier at a lower part of its course. Whether, therefore, on the ice, in the ice, or under the ice, a vast quantity of detritus is continually travelling with the glacier down towards the plains. The rubbish lying on the surface is called *moraine* stuff. Naturally it accumulates on either side of the glacier, where it forms the so-called *lateral moraines.* When two glaciers unite, their two adjacent lateral moraines are brought together, and travel thereafter down the centre of the glacier as a *medial moraine.* A glacier, formed by the union of many tributaries in its upper parts, may have many medial lines of moraine, so many indeed as sometimes to be entirely covered with debris to the complete concealment of the ice. At such parts the glacier resembles a bare field or earthy plain rather than a solid mass of clear ice of which only the surface is dirty with rubbish. At the point where the glacier ends, the pile of loose materials is tumbled upon the valley in what is called the *terminal moraine*.

In such comparatively small and narrow ice-sheets as the present glaciers of Switzerland, the rock-bottom on which the ice moves is usually, as far as it can be examined, swept clean by the trickle or rush of water over it from the melting ice. But when the ice does not flow in a mere big drain (which, after all, the largest Alpine valley really is), but overspreads a wide area of uneven ground, there cannot fail to be a great accumulation of rubbish here and there underneath it. When the broad central plain of Switzerland between the Alps and the Jura was filled with ice, the latter certainly pushed a vast deal of mud, sand, and stones over the floor of the valley. This material is known to Swiss geologists as the *moraine profonde* or *Grundmoräne*.[1]

When from any cause a glacier diminishes in size, it may drop its blocks upon the sides of its valley, and leave them there sometimes in the most threatening positions. Such stranded stones are known as *perched blocks*. They abound in the Swiss valleys, extending even across the great plain of Switzerland, and appearing in numbers high upon the flanks of the Jura. Since the latter mountains consist chiefly of limestone, and the blocks are of various crystalline rocks belonging to the higher parts of the Alps, the proof of transport is irrefragable. The agent of removal is now recognized to have been an enormous extension of the glacier system of the Alps, whereby the whole country was buried under snow and ice. Similar evidence abounds in the valleys among the mountainous parts of Britain, as well as in other parts of Europe and America, no longer the abode of glaciers.

b. Erosion.—The manner in which glacier ice erodes its channel differs in many respects from that in use by any other geological agent, and forms therefore one of the distinguishing features of ice-action. This erosion is effected not by the mere contact and pressure of the ice upon the rocks, though undoubtedly fragments of rock must now and then be detached from this cause. It is by means of the fine sand, stones, and blocks of rock, which fall between the ice and the rocks on which it moves, that the grinding work of the glacier is done. These materials, held by the ice as it creeps along, are pressed against the rocky sides and bottom of the valley so firmly and persistently as to descend into each little hollow and mount over each ridge, yet all the while moving along steadily in one dominant direction with the general movement of the glaciers. As a result, the most compact resisting rocks are ground down, smoothed, polished, and striated. The striæ vary from such fine lines as may be made by the smallest grains of quartz up to deep ruts and grooves. They sometimes cross each other, one set partially effacing an older one, and thus pointing to shiftings in the movement of the ice. On the retirement of the glacier, hummocky bosses of rock having smooth undulating forms like dolphins' backs are conspicuous. These have received the name of *roches moutonnées*. The stones by which this scratching and polishing are effected suffer in exactly the same way. They are ground down and striated, and since they must move in the line of least resistance, or "end on," their striæ run in a general sense lengthwise. It will be seen, when we come to notice the traces of former glaciers, how important is the evidence given by these striated stones.

As rocks present great diversities of structure and hardness, and consequently vary much in the resistance they offer to denudation, they are necessarily worn down unequally. The softer, more easily eroded portions are scooped out by the grinding action of the ice, and basin-shaped or various irregular cavities are dug out below the level of the general surface. Similar effects may be produced by an augmented excavating power of a glacier, as where the ice is strangled in some narrow part of a valley, or where, from change in declivity, it is allowed to accumulate in greater mass as it moves more slowly onward. Such hollows, on the retirement of the ice, become receptacles for water, and form pools, tarns, or lakes, unless indeed they chance to have been already filled up with glacial rubbish. It is now some years since Professor A. C. Ramsay drew attention to this peculiar power of land-ice, and affirmed that the abundance of excavated rock-basins in northern Europe and America was due to the fact that these regions had been extensively eroded by sheets of land-ice. This glaciation was due not to independent glaciers but to the pressure and grinding power of vast masses of continental ice. In short the more northern parts of Europe and North America must have been in a condition like that of North Greenland at the present day. It is therefore among the ice-fields of Greenland rather than among the valley glaciers of isolated mountain-groups that we ought to look for analogies to the operations which produced the widespread general glaciation of the period of the rock-basins. A single valley-glacier retires towards its parent snow-field as the climate ameliorates, leaving its *roches moutonnées*, moraine-mounds, and rock-basins, yet at times discharging its water-drainage in such a way perhaps as to sweep down the moraine-mounds, fill up the basins, bury the ice-worn hummocks of rock, and strew the valley with gravel, earth, sand, and big blocks of rock. Hence the actual floor of the glacier is apt to be very much obscured. But in the case of a vast sheet of land-ice covering continuously a wide region, there can be but little superficial debris. When such a mass of ice retires it must leave behind it an ice-worn surface of country more or less strewn with the subsoil which accumulated under the ice and was pushed along by it. This infra-glacial detritus forms the *Grundmoräne* (*moraine profonde*) or bottom moraine. We know as yet very little regarding its formation in Greenland. Most of our knowledge regarding it is derived from a study of the till or boulder-clay of Britain, which is believed to represent the bottom moraine of an ancient ice-sheet. In countries where true boulder-clay occurs, numerous rock-basins are commonly to be met with among the uncovered portions of the rocks.

The abundant fine sediment which gives the characteristic milky turbidity to all streams that escape from the melting ends of glaciers is an index of the amount of erosion unceasingly effected by the ice. From the end of the Aar glacier, for example, though by no means one of the largest in Switzerland, it has been estimated that there escape every day in the month of August 2 million cubic metres (440 million gallons) of water. containing 284,374 kilogrammes (280 tons) of sand.

B. Oceanic Waters.

The area, depth, temperature, density, and composition of the sea have been already treated of in part ii. Viewed as a dynamical agent in geology, the ocean may be studied under two aspects—(1) its movements, and (2) its geological work.

[1] The present writer examined in 1869 a characteristic section of it near Solothurn, full of scratched stones, and lying on the striated pavement of rock to be immediately described as further characteristic of ice-action.

I. Movements of the Ocean.

These may be grouped as—(1) tides, (2) currents, and (3) waves.

1. *Tides.*—These are oscillations of the mass of the oceanic waters caused by the attraction of the sun and moon. We have at present to deal with them merely in so far as their geological bearings are concerned. In a wide deep ocean the tidal elevation probably produces no perceptible geological change. It passes at a great speed; in the Atlantic its rate is 500 geographical miles an hour. But as this is merely the passing of an oscillation whereby the particles of water are gently raised up and let down again, there can hardly be any appreciable effect upon the deep ocean bottom. When, however, the tidal wave enters a narrow and shallow sea, it has to accommodate itself to a smaller channel, and encounters more and more the friction of the bottom. Hence, while its rate of motion is diminished, its height and force are increased. It is in shallow water and along the shores of the land that the tides acquire their main geological importance. They there show themselves in an alternate advance upon and retreat from the coast. Their upper limit has received the name of *high-water mark*, their lower that of *low-water mark*, the space between being termed the *beach*. If the coast is precipitous, a beach can only occur in the shelving bays and creeks, since elsewhere the tides will rise and fall against a face of rock, as they do on the piers and bulwarks of a port. On such rocky coasts the line of high water is sometimes admirably defined by the grey crust of barnacles adhering to the rocks. Where the beach is flat, and the rise and fall of the tide great, an area of several hundred square miles of sand or mud may be laid bare in one bay at low-water.

The height of the tide varies from zero up to 60 or 70 feet. It is greatest where, from the form of the land, the tidal wave is cooped up within a narrow inlet or estuary. Under such circumstances the advancing tide sometimes gathers itself into one or more large waves, and rushes furiously up between the converging shores. This is the origin of the "bore" of the Severn, which rises to a height of 9 feet, while the rise and fall of the tide there amounts to 40 feet. In like manner the tides which enter the Bay of Fundy, between Nova Scotia and New Brunswick, get more and more cooped up as they ascend that strait, till they reach a height of 70 feet.

While the tidal swelling is increased in height by the shallowness and convergence of the shores, it gains at the same time force and rapidity. No longer a mere oscillation or pulsation of the great ocean, the tide acquires a true movement of translation, and gives rise to currents which rush past headlands and through narrows in powerful currents and eddies. The rocky and intricate navigation of the west of Scotland and Scandinavia furnishes many admirable illustrations of the rapidity of these tidal currents. The famous whirpool of Corryvreckan, the lurking eddies in the Kyles of Skye, the breakers at the Bore of Duncansbay, and the tumultuous tideway, grimly named by the northern fishermen the Merry Men of Mey, in the Pentland Firth, bear witness to the strength of these sea rivers. At the last-mentioned strait the current at its strongest runs at the rate of 10 miles an hour, which is fully three times the speed of most of our larger rivers.

2. *Currents.*—Recent researches in ocean temperature have disclosed the remarkable fact that beneath the surface layer of water affected by the temperature of the latitude there lies a vast mass of cold water, the bottom temperature of every ocean in free communication with the poles being little above and sometimes actually below the freezing point of fresh water. In the North Atlantic a temperature of 40° Fahr. is reached at an average depth of about 800 fathoms, all beneath that depth being progressively colder. In the equatorial parts of the same ocean the same temperature comes to within 300 fathoms of the surface. In the South Atlantic, off Cape of Good Hope, the mass of cold water (below 40°) comes likewise to about 300 fathoms from the surface. This distribution of temperature proves that there must be a transference of cold polar water towards the equator, for in the first place the temperature of the great mass of the ocean is much lower than that which is normal to each latitude, and in the second place it is lower than that of the superficial parts of the earth's crust underneath. On the other hand, the movement of water from the poles to the equator requires a return movement of compensation from the equator to the poles, and this must take place in the superficial strata of the ocean. Apart therefore from those rapid river-like streams which traverse the ocean, and to which the name of currents is given, there must be a general drift of warm surface water towards the poles. This is doubtless most markedly the case in the North Atlantic, where besides the current of the Gulf-stream there is a prevalent set of the surface waters towards the north-east. As the distribution of life over the globe is everywhere so dependent upon temperature, it becomes of the highest interest to know that a truly arctic submarine climate exists everywhere in the deeper parts of the sea. With such uniformity of temperature we may anticipate that the abyssal fauna will be found to possess a corresponding sameness of character, and that arctic types may be met with even on the ocean-bed at the equator.

But besides this general drift or set, a leading part in oceanic circulation is taken by the more defined streams termed currents. The tidal wave only becomes one of translation as it passes into shallow water, and is thus of but local consequence. But a vast body of water, known as the Equatorial Current, moves in a general westerly direction round the globe. Owing to the way in which the continents cross its path, this current is subject to considerable deflexions. Thus that portion which crosses the Atlantic from the African side strikes against the mass of South America and divides, one portion turning towards the south and skirting the shores of Brazil, the other bending north-westward into the Gulf of Mexico, and issuing thence as the well-known Gulf-stream. This equatorial water is comparatively warm and light. At the same time the heavier and colder polar water moves towards the equator, sometimes in surface currents like those which skirt the eastern and western shores of Greenland, but more generally as a cold under-current which creeps over the floor of the ocean even as far as the equator.

Much discussion has arisen in recent years as to the cause of oceanic circulation. Two rival theories have been given. According to one of these the circulation entirely arises from that of the air. The trade-winds blowing from either side of the equator drive the water before them until the north-east and south-east currents unite in equatorial latitudes into one broad westerly-flowing current. Owing to the form of the land portions of this main current are deflected into temperate latitudes, and, as a consequence, portions of the polar water require to move towards the equator to restore the equilibrium. According to the other view the currents arise from differences of temperature (and according to some, of salinity also); the warm and light equatorial water is believed to stand at a higher level than the colder and heavier polar water; the former, therefore, flows down as it were polewards, while the latter moves as a bottom inflow towards the equator; the cold bottom water under the tropics is constantly ascending to the surface, whence, after being heated, it drifts away towards the pole, and on being cooled down there, descends and begins another journey to the equator. There can be no doubt that the winds are directly the cause of such currents as the Gulf-stream, and therefore, indirectly, of return cold currents from the polar regions. It seems hardly less certain that, to some extent at least, differences of temperature, and therefore of density, must occasion movements in the mass of the oceanic waters. The discussion of this subject, however, belongs to another part of this work.[1] The main facts for the geological reader to grasp are—that a system of circulation exists in the ocean; that warm currents move round the equatorial regions, and are turned now to the one side now to the other by the form of the continents along and round which they sweep; that cold currents set in from poles to equator; and that, apart from actual currents, there appears to be an extremely slow "creep" of the polar water under the warmer upper layers towards the equator.

3. *Waves and Ground-Swell.*—A gentle breeze curls into ripples the surface of water over which it blows. A strong gale or furious storm raises the surface into waves. The agitation of the water in a storm is prolonged to a great distance beyond the area of the original disturbance, and then takes the form of the long heaving undulations termed ground-swell. Waves which break upon the land are called breakers, and the same name is applied to the ground-swell as it bursts into foam and spray upon the rocks. The concussion of earthquakes sometimes gives rise to very disastrous earthquake-waves, as already explained.

The height and force of waves depend upon the breadth and depth of sea over which the wind has driven them, and the form and direction of the coast-line. The longer the "fetch," and the deeper the water, the higher the waves. A coast directly facing the prevalent wind will have larger waves than a neighbouring shore which presents itself at an angle to this wind or bends round so as to form a lee-shore. The highest waves in the narrow British seas probably never exceed 15 or 20 feet, and usually fall short of that amount. The greatest height observed by Dr Scoresby among the Atlantic waves was 43 feet.[2]

Ground-swell propagated across a broad and deep ocean produces by far the most imposing breakers. So long as the water remains deep and no wind blows, the only trace of the passing ground-swell on the open sea is the huge broad heaving of the surface. But when the water shallows, the superficial part of the swell travelling faster than the bottom begins to curl and crest as a huge billow or wall of water, which finally bursts with enormous force against the shore. Such billows, even when no wind is blowing, often cover the cliffs of the north of Scotland with sheets of water and foam up to heights of 100 or even nearly 200 feet. At Dunnet Head during north-westerly gales the windows of the lighthouse, at a height of upwards of 300 feet above high-water mark, are said to be sometimes broken by stones swept up the cliffs by the sheets of sea water which then deluge the building.

A single roller of the ground-swell 20 feet high falls, according to Mr Scott Russell, with a pressure of about a ton on every square foot. Mr Thomas Stevenson conducted some years ago a series of experiments on the force of the breakers on the Atlantic and North Sea coasts of Britain. The average force in summer was found in the Atlantic to be 611 ℔ per square foot, while in winter it was 2086 ℔, or more than three times as great. But on several occasions, both in the Atlantic and North Sea, the winter breakers were found to exert a pressure of three tons per square foot, and at Dunbar as much as three tons and a half.[3] Besides the waves produced by ordinary wind action, others of an extraordinary size and destructive power are occasionally caused by a violent cyclone-storm. The mere diminution of atmospheric pressure in a cyclone must tend to raise the level of the ocean within the cyclone limits. But the further furious spiral in-rushing of the air towards the centre of the low pressure area drives the sea onward, and gives rise to a wave or succession of waves having great destructive power. Thus, on 5th October 1864, during a great cyclone which passed over Calcutta, the sea rose in some places 24 feet, and swept everything before it with irresistible force, drowning upwards of 48,000 people.

4. *Ice on the Sea.*—In this place may be most conveniently noticed the origin and movements of the ice which in circumpolar latitudes covers the sea. This ice is derived from two sources—(1) the freezing of the sea itself, and (2) the seaward prolongation of land-ice.

1. Three chief types of sea-ice have been observed. (*a.*) In the Arctic sounds and bays the littoral waters freeze along the shores and form a cake of ice which, upborne by the tide and adhering to the land, is thickened by successive additions below, as well as by snow above, until it forms a shelf of ice 120 to 130 feet broad and 20 or 30 feet high. This shelf, known as the ice-foot, serves as a platform on which the abundant debris loosened by the severe frosts of an arctic winter gathers at the foot of the cliffs. It is more or less completely broken up in summer, but forms again with the early frosts of the ensuing autumn. (*b.*) The surface of the open sea likewise freezes over into a continuous solid sheet which in summer breaks up into separate masses sometimes of large extent. This is what navigators term *floe-ice*, and the separate floating cakes are known as *floes.* Ships fixed among these floes have been drifted with the ice for hundreds of miles until at last liberated by its disruption. (*c.*) In the Baltic Sea, off the coast of Labrador and elsewhere, ice has been observed to form on the sea-bottom. It is known as ground-ice or anchor ice. In the Labrador fishing-grounds it forms even at considerable depths. Seals caught in the lines at those depths are brought up sometimes solidly frozen.

2. In the Arctic regions the vast glaciers which drain the snow-fields and descend to the sea extend for some distance from the land until large fragments break off and float away seawards. These detached masses are icebergs. Their shape and size greatly vary, but lofty peaked forms are common, and they sometimes rise from 200 to 300 feet above the level of the sea. As only about a ninth part of the ice appears above water, these larger bergs must sometimes be from 2000 to 3000 feet thick from base to top. They consequently require water of some depth to float them, but they are often seen aground. In the Antarctic regions, where one vast sheet of ice envelops the land and extends into the sea as a high rampart of ice, the detached icebergs often reach a great size, and are characterized by the frequency of a flat tabular form.

II. Geological Work of the Sea.

I. Influence on Climate.—Were there no agencies in nature for distributing temperature, there would be a regular and uniform diminution in the mean annual temperature from equator to poles, and the *isothermal* lines, or lines of equal heat, would coincide with lines of latitude. But no such general correspondence actually exists. If we look at a chart of the globe with the isothermal lines drawn across it, we shall find that their divergences from the parallels are striking, and most so where they approach and cross the ocean. Currents from warm regions raise the

[1] The reader may consult Maury's *Physical Geography of the Sea*, but more particularly Dr Carpenter's papers in the *Proceedings of the Royal Society* for 1869-73, and *Journal of R. Geographical Society* for 1871-77, on the side of temperature; and Herschel's *Physical Geography*, and Dr Croll's *Climate and Time*, on the side of the winds.

[2] *Brit. Assoc. Rep.*, 1850, p. 26. The reader will find a table of the observed heights of waves round Great Britain in Mr T. Stevenson's treatise on *Harbours*, p. 20.

[3] *Trans. Roy. Soc. Edin.*, xvi. 25; treatise on *Harbours*, p. 42.

temperature of the tracts into which they flow; those from cold regions lower it. The ocean, in short, is the great distributor of temperature over the globe. As an illustration the two opposite sides of the Atlantic may be taken. The cold arctic current flowing southward along the north-east coast of America reduces the mean annual temperature of that region. On the other hand, the Gulf-stream brings to the shores of the north-west of Europe a temperature much above what they would otherwise enjoy. Dublin and the south-eastern headlands of Labrador, lie in the same parallel of latitude, yet differ as much as 18° in their mean annual temperature, that of Dublin being 50°, and that of Labrador 32° Fahr. Dr Croll has calculated that the Gulf-stream conveys nearly half as much heat from the tropics as is received from the sun by the entire Arctic regions.[1]

II. Erosion.—The chemical action of the sea upon the rocks of its bed and shores has not yet been properly studied.[2] It is evident, however, that changes analogous to those effected by fresh water on the land must be in progress. Oxidation, and the formation of carbonates, no doubt continually take place. We may judge indeed of the nature and rapidity of some of these changes by watching the decay of stones and material employed in the construction of piers. At the Bell Rock lighthouse, twenty-five different kinds and combinations of iron were exposed to the action of the sea, and all yielded to corrosion. Mr Mallet—as the result of experiments with specimens sunk in the sea—concluded that from $\frac{2}{10}$ths to $\frac{4}{10}$ths of an inch in depth in iron castings 1 inch thick, and about $\frac{6}{10}$ths of an inch of wrought iron, will be destroyed in a century in clear salt water. Mr Stevenson, in referring to these experiments, remarks that he has in his possession specimens of iron which show even a more rapid rate of decay. In castings used at the Bell Rock the loss has been at the rate of an inch in a century. "One of the bars which was free from air holes had its specific gravity reduced to 5·63, and its transverse strength from 7409 to 4797 ℔, and yet presented no external appearance of decay. Another apparently sound specimen was reduced in strength from 4068 ℔ to 2352 ℔, having lost nearly half its strength in fifty years."[3] Similar results were recently observed by Mr Grothe, resident engineer at the railway bridge across the Firth of Tay. A cast-iron cylinder which had been below water for only sixteen months was found to be so corroded that a penknife could be stuck through it in many places.

An examination of the shore will sometimes reveal a good deal of quiet chemical change on the outer crust of rocks exposed to the waves. Such rocks as basalt have their felspar decomposed, and show the presence of carbonates by effervescing briskly with acid. One of their minerals, augite, is occasionally replaced by *pseudomorphs* of carbonate of iron.

It is mainly by its mechanical action that the sea accomplishes its erosive work. This can only take place where the water is in motion, and, other things being equal, is greatest where the motion is strongest. Hence we cannot suppose that erosion to any appreciable extent can be effected in the abysses of the sea, where the only motion possible is that slow creeping of the polar water along the bottom already referred to. But where the currents are powerful enough to move grains of sand and gravel, very slow erosion may take place even at considerable depths. It is in the upper portions of the sea, however, where, owing to currents, tides, and waves, the water suffers most disturbance, that the main mechanical erosion goes on. The depth to which the influence of waves and ground-swell may extend seems to vary greatly according to the situation. The astronomer-royal states that ground-swell may break in 100 fathoms water.[4] It is common to find boulders and shingle disturbed at a depth of 10 fathoms, and even driven from that depth to the shore, and waves may be noticed to become muddy from the working up of the silt at the bottom when they have reached water of 7 or 8 fathoms in depth.[5] Gentle movement of the bottom water is said to be sometimes indicated by ripple-marks on the fine sand of the sea-floor at a depth of 600 feet. A good test for the absence of serious abrasion is furnished by the presence of fine mud on the bottom. Wherever that is found, we may be tolerably sure that the bottom at that place lies beyond the reach of ordinary breaker action.[6] From the upper limit at which the accumulation of mud is possible to high-water mark, and in exposed places up to 100 feet or more above high-water mark, lies the zone within which the sea does its work of abrasion. To this zone, even where the breakers are heaviest, a greater extreme vertical range can hardly be assigned than 300 feet, and in most cases it probably falls far short of that extent.

The mechanical work of erosion by the sea is done in four ways:—(1) the enormous force of the breakers suffices to tear off fragments of the solid rocks; (2) the alternate compression and expansion of the air in the crevices of rocks exposed to heavy breakers dislocates rocks even above the limits of wave-action; (3) the hydraulic pressure of those portions of large waves which enter fissures and cavities forces asunder masses of rock; (4) the waves make use of the loose fragments within their reach in battering down the cliffs exposed to their fury.

(1.) Abundant examples of the dislodgement of huge blocks of rock from their parent masses are furnished by the precipitous shores of Caithness, and of the Orkney and Shetland Islands. It sometimes happens that demonstration of the height to which the effective force of breakers may reach is furnished at lighthouses built on exposed parts of the coast. Thus, at Unst, a door was broken open at a height of 195 feet above the sea, and at the Bishop Rock lighthouse a bell was wrenched off at a level of 100 feet above high-water mark.[7] Some of the most remarkable instances of the power of breakers have been observed by Mr Thomas Stevenson among the islands of the Shetland group. On the Bound Skerry he found that blocks of rock up to $9\frac{1}{2}$ tons in weight had been washed together at a height of nearly 60 feet above the sea, that blocks weighing from 6 to $13\frac{1}{2}$ tons had been actually quarried out of their original bed, at a height of from 70 to 75 feet, and that a

block of nearly 8 tons had been driven before the waves at the level of 20 feet above the sea, over very rough ground, to a distance of 73 feet (figs. 7 and 8). He likewise records the moving of a 50-ton block by the waves at Barrahead, in the Hebrides.[1] At Plymouth also, blocks of several tons in weight have been known to be washed about the breakwater like pebbles.[2]

(2.) But, besides their mechanical force, waves acquire a singular and most effective aid from the air. It is a fact familiar to engineers that, even from a vertical and apparently perfectly solid wall of well-built masonry exposed to heavy seas, stones will sometimes be started out of their places, and that when this happens a rapid enlargement of the cavity may be effected, as if the walls were breached by a severe bombardment. At the Eddystone lighthouse, during a storm in 1840, a door which had been securely fastened against the force of the surf from without, was actually driven outward by a pressure acting from within the tower, in spite of the strong bolts and hinges, which were broken. We may infer that, by the sudden sinking of a mass of water hurled against the building, a partial vacuum was formed, and that the air inside forced out the door in its efforts to restore the equilibrium.[3] This explanation may partly account for the way in which the stones are started from their places in a solidly built sea-wall. But besides this cause we must also consider a perhaps still more effective one in the condensation of the air driven before the wave between the joints and crevices of the stones, and its subsequent instantaneous expansion when the wave drops. During gales when large waves are driven to shore, many tons of water are poured suddenly into each cleft and cavern within reach. These volumes of water, as they rush in, compress the air into every joint and pore of the rock at the further end, and then quickly retiring, exert such a suction as from time to time to bring down part of the walls or roof. The sea may thus gradually form an inland passage for itself to the surface above, in a "blow-hole" or "puffing-hole," through which spouts of foam and spray are in storms shot high into the air. On the more exposed portions of the west coast of Ireland numerous examples of such blow-holes occur. In Scotland, likewise, they may often be observed, as in the Bullers (boilers) of Buchan on the coast of Aberdeenshire, and the Geary Pot near Arbroath. Magnificent instances occur among the Orkney and Shetland Islands, some of the more shattered rocks of these northern coasts being, as it were, honeycombed by sea-tunnels, many of which open up into the middle of fields or moors.

(3.) The sea-water which, as part of an inrushing wave, fills the gullies and chinks of the shore-rocks exerts the same pressure upon the walls between which it is confined as the rest of the wave is doing upon the face of the cliff. Each cleft so circumstanced becomes a kind of hydraulic press, the potency of which is to be measured by the force with which the waves fall upon the rocks outside—a force which often amounts to three tons on the square foot. There can be little doubt that by this means considerable pieces of a cliff are from time to time dislodged.

(4.) But probably by far the largest amount of erosion accomplished by the sea is due not to its own direct mechanical impetus, but to the blows dealt by the boulders, gravel, or sand which it hurls against the shores. This action was aptly compared by Playfair to a kind of artillery.[4] During a storm upon a shingly coast we may hear, at a distance of several miles, the grind of the stones against each other, as they are dragged back by the recoil of the waves which had launched them forward. In this tear and wear the loose stones are ground smaller, and acquire the smooth round form so characteristic of a surf-beaten beach. At the same time they bruise and wear down the solid cliffs against which they may be driven. Wherever the rock is much jointed, or from any cause presents less resistance to attack, it is excavated into gullies, creeks, and caves; its harder parts standing out as promontories are pierced; gradually a series of detached buttresses and sea-stacks appears as the cliff recedes, and these in turn are wasted until they become mere skerries and sunken surf-beaten reefs. Of this progress of destruction the more exposed parts of the British coast-line furnish many admirable examples. The west coast of Ireland, exposed to the full swell of the Atlantic, is in innumerable localities completely undermined by caverns, into which the sea enters from both sides. In many places the cliffs are as vertical as walls, this feature depending upon their joints, which enable slice after slice to be undermined and removed. The precipitous coasts of Skye, Sutherland, Caithness, Forfar, Kincardine, and Aberdeenshire abound in the most impressive lessons of the waste of a rocky sea-margin; while the same picturesque features are prolonged into the Orkney and Shetland Islands, the magnificent cliffs of Hoy towering as a vast wall some 1200 feet above the Atlantic breakers, which are tunnelling and fretting their base.

If such is the progress of waste where the materials consist of the most solid rocks, we may expect to meet with at least equally impressive proofs of decay where the coast-line can oppose only soft sand or clay to the march of the breakers. Again, the geological student in Britain can examine for himself many illustrations of this kind of destruction around the shores of these islands. Within the last few hundred years entire parishes with their towns and villages have been washed away, and the tide now ebbs and flows over districts which in old times were cultivated fields and cheerful hamlets. The coast of Yorkshire between Flamborough Head and the mouth of the Humber, and also that between the Wash and the mouth of the Thames, suffer at a specially rapid rate, for the cliffs in these parts consist in great measure of soft clay. In some places this loss is said to amount to 3 feet per annum.

While investigating the proofs of decay along the shore, the geologist endeavours to ascertain to what extent the action of the waves is assisted by that of rain, springs, frosts, and general atmospheric disintegration. He often finds that the progress of the waves depends not so much upon their own labours as upon those of the terrestrial agencies already described. A crumbling cliff, battered and wasted by the breakers, will yield to him abundant evidence of the manner in which the other agents of destruction prepare the way for its final demolition and removal by the sea; and he will learn that the very blocks of stone which give the waves so much of their efficacy are in great measure furnished to them by these co-operating agents. If the cutting back of a cliff were mainly the work of the sea, we ought to find the cliff overhanging, because the sea acts only at its base. But the fact that in the vast majority of cases sea-cliffs, instead of overhanging, slope backward, at a greater or less angle, from the sea, shows that the waste from subaerial action is

[1] Stevenson, *op. cit.*, pp. 21–37.

[2] The reader will bear in mind that the specific gravity of bodies is greatly reduced when in water, and still more in sea-water. The following examples will illustrate this fact (Stevenson on *Harbours*, p. 107):—

	Spec. Grav.	No. of cub. feet to a ton in air.	No. of feet to a ton in sea-water of sp. grav. 1·028.
Basalt	2·99	11·9	18·26
Red granite	2·71	13·2	21·30
Sandstone	2·41	14·8	26·00
Cannel coal	1·54	23·3	70·00

[3] Walker, *Proc. Inst. Civ. Engin.*, i. 15; Stevenson's *Harbours*, p. 10

[4] *Illustrations of the Huttonian Theory*.

really greater than that from the action of the breakers. What the sea chiefly does is to break down and wash away the rubbish that falls from the cliffs, and thus to leave an ever fresh surface for renewed denudation.

(5.) Among the erosive operations of the sea must be included what is performed by floating ice. Along the margin of arctic lands a good deal of work is done by the broken up floe-ice and ice-foot. These cakes of ice, driven ashore by storms, tear up the soft shallow-water or littoral deposits, rub and scratch the rocks, and push gravel and blocks of rock before them as they strand on the beach. Icebergs also, when they get aground in deep water, must greatly disturb the sediment accumulating there, and must grind down any submarine rock on which they grate as they are driven along.

The general result of the erosive action of the sea on the land is the production of a submarine plain. As the sea advances by cutting slice after slice away from the coast, successive lines of beach pass under low-water mark. The whole of the littoral belt, as far down as wave action has influence, is continually being ground down by the moving detritus. If no change of level between sea and land should take place, the sea might conçeivably eat its way slowly far into the land, and produce a gently sloping yet almost horizontal selvage of plain covered permanently by the waves. In such a submarine plain the influence of geological structure, and notably of the relative powers of resistance of different rocks, would make itself conspicuous. The present promontories caused by the superior hardness of their component rocks would no doubt be represented by ridges on the subaqueous plateau, while the existing bays and creeks worn out of softer rocks would be marked by lines of valleys or hollows.

III. Transport.—The sea by means of its surface-drifts and currents carries sedimentary material to great distances and strews them over its floor. Near land, where the movements of the water are active, much coarse detritus is transported along shore or swept farther out to sea. A prevalent wind, by creating a current in a given direction along a coast-line, will cause the shingle to travel coastwise, the stones getting more and more rounded and reduced in size as they recede from their sources. The Chesil Bank, which runs as a natural breakwater 16 miles long connecting the Isle of Portland with the mainland of Dorsetshire, consists of rounded shingle which is constantly being driven westwards. On the Moray Firth the reefs of quartz-rock about Cullen furnish abundance of shingle, which moves westwards along the coast for more than 15 miles. The coarser sediment probably seldom goes much beyond the littoral zone. Fine gravel, however, is pushed along the bottom by currents even at 600 fathoms; for at that depth in the North Atlantic between the Faroe Islands and Scotland small pebbles of volcanic and other rocks are dredged up which have probably been carried by an arctic under-current from the north. At greater depths the force of currents at the bottom must be too feeble to push along any detritus. But much fine sediment is carried in suspension by the sea for long distances from land. Some rivers, as the Amazon, pour so much silt into the sea as to discolour its water for several hundred miles away from land. After wet weather the coast-waters round the shores of the British Islands are sometimes made turbid from the quantity of mud brought down from the land. Dr Carpenter found the bottom waters of the Mediterranean to be everywhere permeated by an extremely fine mud, derived no doubt from the rivers and shores of that sea, borne away out far from land, and settling slowly down upon the bottom. He remarks that the characteristic blueness of the Mediterranean may be explained, like that of the Lake of Geneva (as shown by Dr Tyndall), by the diffusion of those exceedingly minute sedimentary particles through the water.

But the most startling evidence of the wide extent to which transport takes place in the ocean is that supplied by the observations made during the voyage of the "Challenger." From the abysses of the Pacific Ocean, at the furthest distances from land, the dredge brought up bushels of rounded pieces of pumice of all sizes up to blocks a foot in diameter. These fragments were all evidently water-worn, and almost certainly were derived from the land. Some small pieces indeed were taken on the surface in the tow-net. Round volcanic islands, and off the coasts of volcanic tracts of the mainland, the sea is sometimes covered with floating pieces of water-worn pumice swept out by flooded rivers. These fragments drift away for hundreds or even thousands of miles until, becoming water-logged, they sink to the bottom. Their universal distribution was one of the most noticeable features in the dredgings of the "Challenger." The clay which is found on the bottom of the ocean at the greatest distances from any shore may be partly due to its transport in that condition from land, but more probably to the decomposition of the drifted pumice.[1]

Another not unimportant process of marine transport is that performed by floating ice. Among the arctic glaciers moraine stuff is of rare occurrence; but occasional blocks of rock and heaps of earth and stones fall from the cliffs which rise above the general waste of snow. Hence on the icebergs that float off from these glaciers, rock debris sometimes may be observed. It is transported southward for hundreds of miles until, by the shifting or melting of the bergs, it is dropped into deep water. The floor of certain portions of the North Atlantic in the pathway of the bergs must be plentifully strewn with this kind of detritus. By means of the ice-foot also, an enormous quantity of earth and stones is every year borne away from the shore as the ice breaks up, and strewn over the floor of the sounds, bays, and channels.

IV. Reproduction.—The sea being the receptacle for the material worn away from the land must receive and store up in its depths all that vast amount of detritus by the removal of which the level and contours of the land are in the course of time so greatly changed. The deposits which take place within the area covered by the sea may be divided into two groups—the inorganic and organic. It is the former with which we have at present to deal; the latter will be discussed with the other geological functions of plants and animals. The inorganic deposits of the sea-floor are partly (*a*) land-derived or terrigenous, partly (*b*) abyssal.

(*a*.) *Land-derived or Terrigenous.*—These may be conveniently grouped according to their relative places on the sea-bed.

(1.) Shore Deposits.—The most conspicuous and familiar are the layers of gravel and sand which accumulate between tide-marks. As a rule, the coarse materials are thrown up about the upper limit of the beach. They seem to remain stationary there; but if watched and examined from time to time, they will be found to be continually shifted by high tides and storms, so that the bank or bar of shingle retains its place though its component pebbles are being constantly moved. Below the limit of coarse shingle upon the beach lies the zone of fine gravel, and then that of sand. These zones are far from being constant; yet when they all occur on the same beach, they tend to range themselves according to their relative coarseness, the rougher detritus lying at the upper, and the finer towards the lower edge of the shore. The nature of the littoral accumulations on any

[1] Murray, *Proc. Roy. Soc. Edin.*, 1876–7, p. 247.

given part of a coast-line must depend either upon the character of the shore-rocks which at that locality are broken up by the waves, or upon the set of the shore-currents and the kind of detritus they bear with them. Coasts exposed to heavy surf, especially where of a rocky character, are apt to present beaches of coarse shingle between their projecting promontories. Sheltered bays, on the other hand, where wave action is comparatively feeble, afford a gathering ground for fine sediment such as sand and mud. Estuaries and inlets into which rivers enter frequently show wide muddy flats at low water. The mud brought down by the fresh water is allowed to sink to the bottom when the motion of the current is checked as it enters the sea.

(2.) Infra-Littoral and Deeper-Water Deposits.—These extend from below low-water mark to a depth of sometimes as much as 2000 fathoms, and reach a distance from land varying up to 200 miles or even more. Near land, and in comparatively shallow water, they consist of banks or sheets of sand more rarely mixed with gravel. The bottom of the North Sea, for example, which between Britain and the continent of Europe lies at a depth never reaching 100 fathoms, is irregularly marked by long ridges of sand enclosing here and there hollows where mud has been deposited. In the English Channel large banks of gravel extend through the Straits of Dover as far as the entrance to the North Sea. These features seem to indicate the line of the chief mud-bearing streams from the land, and the general disposition of currents and eddies in the sea which covers that region, the gravel ridges marking the tracks of the more rapidly moving currents, while the muddy hollows point to the eddies where the fine sediment is permitted to settle on the bottom. It is possible, however, that the inequalities on the floor of the North Sea, and their peculiarities of sediment, may not be due wholly to modern accumulations, but partly to the contour of the ground before it was submerged and the land connexion between Britain and Europe was destroyed

During the course of the voyage of the "Challenger," the approach to land could always be foretold from the character of the bottom, even at distances of 150 and 200 miles from land. The deposits were found to consist of blue and green muds derived from the degradation of older crystalline rocks. At depths of 100 to 700 fathoms they are often coloured green by glauconite. At greater depths they consist of blue or dark slate-coloured mud with a thin upper layer of red or brown. Throughout these land-derived sediments particles of mica, quartz, and other minerals are distributed, the materials becoming coarser towards land. Pieces of wood, portions of fruits, and leaves of trees occur in them, and further indicate the reality of the transport of material from the land. Shells of pteropods, larval gasteropods, and lamellibranchs are tolerably abundant in these muds, with many infra-littoral species of *Foraminifera*, and diatoms. Below 1500 or 1700 fathoms pteropod shells seldom appear, while at 3000 fathoms hardly a foraminifer or any calcareous organism remains (Murray, *Proc. Roy. Soc. Edin.*, 1876, p. 519). Round volcanic islands the bottom is found to be covered with grey mud and sand derived from the degradation of volcanic rocks. These deposits can be traced to great distances, as at Hawaii for 200 miles or more. Pieces of pumice, scoriæ, &c., occur in them, mingled with marine organisms, and more particularly with abundant grains, incrustations, and nodules of an earthy peroxide of manganese. Near coral-reefs the sea-floor is coated with a white calcareous mud derived from the abrasion of the coral. The east coast of South America supplies a peculiar red mud which is spread over the Atlantic slope down to depths of more than 2000 fathoms.

(*b.*) *Abyssal.*—Passing over at present the organic deposits which form so characteristic a feature on the floor of the deeper and more open parts of the ocean, we come to certain red and grey clays found at depths of more than 2000 fathoms down to the bottoms of the deepest abysses. These consist of exceedingly fine clay, coloured sometimes red by iron-oxide, sometimes of a chocolate tint from manganese oxide, with grains of quartz, mica, pumice, scoriæ, peroxide of manganese, and other mineral substances, together with *Foraminifera*, and in some regions a large proportion of siliceous *Radiolaria*. Mr Murray has shown the high probability that these clays result from the decomposition of pumice and fine volcanic dust transported from volcanic islands into mid-ocean. The extreme slowness of their deposit is strikingly brought out in the tracts farthest removed from land. From these localities great numbers of sharks' teeth, with ear-bones and other bones of whales, were dredged up in the "Challenger" expedition,—some of them quite fresh, others partially crusted with peroxide of manganese, and some completely and thickly surrounded by that substance. We cannot suppose that sharks and whales so abound in the sea as to cover the floor of the ocean with a continuous stratum of their remains. No doubt each haul of the dredge which brought up so many bones represented the droppings of many generations. The successive stages of manganese incrustation point to a long, slow, undisturbed period, when so little sediment accumulated that the bones dropped at the beginning remained at the end still uncovered, or only so slightly covered as to be easily scraped up by the dredge. In these deposits, moreover, Mr Murray has found numerous minute spherular particles of metallic iron which there is every reason to believe are of cosmic origin—portions of the dust of meteorites which in the course of ages have fallen upon the sea-bottom. Such particles no doubt fall all over the ocean; but it is only on those parts of the bottom which, by their distance from any land, receive accessions of deposit with extreme slowness, and where therefore the present surface may contain the dust of a long succession of years, that it has been possible to detect them.

The abundant deposit of peroxide of manganese over the floor of the deep sea is one of the most singular features of recent discovery. It occurs as an earthy incrustation round bits of pumice, bones, and other objects. The nodules possess a concentric arrangement of lines not unlike those of urinary calculi. That they are formed on the spot, and not drifted from a distance, was made abundantly clear from their containing abyssal organisms, and enclosing more or less of the surrounding bottom, whatever its nature might happen to be. Mr Murray refers their origin to the decomposition of the manganese-bearing minerals in the universally diffused volcanic detritus. Quite recently Mr J. Y. Buchanan has dredged similar manganese concretions from some of the deeper parts of Loch Fyne. In connexion with the chemical reactions indicated by these nodules as taking place on the sea-bottom, reference may be made to a still more remarkable but yet unpublished discovery made by Mr Murray in the course of his examinations of the materials brought up from the same abyssal deposits. He has detected abundant minute concretions or bundles of crystals which on analysis are found to resemble olivine in composition. These silicates (there may be several of them) have certainly been formed directly on the sea-bottom, for they are found gathered round abyssal organisms. It is difficult to overestimate the importance of this fact in reference to the chemistry of marine deposits.

From a comparison of the results of the dredgings made in recent years in all parts of the oceans, it is impossible to resist the conclusion that there is nothing in the character of the deep-sea deposits which finds a parallel among the marine geological formations visible to us on the land. It is only among the comparatively shallow water accumulations of the existing sea that we encounter analogies to the older formations. And thus we reach by another and a new approach the conclusion which on very different grounds has been arrived at, viz., that the present continental ridges have existed from the remotest times, and that the marine strata which constitute so large a portion of their mass have been accumulated not as deep water formations, but in comparatively shallow water along their flanks.

Section III.—Life.

Among the agents by which geological changes are carried on upon the surface of the globe living organisms must be enumerated. Both plants and animals co-operate with the inorganic agents in promoting the degradation of the land; and in some cases, on the other hand, they protect rocks from decay. Again by the accumulation of their remains they form extensive formations both upon the land and in the sea. Their operations may hence be described as alike destructive, conservative, and reproductive. Under this heading also we may notice the influence of man as a geological agent.

I. Destructive Action.—Plants aid in the general progress of disintegration in various ways. 1. By keeping the surfaces of rocks moist, and thus promoting both the mechanical and chemical dissolution of the rocks. This action is especially shown by liverworts, mosses, and other plants which only thrive in copious moisture. 2. By producing through their decay carbonic and other acids, which, with decaying organic matter taken up by passing moisture, become potent in effecting the chemical decomposition of rocks, and in promoting the disintegration of soils. 3. By inserting their roots or branches between joints of rock, which are thereby loosened, so that large slices may be eventually wedged off. On the sides of wooded hills and cliffs this process may often be seen; even among old ruins an occasional sapling ash or elm may be found to have cast its roots round a portion of the masonry and to be slowly detaching it from the rest of the wall. 4. By attracting rain, as thick woods, forests, and mosses do, and thus accelerating the general scouring of a country by running water. The indiscriminate destruction of the woods in the Levant has been assigned with much plausibility as the main cause of the present desiccation of that region. 5. By promoting the decay of diseased and dead plants and animals, as when fungi overspread a damp rotting tree or the carcase of a dead animal.

Of the destructive influences of animal life numerous illustrations might be given. 1. The composition and arrangement of soil are affected. Worms are continually engaged in bringing up the lower portions of the soil to the surface, and thus increase its fertility and its capability of being washed away by rain. Burrowing animals, by throwing up the soil and subsoil, expose these to be dried and blown away by the wind. At the same time their subterranean passages serve to drain off the superficial water and to injure the stability of the surface of the ground above them. In Britain the mole and rabbit are familiar examples. In North America the prairie dog has undermined extensive tracts of pasture land in the west. In Cape Colony wide areas of open country seem to be in a constant state of eruption from the burrowing operations of multitudes of *Bathyergi* and *Chrysochloris*—small mole-like animals which bring up the soil and bury the grassy vegetation under it. 2. The flow of streams is sometimes interfered with, or even diverted, by the operations of animals. Thus the beaver, by constructing dams, checks the current of water-courses, intercepts floating materials, and sometimes even diverts the water into new channels. This action is typically displayed in Canada and other parts of North America. The embankments of the Mississippi are sometimes weakened to such an extent by the burrowings of the cray-fish as to gave way and allow the river to inundate the surrounding country. Similar results have happened in Europe from the subterranean operations of rats. 3. Some Mollusca (*Pholas*, *Saxicava*, *Teredo*, &c.) bore into stone or wood, and by the number of contiguous perforations greatly weaken the material. Pieces of drift-wood are soon riddled with long holes by the teredo; while wooden piers, and the bottom of wooden ships, are often rapidly perforated. The saxicavous shells, by piercing rocks and leaving open cavities for rain and sea water to fill, promote the decay of the stone. 4. Many animals exercise a ruinously destructive influence upon vegetation. Of the many insect plagues of that kind it will be enough to enumerate the locust, phylloxera, and Colorado beetle. The pasture in some parts of the south of Scotland has in recent years been much damaged by mice, which have increased in numbers owing to the indiscriminate shooting and trapping of owls, hawks, and other predaceous creatures. Grasshoppers cause the destruction of vegetation in some parts of Wyoming and other western territories of the United States. The way in which animals destroy each other, often on a great scale, may likewise be included among the geological operations now under description.

II. Conservative Action.—This is admirably shown by many kinds of vegetation. 1. The formation of a stratum of turf protects the soil and rocks from being rapidly disintegrated and washed away by atmospheric action. Hence the surface of a district so protected is denuded with extreme slowness except along the lines of its water-courses. 2. Many plants, even without forming a layer of turf, serve by their roots or branches to protect the loose sand or soil on which they grow from being removed by wind. The common sand-carex and other arenaceous plants bind the loose sand-dunes of our coasts, and give them a permanence which would at once be destroyed were the sand laid bare again to storms. In North America the sandy tracts of the western territories are in many places protected by plants known as sage-brush and grease-wood. The growth of shrubs and brushwood along the course of a stream not only keeps the alluvial banks from being so easily undermined and removed as would otherwise be the case, but serves to arrest the sediment in floods, filtering the water, and thereby adding to the height of the flood plain. On some parts of the west coast of France extensive ranges of sand-hills have been gradually planted with pine woods which, while preventing the destructive inland march of the sand, also yield a large revenue in timber, and have so improved the climate as to make these districts a resort for pulmonary invalids. In tropical countries the mangrove grows along the margin of the sea, and not only protects the land, but adds to its breadth, by forming and increasing an alluvial belt along the coast. 3. Some marine plants likewise afford protection to shore rocks. This is done by the calcareous nullipores, which form upon them a hard incrustation; likewise by the tangles and smaller fuci which grow abundantly on the littoral zone and break the force of the waves, or diminish the effects of ground swell. 4. Forests and brushwood protect the soil, especially on slopes, from being washed away by rain. This is shown by the disastrous results of the thoughtless destruction of such woods. According to Reclus (*La Terre*, p. 410), in the three centuries from 1471 to 1776, the "vigueries," or provostry-districts of the French Alps, lost a third, a half, and even three-fourths of their cultivated ground, and the population has diminished in somewhat similar proportions. From 1836 to 1866 the departments of Hautes and Basses Alpes lost 25,000 inhabitants, or nearly one-tenth of their population—a diminution which has with plausibility been assigned to the reckless removal of the pine forests, whereby the steep mountain sides have been washed bare of their soil. The desiccation of the countries bordering the eastern Mediterranean has been ascribed to a similar cause. 5. In mountain districts pine forests exercise also an important conservative function in preventing the formation or arresting the progress of avalanches. In Switzerland some of the forests which cross the lines of frequent snow-falls are carefully preserved.

Animals do not exert any important conservative action upon the earth's surface, save in so far as they form new deposits, as will be immediately referred to. In the prairie regions of Wyoming and other tracts of North America, some interesting minor effects are referable to the herds of roving animals which migrate over these territories. Professor Comstock describes the trails made by the bison, the elk, and the big-horn or mountain-sheep as firmly-trodden tracks on which vegetation will not grow for many years. All over the region traversed by the bison numerous circular patches of grass are to be seen which have been formed on the hollows where this animal has wallowed. Originally they are shallow depressions formed in great numbers where a herd of bisons has rested for a time. On the advent of the rains they become pools of water; thereafter grasses spring up luxuriantly, and so bind the soil together that these grassy patches, or "bison-wallows," may actually become slightly raised above the general level if the surrounding ground becomes parched and degraded by the winds (*Reconnaissance of N.W. Wyoming*, 1875, p. 175).

III. Reproductive Action.—Both plants and animals contribute materials towards new geological formations. Their remains are enclosed in deposits of sand and mud and there preserved. But they form of themselves not unimportant accumulations. Of plant formations the following illustrative examples may be given. (1.) *Peat-Mosses.*—These are accumulations of marshy vegetation which occur in temperate and arctic latitudes, sometimes to a depth of 40 feet or more. In Europe they have been largely formed by plants of the genus *Sphagnum*, which, growing as a spongy fibrous mass over wet ground, die in their lower parts and send out new fibres above. It is this lower decaying stratum which forms the peat. Every stage of the process may be seen in a large moss, from the green living plants at the top, through fibrous brown turf full of the scarcely decayed rootlets of the *Sphagnum*, down to the compact brown or almost black peat at the bottom. Many peat-mosses were at one time lakes which have been gradually filled up by the accumulation of marsh-plants. Peat possesses a great antiseptic power; the bodies of animals which have been entombed in it are sometimes preserved for many centuries. (2.) *Mangrove Swamps.*—On the low moist shores and river mouths of tropical countries, the mangrove tree plays an important geological part. It grows in such situations in a dense jungle, sometimes 20 miles broad, which fringes the coast as a green selvage, and runs up if it does not quite occupy creeks and inlets. The mangrove flourishes in sea-water even down to low-water mark, forming there a dense thicket which, as the trees drop their radicles and take root, grows outward into the sea. It is singular to find terrestrial birds nestling in the branches above and crabs and barnacles living among the roots below. By this network of subaqueous radicles and roots the water is filtered of its sediment, which, retained among the vegetation, helps to turn the spongy jungle into a firm soil. On the coast of Florida the mangrove swamps stretch for long distances as a belt from 5 to 20 miles broad, which winds round the creeks and inlets. At Bermuda the mangroves co-operate with grasses and other plants to choke up the creeks and brackish lakes. In these waters calcareous algæ abound, and as their remains are thrown up amidst the sand and vegetation they form a remarkably calcareous soil. (3.) *Diatom Mud or Earth.*—As the minute siliceous plants called diatoms occur both in fresh and salt water, the deposit formed from their congregated remains is found both on the sites of lakes and on the sea-floor. "Infusorial" earth and "tripoli powder" consist mainly of the frustules and fragmentary debris of diatoms which have accumulated on the bottoms of lacustrine areas. Towards the Antarctic circle the "Challenger" met with *Diatomaceæ* in abundance, both in the surface waters of the ocean and on the bottom. They form at depths of from 1260 to 1975 fathoms a pale straw-coloured deposit, which when dried is white and very light.

Animal formations are chiefly composed of the remains of the lower grades of the animal kingdom, especially of *Mollusca*, *Actinozoa*, and *Foraminifera*. (1.) In some cases they are *calcareous.* Lime, chiefly in the form of carbonate, is the mineral substance of which the solid parts of animals are mainly built up. Hence the great majority of the accumulations formed of animal remains are calcareous. In fresh water they are represented by the *marl* of lakes—a white, chalky deposit consisting of the mouldering remains of *Mollusca*, *Entomostraca*, and partly of fresh-water algæ. On the sea-bottom in shallow water they consist of beds of shells, such as the oyster-banks of English seas. The fringing, barrier, and atoll coral-reefs of warm seas are conspicuous examples of wide and thick masses of rock formed from the accumulated growth of animal organisms. The great reef of Australia, for example, is 1250 miles long, from 10 to 90 miles broad, and more than 1800 feet thick. The coral rock, though formed by the continuous growth of the polyps, gradually loses any distinct organic structure, and acquires an internal crystalline character owing to the infiltration of water through its mass, whereby carbonate of lime is carried down and deposited in the pores and crevices as in a growing stalactite. Great quantities of calcareous mud are produced by the breakers which beat upon the outer edge of the reefs. This mud is partly washed up upon the reefs and aids in their consolidation, but in great measure it is swept away by the ocean currents and distributed over many thousands of square miles of the sea-floor. In deep water over the bed of the Atlantic and other oceans a remarkable calcareous ooze occurs which is formed of the remains of *Foraminifera*, and chiefly of species of the genus *Globigerina*. It is next in abundance to the red and grey clays of the deep sea. It is a pale-grey marl, sometimes red from peroxide of iron, or brown from peroxide of manganese; and it usually contains more or less clay, even with occasional fragments of pumice. (2.) *Siliceous* deposits formed from animal exuviæ are illustrated by another of the deep-sea formations brought to light by the "Challenger" researches. In certain regions of the western and middle Pacific Ocean, the bottom was found to be covered with an ooze consisting almost entirely of *Radiolaria.* These minute organisms occur, indeed, more or less abundantly in almost all deep oceanic deposits. From the deepest sounding yet taken (4575 fathoms, or more than 5 miles) a radiolarian ooze was obtained. The spicules of sponges likewise furnish materials towards these siliceous accumulations. (3.) *Phosphatic* deposits, in the great majority of cases, betoken some of the vertebrate animals, seeing that phosphate of lime enters largely into the composition of their bones and occurs in their excrement. The most typical modern accumulations of this nature are the guano beds of rainless islands off the western coasts of South America and Southern Africa. In these regions immense flocks of sea-fowl have in the course of centuries covered the ground with an accumulation of their droppings to a depth of sometimes 30 to 80 feet, or even more. This deposit, consisting chiefly of organic matter and ammoniacal salts, with about 20 per cent. of phosphate of lime, has acquired a high value as a manure, and is being rapidly cleared off. It could only have been preserved in a rainless or almost rainless climate. On the west of Europe isolated stacks and rocky islands in the sea are often seen to be white from the droppings of clouds of sea birds; but it is merely a thin crust, which is not allowed to grow thicker in a climate where rains are frequent and heavy.

IV. MAN AS A GEOLOGICAL AGENT.—No survey of the geological workings of plant and animal life upon the surface of the globe can be complete which does not take account of the influence of man—an influence of enormous and increasing consequence in physical geography, for man has introduced, as it were, an element of antagonism to nature. Not content with gathering the fruits and capturing the animals which she has offered for his sustenance, he has, with advancing civilization, engaged in a contest to subdue the earth and possess it. His warfare indeed has often been a blind one, successful for the moment, but leading to sure and sad disaster. He has, for instance, stripped off the woodland from many a region of hill and mountain, gaining his immediate object in the possession of their stores of timber, but thereby laying bare the slopes to parching droughts or fierce rains. Countries once rich in beauty, and plenteous in all that was needful for his support, are now burnt and barren, or washed bare of their soil. It is only in comparatively recent years that he has learnt the truth of the aphorism—"*Homo Naturæ minister et interpres.*"

But now, when that truth is coming more and more to be recognized and acted on, man's influence is none the less marked. His object still is to subdue the earth, and he attains it, not by setting nature and her laws at defiance, but by enlisting her in his service. Within the compass of this article it is impossible to give more than merely a reference to this vast subject. The action of man may be witnessed on climate, on the flow of water, on the character of the terrestrial surface, and on the distribution of life.[1]

1. *On Climate.*—Human interference affects meteorological conditions—(1) by removing forests and laying bare to the sun and winds areas which were previously kept cool and damp under trees, or which, lying on the lee side, were protected from tempests; as already stated, it is supposed that the wholesale destruction of the woodlands formerly existing in countries bordering the Mediterranean has been in part the cause of the present desiccation of these districts; (2) by drainage, the effect of this operation being to remove rapidly the discharged rainfall, to lessen the evaporation, and thereby to diminish the rainfall and somewhat increase the general temperature of a country; (3) by the other processes of agriculture, such as the transformation of moor and bog into cultivated land, and the clothing of bare hillsides with green crops or plantations of coniferous and hardwood trees.

2. *On the Flow of Water.*—1. By increasing or diminishing the rainfall man directly affects the course of the waters over the land. 2. By his drainage operations he makes the rain to run off more rapidly than before, and thereby increases the floods in the rivers. 3. By wells, bores, mines, or other subterranean works he interferes with the underground waters and consequently with the discharge of springs. 4. By embanking rivers he confines them to narrow channels, sometimes increasing their scour, and enabling them to carry their sediment further seaward, sometimes causing them to deposit it over the plains and raise their level.

3. *On the Surface of the Land.*—Man's operations alter the aspect of a country in many ways:—(1) by changing forest into bare mountain, or clothing bare mountains with forest; (2) by promoting the growth or causing the removal of peat-mosses; (3) by heedlessly uncovering sand-dunes, and thereby setting in motion a process of destruction which may convert hundreds of acres of fertile land into waste sand, or by prudently planting the dunes with sand-loving vegetation or pines, and thus arresting their landward progress; (4) by so guiding the course of rivers as to make them aid him in reclaiming waste land, and bringing it under cultivation; (5) by piers and bulwarks, whereby the ravages of the sea are stayed, or by the thoughtless removal from the beach of stones which the waves had themselves thrown up, and which would have served for a time to protect the land; (6) by forming new deposits either designedly or incidentally. The roads, bridges, canals, railways, tunnels, villages, and towns with which man has covered the surface of the land will in many cases form a permanent record of his presence. Under his hand the whole surface of civilized countries is very slowly covered by a stratum, either formed wholly by him, or due in great measure to his operations, and containing many relics of his presence. The soil of old cities has been increased to a depth of many feet by the rubbish of his buildings; the level of the streets of modern Rome stands high above that of the pavements of the Cæsars, and that again above the roadways of the early republic. Over cultivated fields his potsherds are turned up in abundance by the plough. The loam has risen within the walls of his graveyards, as generation after generation has mouldered there into dust.

4. *On the Distribution of Life.*—It is under this head, perhaps, that the most subtle of human influences come. Some of man's doings in this domain are indeed plain enough, such as the extirpation of wild animals, the diminution or destruction of some forms of vegetation, the introduction of plants and animals useful to himself, and especially the enormous predominance given by him to the cereals and to the spread of sheep and cattle. But no such extensive disturbance of the normal conditions of the distribution of life can take place without carrying with it many secondary effects, and setting in motion a wide cycle of change and of reaction in the animal and vegetable kingdoms. For example, the incessant warfare waged by man against birds and beasts of prey in districts given up to the chase leads sometimes to unforseen results. The weak game is allowed to live, which would otherwise be killed off and give more room for the healthy remainder. Other animals which feed perhaps on the same materials as the game are by the same cause permitted to live unchecked, and thereby to act as a further hindrance to the spread of the protected species. But the indirect results of man's interference with the *régime* of plants and animals still require much prolonged observation.

From this brief and imperfect outline the reader may perceive that man takes an important place as a geological agent, and that in future ages the traces of his interference will introduce a new element of difficulty into the study of geological phenomena.

PART IV.—STRUCTURAL GEOLOGY,

OR THE ARCHITECTURE OF THE EARTH'S CRUST.

Having considered the nature of the materials constituting the crust of the earth, and the operation of the different agencies by which these materials are produced, arranged, and modified, we may now proceed to examine the structure of the crust itself with the view of marking how its component parts have been put together. Since by far the largest portion of the crust consists of sedimentary or

[1] The reader will find much suggestive matter in Marsh's *Man and Nature*, a work which, as its title denotes, specially treats of this subject. A new and enlarged edition of this volume was published in 1874 under the title of *The Earth as Modified by Human Action.*

aqueous rocks, it will be of advantage to treat of them first, noting, in the first place, their original characters as resulting from the circumstances under which they were formed, and afterwards, the modifications subsequently effected upon them. Many of these superinduced structures, which are not peculiar to sedimentary, but occur more or less markedly in all rocks, may be conveniently described together. The distinctive characters of the igneous or eruptive rocks, as portions of the architecture of the crust will then be described; and lastly, those of the crystalline schists and other associated rocks to which the name of metamorphic is usually applied.

I. Stratification and its Accompaniments.

The term "stratified," so often applied as a general designation to the aqueous or sedimentary rocks, expresses their leading structural feature. They are arranged in layers or strata, an arrangement characteristic of them alike in hand-specimens and in the cliffs of mountains. Not that every morsel of aqueous rock exhibits evidence of stratification. But it is this characteristic which is least frequently absent. The general aspects of stratification will be best followed in an explanation of the terms by which they are expressed.

Laminæ are the thinnest paper-like layers of deposit in a stratified rock. Such fine layers only occur where the material is fine-grained, as in mud or shale, or where fine scales of some mineral have been plentifully deposited, as in micaceous sandstone. In some laminated rocks the laminæ cohere so firmly that they can hardly be split open, and the rock will break more readily across them than in their direction. More usually, however, the planes of lamination serve as convenient divisional planes by means of which the rock can be split open. The frequency with which laminæ can be separated from each other, indicating, as it does, a failure of coherence between the layers of deposit, may probably be taken as a proof that these layers were originally laid down at intervals of sufficient duration to admit of a considerable amount of consolidation of one layer before the deposition of the next. It is quite possible that in many, if not in most cases, these intervals were of longer duration than those required for the successive deposit of the laminæ. In estimating therefore the length of time represented by say one foot of such finely laminated rock, we might reasonably regard the actual time occupied in deposition as only a small fraction of the whole interval.

The existence of laminæ points to tranquil conditions of slow intermittent deposit. The sediment has been borne at intervals and fallen over the same area of undisturbed water. Regularity of thickness and persistence of lithological character among the laminæ may be taken to indicate periodic currents, of approximately equal force, from the same quarter. In some cases successive tides in a sheltered estuary may have been the agent of deposition. In others the sediment was doubtless brought by recurring river-floods. A great thickness of laminated rock, like the massive shales of Palæozoic formations, points to a prolonged period of quiescence, and probably, in most cases, to slow, tranquil subsidence of the sea-floor. On the other hand, the alternation of thin bands of laminated rock with others coarser in texture and non-laminated suggests considerable oscillation of currents from different quarters bearing different qualities and amounts of sediment.

Strata or *Beds* are layers of rock varying from an inch or less up to many feet in thickness. A stratum may be made up of many laminæ, if the nature of the sediment and mode of deposit have favoured the production of this structure. This has very commonly been the case where the sediment has been exceedingly fine-grained. Where the materials are of coarser grain, the strata, as a rule, are not laminated, but form the thinnest parallel divisions of the mass of rock. Strata, like laminæ, may either cohere firmly, or, as more usually happens, be separable with more or less ease from each other. In the former case we may suppose the upper to have followed the lower bed without the lapse of an interval long enough to allow of the consolidation of the latter. The common merging of a stratum into that which overlies it must no doubt be regarded as evidence of more or less gradual change in the conditions of deposit. Where the overlying bed shows no cohesion with that below it, the interval was probably of some duration. A stratum may be one of a series of similar beds in the same mass of rock. Thus a thick sandstone consists of many individual strata, varying it may be very considerably in their respective thicknesses. Or a stratum may be complete and distinct in itself, as where one of limestone or ironstone runs through the heart of a series of shales. As a general rule we may conclude that wherever among sedimentary accumulations stratification is exceedingly well-marked the rocks were formed rather slowly, and that where it is weak or absent the conditions of deposit were more rapid, without the intervals and changes necessary for the production of the distinctly stratified structure.

False-bedding, Current-bedding.—Some strata, particularly sandstones, are marked by an irregular lamination, wherein the laminæ, though for short distances parallel to each other, are oblique to the general stratification of the mass, at constantly varying angles and in different directions. The accompanying section (fig. 9) illustrates this

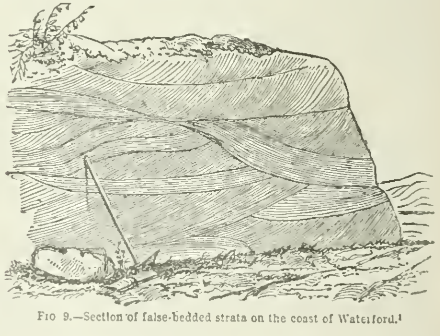

Fig. 9.—Section of false-bedded strata on the coast of Waterford.[1]

structure, which is known by the name of false-bedding or current-bedding. The finer lines in this drawing represent the laminæ of deposit, the stronger lines mark successive surfaces on which these laminæ were laid down. Such a structure points to frequent changes in the direction of the currents by which the sediment was carried along and deposited. Sand pushed over the bottom of a sheet of water by varying currents tends to accumulate irregularly in bands and ridges, which often advance with a steep slope in front. The upper and lower surfaces of the bank or bed of sand may remain parallel with each other as well as with the underlying bottom, yet the successive laminæ composing it may lie at an angle of 30° or even more. We may illustrate this structure by the familiar formation of a railway embankment. The top of the embankment on which the permanent way is to be laid is kept level, but the advancing end of the earth-work shows a steep slope over which the

[1] The woodcuts in this Part are (with the exception of Nos. 20 and 31) from the article Geology in the last edition of the *Ency. Brit.*, written by the late J. B. Jukes, F.R.S.

workmen are constantly discharging waggon-loads of rubbish. Hence the embankment, if cut open longitudinally, would present a "false-bedded" structure, for it would be found to consist of many irregular layers inclined at a high angle in the direction in which the formation of the mound had advanced. In the accompanying figure (fig. 10) the water

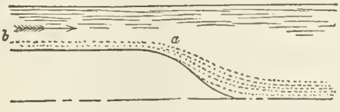

FIG. 10.—Section illustrating the production of false-bedding.

moving in the direction of the arrow may drop sand at *b*, which will correspond in lamination with the general stratification of the locality; but when the current reaches the steep front of one of the advancing sand sheets it will allow the sand to roll down the slope, and may continue to bring fresh supplies of sediment until the slope is gradually effaced. Now and then, however, instead of laying down sediment, a current of greater strength than usual may appear and sweep away portions of the sediment already deposited.

Irregularities of Bedding due to Inequalities of Deposition or of Erosion.—A sharp ridge of sand or gravel may be laid down under water by current-action of some strength. Should the motion of the water diminish, finer sediment may be brought to the place and be deposited around and above the ridge. In such a case the stratification of the later accumulation will end off abruptly against the flanks of the older ridge, which will appear to rise up through the overlying bed. In fig. 11, for example, the lower bed

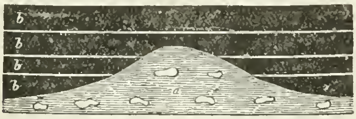

FIG. 11.—Mound of clay with ironstone balls (*a*), covered by beds of coal (*bb*).

seems to have been locally heaped up into the shape of a mound or ridge before the coal was accumulated over it. Appearances of this kind are not uncommon in some coal-fields, where they are known to the miners as "rolls," "swells," or "horses' backs." A structure exactly the reverse of the preceding occurs where a stratum has been scooped out before the deposition of the layers which cover it. This has often been observed in mining for coal. Channels have been cut out of a coal-seam, or rather out of the bed of vegetation which ultimately became coal, and these channels, ramifying and winding sometimes like those of streamlets on flat ground, have been filled up with sandy

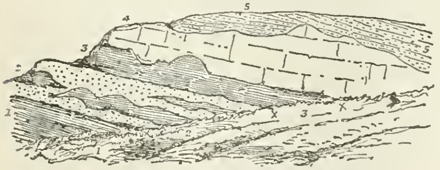

FIG. 12.—Section of New Red Sandstone, road-cutting near Wolverhampton. 1, Red and white clay or marl; 2, Brown sandstone with irregular patches of marl; 3, Red marl, partially eroded before the deposition of 4, Brown sandstone eroded before the formation of 5, Calcareous sandstone or cornstone.

or muddy sediment. In fig. 12 a section is given of a remarkable series of such erosions, where beds of clay and sandstone have been extensively denuded in the intervals between the deposit of the successive beds. In these and similar cases it is evident that the erosion took place contemporaneously with the accumulation of the deposits as a whole. We cannot tell, of course, how long an interval elapsed between the formation of a given stratum and that of the next stratum which lies upon its eroded surface, nor how much depth of rock may have been removed in the erosion. When, however, as in the instances with which we are dealing, the structure occurs among conformable strata, evidently united as one lithologically continuous series of deposits, we may reasonably infer that the missing portions are of small moment and that the erosion was merely due to the irregular and more violent action of the very currents by which the sediment of the successive strata was supplied.

The case is very different when the eroded strata are inclined at a different angle to those above them, and are strongly marked off by lithological distinctions. In some of the coal-mines in central Scotland, for instance, deep channels have been met with entirely filled with sand, gravel, or clay belonging to the general superficial drift of the country. These channels have evidently been water-courses worn out of the coal-measure strata at a comparatively recent geological period, and subsequently buried under the glacial accumulations. There is a complete discordance between them and the Palæozoic strata below, pointing to the existence of a vast interval of time.

Ripple-mark.—The surface of many beds of sandstone is marked with lines of wavy ridge and hollow, such as may be seen on any shore from which the tide has retired. This kind of surface is known as "ripple-mark." It may be formed on dry blown sand by the action merely of the wind, and it is of everyday occurrence under shallow water, not merely on sea-shores, but on the floors of lakes and of river-pools. The water, gently agitated by the wind in a given direction, throws the surface of the underlying sediment into ripples which tend to run at right angles to the course of movement. But as the wind veers from point to point, producing corresponding changes in the direction of the water-currents, the ripples on the bottom are not strictly parallel, but often coalesce, intersect, and undulate in their course. Their general direction, however, suffices to indicate the quarter whence the chief movement of the water has come. No satisfactory inference can be drawn from the existence of a rippled surface as to the depth of water in which the sediment was accumulated. As a rule it is in water of only a few feet or yards in depth that ripple-mark is formed. But it may be produced at any depth to which the agitation caused by wind on the upper waters may extend.

On an ordinary beach each tide usually effaces the ripple-marks made by its predecessor, and leaves a new series to be obliterated by the next tide. But where the markings are formed in water which is always receiving fresh accumulations of sediment, a rippled surface may be gently overspread by the descent of a layer of sediment upon it and may thus be preserved. Another series of ripples may then be made in the overlying layers, which in turn may be buried and preserved under a renewed deposit of sand. In this way a considerable thickness of such ripple-marked strata may be accumulated, as has frequently taken place among geological formations of all ages.

An examination of any sandy beach from which the sea has recently retired brings before us many modifications of the perfect ripple-mark. The ridges may be seen to grow more and more notched and irregular, until at last the beach seems to be dotted over with little, flat, dome-shaped mounds, or as if the ridges of the ripple-mark had been furrowed across. These modifications are doubtless due to the partial effacement of the ridges by subsequent action of the water agitated by wind from a different quarter. Such indications of shallow-water conditions may often be observed among old arenaceous deposits, as in the Cambrian and Silurian rocks. In like manner we may frequently detect, among these ancient formations, small isolated or connected linear ridges directed from some common quarter, like the current-marks frequently to be found behind projecting fragments of shell, stones, or bits of sea-weed on a beach from which the tide has just retired.

Sun-cracks, Rain-pittings, &c.—Proofs may not infrequently be found that during deposition aqueous strata have been laid bare to air and sun. The nature and validity of this evidence will be best ascertained by observations made at the margin of the sea, or of any inland sheet of water, which from time to time leaves tracts of mud or fine sand exposed to sun and rain. The way in which the muddy bottom of a dried-up pool cracks into polygonal cakes when exposed to the sun may be illustrated abundantly among geological formations of all ages. These desiccation-cracks, or sun-cracks, could not have been produced so long as the sediment lay under water. Their existence therefore among any strata proves that the surface of rock on which they lie was exposed to the air and dried before the next layer of water-borne sediment was deposited upon it.

With these markings are not infrequently associated prints of rain-drops. The familiar effects of a heavy shower upon a surface of moist sand or mud may be witnessed among rocks even as old as parts of the Cambrian system. In some cases the rain-prints are found to be ridged up on one and the same side in such a manner as to indicate that the rain-drops as they fell were driven along in a slanting direction. The prominent side of the markings therefore indicates the side towards which the wind blew.

Numerous proofs of shallow shore-water, and likewise of exposure to the air, are supplied by markings left by animals. Castings and trails of worms, tracks of mollusks and crustaceans, fin-marks of fishes, footprints of birds, reptiles, and mammals, may all be preserved and give their evidence regarding the physical conditions under which sedimentary formations were accumulated. It may frequently be noticed that such impressions are associated with ripple-marks, rain-prints, or sun-cracks; so that more than one kind of evidence may be gleaned from a locality to show that it was sometimes laid bare of water.

Gas-spurts.—The surfaces of some strata, usually of a dark colour and containing much organic matter, may be observed to be raised into little heaps of various indefinite shapes, not, like the heaps associated with worm burrows, connected with pipes descending into the rock, nor composed of different material from the surrounding sandstone or shale. These may be conjectured to be due to the intermittent escape of gas from the decomposing organic matter in the original sand or mud, as we may sometimes witness in operation among the mud flats of rivers and estuaries. On a small scale these protrusions of the upper surface of a deposit may be compared with the well-known mud-lumps at the mouths of the Mississippi, where the muddy bottom rises into mounds sometimes to a height of several yards above the water, from the top of which great quantities of carburetted hydrogen gas make their escape, together with water and mud.

Concretions.—Many sedimentary rocks are marked by the occurrence of concretions in them, either distinct in aspect and composition from the general mass of the rock, or forming really part of that mass, though separated from the rest by their being agglutinated into concretionary forms. Such concretions, where they differ in petrographical characters from the surrounding matter, are almost invariably of original or contemporaneous formation, that is, were formed at the same time as the strata among which they lie. Where, however, they appear to be merely compacted portions of the stratum, they may be regarded as generally due to some subsequent change effected upon the rock.

Contemporaneous concretions most commonly consist of carbonate of iron, carbonate of lime, or silica. Many clay-ironstone beds assume a nodular form, and this mineral occurs abundantly in the shape of separate nodules in shales and clay-rocks. The nodules have frequently formed round some organic body such as a fragment of plant, a shell, bone, or coprolite. That the carbonate of iron was slowly precipitated during the formation of the bed of shale in which its nodules lie may often be satisfactorily proved by the lines of deposit passing continuously through the nodules. In many cases the internal first-formed parts of a nodule have contracted more than the outer and more compact crust; and have cracked into open polygonal spaces which are commonly filled with calcite. Similar concretions of carbonate of lime occur in some clays and in connexion with limestones. Concretions of silica occur in limestone of many geological ages (see *ante*, p. 239). The flints of the English chalk are a familiar example, but similar siliceous concretions occur even in Lower Silurian limestones. The

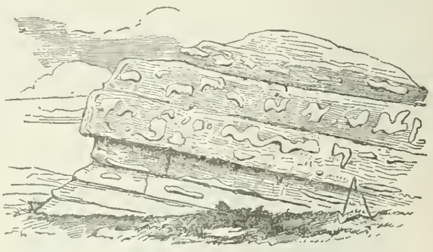

FIG. 13.—Sketch of limestone-beds, with concretions of white chert, Middleton Moor, Derbyshire.

silica in these cases has not infrequently been deposited round organic bodies such as sponges, sea-urchins, and mollusca, which are completely enveloped in it and have even themselves been silicified. Iron-bisulphide (pyrite or marcasite) often assumes the form of concretions, more

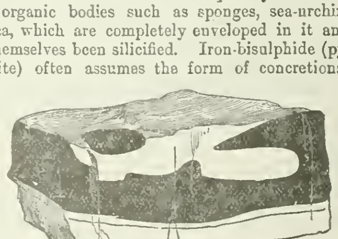

FIG 14.—Sketch of part of a block of black chert in the limestone near Dublin.

particularly among clay-rocks, and these, though presenting many eccentricities of shape, round like pistol-shot or cannon-balls, kidney-shaped, botryoidal, &c., agree in usually possessing an internal fibrous radiated structure. Phosphate of lime is found as concretions in formations where the coprolites and bones of reptiles and other animals have been collected together.

Concretions produced subsequently to the formation of the rock may be observed in some sandstones, which, when exposed to the weather, decompose into large round balls. Some shales exhibit this structure in a still more striking manner, inasmuch as the concretions consist of the general mass of the laminated shale, and the lines of stratification pass through them and mark them out distinctly as superinduced upon the rock. Some magnesian limestones are so concretionary as to resemble masses of conglomerate; yet the concretions, among all their fantastic shapes and with their acquired crystalline texture, may often be found to retain traces of the original stratification of the rock. Beds of rock-salt may likewise be observed to be marked with traces of a concretionary arrangement.

Order of Superposition—the Foundation of Geological Chronology.—As sedimentary strata are laid down upon one another in a more or less nearly horizontal position, the underlying beds must be older than those which cover them. This simple and obvious truth is termed the law of superposition. It furnishes the means of determining the chronology of rocks, and though other methods of ascertaining this point are employed, they must all be based originally upon the observed order of superposition. The only case where the apparent superposition may be deceptive is where the strata have been inverted. In the Alps, for example, the rocks composing huge mountain masses have been so completely overturned that the highest beds appear as if regularly covered by others which ought properly to underlie them. But these are exceptional occurrences, where the true order can usually be made out from other sources of evidence.

Alternations of Strata.—Though great variations occur in the nature of the strata composing a mass of sedimentary rocks, it may often be observed that certain repetitions occur. Sandstones, for example, are found to be interleaved with shale above, and then to pass into shale; the latter may in turn become sandy at the top and be finally covered by sandstone, or may assume a calcareous character and pass up into limestone. Such alternations bring before us the conditions under which the sedimentation took place. A sandstone group indicates water of comparatively little depth, moved by changing currents, bringing the sand now from one side now from another. The passage of such a group into one of shale points to a diminution in the motion and transporting power of the water, perhaps to a sinking of the tract, whereby only fine mud was then intermittently brought into it. The advent of a limestone above the shale serves to show that the water cleared, owing to a deflexion of the sediment-carrying currents, or to continued and perhaps more rapid subsidence, and that *Foraminifera*, corals, crinoids, *Mollusca*, or other lime-secreting organisms, established themselves upon the spot. Shale overlying the limestone would tell of fresh inroads of mud, which destroyed the animal life that had been flourishing on the bottom; while a return of sandstone beds would mark how, in the course of time, the original conditions of troubled currents and shifting sandbanks returned. Such alternating groups of sandy, calcareous, and argillaceous strata are well illustrated among the Jurassic formations of England.

Associations of Strata.—Certain kinds of strata very commonly occur together, because the conditions under which they were formed were apt to arise in succession. One of the most familiar examples is the association of coal and fire-clay. A seam of coal is almost invariably found to lie on a bed of fire-clay, or on some argillaceous stratum. The reason of this union becomes at once apparent when we learn that the fire-clay formed the soil on which the plants grew that went to form the coal. Where the clay was laid down under suitable circumstances vegetation sprang up upon it. Again conglomerate and sandstone occur together rather than conglomerate and shale, because the agitation of the water which could form and deposit coarse detritus, like that composing conglomerate, was too great to admit of the accumulation of fine silt. For a similar reason we may look for shale or clay rather than sandstone as an accompaniment of limestone.

Relative Persistence of Strata.—Observation of what takes place on any lake bottom, estuary, or sea-margin teaches that some kinds of sediment are much more widely spread than others, and prepares us to find that the same has been the case in past time, and therefore that some kinds of sedimentary rocks possess far greater persistence than others. As a general rule it may be said that the coarser the grain the more local the extent of a rock. Conglomerates are thus by much the most variable and inconstant of all sedimentary formations. They suddenly sink down from a thickness of several hundred feet to a few yards, or die out altogether, to reappear perhaps further on, in the same wedge-like or lenticular fashion. Sandstones are less liable to such extremes of inconstancy, but they too are apt to thin away and to swell out again. Shales are much more persistent, the same zone being often traceable for many miles. Limestones sometimes occur in thick local masses, as among the Silurian formations of Wales and Scotland, but they often also display remarkable continuity. Three thin limestone bands, each of them only 2 or 3 feet in thickness, and separated by a considerable thickness of intervening sandstones and shales, can be traced through the coal-fields of central Scotland over an area of at least 1000 square miles. Coal-seams also possess great persistence. The same seams, varying slightly in thickness and quality, may often be traced thoughout the whole of an extensive coal-field.

What is thus true of individual strata may be affirmed also of groups of such strata. A thick mass of sandstone will be found as a rule to be more continuous than one of conglomerate, but less so than one of shale. A series of limestone-beds will usually be found to stretch further than either of them. But even to the most extensive stratum or group of strata there must be a limit. It must end off and give place to others, either suddenly, as a bank of shingle is succeeded by the sheet of sand heaped against its base, or very gradually, by insensibly passing into other strata on all sides.

Great variations in the character of stratified rocks may frequently be observed in passing from one part of a country to another along the outcrop of the same rocks. Thus at one end we may meet with a thick series of sandstones and shales which, traced in a certain direction, may be found passing into limestones. A group of strata may consist of massive conglomerates at one locality, and may graduate into fine fissile flagstones in another. A thick mass of clay may be found to alternate more and more with shelly sands as it is traced outward, until it loses its argillaceous nature altogether. No difficulty need be felt in admitting the strict contemporaneity of these diverse layers of sediment. At the present time we see how coarse shingle may be formed along the beach at the same time that the finest mud is being laid down on the same sea-bottom further from land. Could we raise up that bottom, we should doubtless find as gradual a passage from the littoral to the deeper water deposits as we do among the geological formations of the earth's crust. The existing differences of character between the deposits of the shore and of the opener sea would no doubt continue to be maintained, with slight geographical displacements, even if the whole area were undergoing subsidence, giving rise to a thick group of littoral beds in one tract and of deeper-water accumulations at another. In like manner among the formations of former geological periods the same conditions of deposit appear sometimes to have continued for a considerable period. Hence the thick Mountain or Carboniferous Limestone of Derbyshire is gradually replaced northwards by the thick sandstone shales, ironstones, and coal-seams of Scotland.

Overlap.—When strata have been laid down in a subsiding region wherein the area of deposit gradually increased, the sediment must have spread over a progressively augmenting surface. By this means the later portions of a sedimentary series will extend beyond the limits of the older parts, and will repose directly on the shelving bottom, with none of those older strata underneath them. This relation is called Overlap (see fig. 59). The higher or newer members are said to overlap the older. This structure may often be detected among formations of all geological ages. It brings before us the shore line of ancient land-surfaces, and shows how, as these sank under water, the gravels, sands, and silts gradually advanced and covered them.

Relative Lapse of Time represented by Strata and by the Intervals between them.—Of the absolute length of time represented by any strata or groups of strata we can form no satisfactory estimates. Certain general conclusions may indeed be drawn, and comparisons may be made between different series of rocks. Sandstones full of false-bedding were probably accumulated more rapidly than finely-laminated shales or clays. It is not uncommon in certain Carboniferous formations to find huge coniferous trunks imbedded in an inclined position in sandstone. These trees seem to have been carried along and to have sunk, their heavier or root-end touching the bottom, and their upper end pointing upward in the direction of the current, exactly as in the case of the snags of the Mississippi. The continuous deposit of sand at last rose above the level of the trunks and buried them. It is clear then that the rate of deposit must have been sufficiently rapid to have allowed a mass of 20 or 30 feet of sand to accumulate before the decay of the wood; though modern instances are known where, under certain circumstances, submerged trees may last for some centuries. Continuous layers of the same kind of deposit suggest a persistence of geological conditions; numerous alternations of different kinds of sedimentary matter point to vicissitudes or alternations of conditions. As a rule, we should infer that the time represented by a given thickness of similar strata was less than that shown by the same thickness of dissimilar strata, because the changes needed to bring new varieties of sediment into the area of deposit would usually require the lapse of some time for their completion. But this conclusion might often be erroneous. It would be best supported when, from the very nature of the rocks, wide variations in the character of the water-bottom could be established. Thus a group of shales followed by a fossiliferous limestone would almost always mark the lapse of a much longer period than an equal depth of sandy strata. Limestones made up of organic remains which lived and died upon the spot, and whose remains are crowded together generation above generation, must have demanded many years for their formation.

But in all speculations of this kind we must bear in mind that the length of time represented by a given depth of strata is not to be estimated merely from their thickness or lithological characters. It has already been pointed out that the interval between the deposit of two successive laminæ of shale may have been as long as, or even longer than, that required for the formation of one of the laminæ. In like manner, the interval needed for the transition from one stratum or kind of strata to another may often have been more than equal to the time required for the formation of the strata on either side. But the relative chronological importance of the bars or lines in the geological record can seldom be satisfactorily discussed merely on lithological grounds. This must mainly be decided on the evidence of organic remains, as will be shown in part v. By this kind of evidence it can be made nearly certain that the intervals represented by strata were in many cases much shorter than those not so represented,—in other words, that the time during which no deposit of sediment went on was longer than that wherein deposit did take place.

Groups of Strata.—Passing from individual strata to the masses of stratified rock, the geologist finds it needful for convenience of reference to subdivide these into groups. He avails himself of two bases of classification—(1) lithological characters, and (2) organic remains.

1. The subdivision of stratified rocks into groups according to their mineral aspect is an obvious and easily applied classification. Moreover, it often serves to connect together rocks formed continuously in certain circumstances which differed from those under which the strata above and below were laid down,—so that it expresses natural and original subdivisions of strata. In the middle of the English Carboniferous system of rocks, for example, a zone of sandy and pebbly beds occurs, known as the Millstone Grit. No abrupt and sharp line can be drawn between these strata and those above and below them. They shade upward and downward into the beds between which they lie. Yet they form a conspicuous belt, traceable for many miles by the scenery to which it gives rise. The red rocks of central England, with their red sandstones, marls, rock-salt, and gypsum, form likewise a well-marked group or rather series of groups. It is obvious, however, that characters of this kind, though sometimes wonderfully persistent over wide tracts of country, must be at best but local. The physical conditions of deposit must always have been limited in extent. A group of strata showing great thickness in one region will be found to die away as it is traced into another. Or its place is gradually taken by another group which, even if geologically contemporaneous, possesses totally different lithological characters. Just as at the present time a group of sandy deposits gradually gives place along the sea-floor to others of mud, and these to others of shells or of gravel, so in former geological periods contemporaneous deposits were not always lithologically similar. Hence mere resemblance in mineral aspect usually cannot be regarded as satisfactory evidence of contemporaneity except within comparatively contracted areas. The Carboniferous Limestone of Ireland is a thick calcareous group of rocks, full of corals, crinoids, and other organisms, which bear witness to the formation of these rocks in the open sea. But if these limestones, with their characteristic marine fossils, are traced into the north of England and Scotland, they are found to pass into sandstones and shales, with numerous coal-seams, and only a few thin beds of limestone. The soft clay beneath the city of London is represented in the Alps by hard schists and contorted limestones. We conclude therefore that lithological agreement when pushed too far is apt to mislead us, partly because contemporaneous strata often vary greatly in their lithological character, and partly because the same lithological characters may appear again and again in different ages. By trusting too implicitly to this kind of evidence, we may be led to class together rocks belonging to very different geological periods, and on the other hand to separate groups which really, in spite of their seeming distinction, were formed contemporaneously.

2. It is by the remains of plants and animals imbedded among the stratified rocks that the most satisfactory subdivisions of the geological record can be made, as will be more fully stated in parts v. and vi. A chronological succession of organic forms can be made out among the rocks of the earth's crust. A certain common facies or type of fossils is found to characterize particular groups of rock, and to hold true even though the lithological constitution of the strata should greatly vary. Moreover, though comparatively few species are universally diffused, they possess remarkable persistence over wide areas, and even when they are replaced by others, the same general facies of fossils remains. Hence the stratified formations of two countries geographically distant, and having little or no lithological resemblance to each other, may be compared and paralleled zone by zone, simply by means of their enclosed organic remains.

II. Joints.

All rocks are traversed more or less distinctly by vertical or highly inclined divisional planes termed *Joints*. Soft rocks indeed, such as loose sand and uncompacted clay, do not show these lines; but wherever a mass of clay has been subjected to some pressure and consolidation, it will usually be found to have acquired them. It is by means of the intersection of joints that rocks can be removed in blocks; the art of quarrying consists in taking advantage of these natural planes of division. Joints differ in character according to the nature of the material which they traverse; those in sedimentary rocks are usually distinct from those in crystalline masses.

1. *In Sedimentary Rocks.*—Joints vary in sharpness of definition, in the regularity of their perpendicular and horizontal course, in their lateral persistence, in number, and in the directions of intersection. As a rule, they are most sharply defined in proportion to the fineness of grain of the rock. In limestones and close-grained shales, for example, they often occur so clean-cut as to be invisible until revealed by fracture or by the slow disintegrating effects of the weather. The rock splits up along these concealed lines of division whether the agent of demolition be the hammer or frost. In coarse-textured rocks, on the other hand, joints are apt to show themselves as irregular rents along which the rock has been shattered, so that they present an uneven sinuous course, branching off in different directions. In many rocks they descend vertically in straight lines at not very unequal distances, so that the spaces between them are thus marked off into so many wall-like masses. But this symmetry often gives place to a more or less tortuous course with lateral joints in various random directions, more especially where the different strata vary considerably in lithological characters. A single joint may be traced sometimes for many yards, or even for several miles, more particularly when the rock is fine-grained, as in limestone. But where the texture is coarse and unequal, the joints, though abundant, run into each other in such a way that no one in particular can be identified for so great a distance. The number of joints in a mass of stratified rock varies within wide limits. Among strata which have undergone little disturbance the joints may be separated from each other by intervals of several yards. But in other cases where the terrestrial movement appears to have been considerable, the rocks are so jointed as to have acquired therefrom a fissile character that has nearly or wholly obliterated their tendency to split along the lines of bedding.

An important feature in the joints of stratified rocks is the direction in which they intersect each other. As the result of observation we learn that they possess two dominant trends, one coincident in a general way with the direction in which the strata are inclined to the horizon, and the other running transversely at a right angle or nearly so. The former set is known as *dip-joints*, because they run with the *dip* or inclination of the rocks, the latter is termed *strike-joints*, inasmuch as they conform to the general *strike* or mean outcrop. It is owing to the existence of this double series of joints that ordinary quarrying operations can be carried on. Large quadrangular blocks can be wedged off, which would be shattered if exposed to the risk of blasting. A quarry is usually worked to the dip of a rock, hence the strike-joints form clean-cut faces in front of the workmen as they advance. These are known as "backs," and the dip-joints which traverse them as "cutters." The way in which this double set of joints occurs in a quarry may be seen in fig. 15, where the parallel lines which traverse the shaded and unshaded faces mark the successive strata. The broad white spaces running along the length of the quarry behind the seated figure are strike-joints or "backs," traversed by some highly inclined lines which mark the position of dip-joints or "cutters." The shaded

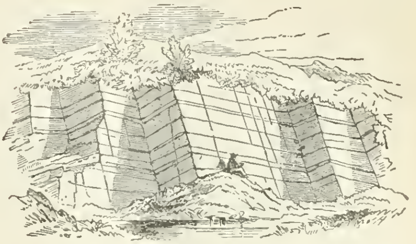

Fig. 15.—Joints in limestone quarry near Mallow, co. Cork. (G. V Du Noyer.)

ends looking towards the spectator are "cutters" from which the rock has been quarried away on one side.

In some conglomerates the joints may be seen traversing the enclosed pebbles as well as the surrounding matrix. Large blocks of hard quartz are cut through by them as sharply as if they had been sliced in a lapidary's machine, and the same joints can be traced continuously through many yards of the rock. Such facts show that the agency to which the jointing of rocks was due must have operated with considerable force.[1] Further indication of movement is often supplied by the rubbed and striated surfaces of joints. These surfaces, termed *slickensides*, have evidently been ground against each other. They are often coated with hæmatite, calcite, chlorite, or other mineral, which has taken a cast of the striæ and then seems itself to be striated.

Joints form natural lines for the passage downward and upward of subterranean water. They likewise furnish an effective lodgment for surface water which, frozen by a lowering of temperature, expands into ice, and wedges off blocks of rock in the manner already described. As they serve, in conjunction with bedding, to divide stratified rocks into large quadrangular blocks, their effect on cliffs and other exposed masses of rock is seen in the apparently splintered, dislocated aspect so familiar in mountain scenery.

Occasionally a prismatic or columnar form of joints may be observed among stratified rocks. When this occurs among unaltered strata it is usually among those which have been chemically formed, as in gypsum, where, as observed by Mr Jukes in the Paris Basin, some beds are divided from top to bottom by vertical hexagonal prisms. A columnar structure has often been superinduced upon stratified rocks by contact with intrusive igneous masses. Sandstones, shale, and coal may be observed in this condition. The columns diverge perpendicularly to the surface of the injected and altering substance, so that when the later is vertical the columns are horizontal, or when it undulates the columns follow its curvatures. Beautiful examples of this character occur among the coal-seams of Ayrshire.

2. *In Crystalline (Igneous) Rocks.*—While in stratified rocks the divisional planes consist of lines of bedding and of joint, cutting each other usually at a high if not a right angle, in massive igneous rocks they include joints only; and as these do not as a rule present the same parallelism as lines of bedding, unstratified rocks, even though as full of joints, have not the same regularity of arrangement as in the stratified formations. Granite, for example, is traversed by two sets of chief or "master-joints," cutting each other somewhat obliquely. Their effect is to divide the rock into long quadrangular, rhomboidal, or even polygonal columns.

[1] See an interesting series of experiments by M. Daubrée (*Comptes Rendus*, lxxxvi., 1878) on the production of faults and joints.

But a third set may usually be noticed cutting across the columns, though less continuous and dominant than the others. When these transverse joints are few in number or occasionally absent, columns many feet in length can be quarried out entire. Such monoliths have been from early times employed in the construction of obelisks and pillars.

In rocks of finer grain than granite, such as many diorites and dolerites, the numerous perpendicular joints give the rock a prismatic character. The prisms however are unequal in dimensions, as well as in the number and proportions of their sides, a frequent diameter being 2 or 3 feet, though they may sometimes be observed three times thicker, and extending up the face of a cliff for 300 or 400 feet. It is by means of joints that precipitous faces of rock are produced and retained, for, as in the case of those in stratified masses, they serve as openings into which

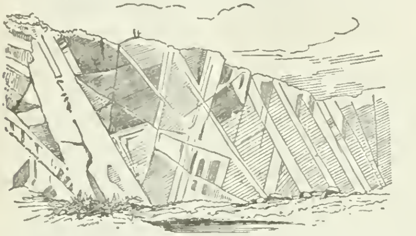

Fig. 16.—Joints in granite, Killiney Hill, Dublin. (G. V. Du Noyer.)

frost drives every year its wedges of ice, whereby huge slices are stripped off. They likewise give rise to the formation of those fantastic pinnacles and fretted buttresses so generally to be observed among igneous rocks in which they occur.

But undoubtedly the most striking series of joints to be found among igneous rocks is in the regularly columnar, or as it is often called, basaltic structure. This structure has been already (*ante*, p. 249) described in connexion with modern volcanic rocks. It may be met with in rocks of all ages. It is as well displayed among the felsites of the Lower Old Red Sandstone, and the basalts of the Carboniferous Limestone in central Scotland, as among the Tertiary lavas of Auvergne or the Vivarais.

3. *In Foliated Rocks.*—The schists likewise possess their joints, which approximate in character to those among the massive igneous rocks, but they are on the whole less distinct and continuous, while their effect in dividing the rocks into oblong masses is considerably modified by the transverse lines of foliation. These lines play somewhat the same part as those of stratification do among the stratified rocks, though with less definiteness and precision.

III. Inclination of Rocks.

The most casual observation is sufficient to satisfy us that the rocks now visible at the earth's surface are seldom in their original position. We meet with sandstones and conglomerates composed of water-worn particles, yet forming the angular scarps of lofty mountains; shales and clays full of the remains of fresh-water shells and land-plants, yet covered by limestones made up of marine organisms, and these limestones rising into great ranges of hills, or undulating into fertile valleys, and passing under the streets of busy towns. Such facts, now familiar to every reader, and even to many observers who know little or nothing of systematic geology, point unmistakably to the conclusion that the rocks have in many cases been formed under water, sometimes in lakes, more frequently in the sea, and that they have been elevated into land.

But examination discloses other and not less convincing evidence of movement. Judging from what takes place at the present time on the bottoms of lakes and of the sea, we confidently infer that when the strata now constituting so much of the solid framework of the land were formed, they were laid down either horizontally or at least at low angles. When, therefore, we find them inclined at all angles, and even standing on end, we conclude that they have been disturbed. Over wide spaces they have been upraised bodily with little alteration of their original horizontality; but in most places some departure from that original position has been effected.

The inclination thus given to rocks is termed their dip. Its amount is expressed in degrees measured from the plane of the horizon. Thus a set of rocks half-way between the horizontal and vertical position would be said to dip at an angle of 45°, while if vertical they would be marked with the angle of 90°. The edges of strata, where they come up to the surface, are termed their *outcrop* or *basset.* When they *crop out*, that is, rise to the surface, along a perfectly level piece of ground, the outcrop runs at a right angle to the dip. But any inequalities of the surface, such as valleys, ravines, hills, and ridges will cause the outcrop to describe a circuitous course, even though the dip should remain perfectly steady all the while. If a line of precipitous gorge should run directly with the dip, the outcrop will there be coincident with the dip. The occurrence of a

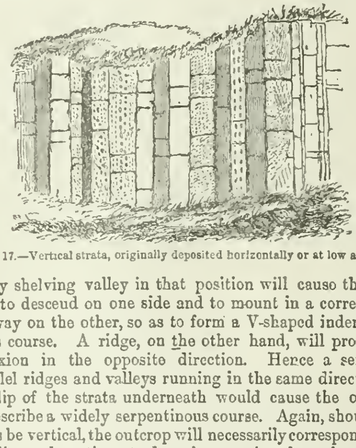

Fig. 17.—Vertical strata, originally deposited horizontally or at low angles.

gently shelving valley in that position will cause the outcrop to descend on one side and to mount in a corresponding way on the other, so as to form a V-shaped indentation in its course. A ridge, on the other hand, will produce a deflexion in the opposite direction. Hence a series of parallel ridges and valleys running in the same direction as the dip of the strata underneath would cause the outcrop to describe a widely serpentinous course. Again, should the rocks be vertical, the outcrop will necessarily correspond with the dip, and continue to do so irrespective altogether of any irregularities of the ground. The lower therefore the angle of inclination the greater is the effect of surface inequalities upon the line of outcrop; the higher the angle the less is that influence, till when the beds stand on end it ceases.

A line drawn at a right angle to the dip is called the *strike* of the rocks. From what has just been said this line must coincide with outcrop when the surface of the ground is quite level, and also when the beds are vertical. At all other times they are not strictly coincident, but the outcrop wanders to and fro across the strike according to the changes in the angle of inclination and in the form of the ground. The strike may be a straight line or may curve rapidly in every direction, according to the behaviour of the dip. If, for instance, a set of beds dips for half a mile continuously to the north, the strike will run for that distance as a straight east and west line. If the dip gradually changes to north-west and west, and then by south-west to south, it is obvious that the strike must curve round by north-east, north, and north-west till it once more becomes parallel with its former course. Both of the parallel lines of strike run in an east-and-west direction, but in the one the dip is to the south, and in the other to the north.

The strike may be conceived as always a level line on the plane of the horizon, so that no matter how much the ground may undulate, or the outcrop may vary, or the dip may change, the strike will remain level. Hence in mining operations it is commonly spoken of as the *level-course* or *level-bearing*. A level or underground road-way, driven through a coal-seam at right angles to the dip, will undulate in its course if the dip changes in direction, but it may be made perfectly level and kept so throughout a whole coal-field so long as it is not interfered with by any dislocations or other disturbances of the regularity of the rocks.

The accompanying figures (figs. 18 and 19) will serve to show some of these terms as expressed on maps and

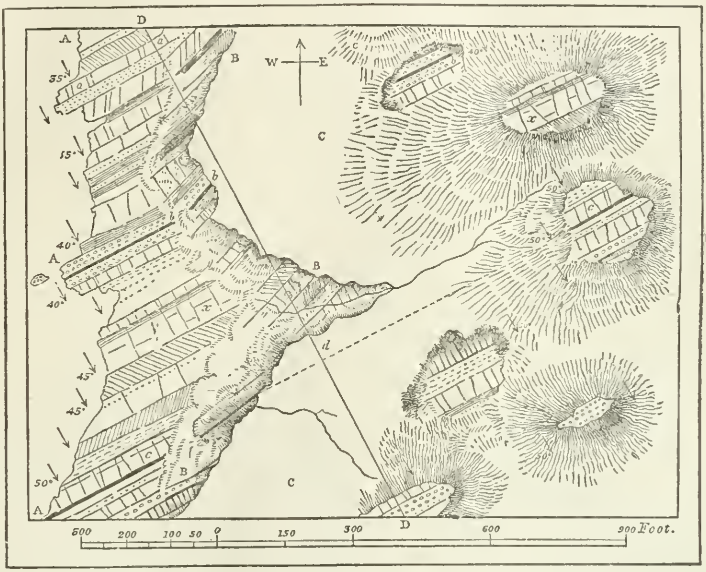

FIG. 18.—Geological map of a portion of a rocky coast-line, and the country inland. (J. B. Jukes.)

sections. Fig. 18 represents a geological map in which a series of strata dips in a south-south-easterly direction (S. 28° E.). The angle of inclination increases from 35° at the northern to 50° at the southern end of the beach. On the flat shore (AA) outcrop and strike coincide, but along the inner margin, where the ground ascends in a line or cliff (BB) to the inland country (CC), the outcrop is seen to be deflected a little so as to cross the plateau along a slightly more northerly line than on the beach. A section drawn at a right angle to the strike along the line DD would show the structure represented in fig. 19. Such a section, expressing graphically the result of careful measurement in the field, would give not only the order of succession of beds at the surface, but their actual depth at any point beneath it. Thus a bore or shaft sunk at the point marked *d* on the map would have to pass through rather more than 425 feet of rock before reaching the stratum *b*. The total thickness of rock measured at right angles to the dip in fig. 19 is somewhat more than 850 feet. These various strata, if restored to their original position, would lie one over the other to that depth. If they were on end they would occupy exactly that breadth of ground. But

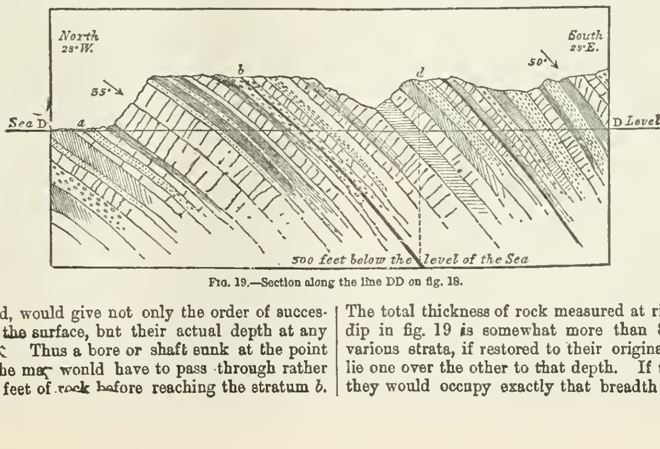

FIG. 19.—Section along the line DD on fig. 18.

the inclined position of strata makes them cover more horizontal space; in the present instance it increases that space to 1200 feet.

A convenient rule was given many years ago by the late Mr Charles Maclaren of Edinburgh for estimating the thickness of strata inclined at angles of less than 45°. The real thickness of a mass of inclined strata is $\frac{1}{12}$th of its apparent thickness for every 5° of dip. Thus if a set of beds dip steadily in one direction at 5° for a horizontal space of 1200 feet measured across the strike, their actual thickness will be $\frac{1}{12}$th or 100 feet. If the dip be 15°, the true thickness will be $\frac{3}{12}$ths or 400 feet, and so on.

IV. Curvatures of Rocks.

A little reflexion will show that though, so far as regards the trifling portions of the rocks visible at the surface, we might regard the inclined surfaces of the strata as parts of straight lines, they must nevertheless be parts of large curves. Take, for example, the section given in fig. 19. At the north end of that section we observe the beds to plunge one after another into the earth at an angle of 35°. By degrees the inclination increases until it reaches 50°. As there is no dislocation or abrupt change of angle, but a gradual transition, it is evident that the beds at the north end cannot proceed indefinitely downward at the same angle which they have at the surface, but must bend round to accommodate themselves to the higher inclination which sets in southwards. By prolonging the lines of the beds for some way beneath the sea-level, we can show graphically the nature of the curve. In every instance therefore where, in walking over the surface, we traverse a series of strata which gradually, and without dislocations, increase or diminish in inclination, we cross part of a great curvature in the strata of the earth's crust.

Such foldings, however, can often be distinctly seen, either on some cliff or coast-line, or in the traverse of a piece of hilly or mountainous ground. The observer cannot long continue his researches in the field without discovering that the rocks of the earth's crust have been almost everywhere thrown into curves, usually so broad and gentle as to escape observation except when specially looked for. The outcrop of beds at the surface is commonly the truncation of these curves. The strata must once have risen above the present surface, and in many cases may be found descending to the surface again with a contrary dip, the intervening portion of the undulation having been worn away.

If then the inclination of rocks is so closely connected with their curvature, a corresponding relation must hold between their strike and curvature. In fact, the prevalent strike of a region is determined by the direction of the axes of the great folds into which the rocks have been thrown. If the curves are gentle and inconstant there will be a corresponding variation in the strike. But should the rocks be strongly plicated, there will necessarily be the most thorough coincidence between the strike and the direction of the plication.

The curvature occasionally shows itself among horizontal or gently inclined strata in the form of an abrupt inclination, and then an immediate resumption of the previous flat or sloping character. The strata are thus bent up and continue on the other side of the tilt at a higher level. Such bends are called *monoclines* or *monoclinal folds*, because they present only one fold, or one half of a fold, instead of the two which we see in an arch or trough. The most notable instance of this structure in Britain is that of the Isle of Wight, of which a section is given in fig. 20. The Cretaceous rocks on the south side of the island rapidly rise in inclination till they become nearly vertical. The Lower Tertiary strata follow with a similar steep dip, but rapidly flatten down towards the north coast. Some

Fig. 20.—Section of the Isle of Wight—a monoclinal curve. *a*, Chalk; *b*, Woolwich and Reading beds; *c*, London clay; *d*, Bagshot series; *e*, Headon series; *f*, *g*, Osborne and Bembridge series.

remarkable cases of the same structure have been brought to light by Mr J. W. Powell in his survey of the Colorado region.

It much more frequently happens that the strata have been bent into arches and troughs, so that they can be seen dipping under the surface on one side of the axis of a fold, and rising up again on the other side. Where they dip away from the axis of movement the structure is termed an *anticline* or *anticlinal fold*; where they dip towards the

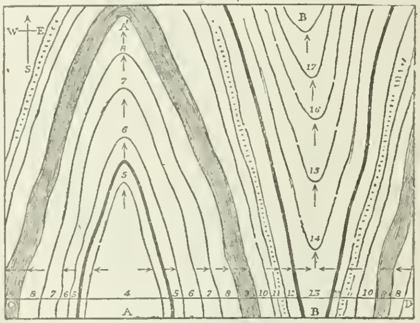

Fig. 21.—Plan of anticlinal and synclinal folds.

axis, it is a *syncline* or *synclinal fold*. The diagram in fig. 21 may be taken to represent a series of strata (1–17) thrown into an anticline (AA′) and syncline (BB′). A section drawn across these folds in the line CD would show

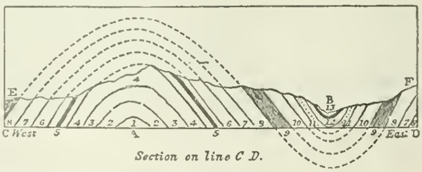

Fig. 22.—Section of anticlinal and synclinal folds on the line CD (fig. 21).

the structure given in fig. 22. Here we see that, at the part of the anticlinal axis (A) where the section crosses, bed No. 4 forms the crown of the arch, Nos. 1, 2, and 3 being concealed beneath it. On the east side of the axis the strata follow each other in regular succession as far as No. 13, which, instead of passing here under the next in order, turns up with a contrary dip and forms the centre of a trough or syncline (B). From underneath No. 13 on the east side, the same beds rise to the surface which passed beneath it on the west side. The particular bed marked EF has been entirely removed by denudation from the top of the anticline, and is buried deep beneath the centre of the syncline.

Such foldings of strata must always die out unless they are abruptly terminated by dislocations. In the cases given in fig. 21, both the arch and trough are represented as diminishing, the former towards the north, the latter towards the south. The observer in passing northwards along the axis of that anticline finds himself getting into progressively higher strata, as the fold sinks down. On the other hand, in advancing southwards along the synclinal axis, he loses stratum after stratum and gets into lower portions of the series. When a fold diminishes in this way it is said to "nose out." In fig. 21 there is obviously a general inclination of the beds towards the north, besides the outward dip from the anticline and the inward dip from the syncline. Hence the anticline noses out to the north and the syncline to the south.

It occasionally happens that the maximum movement either of upheaval or subsidence has taken place not along a line of axis but at some one point. Hence arise, on the one hand, dome-shaped elevations of strata where the dip is outward from a centre (quaquaversal), round which the beds are disposed in successive parallel layers or rings, and, on the other hand, circular basin-shaped depressions, towards the centre of which there is a general inclination of the rocks.

So great has been the compression to which rocks have been subjected during the process of curvature that the folds may often be found inverted. This has taken place

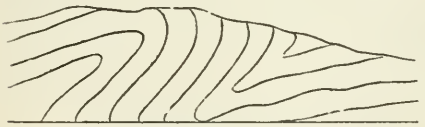

FIG. 23.—Section of inclined axes, showing consequent inversion of strata.

abundantly in regions of great plication. The Silurian uplands of the south of Scotland, for instance, have the arches and troughs tilted in one direction for miles together, so that in one half of each of them the strata lie bottom upwards. It is in large mountain-chains, however, that inversion can be seen on the grandest scale. The Alps furnish numerous striking illustrations. On the north side of that chain the older Tertiary rocks have been so completely turned over for many miles that the lowest beds now form the tops of the hills, while the highest lie deep below them. Individual mountains, such as the Glärnisch, present stupendous examples of inversion, great groups of strata being folded over and over above each other as we might fold carpets.

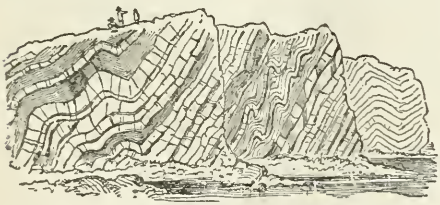

FIG. 24.—Curved and contorted rocks, near Old Head of Kinsale. (Du Noyer.)

Where curvature has been carried so far, we may nearly always discover localities at which it has been so intensified that the strata have been corrugated and crumpled till it becomes almost impossible to follow out any particular bed through the disturbance. On a small scale instances of such extreme contortion may now and then be found at landslips, where fissile shales have been pressed forward by advancing heavy masses of more solid rock. But it is of course among the more plicated parts of mountain-chains that the structure receives it best illustrations. Few travellers who have passed the upper end of the Lake of Lucerne can have failed to notice the remarkable cliffs of contorted rocks near Flnelen. But innumerable examples of equal or even superior grandeur may be observed among the more precipitous valleys of the Swiss Alps. No more impressive testimony could be given to the potency of the force by which mountains were upheaved.

V. DISLOCATIONS OF ROCKS.

The movements which the crust of the earth has undergone have not only folded and corrugated the rocks, but have fractured them in all directions. These dislocations may be either simple *fissures*, that is, rents without any vertical displacement of the mass on either side, or *faults*, that is, rents where one side has been pushed up or has sunk down. It is not always possible in a shattered rock to discriminate between joints and true fissures. The joints indeed have sometimes served as lines along which fissuring has taken place. It is common to meet with traces of friction along the walls of fissures even when no proof of actual vertical displacement can be gleaned. The rock is more or less shattered on either side, and the contiguous faces present numerous slickensided surfaces. Mineral deposits may also commonly be observed encrusting the cheeks of a fissure, or filling up, together with broken fragments of rock, the space between the two walls.

In a large proportion of cases, however, there has been displacement as well as fracture, and the rents have become faults as well as fissures. Faults on a small scale are sometimes sharply-defined lines, as if the rocks had been

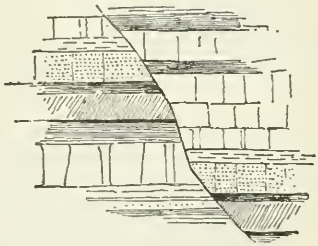

FIG. 25.—Section of clean-cut fault.

sliced through and fitted together again after being shifted (fig. 25). In such cases, however, the harder portions of the dislocated rocks will usually be found slickensided. More frequently some disturbance has occurred on one or both sides of the fault. Sometimes in a series of strata the beds on the side which has been pushed up are bent down

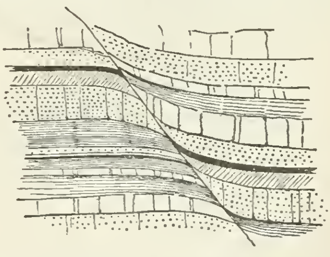

FIG. 26.—Section of strata, bent at a line of fault.

against the fault, while those on the opposite side are bent up (fig. 26). Most commonly the rocks on both sides are considerably broken, jumbled, and crumpled, so that the line of fracture is marked by a belt or wall-like mass of fragmentary rock. Where a dislocation has occurred through materials of very unequal hardness, such as solid limestone bands and soft shales, or where its course has been undulating, the relative shifting of the two sides has occasionally brought opposite prominences together so as to leave wider interspaces, as in fig. 27. The actual breadth

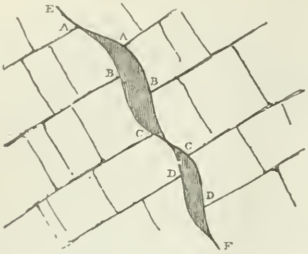

FIG. 27.—Section of fault, showing the alternate expansions and contractions due to the shifting of one side of a sinuous fissure.

of a fault may vary from a mere chink into which the point of a knife could hardly be inserted up to a band of broken rock many yards wide. But in these latter cases we may usually suspect that so great a breadth of fractured materials has been produced not by a single fault but by a series of closely adjoining and parallel faults.

Faults are sometimes vertical, but are generally inclined. The largest faults, that is, those which have the greatest

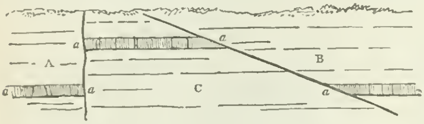

FIG. 28.—Section of a vertical and inclined fault.

vertical displacement, slope at high angles, while those of only a few feet or yards may be inclined as low as 18° or 20°. The inclination of a fault from the vertical is called its *hade*. In fig. 28, for example, the fault between A and C being vertical has no hade, but that between C and B hades at an angle of 70° from the vertical to the right hand. The amount of displacement is represented as the same in both instances, so that the level of the bed *a* is raised between the two faults at C above the uniform horizon which it retains beyond them.

That faults are vertical displacements of parts of the earth's crust is most clearly shown when they traverse stratified rocks, for the regular lines of bedding and the originally flat position of these rocks afford a measure of the disturbance. Accordingly we may consider here the effects of faults as they traverse (1) horizontal, (2) inclined, or (3) undulating strata.

1. In the above section (fig. 28) two faults are supposed to traverse a set of horizontal strata, and to displace them in opposite directions. Hence the portion between them appears as if it had been pushed up, or as if the part on either side had slipped down. The amount of vertical displacement is measured from the end of any given stratum, say *a*, on one side of the fault, to its corresponding end on the other side. Suppose, for example, that the black band in fig. 29 represents a known stratum such as a seam of coal, which, having been explored in underground operations, is known to be cut by a fault at a depth of a hundred yards below the surface at A, and to lie 200 yards deep on the other side of the fault below B. The amount of displacement is the vertical distance between the two severed ends *a* and *b*. This is termed the *throw* of a fault. From these two sections (figs. 28 and 29) we see that the horizontal distance to which the two ends of a faulted stratum may be separated does not depend upon the amount of throw but upon the angle of the hade. In the left-hand fault in fig. 28 there is no hade,

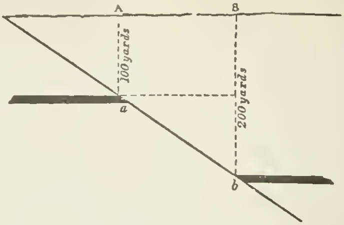

FIG. 29.—Measurement of the throw of a fault.

for the fault is vertical; consequently there is no lateral displacement. In fig. 29, however, where the fault hades considerably, there is a lateral shift of the bed, the end *a* being 150 yards to the left of *b*. In this example the lateral shift is half as much again as the vertical. It is obvious that a fault of this kind must seriously affect the value of a coal-field; for while the coal-seam might be worked up to *a* on the one side and to *b* on the other, there would be a space of 150 yards of barren ground between these two points where the seam never could be found. The lower the angle of hade the greater the breadth of such barren ground. Hence the more nearly vertical the lines of fault, the better for the coal-fields.

In the vast majority of cases faults hade in the direction of downthrow, in other words, they slope away from the side which has risen. Consequently the mere inspection of a fault in any natural or artificial section suffices in most cases to show which side has been elevated. In mining operations the knowledge of this rule is invaluable, for it decides whether a coal seam, dislocated by a fault, is to be sought for by going up or down. In fig. 29, for example, a miner working from the right and meeting with the fault at *b*, would know from its hading towards him that he must ascend to find the coal. On the other hand were he to work from the left and catch the fault at *a*, he would see that it would be necessary to descend. According to this rule a normal fault never brings one part of a bed below another part, so as to be capable of being pierced twice by the same vertical shaft. Exceptional cases, however, where the hade is reversed, do occasionally appear. In fig. 30 a series of strata, 1 to 11, are represented as folded in an inverted anticline, and broken through by a fault along the axis, the portion on the right side having been pushed up.

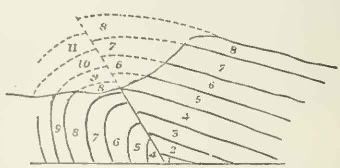

FIG. 30.—Inverted anticline and reversed fault.

The effect of the movement has been to make the ends of the beds on that side overlie higher beds on the other side. A shaft would thus pierce the same stratum twice. Instances of reversed faults are chiefly met with in much disturbed districts, such as mountain chains, where the rocks have been affected by great undulations and corrugations. But instances on a small scale, like that in fig. 31, may now and then be encountered even in lowland districts, where no great disturbance has taken place.

2. Faults traversing inclined strata usually group them-

selves into two series, one running in the same general direction as the dip of the strata, the other approximating

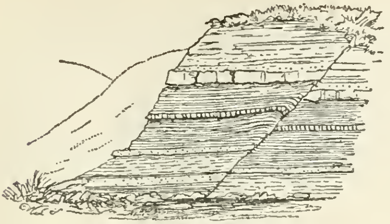

Fig. 31.—Reversed fault, Liddesdale.

to the trend of the strike. They are accordingly classified as *dip-faults* and *strike-faults.* They are not always to be sharply marked off from each other, for the dip-faults will often be observed to deviate considerably from the normal direction of dip, and the strike-faults from the prevalent strike, so that in such cases they pass into each other.

A dip-fault produces at the surface the effect of a lateral shift of the strata. This effect increases in proportion as the angle of dip lessens. It ceases altogether when the beds are vertical. Fig. 32 may be taken as a plan of a dip-fault

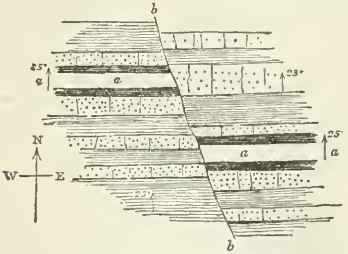

Fig. 32.—Plan of strata cut by a dip-fault.

traversing a series of strata which dip northwards at 25°. The beds on the east side look as if they had been pushed horizontally southwards. That this apparent horizontal displacement is due really to a vertical movement, and to the subsequent planing down of the surface by denuding agents, will be clear if we consider what must be the effect of the vertical ascent or descent of the inclined beds on one side of a dislocation. Take the bed *a* in fig. 32, and suppose it to be still unbroken by the fault. It will then run in a straight east and west line. When the fault takes place, the part on the west side is pushed up, or, what comes to the same, that on the east side is let down. A horizontal plane cutting the dislocated stratum will show the portion on the west side lying to the north of that on the east side of the fracture. The effect of denudation has usually been practically to produce such a plane, and thus to exhibit an apparently lateral shift. This surface displacement has been termed the *heave* of a fault. Its dependence upon the angle of dip of the strata may be seen by a comparison of figs. 33 and 34. In the former figure the bed *a*, once prolonged above the present surface (marked by the horizontal line), is represented as having dropped from *db* to *ec*, the angle of inclination being 25°. The heave amounts to the horizontal distance between *b* and *e*. But if the angle should rise to 60°, as in fig. 34, though the amount of throw or vertical displacement remains the same, we see that the heave or horizontal shift diminishes to about a quarter of what it is in fig. 33. This diminution would continue with every increase of inclination in the strata till among vertical beds there would be no heave at all.

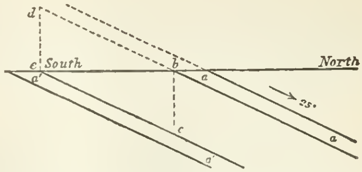

Fig. 33.—Section along the line of a fault in strata dipping at 25°.

Strike-faults, where they exactly coincide with the strike, may sometimes remove the outcrop of some strata by never

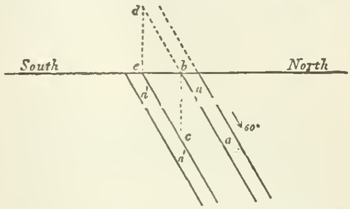

Fig. 34.—Section along the line of a fault in strata dipping at 60°.

allowing them to reach the surface. Fig. 35 shows a plan of one of these faults (FF), having a downthrow to the north. In crossing the ground from north to south we pass successively over the edges of all the beds, except Nos. 3

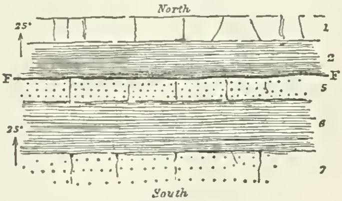

Fig. 35.—Plan of a strike-fault.

and 4, which are cut out by the fault as shown in fig. 36, which is a section drawn across the ground at a right angle to the strike. It seldom happens, however, that such strict coincidence between faults and strike continues for

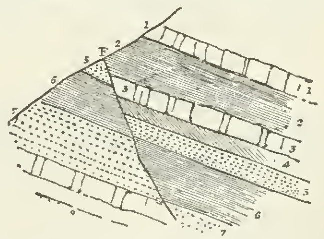

Fig. 36.—Section across the plan, fig. 35.

more than a short distance. The dip is apt to vary a little even among comparatively undisturbed strata, and every such variation causes the strike to undulate and thus to be cut more or less obliquely by the line of dislocation, which may nevertheless run quite straight. Moreover, any increase or diminution in the throw of a strike-fault will of course have the effect of bringing the dislocated ends of the beds against the line of dislocation. In fig. 37, for instance,

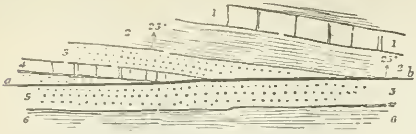

FIG. 37.—Plan of strata traversed by a diminishing strike-fault.

stance, which represents in plan another strike-fault, we see that the amount of throw is diminishing towards the left so as to allow lower beds to successively appear, until, at the extreme left side of the ground, the fault merely brings one part of the same bed (No. 5) against another part.

3. Their effects become more complicated where faults traverse undulating and contorted strata. Sometimes we can distinctly trace an undulation as the result of a fault. In the flat limestone beds shown in fig. 38, for example,

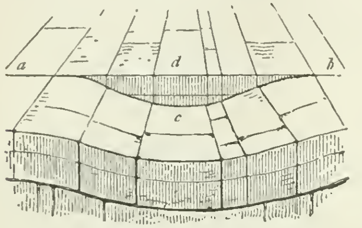

FIG. 38.—Curving of strata on one side of a fault.

there can be no doubt that the gentle depression from *d* to *c* would not have taken place but for the existence of the fault *ab*. But in all countries where the rocks have been thrown into folds and corrugations these structures are traversed by faults. It then often happens that the same fault appears to be alternately a downthrow on opposite sides. Let us suppose a series of gently rolling strata to be cut by a transverse fault as in the diagram in fig. 39.

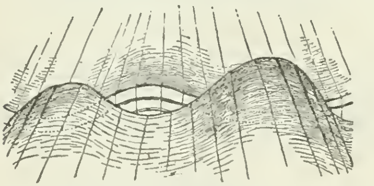

FIG. 39.—Diagram of gently undulating strata cut by a fault, with alternate throw in opposite directions.

At each of the two ridges on the near side of the fault the effect is an upthrow, while in the intervening valley it is a downthrow. On the opposite side of the fault each of these effects is reversed. It rarely happens, however, that a fault makes any such visible crack at the surface. The rocks have all been worn down so much that it is usually only by careful examination of their dip that the existence of faults can be determined.

The influence of faults upon curvatures may be illustrated by a plan and sections of a dislocated anticline and syncline, which will also show clearly how the apparently lateral displacement of outcrop produced by dip-faults is due to vertical movement. Fig. 40 represents a plan of strata thrown into an anticlinal fold AA and a synclinal fold SS, and traversed by a fault FF, which is an upthrow to the left hand. We have seen that a dip-fault always shifts the outcrop to the dip on the upthrow side, and this will be

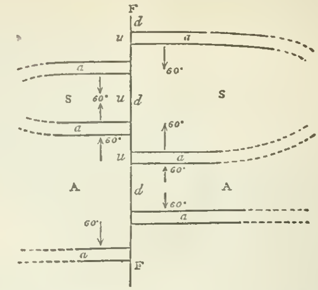

FIG. 40.—An anticline (A) and syncline (S), dislocated by a fault.

observed to be the case here. Beginning at the upper side of the diagram, which may be called north, we notice that the bed *aa*, dipping towards the lower side or south at 60°, is truncated by the fault at *u*, and that the portion on the upthrow side is shifted forwards or southward. Crossing the syncline we meet with the same bed, and as the upthrow of the fault still continues on the same side we must go some way southwards on the downthrow side before we meet with its continuation. On the southern slope of the anticline the same bed once more appears, and again is

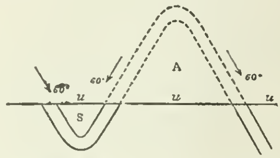

FIG. 41.—Section along the upcast side of the fault in fig. 40.

shifted forwards as before. A section along the left or upcast side (*uu*) of the fault would give the structure represented in fig. 41: while one along the downcast side

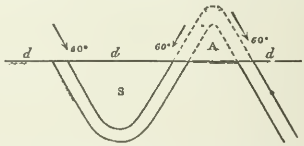

FIG. 42.—Section along the downcast side of same fault.

(*dd*) would be as in fig. 42. These two sections clearly prove that the shifting of the outcrops at the surface can

FIG. 43.—Plan of single fault.

be simply explained by a mere vertical movement. They also show that faults which cross anticlinal and synclinal folds narrow the anticlines but widen the synclines on the downthrow side, while they widen the anticlines and narrow the synclines on the upthrow side.

Dislocation may take place either by a single fault or as the combined effects of two or more. Where there is only one fault, as in fig. 43, one of its sides may be pushed up or let down, or there may be a simultaneous opposite movement on either side. In such cases, there must be a gradual dying out of the dislocation towards either end; and there will usually be one or more points where the displacement has reached a maximum. Sometimes, as shown in fig. 44, a fault with a considerable maximum throw (35 feet, yards, or fathoms, in the drawing) splits into minor faults at the terminations. Examples of this kind occur not infrequently in coal-work-

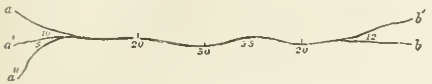

FIG. 44.—Plan of a fault splitting into minor faults.

ings. In other cases the offshoots take place along the line of the main fissure (fig. 45). Exceedingly complicated

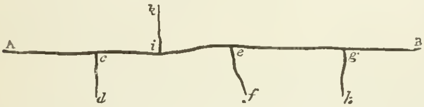

FIG. 45.—Plan of main fault, with branches.

examples occur in some coal-fields, where the connected faults become so numerous that no one of them deserves to be called the main or leading dislocation.

The subsidence or elevation of a large mass or block of rock has more usually taken place by a combination of faults. If we suppose two fissures to meet at a point, as at b in fig. 46, and to die out respectively at a and c, the

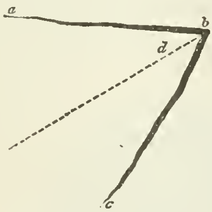

FIG. 46.—Plan of two fissures.

intervening triangular mass cd may be moved upwards or downwards, or it may remain stationary while the surrounding ground is displaced. The maximum displacement in such an instance would be sought for towards b; in the direction e there would be no displacement at all.

It often happens that, by a succession of parallel and adjoining faults, a series of strata is so dislocated that a given stratum which may be near the surface on one side is carried down by a series of steps to some distance below. Excellent examples of these *step-faults* (fig. 47) are to be

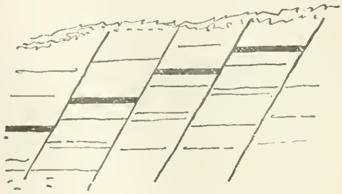

FIG. 47.—Section of strata cut by step-faults.

seen in the coal-fields on both sides of the upper part of the estuary of the Forth. Instead, however, of having the same downthrow, parallel faults frequently show a movement in opposite directions. If the mass of rock between them has subsided relatively to the surrounding ground, they are *trough-faults* (fig. 48). They enclose wedge-shaped masses, of which the apices, formed by the junction of two

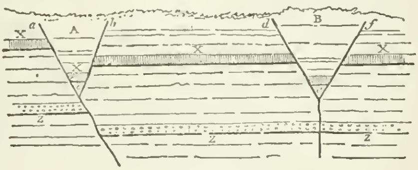

FIG. 48.—Trough-faults.

faults, point downwards. In the accompanying section (fig. 49) of a portion of the thick coal of South Staffordshire, drawn to scale by Mr Johnson of Dudley (*Records of Geol. Survey*, vol. i. part 2, p. 313), the commencement of a trough-fault is shown in the centre of the figure.

The late Mr Jukes carefully described this interesting section, and showed that the coal must once have been more arched than now, and that on the cessation of the elevatory process the fractured pieces adjusted themselves to their new position by means of dislocations. The mass of higher beds (A) driven as a wedge into the coal, has hindered the bed from regaining its horizontality, and at the same time has caused the adjacent parts of the coal (BB) to be so crushed by the enormous pressure as to have been reduced to "a paste of coal dust and very small coal" (*Memoir on South Staffordshire Coal-field*, 2d ed., p. 194).

It will be observed that the hade of the faults is towards

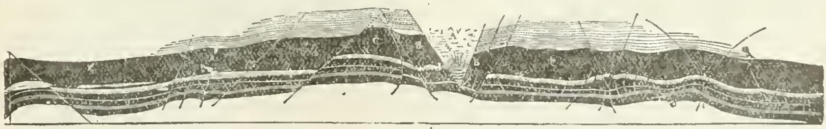

FIG. 49.—Section of a faulted part of the thick coal of South Staffordshire.

the downthrow side, and that the wedged-shaped masses with broad bottoms have risen, while those with narrow bottoms and broad tops have sunk.

It has been already (*ante*, p. 261) pointed out that faults are traceable to the effects of elevation. The general hade or inclination of faults towards the side of downthrow was satisfactorily explained by the late Mr Jukes in the last edition of the present work.

"Suppose," he says, "that in diagram fig. 50 we have a portion of the earth's crust, of which AB is the surface, and CD a plane acted on by some widespread force of expansion tending to bulge upwards the part ABCD. If then a fracture takes place along the line EF, it is obvious that the expanding force will, on the side of AC, have the widest base CF to act upon, while it will have a proportionately less mass to move in the part AECF, which grows gradually smaller towards the surface, than on the other side of the fault, where, with the smaller base FD, the mass FDBE continually grows larger towards the surface. The mass G will consequently be much more easily raised into the position AcC*f*, than the mass H into the position D*f*′B*e*′, the elevation of which could hardly take

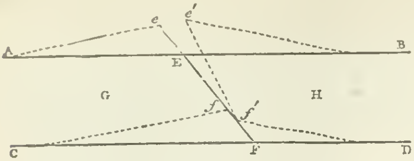

Fig. 50.

place without leaving a great open gap along the line of fault between FE and *f*′*e*′, and, moreover, without leaving the projecting piece *e*′ overhanging without any support.

"This is yet more clearly perceptible if we suppose two such fissures, as in fig. 51, inclining towards each other since, if we sup-

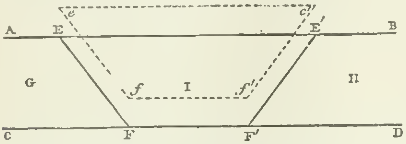

Fig. 51.

pose the included piece I to be elevated into the position indicated by the dotted lines, it becomes utterly unsupported unless we suppose huge dykes or ejections of igneous rock to issue out along each fault. But this would remove the case from the class of fractures we are at present considering."

Trough-faults offer at first some difficulty. In fig. 48, for example, it is evident that in both the wedge-shaped masses (A and B) there has been subsidence. The bed X is cut by four faults. In the space B two of these faults hade towards each other, and as they have the same amount of throw the level of the bed remains unchanged on either side. In the other trough, however, the fault *a* has a throw twice as much as that of *b* which it completely cuts off. The two faults *d* and *f* neutralize each other, and are connected with a vertical fissure without any throw. The fault *a* however descends with its persistent hade and dislocates the bed Z and the other strata below. Mr Jukes proposed the following satisfactory explanation of this kind of structure.

"Suppose the beds AA, BB, &c., (fig. 52) to have been formerly in a state of tension, arising from the bulging tendency of an

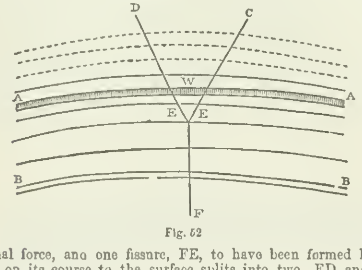

Fig. 52

internal force, and one fissure, FE, to have been formed below, which on its course to the surface splits into two, ED and EC. If the elevatory force were then continued, the wedge-like piece of rock W between these two fissures, being unsupported, as the rocks on each side separated, would settle down into the gap as in fig. 53. If the elevatory action were greater near the fissure than farther from it, the single fissure below would have a tendency to gape upwards, and swallow down the wedge, so that eventually this might settle down, and become fixed at a point much below its previous relative position. Considerable friction and destruction of the rocks, so as to cut off the corner *gh* (fig. 53) on either side, would probably take place along the sides of the fissures, and thus widen the gap, and allow the wedge-shaped piece W to settle down still further.

"When the forces of elevation were withdrawn, the rocks would doubtless have a tendency to settle down again, but these newly-

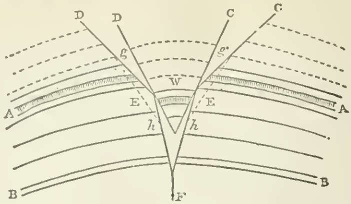

Fig. 53.

included wedge-shaped, and other masses, would no longer fit into the old spaces, so that great compression and great *lateral* pressure might then take place."

In fig. 49 an excellent illustration is afforded of how an arched mass of strata has been faulted, and how trough-faults have been formed.

VI.—Cleavage.

There is yet another system of divisional planes, termed *cleavage*, by which rocks are sometimes traversed. When this structure is well developed it divides a rock into parallel laminæ, which run at a high angle quite independently of stratification or any other divisional planes. It is most perfect in proportion to the fineness of grain of the material in which it occurs. Hence fine argillaceous rocks show it admirably. An ordinary roofing slate may be taken as an illustration of a cleaved rock; its opposite surfaces are *cleavage-planes*, while the opposite faces of a slab of shale would be stratification-planes. Though most perfectly exhibited by clay-slate, cleavage occurs in other rocks, even in old lavas and tuffs, limestones, and sandstones or greywackes; but as the texture increases in coarseness the cleavage lines become more undecided and further apart. The structure may be observed to vary in distinctness in the same face of rock, being well-defined among bands of slate, but becoming faint or even disappearing in intercalated beds of sandstone or grit.

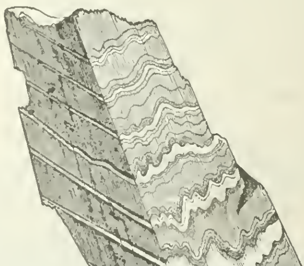

Fig. 54.—Sketch (by the late Mr Du Noyer) of a block of variegated slate from Devil's Glen, county Wicklow. The crumpled bands mark the bedding, and the fine perpendicular striæ in front are the cleavage planes; the fine lines on the darkened side merely represent *shadow*, and must not be taken for planes of division in the rock. It will be observed that the cleavage planes do not pass through the white bands.

The direction of cleavage usually remains persistent over considerable regions, and, as was shown by Sedgwick, corresponds on the whole with the strike of the rocks. It is, however, independent of bedding. Among curved rocks the cleavage planes may be seen traversing the contortions without sensible deflexion from their normal direction, parallelism, and high angle. Mr Jukes pointed out that over the whole of the south of Ireland the trend of the cleavage seldom departs 10° from the normal direction E. 25° N., no matter what may be the differences in character and age of the rocks which it crosses. Some of the more obvious characters of cleavage are shown in fig. 54, which represents a block of cleaved variegated slate about 18 inches in height. The left side of the block which is in shadow is formed by a smooth cleavage plane, and the whole block might be split into laminæ parallel to that plane as shown by the cleavage lines in front. The lines of stratification are marked by the white and dark contorted bands, the axes of which evidently correspond nearly with the direction of the cleavage. These bands are commonly marked in nature by zones of different colour, and sometimes of texture. In the present instance the white bands are more sandy than the rest of the mass, and the cleavage-planes only partially enter them. This specimen is further interesting as it bears witness by its puckered bedding to the great lateral pressure in virtue of which, as we have already seen (*ante*, p. 261), the cleavage structure has been produced.

VII. Igneous Rocks as Part of the Structure of the Earth's Crust.

In this section we shall consider the part taken by igneous rocks in the architecture of the earth's crust. Their lithological differences having already been described in part ii., it is their larger features in the field that now require attention,—features which in some cases can be well illustrated by reference to the action of modern volcanoes, and in other cases bring before us parts of the economy of volcanoes which can never be reached in any recent cone. A study of the igneous rocks of former ages thus serves to augment our knowledge of volcanic action.

At the outset an obvious distinction must be drawn between those igneous masses which reached the surface and consolidated there, like modern lava streams or showers of ashes, and those which we must believe never found their way to the surface but consolidated at a greater or less depth beneath it. There must be the same division to be drawn in the case of every active volcano of the present day. But we can examine only the materials which reach the surface, and we can but speculate as to the nature and arrangement of what still lies underneath. In the revolutions to which the crust of the earth has been subjected, however, the subterranean continuations of volcanic sheets have often been laid bare, and not only so, but sections have been opened into the very heart of masses which, though molten and eruptive, seem never to have been directly connected with actual volcanic outbursts. All those subterranean intruded masses, which are now revealed at the surface only after the removal of the depth of rock which once covered them, may be grouped together into one division under the names *plutonic*, *intrusive*, or *subsequent*. On the other hand, all those which came up to the surface as ordinary volcanic rocks, whether molten or fragmental, and were consequently contemporaneously interstratified with the formations which happened to be in progress on the surface at the time, may be classed in a second group under the names *volcanic*, *interbedded*, or *contemporaneous*.

It is obvious of course that these are only relative terms. Every truly volcanic mass which, by being poured out as a lava-stream at the surface, came to be regularly interstratified with contemporaneous accumulations, must have been directly connected below with molten matter which did not reach the surface. One part of the total mass therefore would be included in the second group, while another portion, if ever exposed by geological revolutions, would be classed with the first group. Seldom, however, can the same masses which flowed out at the surface be traced directly to their original underground prolongations. It is evident that an intrusive rock, though necessarily subsequent in age to the rocks through which it has been thrust, need not be long subsequent. Its relative date can only be certainly affirmed with reference to the rocks through which it has broken. It may be older than other rocks through which it has not been intruded but which lie almost immediately above it. The probable geological date of its eruption must be decided by the evidence to be obtained from the grouping of the rocks all around. Its intrusive character can only certainly determine the limit of its antiquity. We know that it must be younger than the rocks it has invaded; how much younger must be otherwise determined. On the other hand, an interbedded or contemporaneous igneous rock has its date precisely fixed by the geological horizon on which it lies. A lava-bed or tuff intercalated among strata containing *Sphenopteris affinis*, *Lepidodendron veltheimianum*, *Leperditia*, and other associated fossils, would unequivocally prove the existence of volcanic action at the surface during the Lower Carboniferous period, and at that particular part of the period represented by the horizon occupied by the volcanic bed. An interbedded and an intrusive mass found on the same platform of strata would not necessarily be coeval. On the contrary, the latter, if clearly intruded along the horizon of the former, would necessarily be posterior in date. It will be understood then that the two groups have their respective limits determined solely by their relations to the rocks among which they may happen to lie.

The value of this classification for geological purposes is great. It enables the geologist to place and consider by themselves the granites, quartz-porphyries, and other crystalline masses which, though lying sometimes perhaps at the roots of ancient volcanoes, and therefore intimately connected with volcanic action, yet owe their special characters to their having consolidated under pressure at some depth within the earth's crust; while he arranges in another series the lavas and tuffs which, thrown out to the surface, bear the closest resemblance to the ejected materials from modern volcanoes. He is thus presented with the records of hypogene igneous action in the one group, and with those of superficial volcanic action in the other. He is furnished with a method of chronologically arranging the volcanic phenomena of past ages, and is thereby enabled to collect materials for a history of volcanic action over the globe.

In adopting this classification for unravelling the geological structure of a region where igneous rocks abound, the geologist will encounter instances where it may be difficult or impossible to decide in which group a particular mass of rock must be placed. He will bear in mind, however, that after all, such schemes of classification are proposed only for convenience in systematic work, and that there are no corresponding hard and fast lines in nature. He will recognize that all crystalline or glassy igneous rocks, whether the portion visible be interbedded or intrusive, must be intrusive at a greater or less depth from the surface. Every contemporaneous sheet has proceeded from some internal pipe or mass, so that though interbedded and contemporaneous with the strata at the top, it is intrusive in relation to the strata below. But we cannot always assert that an intrusive mass must have been connected with an outflowing interbedded sheet above.

Section I.—Plutonic, Intrusive, or Subsequent Igneous Rocks.

Under this section we have to consider the part played by igneous rocks which, either possessing a crystalline (sometimes glassy or felsitic) structure have been injected in a fluid or at least viscous condition into other rocks, or having been blown into fragments have consolidated in volcanic pipes. After some practice in the field the geologist learns to recognize these rocks, and to distinguish them from the similar masses which must be placed in the contemporaneous series. As a rule their crystalline texture is coarser than in that series; only in a few rare cases does a cellular or amygdaloidal character appear, and the fragmental accompaniments so characteristic of the contemporaneous sheet are only found in the actual vents of eruption. Granite, syenite, felsite, diorite, basalt, and agglomerate occur in this form.

The general law which has governed the intrusion of igneous rock within the earth's crust may be thus stated: every fluid mass impelled upwards by pressure from below, or by the expansion of its own imprisoned vapour, has sought egress along the line of least resistance. What that line was to be has depended in each case upon the structure of the terrestrial crust and the energy of eruption. In many instances it has been determined by an already existent dislocation; in others by the planes of stratification, or by the surface of junction of two unconformable formations, or by irregular cracks and rents, or by other more complex lines of weakness. Sometimes the intruded mass has actually fused and obliterated some of the rock which it has invaded, incorporating this portion into its own substance. The shape of the channel of escape has necessarily determined the form of the intrusive rock, as the mould regulates the form assumed by a mass of cast-iron. This offers a very convenient means of classifying the intrusive rocks. According to the shape of the mould in which they have solidified, they may be arranged as—(1) amorphous masses. (2) sheets, (3) veins and dykes, and (4) necks.

I. Amorphous Masses.—These consist chiefly of crystalline coarse-textured rocks. Granite and syenite are the most conspicuous, but there are to be included also various quartz-porphyries, felsites, diorites, &c. Where rocks occur in this form which also are found in sheets and dykes as well as contemporaneous beds, it is commonly observed that they are more coarsely crystalline in the form of amorphous masses than in any other. Doleritic rocks afford many examples of this characteristic.

Granitic Bosses.—It was once a firmly-held tenet that granite is the oldest of rocks, the foundation on which all other rocks have been laid down. This idea no doubt originated in the fact that granite is found rising from beneath gneiss, schist, and other crystalline masses which in their turn underlie very old stratified formations. The intrusive character of granite, shown by its numerous ramifying veins, proved it to be later than at least those rocks which it had invaded. Nevertheless the composition and structure of gneiss and mica-schist were believed to be best explained by supposing these rocks to have been derived from the waste of granite, and thus, though the existing intrusive granite had to be recognized as posterior in date, it was regarded as only a subsequent protrusion of the vast underlying granitic crust. In this way the idea of the primeval or fundamental nature of granite held its ground.

From what has already (*ante*, p. 258) been said regarding the fusion and consolidation of rocks, and the evidence supplied on this subject by granite itself, it will readily be understood that the first or original crust could hardly have been one of granite. That rock, so far as can be made out by careful microscopic examination, appears to have always consolidated under considerable pressure, and in the presence of superheated water and even of liquid carbonic acid—conditions which probably never obtained at the earth's immediate surface. The original crust may have been of a glassy character like some of the vitreous lavas; but whatever it was, no trace of it has ever been or is ever likely to be found.

The presence of granite at the existing surface must in all cases be due to the removal by denudation of the masses of rock under which it originally consolidated. The fact that, wherever extensive denudation of an ancient series of crystalline rocks has taken place, a subjacent granite nucleus is apt to appear does not prove that rock to be of a primeval origin. It shows, however, that the lower portions of crystalline rocks very generally assume a granitic type, and it suggests that if at any part of the earth we could bore deep enough into the crust we should probably come to a granitic layer. That this layer, even if general round the globe, is not always of the highest geological antiquity is abundantly clear from the fact that in many cases it can be proved to be of later date than fossiliferous formations the geological position of which is known; that is, the granitic layer has invaded these formations, rising up through them, and probably melting down portions of them in its progress. This is true not only of ancient Palæozoic but of other stratified rocks of various much more recent ages. So that we must conclude that granite does not belong exclusively to the earliest nor to any one geological period, but rather that it has been formed at various epochs, and may even be forming now, wherever the conditions required for its production have existed. As a matter of fact granite occurs much more frequently in association with older and therefore lower than with newer and higher rocks. But a little reflexion shows us that this must be the case. Granite having a deep-seated origin must rise through the lower and more ancient masses before it can reach the overlying more recent formations. But many protrusions of granite would doubtless never ascend beyond the lower rocks. Subsequent denudation would be needed to reveal these protrusions, and this very process would remove the later formations and at the same time any portions of the granite which might have reached them.

Granite frequently occurs in the central parts of mountain chains; sometimes it forms there a kind of core round which the various gneisses, schists, and other crystalline rocks are arranged with more or less irregularity. More frequently it appears in large eruptive bosses which traverse indifferently the rocks on the line of which they rise. Sometimes it even overlies the schistose and other rocks, as in the Piz de Graves in the upper Engadine, where a wall-like mass of granite, with syenite, diorite, and altered rocks, may be seen resting upon schists. In the Alps and other mountain ranges it is found likewise in large bed-like masses which run in the same general direction as the rocks with which they are associated.

Many of the most characteristic features of granitic bosses can be admirably studied where the rock has risen through contorted sedimentary formations, which form undulating or hilly ground rather than mountains. The granite of the south-east and east of Ireland, the south of Scotland, and the south-west of England may be taken as illustrative examples.

In the south-east of Ireland a mass of granite 70 miles in length and from 7 to 17 in width stretches from north-east to south-west, nearly along the strike of the Lower Silurian rocks. These strata, however, have not been upraised by it in such a way as to expose their lowest beds dipping away from the granite. On the contrary, they seem to have been contorted prior to the appearance of that rock; at least they often dip towards it, or lie horizontally or undulate upon it, apparently without any reference to movements which it could have produced. As Mr Jukes has shown, the Silurian strata are underlaid by a vast mass of Cambrian rocks, all of which must have been invaded by the granite before it could have reached its present horizon. He infers that the granite must have slowly and irregularly eaten its way upward through the Silurian rocks, absorbing much of them into its own mass as it rose. For a mile or more the stratified beds next the granite have been altered into mica-schist, and are pierced by numerous veins from the invading rock. Within the margin of the granitic mass belts or rounded irregular patches of schist are enclosed; but in the central tracts where the granite is widest, and where therefore we may suppose the deepest parts of the mass have been laid bare, no such included patches of altered rock occur. From the manner in which the schistose belt is disposed round the granite, it is evident that the upper surface of the latter rock where it extends beneath the schists must be very uneven. Doubtless it rises in some places much nearer to the present surface of the ground than at others, and sends out veins and strings which do not appear above ground. If, as Mr Jukes supposes, a thousand feet of the schists could be restored at some parts of the granite belt, no doubt the belt would there be entirely buried; or if, on the other hand, the same thickness of rock could be stripped off some parts of the band of schist, the solid granite underneath would be laid bare. The extent of granite surface exposed must thus be largely determined by the amount of denudation, and by the angle at which the upper surface of the granite is inclined beneath the schists. Where the inclination is high, prolonged denudation will evidently do comparatively little in widening the belt. But where the slope is gentle, and especially where the surface undulates, the removal for some distance of a comparatively slight thickness of rock may uncover a large breadth of underlying granite.[1]

Recent observations by Professor Hull and Mr Traill of the Geological Survey have shown that in the Mourne Mountains a mass of granite has in some parts risen up through highly inclined Silurian rocks, which consequently seem to be standing almost upright upon an underlying boss of granite. The strata are sharply truncated by the crystalline mass, and are indurated but not otherwise altered. The intrusive nature of the granite is well shown by the way in which numerous dykes of dark melaphyre are cut off when they reach that rock.[2]

In the Lower Silurian tract of the south of Scotland several large intrusive bosses of granite occur. The strata do not dip away from them on all sides, but with trifling exceptions maintain their normal N.E. and S.W. strike up to the granite on one side, and resume it again on the other. The granite indeed occupies the place of so much Silurian greywacke and shale. There is usually a metamorphosed belt of variable width in which, as they approach the granite, the stratified rocks assume a schistose or gneissoid character. Numerous small, dark, often angular patches or fragments of mica-schist may be observed along the marginal parts of the granite. Similar features are presented by the granite bosses of Devon and Cornwall which have risen through Devonian strata.

The manner in which some bosses of granite penetrate the rocks among which they occur strongly reminds one of the structure of volcanic necks or pipes. The granite is found as a circular or elliptical mass which seems to descend vertically through the surrounding rocks without seriously altering or disturbing them, as if a tube-shaped opening had been blown out of the crust of the earth up which the granite had risen. Several of the granite masses of the south of Scotland exhibit this character very strikingly. That granite and granitoid rocks have actually been associated with volcanic action is shown by the way in which they occur in connexion with the Tertiary volcanic rocks of Skye, Mull, and other islands in the Inner Hebrides. As Mr Jukes suggested many years ago, granite or granitoid masses may lie at the roots of volcanoes, and may be the source whence the more silicated lavas, such as trachyte and liparite, proceed.[3]

That some granite, however, is of metamorphic origin, that is to say, has been produced by the gradual softening and recrystallization of other rocks at some depth within the crust of the earth, seems to be now satisfactorily established. Such granite may be looked upon as the extreme of metamorphism, the various schists and gneisses being less advanced stages of the process. Provided the chemical composition of the altered rock be the same as that of granite, it is not necessary that the granite resulting from its alteration should be supposed to differ in any noteworthy particular from ordinary intrusive or igneous granite. The members of the Geological Survey of Ireland have indeed distinguished two granites in Galway, one of which they regard as metamorphic, the other as igneous. The former is characterized by the occurrence of two felspars (orthoclase and oligoclase); the latter contains only one (orthoclase). More recently, however, in the east of the country they have separated two groups of granites, of which the intrusive masses are composed of dark-coloured quartz, orthoclase, albite, and black mica (Mourne Mountains), while the metamorphic variety is formed of grey felspar, quartz, and black mica. The mineralogical composition of granite formed by the metamorphism of other and specially sedimentary rocks must necessarily vary with that of the masses out of which it has arisen. In some cases there is a regular gradation from true granite outward into the schistose and gneissose masses. But this passage need not always occur, for if the granite was subject to unequal pressure (which it assuredly would in most cases be) it would in its soft, pasty condition undoubtedly be squeezed into any rents made in the surrounding rocks, and would thus imitate exactly a truly igneous mass, which in actual fact it would then be. When a mass of granite rises through unaltered or only locally altered strata, it may fairly be assumed to be igneous and intrusive. When, on the other hand, it is intimately associated with extensive masses of schist and gneiss, many of which can only be distinguished from it by their foliated structure, its metamorphic origin may at least be strongly suspected. Fundamentally, indeed, igneous and metamorphic granite seem to be due only to different modifications of the same subterranean processes. A mass of originally sedimentary rocks may be depressed to a depth of several thousand feet within the earth's crust, subjected there to vast pressure and considerable heat in presence of interstitial water or steam, and may thus be metamorphosed into crystalline schists. A portion of this mass, undergoing extreme alteration, may so completely lose all trace of its original fissile structure as to become amorphous crystalline granite, some of which may even be thrust as veins into the less highly changed parts above and around. One stage further would bring before us a connexion opened between the surface and such a deep-seated granitic mass, and the consequent ascent and outburst of acid lavas and their fragmental accompaniments.

Amorphous Masses of Diorite, &c.—On a smaller scale usually than granite, other crystalline rocks assume the condition of amorphous bosses. Syenite, diorite, quartz-porphyry, and members of the basalt family have often been erupted in irregular masses, partly along fissures, partly along the bedding, but often involving and appar-

[1] See Jukes's *Manual of Geology*, 3d ed., p. 243. *Horizontal Section No. 22. Geol. Surv. Ireland.*

[3] *Manual of Geology*, 2d ed., p. 93; Geikie, *Trans. Geol. Soc. Edin.*, ii. 301; Judd, *Quart. Journ. Geol. Soc.*, xxx. 220.

ently melting up portions of the rocks through which they have made their way. Such bosses have frequently tortuous boundary-lines, since they send out veins into or cut capriciously across the surrounding rocks. In Wales, as shown by the maps and sections of the Geological Survey, the Lower Silurian formations are pierced by huge bosses of different crystalline rocks, mostly included under the old term "greenstone," which, after running for some way with the strike of the strata, turn round and break across it, or branch and traverse a considerble thickness of stratified rock. In central Scotland numerous masses of dolerite and quartziferous diabase have been intruded among the Lower Carboniferous formations. One horizon on which they are particularly abundant lies about the base of the Carboniferous Limestone series. Along that horizon they rise to the surface for many miles, sometimes ascending or descending in geological position, and breaking here and there abruptly across the strata. There can be little doubt that they have actually melted down some parts of the stratified rocks, particularly the limestone. Considerable petrographical differences occur among them which may perhaps be in some measure due to the incorporation of such extraneous material into their mass. Gaps occur where these intrusive rocks do not rise to the surface, but as they resume their position again not far off, it may be presumed that they are really connected under these blank intervals.

The amount and nature of the alteration produced on contiguous rocks by the invasion of an intrusive boss vary necessarily with the character and bulk of the igneous mass, as well as with the susceptibility of the surrounding rock to metamorphism. Induration is generally traceable; shales are hardened into porcelain, jasper, Lydian-stone, or some other flinty argillaceous rock. Sandstones are converted into a kind of lustrous quartz-rock. Limestones are made to assume a granular or crystalline texture, passing into marble or sometimes into dolomite. Under favourable conditions crystals of garnet, analcime, pyrite, and other minerals are developed in the surrounding altered rock.

There can be little doubt that, though the portions of these rocks now visible consolidated under a greater or less depth of overlying rock, they must in many cases have been directly connected with superficial volcanic action. Some of them may have been underground ramifications of the ascending molten rock which poured forth at the surface in streams of lava. Others may mark the position of intruded masses which were arrested in their ascent in the unsuccessful attempt to open a new volcanic vent.

II. SHEETS.—These are masses of crystalline rock which have been intruded as sheets between other rocks, and now appear as more or less regularly defined beds. In almost all cases it will be found that these intrusions have taken place between the planes of stratification. The ascending mass of molten matter, after breaking across the rocks, or rather after ascending through fissures either previously formed or opened at the time of the outburst, has at last found its path of least resistance to lie along the bedding planes of the strata. Accordingly it has thrust itself between the beds, raising up the overlying mass and solidifying as a nearly or exactly parallel cake or bed.

It is evident that one of these intercalated intrusive sheets of igneous rock must present such points of resemblance to a truly contemporaneous bed of lava as to make it occasionally a somewhat difficult matter to determine its true character, more especially when, owing to extensive denudation, only a small portion of the rock can now be seen. The following characters mark intrusive sheets, though they must not be supposed to be all present in every case. (1.) They do not rigidly conform to the bedding, but sometimes break across it and run along on another platform. (2.) They catch up and involve portions of the surrounding strata. (3.) They are commonly most close grained at their upper and under surfaces, and most coarsely crystalline in the central portions. (4.) They are very rarely cellular or amygdaloidal. (5.) The rocks both above and below them are usually hardened and otherwise more or less altered.

Many of the older volcanic rocks occur in this form, as felstone, quartz-porphyry, diorite, melaphyre, diabase, dolerite, basalt, and others. The remarks above made regarding the connexion of intrusive bosses with volcanic action may be repeated with even greater definiteness here. Intrusive sheets abound in old volcanic districts intimately associated with dykes and surface outflows, and thus bringing before our eyes traces of the underground mechanism of the volcanoes.

The same kinds of alteration may be observed along the line of junction of intrusive sheets with the adjacent rocks as in the case of amorphous masses; but as the boundary lines are often very sharply defined they present the process of alteration in a more generally accessible and interesting form. Sandstone, for example, besides being indurated and acquiring the distinct lustre of quartzite, may occasionally be seen to possess a distinctly prismatic structure—the prisms or columns diverging at right angles to the line of junction with the igneous rock. Even microscopic black microlites, like those which occur in basalt-rocks, have been detected in altered sandstone, in the minute fissures of which they may be supposed to have been sublimed from the molten injected mass. Argillaceous rocks are commonly converted into hard flinty textures to which the names of flinty-slate, Lydian-stone, jasper, and porcellanite have been applied. Coal-seams when invaded by intruded sheets of igneous matter assume different aspects according to the thickness and nature of the invading sheet, the depth of the coal-seam, and probably to other less easily recognizable causes. In some cases the coal has been fused and has acquired a blistered or vesicular texture, the gas cavities being either empty or filled with mineral matter such as calcite. In other cases it has nearly disappeared, the remaining portion being a black soot or ash. In others it has become hard and brittle, and has been converted into a kind of anthracite or "blind-coal," owing to the loss of its more volatile portions. In the Ayrshire coal-fields the coal seams have sometimes become beautifully columnar owing to the intrusion of a sheet of basalt along them. The hexagonal and pentagonal columns diverge like rows of stout pencils from the surfaces of the basalt. In one coal-field of that county a seam of coal has been converted into graphite. The accompanying section (fig. 55) by the late

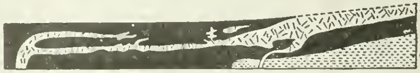

FIG. 55.—Sheets and strings of intrusive rock in the Ten-yard Coal, South Staffordshire.

Mr Jukes represents one of the numerous sheets of "white rock" intruded into the South Staffordshire coal-field. The horizontal distance shown in this section is more than 100 yards. The coal (*b*) resting on sandstone (*c*) is traversed by irregular strings and sheets (*a*) of what the miners term "white-rock," which proceed from the large basalt masses of the district. The coal has there become dull and anthracitic, and is not worth being extracted.

When a coal-field is much invaded by igneous rocks the seams of coal are usually found to have suffered more than the other strata, not merely because they are specially liable to alteration from the proximity of heated surfaces, but because they have presented lines of more easy escape for the igneous matter pressed from below. The molten rock has very generally insinuated itself along the coal-seams, sometimes taking the lower, sometimes the upper surface, and not infrequently forcing its way along the centre.

In the destruction or alteration of coal and bituminous shales a process of subterranean distillation must often have been set in progress. The gases evolved would find their way to the surface through joints and pores of the overlying rock. The liquid products, on the other hand, would be apt to collect in fissures and cavities. In central Scotland, where the coal-fields have been so abundantly pierced by igneous masses, petroleum and asphaltum are of frequent occurrence in many districts, sometimes in chinks and veins of sandstones and other sedimentary strata, sometimes in the cavities of the igneous rocks themselves.

It is a remarkable fact that, striking as is the change produced by the intrusion of basalt into coals and bituminous shales, it is hardly more conspicuous than the alteration effected on the invading masses themselves. A compact crystalline black heavy basalt or dolerite, when it sends sheets and veins into a coal or highly carbonaceous shale, becomes yellow or white, earthy, and friable, loses weight, ceases to have any apparent crystalline texture, and in short passes into what any observer would at first unhesitatingly pronounce to be a mere clay. It is only when the distinctly intrusive character of this substance is recognized in the veins and fingers which it sends out, and in its own irregular course in the coal, that its true nature is made evident (see fig. 55). Microscopical examination shows that this "white-rock" or "white-trap" is merely an altered form of basalt, wherein the felspar crystals, though much decayed, can yet be traced, the augite, olivine, and magnetite being more or less completely changed into a mere pulverulent earthy substance. A specimen of this altered rock was analysed by Mr Henry with the following results:—

Silica	38·830
Alumina	13·250
Lime	3·925
Magnesia	4·180
Soda	0 971
Potash	0·422
Protoxide of iron	13 830
Peroxide of iron	4·335
Carbonic acid	9 320
Water	11·010
	100·073

It is evident that most of the alkalies and much of the silica have been removed, and that most of the iron exists as carbonate of the protoxide.

In connexion with the alteration produced by igneous sheets upon their contiguous stratified rocks, reference may here be made to the lithological differences traceable within the igneous masses. The close grain already referred to as characteristic of the upper and under portions of an intrusive sheet evidently depends upon more rapid cooling towards the surface of contact with the adjacent cold rocks. When thin slices of these marginal parts are placed under the microscope, they sometimes show abundant black microlites which disappear as the rock is traced away from the margin. They may be regarded as incipient stages in the crystallization of the magnetite, arrested in their development by the rapid consolidation of the outer parts of the rock. In the central portions they have had an opportunity of coalescing into octahedra or groups of definite isometric crystals. A series of sections of a rock, from the outer edge where the arrested crystallites occur to the centre where definitely-built crystals appear, brings in this way before us a history of the stages in the consolidation of the mass.

But considerable differences in composition may also be detected in different portions of the same intrusive sheet. A rock which at one place gives under the microscope a coarsely crystalline texture with the petrographical elements of dolerite will at a short distance show abundant orthoclase and free quartz—minerals which do not belong to normal dolerite. These differences, like those above referred to as noticeable among amorphous bosses, seem too local and sporadic to be satisfactorily referred to original differences in the composition of various parts of the molten mass, or to segregation by gravitation or otherwise. They suggest rather that the great intrusive sheets, in their passage through the rocks underneath, have here and there involved and melted down portions of these rocks, and have thus acquired locally an abnormal composition.

III. Veins and Dykes.—Veins of igneous rock may occur indifferently in igneous, aqueous, or metamorphic rocks. They may range in diameter from mere thread-like filaments up to huge bands many feet or yards broad. In regard to their origin they may be grouped into two series —(1) veins of segregation, and (2) veins of intrusion.

Veins of Segregation.—These include most of what were formerly and not very happily termed "contemporaneous veins." They are peculiar to crystalline rocks. They abound in many granites, likewise in some gneisses and schists. They may not infrequently be observed in sheets of diorite, dolerite, and diabase. They run as straight, curved, or branching ribands, seldom exceeding a foot in thickness. Most frequently they are finer in texture than the rock which they traverse, though now and then the reverse is the case, more especially in granite. Close examination of them shows that they are not sharply defined by a definite junction line with the enclosing rock, but that on the contrary they are welded into that rock in such a way that they cannot easily be broken along the plane of union. This welding is found to be due to the mutual protrusion of the component crystals of the vein and of the surrounding rock—a structure sometimes admirably revealed under the microscope. Veins of this kind are evidently to be referred to the earliest condition of the rocks in which they occur. They point to some process, still unexplained, whereby into rents formed in the deeply buried, and at least partially consolidated or possibly colloid, mass there was a transfusion or exosmosis of some of the crystallizing minerals.

Veins of Intrusion.—These are portions of once-melted or at least pasty matter which have been injected into rents of previously solidified rocks. When traceable sufficiently far, they may be seen to swell out and merge into their large parent mass, while in the opposite direction they may become attenuated into mere threads. Sometimes they

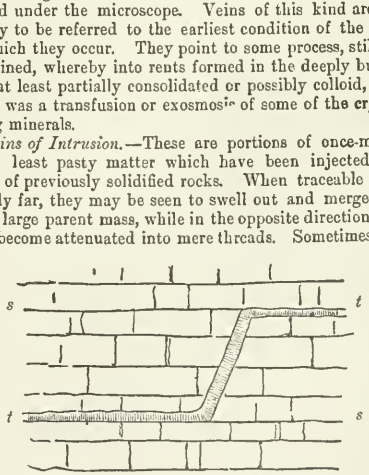

FIG. 56.—Intrusive igneous rock.

run for many yards in tolerably straight lines, and when this takes place along the stratification they look like beds. At these parts, they are of course really intrusive sheets. But they may frequently be found to start suddenly upward or downward, and to break across the bedding in a very irregular manner. In fig. 56 *t* represents an intrusive igneous rock running through horizontal strata *s*. If we saw merely the horizontal portion below or above, the really igneous and intrusive nature of the rock *t* might escape us, but the intermediate connecting vein makes its character at once apparent.

No rock exhibits so admirably as granite the varieties assumed by veins. In many cases the veins which traverse the granite itself must be regarded as segregation or infiltration veins, as already described. But where they proceed from the granite, and traverse surrounding rocks, they are probably in most cases intrusive, though where granite and highly granitic gneiss are in contact we may conceive that some of the veins traversing both rocks may be segregation veins. Most large masses of granite send veins into the surrounding rocks. Frequently the veins so abound as to form a complicated net-work. They vary in breadth from several feet or even yards down to fine filaments at the ends of the smaller branches. They frequently cross each other, not only outside of the granite mass, but even within it. They vary much in texture and in composition. Sometimes they are coarsely crystalline; but probably most of the veins of this kind are due rather to segregation than intrusion. Most frequently granite veins traversing granite are finer-grained than the main mass. Veins which are clearly intrusive are not only finer in grain than the parent granite, but sometimes present considerable differences in mineralogical composition. The mica, for example, may be reduced to exceedingly minute and not very abundant flakes, and may almost disappear. The quartz also occasionally assumes a subordinate place, and the rock of the veins passes into eurite, elvanite, or one of the varieties of porphyry.

The rocks surrounding a granite mass and traversed by granite veins are almost always more or less metamorphosed in a belt varying in breadth from a few yards up to a mile or more. It is in this zone that the granite veins typically occur. The altered rocks have assumed the characters of gneiss, mica-schist, or other metamorphic product, but resume their usual condition as we trace them away from the granite. Curious angular portions of them may often be observed within the granite veins and in the main granite mass. In Cornwall the granite and surrounding slates are traversed by veins of quartz-porphyry termed *elvans*, which are most numerous near the granite. They vary in width from a few inches or feet to 50 fathoms, their central portions being commonly more crystalline than the sides. In the great granite region of Leicester Mr Jukes traced some of the elvans for several miles running in parallel bands, each only a few feet thick, with intervals of 200 or 300 yards between them. Many of the other intrusive rocks likewise present the phenomena of veins; diorite, diabase, melaphyre, and basalt furnish numerous illustrations.

Dykes are wall-like masses of igneous rock, filling vertical or highly-inclined fissures. They differ therefore from veins in the greater parallelism of their sides, their verticality, and their greater regularity of breadth and persistence of direction. They present as great a variety of thickness as that which is shown by veins. Sometimes they occur as mere plates of rock not more than an inch or two in thickness; at other times they attain a breadth of ten or twelve fathoms. The smaller or thinner dykes can seldom be traced more than a few yards; but the larger examples may be followed sometimes for miles. Thus in the south of Scotland a remarkable series of basalt-dykes can be traced across all the geological formations of that region and even across powerful faults. They run parallel to each other in a general north-west and south-east direction for distances of 20 and 30 miles. A remarkable dyke crosses the north of England from the coast of Yorkshire for fully 60 miles inland.

The name dyke is applied to these masses of igneous rock on account of their resemblance to walls (*Scotice*, dykes). Their sides are often as parallel and perpendicular as those of a piece of masonry. Moreover, the resemblance to human workmanship is sometimes brought out still more by the numerous joints which, intersecting each other along the face of a dyke, remind us of well-fitted masonry. Where the surrounding rock has decayed, the dykes may be seen projecting above the ground exactly like walls; indeed in many parts of the west of Scotland they are made use of for enclosures. The material of the dykes has in other cases decayed, and deep ditch-like hollows are left to mark their sites. The coast-lines of many of the Inner Hebrides and of the Clyde Islands furnish numerous admirable examples of both kinds of scenery.

While veins have been injected into irregular branching cracks, dykes have been formed by the welling upwards of liquid rock in vertical or steeply inclined fissures. Sometimes the line of escape has been along a fault. In Scotland, however, which may be regarded as a typical region for this kind of geological structure, the vast majority of dykes rise along fissures which have no throw, and are therefore not faults. On the contrary the dykes may be traced across some of the largest faults in the midland counties.

While the term dyke might be applied to some of the wall-like intrusions of porphyry, elvanite, and even of granite, it is more typically illustrated among the augitic igneous rocks, such as basalt, diabase, &c., though also among diorites, porphyries, pitchstones, &c. The central parts of a dyke are usually most crystalline. Towards the margin the grain becomes finer, and even sometimes passes into a vitreous condition. Many of the basalt dykes in different parts of Scotland are coated along the sides with a film or crust of black vitreous tachylite. Lines of amygdaloidal kernels may not infrequently be traced along the centre of a dyke.

When the rock on one side is freshly stripped off, the dyke is usually observed to present a system of polygonal jointing. The joints start from each face or cheek, and either go right across to the opposite side, or branch and lose themselves about the centre. They thus divide the dyke into irregular prisms which, when the dyke is vertical, lie of course in a horizontal position, whence they depart in proportion as the dyke is inclined. Occasionally the prisms are as well-formed as in any columnar bed of basalt. A less prominent set of joints runs parallel with the two cheeks of a dyke.

There is usually some alteration of the stratified rocks in contact with a dyke; but the nature and amount of the change vary within a wide range. The most sensitive material to this influence is undoubtedly coal. A seam of coal 6 or 8 feet in thickness may be observed to grow dull and brittle at a distance of 50 yards from a large dyke, becoming what is termed "blind coal," as it then burns without flame. Still nearer to the intrusive mass the coal passes into a kind of pyritous cinder scarcely half the original thickness of the seam. At the actual contact with the dyke it becomes by degrees a kind of caked soot not more perhaps than a few inches thick. Sandstones are hardened into a kind of lustrous quartzite, and sometimes made columnar, shales into flinty slate or porcellanite; limestones are occasionally rendered crystalline and even dolomitic. Occasionally a segregation of new minerals has taken place in the rocks adjoining a dyke. But cases are by no means infrequent where dykes have produced little or no appreciable change upon the contiguous rocks.

IV. Necks.—Under this term are included the filled-up pipes or funnels of former volcanic vents. Every series of volcanic sheets poured out at the surface must have been connected with one or more orifices which, on the cessation of the eruptions, would remain more or less completely filled with lava or with fragmentary matter. But unless subsequent denudation should remove the overlying cone and its surrounding piles of lava and tuff, these vents must remain buried under the materials which came out of them. So extensive, however, has been the waste of the surface in many old volcanic regions that the sites of the vents have been laid bare. In the study of these we have before us some of the more deep-seated phenomena of volcanic action never to be seen in any modern volcano.

A neck is of a circular or elliptical, but occasionally of a more irregular branching form. It varies in diameter from a few yards up to a mile, or even more. It descends into the earth perpendicularly to the stratification of the formation to which it belongs. Thus, if a neck was formed and filled up during the accumulation of a certain group of strata, it would rise on the whole vertically through these strata, and its ejected lava or tuff would spread out conformably among them Should the rocks be subsequently tilted the neck would of course be thrown out of the vertical. As a rule, however, the vertical descent of the necks into the earth's crust has been comparatively little interfered with.

The materials filling up ancient volcanic orifices are sometimes crystalline, sometimes fragmental. The neck may be occupied by some form of lava, as felstone, quartz-porphyry, diabase, porphyrite, basalt; or by the fragmentary materials which fell back into the throat of the volcano and finally solidified there; or by both kinds of rock combined. Among the Palæozoic volcanic districts of Britain the necks not infrequently are filled with some siliceous crystalline rock, such as a quartz-porphyry or felstone, even where the surrounding lavas are basic. Necks of agglomerate and fine tuff abound among the Carboniferous and Permian volcanic regions of Scotland.

The fragmentary materials consist mainly of different lava-form rocks imbedded in a gravelly *peperino*-like matrix of more finely comminuted debris of the same rocks; but they also contain, sometimes in abundance, fragments of the strata through which the necks have been drilled. Pieces of fine stratified tuff not infrequently appear in the agglomerates. This fact, coupled with the not uncommon occurrence of a tumultuous fractured and highly-inclined bedding of the materials in the necks, appears to show that the pipes were partly filled up by the subsidence of the tuff consolidated in beds within the crater and at the upper part of the funnel. Veins of basalt abound in many of the necks of Carboniferous age in central Scotland.

The strata round a neck are usually somewhat hardened. The sandstones have acquired sometimes a vitreous lustre; argillaceous beds have been indurated into porcellanite; coal-seams have been burnt and rendered unworkable. These changes may be due partly to the heat of the ascending column of molten rock or ejected fragments, partly to the ascent of heated vapours, even for a long time subsequently to the volcanic explosions. Proofs of a metamorphism probably due to the latter cause may sometimes be seen within the area of a neck. It is where the altered materials are of a fragmentary character that the nature and amount of this change can be best estimated. What was originally volcanic dust has been converted into a crystalline and even porphyritic mass, through which, however, the likewise intensely altered blocks interspersed through the agglomerate are still recognizable. Such blocks as, from the nature of their substance, must have offered most resistance to change,—pieces of sandstone or quartz, for example,—stand out prominently in the altered mass, though even they have undergone more or less modification, the sandstone being converted into vitreous quartz-rock.

Section II.—Volcanic, Interbedded, or Contemporaneous Igneous Rocks.

The rocks comprised in this section have all been ejected to the surface like the lava-streams and showers of ashes of modern volcanoes. It is evident that on the whole they must agree in lithological characters with those rocks, described in the previous section, which have been extravasated by volcanic efforts though not quite reaching the surface. Yet they have some well-marked general characters, of which the most important may be thus stated. (1.) They occur as beds or sheets which conform to the bedding of the strata among which they are intercalated. (2.) They do not break into or involve portions of the overlying beds. (3.) The upper and under portions of the lava sheets present commonly a scoriaceous or vesicular character, which may even be found extending throughout the whole of a sheet. (4.) Beds of tuff are frequently interstratified with the crystalline sheets.

I. Crystalline.—While the underground course of a protruded mass of molten igneous rock has widely varied according to the shape of the channel through which it proceeded, and in which, as in a mould, it solidified, the behaviour of the rock, once poured out at the surface, has been much more uniform. As in modern lava, the erupted rock has rolled along, varying in thickness and other minor characters, but retaining the broad general aspect of a bed or sheet. A comparison of such a bed with one of the intrusive sheets already described shows that in several important respects they differ from each other. An intrusive sheet is closest in grain near its upper and under surfaces. A contemporaneous bed or true lava-flow, on the contrary, is there usually most open and scoriaceous. In the one case we rarely see vesicles or amygdules, in the other they often abound. However rough the upper surface of an interbedded sheet may be, it never sends out veins into nor encloses portions of the superincumbent rocks, which, however, sometimes contain portions of it, and wrap round its hummocky irregularities as shown in fig. 57. Occasionally it may be observed to be full of rents which have been filled up with sandstone or other sedimentary material. In these cases we see that the lava cracked in solidifying, and that sand was washed into the fissures where it consolidated. The amygdaloidal cavities throughout an interbedded sheet, but more especially at the top, may often be noticed with an elongated form, and even pulled out into tube-like hollows in one general direction, which was obviously the line of movement of the yet viscous mass.

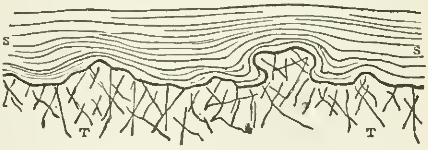

Fig 57.—Section of the upper surface of an interbedded sheet T, showing how its unevenesses are wrapped round and covered by the sedimentary rocks S.

Some kinds of rock when occurring in interbedded sheets are apt to assume a system of columnar jointing. Basalt in particular is distinguished by the frequency and perfection of its columns. The Giant's Causeway and the cliffs of Staffa, of Ardtun in Mull, and of Loch Staffin in Skye are well-known examples. The columns are set perpendicularly to the two cooling surfaces, that is, to the top and bottom of the bed. Any inclination from the horizontal in the disposition of the bed will cause a corresponding departure from the vertical on the part of the columns. Sometimes the columns are arched or curved, as in the Clam-shell Cave, Staffa.

A single interbedded sheet of crystalline rock seldom occurs by itself without any other volcanic accompaniment. It is usually associated at least with bands of tuff showing that the emission of lava was not unattended with fragmentary ejections. In the majority of cases it will be found to form part of a series of interbedded sheets with intercalated tuffs. Vast piles of such consecutive flows, reaching a total depth of several thousand feet, remain to witness the energy of former volcanic vents.

II. FRAGMENTAL.—The rocks embraced under this term include all the fragmentary volcanic ejections which enter into the composition of the earth's crust, from the coarsest agglomerate to the finest tuff. They differ in lithological character, according to the nature of the lavas with which they are associated and from which they have been derived. Thus in a region of trachyte-lavas, we have trachyte-tuffs, trachyte-breccias; in one of basalts, we find basalt-breccias, basalt-agglomerates, basalt-tuffs; in one of obsidians, we meet with pumiceous tuffs and breccias. The fragmentary matter has been ejected from volcanic vents, and has fallen partly back into the funnels of discharge, partly over the surrounding area. It is therefore apt to be more or less mingled with ordinary sedimentary detritus. We find it indeed passing insensibly into sandstone, shale, limestone, and other strata.

Great differences occur in the texture of fragmental rocks even in the same volcanic districts. They are often coarse and tumultuous at or near the vents, and fine-grained at a distance. Alternations of gravelly *peperino*-like tuff with a very fine-grained "ash" may frequently be observed. Large blocks of lava-form rock, as well as of the strata through which the volcanic explosions have taken place, occur in the tuffs of most old volcanic districts.

It has been already pointed out that agglomerate and tuff are not infrequently to be met with occupying the sites of the vents of eruption. Their most common disposition, however, is in beds either alone or associated with interbedded lavas. Masses of fine or gravelly tuff several hundreds of feet in thickness, without the intervention of any lava-bed, may be observed in the volcanic districts of the Old Red Sandstone and Carboniferous systems in Scotland. On the other hand, in these same areas thin seams of tuff may be seen interlaminated with ordinary sandstone, shale, or limestone. In the one case we have evidence of long-continued and powerful volcanic action, during which fragmentary materials were showered out and spread over the water-basins to the exclusion of ordinary sediment. In the other we have proof of feeble intermittent volcanic explosions, whereby light showers of dust were discharged, which settled down quietly amidst the sand, mud, or limestone accumulating around at the time. Under these latter circumstances tuffs often became fossiliferous; they enclose the remains of such plants and animals as might be lying on the lake-bottom or sea-floor over which the showers of volcanic dust fell, and thus they form a connecting link between aqueous and igneous rocks.

VIII.—METAMORPHIC ROCKS AS PARTS OF THE ARCHITECTURE OF THE EARTH'S CRUST.

In part ii. (*ante*, p. 235) some account has been given of the composition of certain foliated rocks frequently met with in the central portions of mountain chains and elsewhere, lying beneath geological formations of high antiquity. In part iii., in the discussion of the hypogene causes of change within the earth's crust, reference was again made to these rocks, and they were alluded to as examples of the effects of subterranean processes altering the original character of large mineral masses (*ante*, p. 263). They were there cited as *metamorphic* rocks, but their characters as integral parts of the earth's crust were reserved for discussion in the present part of this article.

At the outset some caution must be employed as to the exact meaning in which the terms "metamorphism" and "metamorphosed" are employed. In a certain sense it may be said that all or nearly all rocks have been metamorphosed, since it is exceptional to find any, at least among such as are not in a geological sense of modern date, which do not show, when closely examined, proofs of having been altered by the action of percolating water or other daily acting metamorphic agent. Even a solid crystalline mass which, when viewed on a fresh fracture with a good lens, seems to consist of unchanged crystalline particles will usually betray under the microscope unmistakable evidence of alteration. And this alteration may go on until the whole internal organization of the rock has been readjusted, though the external form may still remain such as hardly to indicate the change, or to suggest that any new name should be given to the recomposed rock. Among many igneous rocks, particularly the more basic kinds, as basalts, diorites, olivine rocks, &c., metamorphism of this kind may be studied in all its stages.

But it is not to alteration of this nature, effected at the surface by meteoric water, that the term metamorphism is properly applied. That word is reserved for the process of subterranean change above treated of (*ante*, p. 258), whereby a more or less complete transformation has been effected throughout vast mineral masses which, while undergoing crystalline rearrangement, have usually suffered simultaneously enormous compression. Gneiss, mica-schist, and the other schistose or foliated rocks are typical examples of the results of this metamorphic process.

Three antagonistic opinions are at present entertained regarding the origin of these rocks. Some geologists regard the crystalline schists as plutonic rocks representing the early cooled crust of the earth, and suppose that a similar schistose structure has occasionally been superinduced by plutonic action on later sedimentary formations. Again, by some recent writers the Wernerian notion of chemical precipitation has been revived, and the idea of metamorphism has been discarded. These authors suppose that the schistose rocks, in common with many pyroxenic and hornblendic rocks (diabases, diorites, &c.), as well as masses in which serpentine, talc, chlorite, and epidote are prevailing minerals, have been deposited "for the most part as chemically-formed sediments or precipitates, and that the subsequent changes have been simply molecular, or at most confined in certain cases to reactions between the mingled elements of the sediments, with the elimination of water and carbonic acid." To support this view, it is necessary to suppose that the rocks in question were formed during a period of the earth's history when the ocean had a considerably different relative proportion of mineral substances dissolved in its waters, and consequently that they must be assigned to a very early geological period, anterior indeed to what are usually termed the Palæozoic ages. And it becomes further needful to discredit the belief that any gneiss or schist can by possibility belong to one of the later stages of the geological record. The more thorough-going advocates of the pristine or "eozoic" date and original chemical deposition of the so-called "metamorphic" rocks do not hesitate to take this step, and endeavour, by ingenious explanations, to show that the majority of geologists have mistaken the geological structure of the districts where these rocks have been supposed to be metamorphosed equivalents of what elsewhere are Palæozoic, Secondary, or Tertiary strata.[1] Prevalent opinion supports the third or metamorphic theory, according to which the schistose rocks

[1] See Sterry Hunt's *Chemical Essays*, p. 283 *sq.*

are held to be crystalline transformations of ordinary sedimentary strata. The problem whether or not certain masses of gneiss or schist represent equivalent unaltered sedimentary rocks of other districts is mainly one of structural geology. It must be decided by the geologist rather than the chemist. It has been answered in the affirmative by the great majority of stratigraphical geologists all over the world. We may not be entitled to assert that every mass of gneiss or schist is a metamorphosed sedimentary rock. Possibly some foliated rocks of extreme antiquity may have originated directly from chemical precipitation. But when it can be shown that ordinary stratified rocks have been converted into schist and gneiss, it seems permissible to hold that all such rocks have had a similar origin, at least until good reasons can be adduced against that view.

It is evident that if the so-called metamorphic rocks can anywhere be seen to graduate into unaltered strata, it is there that they ought to be specially studied, and that light may be expected to be cast on their origin and history. It is customary to speak of metamorphism as being either local or regional, that is, being confined to one limited portion of a mass of rock, or as extending throughout the whole of the rock and over wide districts. It is doubtless from the first of these developments that we may hope to learn most regarding metamorphic changes.

Local (*Contact*) *Metamorphism.*—The simplest and most obvious examples of this kind of alteration occur where a mass of igneous rock has invaded sedimentary strata, which have in consequence been affected in lithological character along the margin of contact with the intrusive rock. Allusion has already been made to changes of this kind effected by intrusive sheets and dykes, and likewise traceable round the edges of ancient volcanic vents. Sandstones are converted into a lustrous crystalline quartz-rock; shales and argillaceous strata are indurated into porcellanite, jasper, flinty-slate, or some analogous product. Limestones are made crystalline; coals are charred, turned into anthracite, and sometimes even into graphite. These metamorphisms extend to very variable distances from the intrusive rock. Sometimes they are scarcely perceptible at all, and disappear within a space of a few inches. In other cases they extend for some feet, and in the case of some coal-seams even to 50 yards or more.

It is around bosses of granite however that the most marked examples of local metamorphism can be observed. On a previous page some account has been given of the way in which the Silurian rocks of Ireland and the south of Scotland are pierced by large masses of granite, and how, as they approach the granite even at a horizontal distance of a mile or more, they begin to assume a micaceous foliated texture which becomes more and more marked until, along the margin of the granite, they pass into true mica-schist and gneiss. The identity of origin between these schistose masses and the greywackes and shales beyond the metamorphic zone does not admit of any question. The unaltered rocks can be followed step by step into and through the stages of alteration, until they are found to have acquired the genuine gneissic or schistose structure. Moreover, it may be observed that all the bands of sedimentary rock do not give rise to the same kinds of metamorphic products. Some kinds of strata are more prone to alteration than others, and give rise to more perfect schists. In the south of Scotland, for example, certain greywackes and grits formed of a granular mixture of quartz-sand, felspar, clay, and various decomposition products have been metamorphosed into perfect mica-schist, while some bands of black anthracitic and graptolitic shale have merely been intensely indurated and shattered. Many districts in Scotland, in Ireland, in the lake country of England, and in Wales might be cited as furnishing examples of this gradual conversion of ordinary sedimentary rocks into true schists.

Regional Metamorphism.—If then it can be proved that over limited areas thoroughly foliated rocks have been produced by the transformation of ordinary sedimentary strata, a presumption is established in favour of a similar mode of origin for foliated rocks elsewhere and over wider regions. There occur many vast spaces of the earth's surface occupied by foliated rocks. In Finland, Scandinavia, and the Scottish Highlands tracts many thousands of square miles in extent consist of gneiss, mica-schist, hornblende-rock, and other members of the same great family of rocks. A large portion of British North America lies upon similar mineral masses. Rocks of this type commonly rise also along the core of great mountain ranges, as in the Alps and in the Rocky Mountains. If these rocks which cover such vast areas were originally ordinary sedimentary rocks, they must have been metamorphosed, not by mere local protrusions of igneous matter, but by some general process.

Gradations of Metamorphism.—We have seen above that the nature and extent of the alteration experienced by rocks have been regulated, not merely by the vigour of the metamorphic process, but by the composition and structure of the rocks themselves. A siliceous sandstone, for instance, containing little or no aluminous or other admixture, seems to be capable of retaining much of its original character, while surrounding or intercalated less purely quartzose beds have been completely changed. It is converted into quartz-rock, but still shows the rounded quartz grains of the original sand. In proportion as the sand has been mixed with clay it has produced a rock more susceptible of change. The argillaceous (or magnesian) cement has been attacked, and in the process of change the quartz-sand has been affected. Mica in one or other of its various forms, aluminous or magnesian, has very generally appeared, and in proportion to its development has the foliated structure been made apparent. Hence we may obtain every gradation from a quartz-rock or grit into a true mica-schist or gneiss.

Production of Foliation.—The term "foliation" means the separation of a rock into approximately parallel or lenticular crystalline layers or folia of different mineral composition. It implies a segregation and crystallization of mineral matter along distinct planes. Those who maintain the original chemical precipitation of the most ancient gneisses and schists believe that the folia mark the stratification of the successive layers of deposit. Those, on the other hand, who hold that all the schistose rocks about the origin of which any satisfactory conclusion can be reached were originally mechanical sediments of ordinary kinds, regard the folia as coincident generally with the stratification of these sediments.

The folia of a gneiss or schist are crystalline aggregates which along their planes of mutual contact are as it were welded or felted into each other by the interlacing of their several component crystals. They are destitute, as a rule, of the parallelism, flatness, and persistence so characteristic of stratification. On the contrary they are apt to swell out into thick concretionary aggregations and to die out rapidly; they exhibit a wavy, crumpled, or puckered arrangement traceable in vast folds on the side of a mountain, and yet descending even to such minute corrugation as can only be detected by the microscope.

Foliation occurring in altered sedimentary rocks must be due to a crystallization and rearrangement of the chemical constituents of these rocks along certain lines. On a former page (*ante*, p. 263) it was pointed out that this kind of metamorphism would as a rule proceed along the lines of stratification. Doubtless in the vast majority of cases the planes of foliation are coincident with the general direction of this stratification. The metamorphic rocks of the Scottish Highlands furnish admirable proofs of this fact. Bands of quartz-rock and schist alternate with each other and with zones of limestone, precisely as beds of sandstone, shale, and limestone do in unaltered formations. Thin seams of pebbly grit with well-rounded water-worn pebbles may be observed running parallel with the folia of a schist, as a seam of fine grit or conglomerate may be seen to do in a series of shales. Nay, even the false-bedding so characteristic of mechanical sediment may be observed among these metamorphic rocks. The metamorphism is not uniform in these regions. Here and there it becomes intensified, and the rocks assume a thoroughly crystalline and much disturbed aspect. But as they recede from these areas they are found to lose much of their foliated character, and indeed to present such slight traces of metamorphism that they can be at once recognized as greywackes, grits, and shales. Moreover, they have been thrown into anticlinal and synclinal folds, and in these and other larger features of geological structure they differ in no essential respect from ordinary unaltered strata. Lastly, fossiliferous limestones containing Silurian shells have been found at their base, so that they have all been formed long after the seas over the area of Britain had been tenanted by living organisms.

Professor Sedgwick and Mr Darwin pointed out many years ago that a crystalline rearrangement of mineral matter has in some cases taken place along the planes of cleavage. We have already observed that the water which has been the great agent of metamorphism must always have followed the dominant divisional planes of a rock. If these planes were those of cleavage, the foliation would doubtless be produced along them, irrespective of the original laminæ of deposit. So long as the rock remained tolerably homogeneous in chemical composition, there seems no reason why foliation along the cleavage should differ in any material respect from that along stratification. But it may be doubted whether a cleavage foliation could run without sensible and even very serious interruptions over wide areas. For, in the first place, in most large masses of sedimentary matter we encounter alternations of different kinds of sediment, which could not but produce distinct kinds of rock under the influence of metamorphic change. In the second place, cleavage depends for its perfection and continuity on the fineness of grain of the rock through which it runs. While exceedingly perfect in a mass of argillaceous strata, it becomes feebler or even dies out in a coarse sandy or gritty rock. Hence, where foliation coincides with cleavage over large tracts, there will almost certainly be bands, more or less distinct, coincident with the original stratification, and running oblique to the general foliation, like bedding and cleavage, save where these two kinds of structure may happen to coalesce.

In a region of intense metamorphism the foliation of the schists may be observed to become here and there somewhat indefinite, until it disappears altogether, and the rocks assume a thoroughly granitic character. Between gneiss and granite there is no difference in mineralogical composition; in the one rock the minerals are arranged in folia, in the other they have no definite arrangement. Gneiss might be called a foliated granite; granite might be termed a non-foliated gneiss. The two rocks may be observed to graduate into each other. In Aberdeenshire, for example, the common grey mica-schist and gneiss may be seen to pass insensibly into the ordinary grey granite. In such cases it has been naturally concluded that granite is the ultimate stage of metamorphism. Judged merely from their composition and microscopic structure, an intrusive granite connected with igneous protrusions and a metamorphic granite representing the thorough transformation of stratified rock cannot be distinguished from each other.

There is thus nothing improbable in the idea that the same mineral particles may have gone through many successive cycles of change. We may suppose them to have been originally part of a granite mass, and to have been subsequently exposed at the surface by enormous denudation. Worn away from their parent granite they would be washed down with other particles, and spread out under water as parts of sandy or muddy deposits. Buried under a gradual accumulation of sedimentary material thousands of feet in thickness they might be depressed deep beneath the surface, and be thus brought within the influence of metamorphism. Gradually recomposed, crystallized, and converted into schistose rock, they might be eventually reduced to the condition of granite, and protruded into some of the overlying less metamorphosed masses in the form of granite veins. Or we may conceive, as already (*ante*, p. 309) suggested, that a communication was opened between the granite thus produced and the surface, and that the original mineral particles, whose vicissitudes we have been tracing, were erupted to the surface as part of a stream of lava.

Possible Metamorphism of Igneous Rocks.—In most large tracts of foliated rocks there occur masses less distinctly foliated or quite granitoid in texture, formed mainly of hornblende or of that mineral in combination with others. Zones or bosses of hornblende-rock and hornblende-schist frequently appear among gneiss and mica-schist. Varieties of quartz-porphyry occur in a similar way. Bands of fine unctuous chloritic schists may also often be traced. It is not easy to understand how such rocks, at least those containing a large percentage of magnesia, could be produced by the metamorphism of ordinary sediment. The difficulty may perhaps be removed if we regard them as having originally been igneous rocks, either erupted at the surface or intrusively injected among the surrounding rocks previous to metamorphism. Such mineral masses as varieties of syenite and diorite, rich in hornblende or other magnesian silicates, might have been the original condition of many of the rocks here referred to. The fine magnesian schists might be regarded as having been at first tuffs associated with the lava-form masses.

Structure of Metamorphic Rocks in the Field.—As the series of metamorphic rocks ranges from scarcely altered sedimentary strata on the one hand to crystalline amorphous granitic masses on the other, they must obviously possess a great range of structure as parts of the architecture of the solid land. In particular they must under different circumstances present the features now of aqueous and now of igneous rocks. The most typical form of metamorphism being foliation, we may consider the structure of foliated rocks as the most characteristic. From what has been said above, it is evident that the planes of foliation give the rocks a general resemblance to stratified sedimentary masses. But these planes are seldom so definite and persistent as those of stratification. They do not impart to the rocks the same tendency to split up into well-marked parallel beds. On the contrary they are often so felted or welded together, especially in the coarse and most crystalline gneisses, that they hardly serve as divisional planes at all, but leave the firm tough rock to split up along other lines.

With care and patience lines of anticlinal and synclinal fold may often be traced among foliated as well as among unaltered rocks. But the unravelling of these and other features of structure is much more difficult than among ordinary stratified formations. This arises partly from the frequent absence of conspicuous and persistent bands which could be used as horizons in working out geological structure, partly from the abundant crumpling which most foliated rocks have undergone, whereby the continuity of the individual bands is much disturbed or entirely destroyed.

The joints among foliated rocks to which the regular and parallel folia impart a marked fissility resemble those among sedimentary strata. Where, however, the foliation is of a more massive kind, as in the coarser varieties of gneiss, the system of jointing approximates to that of granite or one of the more crystalline igneous rocks.

IX. Mineral Veins.

The fissures which so abundantly traverse the crust of the earth have in many instances served as places for the deposit of mineral matter quite distinct from that of the rocks through which they run. As metallic ores frequently occur among the minerals so deposited, and have been extensively worked, a large amount of information has been obtained by mining operations regarding these fissures, or, as they are termed, *mineral veins*. A general though not invariable relation exists between the nature of the minerals in the fissures and that of the contiguous rocks. When the latter are calcareous, calcite usually forms a conspicuous feature in the veins; among siliceous rocks quartz is abundant. These and the other minerals are for the most part well crystallized or at least largely crystalline in the veins, even when the adjoining rocks are granular or amorphous. They are termed *vein-stones*. Since the joints, faults, and fissures which have been filled with new mineral substances are commonly highly inclined or vertical, mineral veins generally run as steep wall-like bands across the rocks in which they occur. Their minerals are arranged in strips, which on the whole run parallel with the walls of the vein (fig. 58).

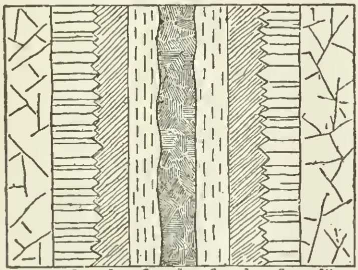

FIG. 58.—*a*, Coating of one mineral, say quartz; *b*, coating of a second mineral, say fluor spar; *c*, coating of first mineral, or of a third, say sulphate of baryta; *d*, rib of ore, as copper or lead; *w*, *w*, walls of the lode.

Mineral veins become *metalliferous*, when among their vein-stones there occur detached crystals or particles, or branching strings and threads, or concretionary masses or parallel bands of native metal, or of the sulphides, oxides, or other ores of metals. The association of these various substances within the two walls or cheeks of a vein is often in a double set of parallel bands, those in one-half of the vein being repeated in the other. The middle of the vein, for example, may consist of galena flanked and partially mixed up with zinc-blende and pyrites. On either side of this central rib there may be a layer of some veinstone, perhaps fluor spar, then a duplicate band of another veinstone, such as barytes or quartz, and so on, to the outer edge of the vein (fig. 58). In other cases, as in auriferous veins of quartz, the vein consists wholly or almost wholly of one vein-stone through which the ore is disseminated in minute grains and strings, so that the vein-stone must be extracted and crushed to obtain the metal by washing.

Mineral veins (*lodes*, *rake-veins*) vary in thickness from only an inch or less up to many fathoms. Extraordinary variations may be traced even in the course of the same vein, a breadth of several feet or yards rapidly diminishing until the two walls nearly or quite meet, to the exclusion of the minerals of the vein. Similar diversities may be observed in the horizontal extent of veins, some being traceable for miles, others disappearing in a few yards.

They sometimes occupy fissures without any throw, but most frequently seem to occur along lines of fault. In some cases indeed it can be shown that dislocation has taken place after some portion of the vein had been formed, but before the completion of the process. They usually send out branches, and in some mining districts do this to such an extent that it becomes hardly possible to identify the main vein among its numerous offshoots.

The direction of the veins varies in different districts. Two series may often be traced,—a principal series running in one general direction, and a minor set crossing the first at right angles or obliquely. Great differences in the richness of a metallic lode may be observed as it is worked vertically and horizontally, some of these depending in a way not easily explained upon the nature of the surrounding rock. Among the Cornish lodes, for example, some contain copper only where they traverse the Devonian slates, and lose it where they enter the granite, where tin takes its place. In the lead tracts of the north of England the metal diminishes where the veins lie in shale, and augments where they run through limestone.

In some rocks, more especially in limestones, large subterranean cavities have been filled with vein-stones and ores. The iron mines of the English lake district, for example, lie in the Carboniferous Limestone, where tunnels and caverns anciently dissolved out of the rock by percolating or running water have been subsequently filled up with hæmatite. In the lead districts of the north of England also, similar cavities have received a plentiful deposit of vein-stones and galena with its accompanying ores.

Various theories have been proposed to account for the infilling of mineral veins. Of these the most noteworthy are—(1) the theory of lateral segregation,—which teaches that the substances in the veins have been derived from the adjacent rocks by a process of solution and redeposit; and (2) the theory of infilling from below,—according to which the minerals and ores were introduced from below dissolved in water or steam or by sublimation, or by igneous fusion and injection.

The fact that the nature and amount of the minerals, and especially of the ores, in a vein vary with the nature of the surrounding rocks seems to show that these rocks have had a certain influence on the precipitation of mineral matter in the fissures passing through them. But that this mineral matter came chiefly from below appears almost certain. The phenomena of the ascent of hot water in volcanic districts afford a close analogy to what has occurred in mineral veins. It is known that at the present time various minerals, including silica, both crystalline and calcedonic, and various metallic sulphides, are being deposited in fissures up which hot water rises. At the same time it is conceivable that to some extent there may be a decomposition of the rocks on either side of a fissure, and that a portion of the mineral matter abstracted may be laid down in another form along the walls of the fissure, or, on the other hand, that the rocks on either side of the fissure may be permeated for some distance by the ascending waters, and that some of the mineral substances carried up in solution may be deposited in the pores and cavities of these rocks as well as in the fissure itself.

X. Unconformability

Where one series of rocks, whether of aqueous or igneous origin, has been laid down continuously and without disturbance upon another series, they are said to be *conformable.* Thus in fig. 59 the sheets of rock numbered 1, 2, 3,

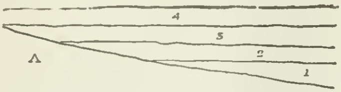

Fig. 59.—Overlap of conformable strata.

and 4 have succeeded each other in regular order, and exhibit a perfect conformability. They overlap each other, however, No. 2 extending beyond the edge of No. 1, No. 3 beyond that of No. 2, and so on. As already explained (p. 295), this structure points to a gradual subsidence and enlargement of the area of deposit. But all these conformable beds repose against the older platform A, with which they have no direct connexion. That platform may consist of horizontal or inclined strata, or contorted schist, or crystalline igneous rocks. In any case there is a complete break between it and the overlying rocks, which rest successively on different parts of the older mass. This relation is termed an unconformability. The upper conformable beds in fig. 59 are said to lie unconformably upon A.

It is evident that this structure may occur in ordinary stratified, or in igneous, or in metamorphic rocks, or between any two of these great series. It is most familiarly displayed among stratified masses, and can there be most satisfactorily studied. The lines of bedding furnish a ready means of detecting differences of inclination and discordance of superposition. But even among igneous protrusions and in ancient metamorphic masses, distinct evidence of unconformability is not always difficult to trace.

Though conformable rocks may usually be presumed to have followed each other continuously without any great disturbance of geographical conditions, we cannot always be safe in such an inference. But an unconformability leaves no room to doubt that it marks a decided break in the continuity of deposit. Hence no kind of geological structure is of higher importance in the interpretation of the history of the stratified formations of a country. In rare cases an unconformability may occur between two horizontal groups of strata. In fig. 60, for instance, a set of beds C is shown

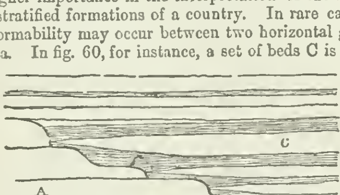

Fig. 60.—Unconformability among horizontal beds.

to lie conformably for some distance upon an older series *d.* Were nothing more to be seen than what appears towards the right hand, we might justifiably conclude the whole of the rocks to be conformable. By passing to the left, however, we should find evidence of the older group having been upraised and unequally denuded before the deposition of the newer. The denudation would show that the conformability was accidental, that the older rocks had really been upraised and worn down before the formation of the newer. In such a case the upheaval must have been so equable as not to disturb the horizontality of the lower rocks.

As a rule, however, it seldom happens that movements of this kind have taken place over an extensive area so equably as not to produce a want of conformability somewhere between the older and newer rocks. Most frequently the older formations have been disturbed, tilted at various angles, or even placed on end. They have likewise been irregularly and enormously worn down. Hence, instead of lying parallel, the younger beds run transgressively across the upturned denuded ends of the older. The greater the

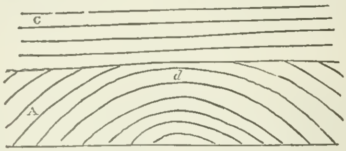

Fig. 61.—Section of unconformable rocks.

disturbance of the older rocks the more marked is the unconformability. In fig. 61, for instance, the series of beds A is uncomformably covered by the series C. At both sides of the arch the uncomformability is strongly marked, but at the centre *d* the two series seem to be conformable. An unconformability forms one of the great breaks in the geological record. In the foregoing figure, by way of illustration, we see at once that a notable hiatus in deposition, and therefore in geological chronology, must exist between series A and C. The older rocks had been deposited, folded, upheaved, and worn down before the accumulation of the newer series upon their denuded edges. These changes must have demanded a considerable lapse of time. Yet, looking merely at the structure in itself, we have evidently no means of fixing, even relatively, the length of interval marked by an unconformability. The mere violence of contrast between a set of vertical beds below and a horizontal group above it is no reliable criterion of the relative lapse of time between their deposition, for an older portion of a given formation might be tilted on end and be overlaid unconformably by a later part of the same formation. A set of flat rocks of high geological antiquity might, on the other hand, be covered by a formation of comparatively recent date, yet in spite of the want of discordance between the two, they might have been separated by a large portion of the total sum of geological time. It is by the evidence of organic remains that the relative importance of unconformabilities must be measured, as will be explained in part v.

Paramount though the effect of an unconformability may be in the geological structure of a country, it must nevertheless be in almost all cases local. The disturbance by which it was produced can have effected but a comparatively circumscribed region, beyond the limits of which the continuity of sedimentation may have been undisturbed. We may therefore always expect to be able to fill up the gaps in one district from the more complete geological formations of another. In fig. 61 we see that something is wanting between A and C. But in the structure of another country or a different part of the same country we might discover

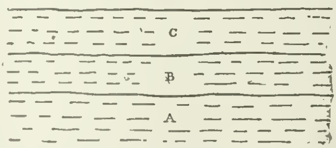

Fig. 62.—Section showing the groups of fig. 61 in conformable sequence, with the intervening blank (S) supplied.

the complete succession, as in fig. 62, where the whole of the rocks succeed each other conformably, and where the gap between A and C marked by the unconformability in fig. 61 is bridged over by the intermediate group of strata B.

PART V.—PALÆONTOLOGICAL GEOLOGY.

Palæontology is the science which treats of the structure, affinities, classification, and distribution in time of the forms of plant and animal life embedded in the rocks of the earth's crust. In one sense it may be regarded as a branch of zoology and of botany, its claim in this view to rank as a separate science resting almost solely on the fact that of the forms with which it deals but a small proportion belongs to the living world. In another aspect it may be looked upon as a branch of geology, seeing that its assistance is absolutely indispensable in many of the most familiar and fundamental problems of the latter science. It is under this last aspect that we have to regard it here. We shall consider merely those leading features of palæontological inquiry without some knowledge of which progress in modern geology would be impossible.

Fossils.—Palæontological geology, then, deals with the *fossils* or organic remains preserved in the rocks, and endeavours to gather from them information as to the history of the globe and its inhabitants. The term "fossil," meaning literally anything "dug up," was formerly applied indiscriminately to any mineral substance taken out of the earth's crust, whether organized or not. Ordinary minerals and rocks were thus included as fossils. For many years, however, the meaning of the word has been restricted, so as to include only the remains or traces of plants and animals preserved in any natural formation whether hard rock or superficial deposit. The idea of antiquity or relative date is not necessarily involved in this conception of the term. Thus the bones of a sheep buried under gravel and silt by a modern flood, and the obscure crystalline traces of a coral in ancient masses of limestone, are equally fossils.

Nor has the term fossil any limitation as to organic grade. It includes not merely the remains of organisms, but also whatever was directly connected with or produced by these organisms. Thus the resin which was exuded from trees of long-perished forests is as much a fossil as any portion of the stem, leaves, flowers, or fruit, and in some respects is even more valuable to the geologist than more determinable remains of its parent trees, because it has often preserved in admirable perfection the insects which flitted about in the woodlands The burrows and trails of a worm preserved in sandstone and shale claim recognition as fossils, and indeed are commonly the only indications to be met with of the existence of annelide life among old geological formations. The droppings of fishes and reptiles, called coprolites, are excellent fossils, and tell their tale as to the presence of vertebrate life in ancient waters. The little agglutinated cases of the caddis-worm remain as fossils in formations from which perchance most other traces of life may have passed away. Nay, the very handiwork of man, when preserved in any natural manner, is entitled to rank among fossils; as where his flint-implements have been dropped into the prehistoric gravels of river-valleys, or where his canoes have been buried in the silt of lake-bottoms.

The term fossil, moreover, suffers no restriction as to the condition or state of preservation of any organism. In some rare instances the very flesh, skin, and hair of a mammal have been preserved for thousands of years, as in the case of the mammoths entombed within the frozen mud cliffs of Siberia. In most cases all or most of the original animal matter has disappeared, and the organism has been more or less completely mineralized or petrified. It often happens that the whole organism has decayed, and a mere cast in amorphous mineral matter, as sand, clay, ironstone, silica, or limestone remains; yet all these variations must be comprised in the comprehensive term fossil.

Conditions for the Preservation of Organic Remains.—At the outset the question naturally suggests itself how the remains of plants and animals come to have been preserved in rocks at all. If we observe what takes place at the present day, and argue that it may fairly be taken as an indication of what has been the ordinary condition of things in the geological past, we see that there must have been so many chances against the conservation of either animal or plant remains that their occurrence among stratified formations should be regarded as exceptional, and as the result of various fortunate accidents.

I. Consider, in the first place, what chances exist for the preservation of remains of the present fauna and flora of a country. The surface of the land may be densely clothed with forest, and abundantly peopled with animal life. But the trees die and moulder into soil. The animals, too, disappear, generation after generation, and leave no perceptible traces of their existence. If we were not aware from authentic records that central and northern Europe was covered with vast forests at the beginning of our era, how could we know this fact? What has become of the herds of wild oxen, the bears, wolves, and other denizens of primeval Europe? How could we prove from the examination of the surface soil of any country that those creatures had once abounded there? We might search in vain for any such superficial traces, and would learn by so doing that the law of nature is everywhere "dust to dust."

The conditions for the preservation of any relics of the plant and animal life of a terrestrial surface must therefore be always exceptional. They are supplied only where the organic remains can be protected from the air and superficial decay. Hence they may be observed in

1. *Lakes.*—Over the floor of a lake deposits of silt, peat, marl, &c., are formed. Into these the stems, branches, leaves, flowers, fruits, or seeds of plants from the neighbouring land may be carried, together with the bodies of land animals, insects, and birds. An occasional storm may blow the lighter debris of the woodlands into the water. Such portions of the wreck as did not float, and were not washed ashore again, might sink to the bottom. Of these the larger part would in most cases probably rot away, so that, in the end, only a very small fraction of the whole vegetable matter cast over the lake by the wind would be covered up and preserved at the bottom. In like manner the animal remains swept by winds or by river floods into the lake would run so many risks of dissolution that only a proportion of them, and probably merely a small proportion, would be preserved. When we consider these chances against the conservation of the vegetable and animal life of the land, we must admit that, at the best, lake-bottoms can contain but a meagre and imperfect representation of the abundant life of the adjacent hills and plains.

But lakes have a distinct flora and fauna of their own. Their aquatic plants may be entombed in the gathering deposits of the bottom. Their mollusks, of characteristic types, sometimes form, by the accumulation of their remains, sheets of soft calcareous marl, in which many of the undecayed shells are preserved. Their fishes, likewise distinctly lacustrine, no doubt must often be entombed in the silt or marl.

2. *Peat-mosses.*—Wild animals venturing on the more treacherous watery parts of a peat-bog are sometimes engulphed or "laired." The antiseptic qualities of the peat preserve such remains from decay. Hence from European peat-mosses numerous remains of deer and oxen have been exhumed. Evidently the larger beasts of the forest ought chiefly to be looked for in these localities.

3. *Deltas at River Mouths.*—From what has been said in previous pages (*ante*, pp. 276–8) regarding the geological operations of rivers, it is obvious that to some extent both the flora and the fauna of the land may be buried among the sand and silt of deltas. When we consider, however, that though occasional or frequent river-floods sweep dow

trees, herbage, and the bodies of land animals, the remains so transported run every risk of decaying or being otherwise destroyed while still afloat, and that even if they reach the bottom they will tend to dissolution there unless speedily covered up and protected by fresh sediment, we must perceive that delta formations can scarcely be expected to give us more than a meagre outline of the varied terrestrial flora and fauna.

4. *Caverns.*—These are eminently adapted for the preservation of the higher forms of terrestrial life. Most of our knowledge of the prehistoric mammalian fauna of Europe is derived from what has been disinterred from *bone-caves.* As these recesses lie for the most part in limestone or in calcareous rock, their floors are commonly coated with stalagmite from the drip of the roof; and as this deposit is of great closeness and durability it has effectually preserved whatever it has covered or enveloped. The caves have in many instances served predatory beasts, like the hyæna, cave-lion, and cave-bear, as dens in which they slept, and into which some of them dragged their prey. In other cases they have been merely holes into which different animals crawled to die, or into which they fell or were swept by inundations. Under whatever circumstances the animals left their remains in these subterranean retreats, the result has been that the bones have been covered up and preserved. Still, we must admit that after all but a mere fraction even of the mammals of the time would enter the caves, and therefore that the evidence of the cavern-deposits, profoundly interesting and valuable as it is, presents us with merely a glimpse of one aspect of the life of the land.

II. In the next place, if we turn to the sea, we find certainly many more favourable conditions for the preservation of organic forms, but also many circumstances which operate against it. While the level of the land remains stationary, there can be but little effective entombment of marine organisms in littoral deposits; for only a limited accumulation of sediment will be formed until subsidence of the sea-floor takes place. In the trifling beds of sand or gravel thrown up on a stationary shore, only the harder and more durable forms of life, such as gasteropods and lamellibranchs, which can withstand the triturating effects of the beach waves, are likely to remain uneffaced.

Below tide-marks, along the margin of the land where sediment is gradually deposited, the conditions are favourable for the preservation of marine organisms. Sheets of sand and mud are there laid down. In those sediments the harder parts of many forms of life may be entombed and protected from decay. But only a small proportion of the total marine fauna may be expected to occur in such deposits. At the best, merely littoral and shallow-water forms will occur, and even under the most favourable conditions they will represent but a fraction of the whole assemblage of life in these juxta-terrestrial parts of the ocean. As we recede from the land the rate of deposition of sediment on the sea-floor must become feebler, until in the remote central abysses it reaches a hardly appreciable minimum. Except, therefore, where organic deposits, such as ooze, are forming in these more pelagic regions, the conditions must be on the whole unfavourable for the preservation of any adequate representation of the deep-sea fauna. Hard enduring objects, such as teeth and bones, may slowly accumulate and be protected by a coating of peroxide of manganese, or of some of the silicates above (p. 288) referred to as now forming here and there over the deep-sea-bottom. But such a deposit, if raised into land, would supply but a meagre picture of the life of the sea.

We must conclude therefore that of the whole sea-floor the area best adapted for preserving a varied suite of marine organic exuviæ is that belt which, running along the margin of the land, is ever receiving fresh layers of sediment transported by rivers and currents from the adjacent shores. The most favourable conditions for the accumulation of a thick mass of marine fossiliferous strata will arise when the area of deposit is undergoing a gradual subsidence. If the rate of depression and that of deposit were equal, or nearly so, the movement might proceed for a vast period without producing any great apparent change in marine geography, and even without seriously affecting the distribution of life over the sea-floor within the area of subsidence. Hundreds or thousands of feet of sedimentary strata might in this way be heaped up round the continents, containing a fragmentary series of organic remains belonging to those forms of shallow-water life which had hard parts capable of preservation.

There can be little doubt that such has in fact been the history of the main mass of stratified formations in the earth's crust. These piles of marine strata have unquestionably been laid down in comparatively shallow water within the area of deposit of terrestrial sediment. Their great depth seems only explicable by prolonged and repeated movements of subsidence, interrupted, however, as we know, by other movements of a contrary kind. These geographical changes affected at once the deposition of inorganic materials and the succession of organic forms. One series of strata is sometimes abruptly succeeded by another of a very different character, and we generally find a corresponding contrast between their respective organic contents.

It follows from these conclusions that representatives of the abyssal deposits of the central oceans are not likely to be met with among the geological formations of past times. Thanks to the great work done by the "Challenger" expedition, we now know what are the leading characters of these abyssal deposits of the present day. They have absolutely no analogy among the formations of the earth's crust. They differ, indeed, so entirely from any formation which geologists considered to be of deep-water origin as to indicate that, from early geological times, the present great areas of land and sea have remained on the whole where they are, and that the land consists mainly of strata formed at successive epochs of terrestrial debris laid down in the surrounding shallow sea.

Relative Value of Organic Remains as Fossils.—As the conditions for the preservation of organic remains exist more favourably under the sea than on land, marine organisms must be far more abundantly conserved than those of the land. This is true to-day, and has been true in all past geological time. Hence for the purposes of the geologist the fossil remains of marine forms of life far surpass all others in value. Among them there will necessarily be a gradation of importance regulated chiefly by their relative abundance. Now, of all the marine tribes which live within the juxta-terrestrial belt of sedimentation, unquestionably the *Mollusca* stand in the place of pre-eminence as regards their aptitude for becoming fossils. In the first place they almost all possess a hard durable shell, capable of resisting considerable abrasion, and readily passing into a mineralized condition. In the next place they are extremely abundant both as to individuals and genera. They occur on the shore within tide mark, and range thence down into the abysses. Moreover, they appear to have possessed those qualifications from early geological times. In the marine *Mollusca*, therefore, we have a common ground of comparison between the stratified formations of different periods. They have been styled the alphabet of palæontological inquiry. It will be seen, as we proceed, how much in the interpretation of geological history depends upon the testimony of sea-shells.

Looking at the organisms of the land, we perceive that as a rule the abundant terrestrial flora has a comparatively small chance of being well represented in a fossil state, that indeed, as a rule, only that portion of it of which the leaves, twigs, flowers, and fruits are blown into lakes is likely to be partially preserved. Terrestrial plants, therefore, occur in comparative rarity among stratified rocks, and furnish in consequence only limited means of comparison between the formations of different ages and countries. Of land animals the vast majority perish and leave no permanent trace of their existence. Predatory and other forms whose remains may be looked for in caverns or peat-mosses, must occur more numerously in the fossil state than birds, and are correspondingly more valuable to the geologist for the comparison of different strata.

Relative Age of Fossils.—Although absolute dates cannot be fixed in geological chronology, it is not difficult to determine the relative age of different strata, and consequently of their enclosed organic remains. For this purpose the fundamental law is based on what is termed the "order of superposition." This law may be thus defined:—in a series of stratified formations the older must underlie the younger. It is not needful that we should actually see the one lying below the other. If a continuous conformable succession of strata dips steadily in one direction we know that the beds at the one end must underlie those at the other, because we can trace the whole succession of beds between them. Rare instances occur where strata have been so folded by great terrestrial disturbance that the younger are made to underlie the older. But this inversion can usually be made quite clear from other evidence. The true order of superposition is decisive of the relative ages of stratified rocks.

If therefore formations lie regularly above each other, B upon A, C upon B, D upon C, and so on, it is evident that the organic remains found in A must have lived and died before those in B were entombed; the latter must have been covered up before those in C, and these again before those in D. The chronological sequence of fossils must be determined first of all by the order of superposition of their enclosing strata. There is nothing in the fossils themselves, apart from experience, to fix their date. Unless, for example, we knew from observation or testimony that *Rhynchonella pleurodon* is a shell of the Carboniferous Limestone, and *Rhynchonella tetrahedra* is a shell of the Lias, we could not, from mere inspection of the fossils themselves, pronounce as to their real geological position. It is quite true that by practice a palæontologist has his eye so trained that he can make shrewd approximations to the actual horizon of fossils which he may never have seen before; but he can only do this by availing himself of a wide experience based upon the ascertained order of appearance of fossils as determined by the law of superposition. For geological purposes therefore, and indeed for all purposes of comparison between the faunas and floras of different periods, it is absolutely essential first of all to have the order of superposition of strata rigorously determined. Unless this is done the most fatal mistakes may be made in palæontological chronology. But when it has once been done in one typical district, the order thus established may be held as proved for a wide region where, from paucity of sections, or from geological disturbance, the true succession of formations cannot be satisfactorily determined.

Uses of Fossils in Geology.—There are two main purposes to which fossils may be put in geological research:—(1) to throw light upon former conditions of physical geography, such as the presence of land, rivers, lakes, and seas, in places where they do not now exist, changes of climate, and the former distribution of plants and animals; and (2) to furnish a guide in geological chronology whereby rocks may be classified according to relative date, and the facts of geological history may be arranged and interpreted as a connected record of the earth's progress.

1. A few examples will suffice to show the manifold assistance which fossils furnish to the geologist in the elucidation of ancient geography.

(*a.*) Former land-surfaces are revealed by the presence of tree-stumps in their positions of growth, with their roots branching freely in the underlying stratum, which, representing the ancient soil, often contains leaves, fruits, and other sylvan remains, together with traces of the bones of land animals, remains of insects, land-shells, &c. Ancient woodland surfaces of this kind are found between tide-marks, and even below low-water line, round different parts of the British coast. They unequivocally prove a subsidence of the land. Of more ancient date are the "dirt-beds" of Portland, which, by their layers of soil and tree-stumps, show that woodlands of cycads sprang up over an upraised sea-bottom and were buried beneath the silt of a river or lake. Still further back in geological history come the numerous coal-growths of the Carboniferous period, pointing to wide jungles of terrestrial or aquatic plants, like the modern mangrove swamps, which were submerged and covered with sand and silt.

(*b.*) The former existence of lakes can be satisfactorily proved from beds of marl or lacustrine limestone full of fresh-water shells, or from fine silt with leaves, fruits, and insect remains. Such deposits are abundantly forming at the present day, and they occur at various horizons among the geological formations of past times. The well-known nagelflue of Switzerland—a mass of conglomerate attaining a thickness of fully 6000 feet—can be shown from its fossil contents to be essentially a lacustrine formation.

(*c.*) Old sea-bottoms are vividly brought before us by beds of marine shells and other organisms. Layers of water-worn gravel and sand, with rolled shells of littoral and infra-littoral species, unmistakably mark the position of a former shore line. Deeper water is indicated by finer muddy sediment, with relics of the fauna which prevails beneath the reach of waves and ground-swell. Limestones full of corals, or made up of crinoids, point to the slow continuous growth and decay of generation after generation of organisms in clear sea-water.

(*d.*) Variations in the nature of the water or of the sea-bottom may sometimes be shown by changes in the size or shape of the organic remains. If, for example, the fossils in the central and lower parts of a limestone are large and well-formed, but in the upper layers become dwarfed and distorted, we may reasonably infer that the conditions for their continued existence at that locality must have been gradually impaired. The final complete cessation of these favourable conditions is shown by the replacement of the limestone by shale, indicative of the water having become muddy, and by the disappearance of the fossils, which had shown their sensitiveness to the change.

(*e.*) That the sea-floor represented by a fossiliferous stratum was not far from land is sufficiently proved by mere lithological characters, as has been already explained; but the conclusion may be further strengthened by the occurrence of leaves, stems, and other fragments of terrestrial vegetation which, if found in some numbers among marine organisms, would make it improbable that they had been drifted far from land.

(*f.*) The existence of different conditions of climate in former geological periods is satisfactorily demonstrated from the testimony of fossils. Thus an assemblage of the remains of palms, gourds, and melons, with bones of crocodiles, turtles, and sea-snakes, proves a sub-tropical climate to have prevailed over the south of England in the time of the older Tertiary formations. On the other hand, the presence of an intensely cold or arctic climate far south in Europe during post-Tertiary time can be shown from different kinds of evidence, such as the existence of the remains of arctic animals even as far as the south of England and of France.

This is a use of fossils, however, where great caution must be used. We cannot affirm that, because a certain species of a genus lives now in a warm part of the globe, every species of that genus must always have lived in similar circumstances. The well-known example of the mammoth and woolly rhinoceros having lived in the cold north, while their modern representatives inhabit some of the warmest regions of the globe, may be usefully remembered as a warning against any such conclusions. When, however, we find that not one fossil merely, but the whole assemblage of fossils in a formation has its modern analogue in a certain general condition of climate, we may at least tentatively infer that the same kind of climate prevailed where that assemblage of fossils lived. Such an inference would become more and more unsafe in proportion to the antiquity of the fossils and their divergence from existing forms.

2. When the order of superposition has been determined in a great series of stratified formations, it is found that the fossils at the bottom are not quite the same as those at the top of the series. As we trace the beds upward we discover that species after species of the lowest platforms disappears, until perhaps not one of them is found. With the cessation of these older species others make their entrance. These in turn are found to die out and to be replaced by newer forms. After patient examination of the rocks, it is ascertained that every well-marked formation is characterized by its own species or genera, or by a general assemblage or *facies* of organic forms. This can only, of course, be determined by actual practical experience over an area of some size. When the typical fossils of a formation are known, they serve to identify that formation in its progress across a country. Thus, as we trace the formation into tracts where it would be impossible to determine the true order of superposition, owing to the want of sections, or to the disturbed condition of the rocks, we can employ the fossils as a means of identification, and speak with confidence as to the succession of the rocks. We may even demonstrate that in some mountainous ground the beds have been turned completely upside down, if we can show that the fossils in what are now the uppermost strata ought properly to lie underneath those in the beds below them.

Observations made over a large part of the surface of the globe have enabled geologists to divide the stratified part of the earth's crust into systems, formations, and groups or series. These subdivisions are frequently marked off from each other by lithological characters. But mere lithological differences would afford at the best but a limited and local ground of separation. Two masses of sandstone, for example, having exactly the same general external and internal characters, might belong to very different geological periods. On the other hand, a series of limestones in one locality might be the exact chronological equivalent of a set of sandstones and conglomerates at another, and of a series of shales and clays at a third.

It is by their characteristic fossils that the divisions of the stratified rocks can be most satisfactorily made. Each formation being distinguished by its own assemblage of organic remains, it can be followed and recognized even amid the crumplings and dislocations of a disturbed region. The same general succession of organic types can be observed over a large part of the world, though, of course, with important modifications in different countries. This similarity of succession has been termed *homotaxis*—a term which expresses the fact that the order in which the leading types of organized existence have appeared upon the earth has been similar even in widely separated regions.

It is evident that in this way a method of comparison is furnished whereby the stratified formations of different parts of the earth's crust can be brought into relation with each other. We find, for example, that a certain series of strata is characterized in Britain by certain genera and species of corals, brachiopods, lamellibranchs, gasteropods, and cephalopods A group of rocks in Bohemia, differing more or less from these in lithological aspect, contains on the whole the same genera, and many even of the same species. In Scandinavia a set of beds may be seen unlike, perhaps, in external characters to the British type, but yielding many of the same fossils. In Canada and many parts of the northern United States, other rocks enclose many of the same, and of closely allied genera and species. All these groups of strata are classed together as *homotaxial*, that is, as having been deposited during the same relative period in the general progress of life in each region.

It was at one time believed, and the belief is still far from extinct, that groups of strata characterized by this community or resemblance of organic remains were chronologically contemporaneous. But such an inference rests upon most insecure grounds. We may not be able to disprove the assertion that the strata were strictly coeval, but we have only to reflect on the present conditions of zoological and botanical distribution, and of modern sedimentation, to be assured that the assertion of contemporaneity is a mere assumption. Consider for a moment what would happen were the present surface of any portion of central or southern Europe to be submerged beneath the sea, covered by marine deposits, and then re-elevated into land. The river-terraces and lacustrine marls formed before the time of Julius Cæsar could not be distinguished by any fossil tests from those laid down in the days of Victoria, unless, indeed, traces of human implements were obtainable whereby the progress of civilization during 2000 years might be indicated. So far as regards the shells, bones, and plants preserved in the various formations, it would be absolutely impossible to discriminate their relative dates; they would be classed as "geologically contemporaneous," that is, as having been formed during the same period in the history of life in the European area; yet there might be a difference of 2000 years or more between many of them. Strict contemporaneity cannot be asserted of any strata merely on the ground of similarity or identity in fossils.

But the phrase "geologically contemporaneous" is too vague to have any chronological value except in a relative sense. To speak of two formations as in any sense contemporaneous which may have been separated by thousands of years seems rather a misuse of language, though the phraseology has now gained such a footing in geological literature as probably to be inexpugnable. If we turn again for suggestions to the existing distribution of life on the earth we learn that similarity or identity of species and genera holds good on the whole only for limited areas, and consequently, if applied to wide geographical regions, ought to be an argument for diversity rather than for similarity of age. If we suppose the British seas to be raised into dry land, so that the organic relics preserved in their sands and silts could be exhumed and examined, a general common facies or type would be found, though some species would be more abundant in or entirely confined to the north, while others would show a greater development in the opposite quarter. Still there would be such a similarity throughout the whole that no naturalist would hesitate to regard the organisms as those of one biological province, and belonging to the same great geological period. The region is so small, and its conditions of life so uniform and uninterrupted, that no marked distinction is possible between the forms of life in its different parts.

Widening the area of observation, we perceive that as we recede from any given point the forms of life gradually change. vegetation alters its aspect from climate to climate, and with it come corresponding transformations in the character of insects, birds. and wild animals. A lake bottom would preserve one suite of organisms in England, but a very different group at the foot of the Himalaya Mountains, yet the deposits at the two places might be absolutely coeval, even as to months and days. Hence it becomes apparent that while strict contemporaneity cannot be predicated of deposits containing the same organic remains, it may actually be true of deposits in which they are quite distinct.

If, then, at the present time, community of organic forms obtains only in districts, regions, or provinces, it may have been more or less limited also in past time. Similarity or identity of fossils among formations geographically far apart, instead of proving contemporaneity, ought rather to be looked upon as indicative of great discrepancies in the relative epochs of deposit. For in any theory of the origin of species, the spread of any one species, still more of any group of species to a vast distance from the original centre of dispersion, must in most cases have been inconceivably slow. It must have occupied so prolonged a time as to allow of almost indefinite changes in physical geography. A species may have disappeared from its primeval birthplace while it continued to flourish in one or more directions in its outward circle of advance. The date of the first appearance and final extinction of that species would thus differ widely according to the locality at which we might examine its remains.

The grand march of life, in its progress from lower to higher forms, has unquestionably been broadly alike in all quarters of the globe. But nothing seems more certain than that its rate of advance has not everywhere been the same. It has moved unequally over the same region. A certain stage of progress may have been reached in one quarter of the globe thousands of years before it was reached in another; though the same general succession of organic forms might be found in each region.

The geological formations form the records of these ages of organic development. In every country where they are fully displayed, and where they have been properly examined, they can be separated out from each other according to their organic contents. Their relative age within a limited geographical area can be demonstrated by the mere law of superposition. When, however, the formations of distant countries are compared, all that we can safely affirm regarding them is that those containing the same or a representative assemblage of organic remains belong to the same epoch in the history of biological progress in each area. They are *homotaxial*; but we cannot assert that they are contemporaneous, unless we are prepared to include within that term a vague period of perhaps thousands of years.

Doctrine of Colonies.—M Barrande, the distinguished author of the *Système Silurien de la Bohême*, drew attention more than a quarter of a century ago to certain remarkable intercalations of fossils in the series of Silurian strata of Bohemia. He showed that, while these strata presented a normal succession of organic remains, there were nevertheless exceptional bands, which, containing the fossils of a higher zone, were yet included on different horizons among inferior portions of the series. He termed these precursory bands "colonies," and defined the phenomena as consisting in the partial co-existence of two general faunas, which, considered as a whole, were nevertheless successive. He supposed that during the later stages of his second Silurian fauna in Bohemia the first phases of the third fauna had already appeared, and attained some degree of development in some neighbouring but yet unknown region. At intervals, corresponding doubtless to geographical changes, such as movements of subsidence or elevation, volcanic eruptions, &c., communication was opened between that outer region and the basin of Bohemia. During these intervals a greater or less number of immigrants succeeded in making their way into the Bohemian area, but as the conditions for their prolonged continuance there were not yet favourable, they soon died out, and the normal fauna of the region resumed its occupancy. The deposits formed during these partial interruptions, notably graptolitic schists, accompanied by igneous sheets, contain, besides the invading species, remains of some of the indigenous forms. Eventually, however, on the final extinction of the second fauna, and, we may suppose, on the ultimate demolition of the physical barriers hitherto only occasionally and temporarily broken, the third fauna, which had already sent successive colonies into the Bohemian area, now swarmed into it, and peopled it till the close of the Silurian period.

This original and ingenious doctrine has met with much opposition on the part of geologists and palæontologists. Of the facts cited by M. Barrande there has been no question, but other explanations have been suggested for them. It has been said, for example, that the so-called colonies are merely bands of the Upper Silurian rocks or third fauna, which by great plications have been so folded with the older rocks as to seem regularly interstratified with them. But the author of the *Système Silurien* very justly contends that of such foldings there is no evidence, but that, on the contrary, the sequence of the strata appears normal and undisturbed. Again it has been urged that the difference of organic contents in these so-called colonies is due merely to a difference in the conditions of water and sea-bottom, particular species appearing with the conditions favourable to their spread, and disappearing when these ceased. But this contention is really included in M. Barrande's theory. The species which disappear and reappear in later stages must have existed in the meanwhile outside of the area of deposit, which is precisely what he has sought to establish. Much of the opposition which his views have encountered has probably arisen from the feeling that if they are admitted they must weaken the value of palæontological evidence in defining geological horizons. A palæontologist, who has been accustomed to deal with certain fossils as unfailing indications of particular portions of the geological series, is naturally unwilling to see his generalizations upset by an attempt to show that the fossils may occur on a far earlier horizon.

If, however, we view this question from the broad natural history platform from which it was regarded by M. Barrande, it is impossible not to admit that such phenomena as he has sought to establish in Bohemia must have constantly occurred in all geological periods and in all parts of the world. No one now believes in the sudden extinction and creation of entire faunas Every great fauna in the earth's history must have gradually grown out of some pre-existing one, and must have insensibly graduated into that which succeeded. The occurrence of two very distinct faunas in two closely consecutive series of strata does not prove that the one abruptly died out and the other suddenly appeared in its place. It only shows, as Darwin has so well enforced, the imperfection of the geological record. In the interval between the formation of two such contrasted groups of rocks the fauna of the lower strata must have continued to exist elsewhere, and gradually to change into the newer facies which appeared when sedimentation recommenced with the upper strata. Distinct zoological provinces have no doubt been separated by narrow barriers in former geological periods, as they still are to-day. There seems, therefore, every probability that such migrations as M. Barrande has supposed in the case of the Silurian fauna of Bohemia have again and again taken place. Two notable examples will be given in later pages, one in the Lower and one in the Upper Old Red Sandstone of Scotland.

Gaps in the Geological Record.—The history of life has been very imperfectly preserved in the stratified parts of the earth's crust. Apart from the fact that, even under the most favourable conditions, only a small proportion of the total flora and fauna of any period could be preserved in the fossil state, enormous gaps occur where no record has been preserved at all. It is as if whole chapters and books were missing from an historical work. Some of these lacunæ are sufficiently obvious. Thus, in some cases, powerful dislocations have thrown considerable portions of the rocks out of sight. Sometimes extensive metamorphism has so affected them that their original characters, including their organic contents, have been destroyed. Oftenest of all, denudation has come into play, and vast masses of fossiliferous rock have been entirely worn away. That this cause has operated frequently is shown by the abundant unconformabilities in the structure of the earth's crust.

While the mere fact that one series of rocks lies unconformably on another proves the lapse of a considerable interval between their respective dates, the relative length of this interval may sometimes be demonstrated by means of fossil evidence and by this alone. Let us suppose, for example, that a certain group of formations has been disturbed, upraised, denuded, and covered unconformably by a second group. In lithological characters the two may closely resemble each other, and there may be nothing to show that the gap represented by their unconformability is not of a trifling character. In many cases, indeed, it would be quite impossible to pronounce any well-grounded judgment as to the amount of interval, even measured by the vague relative standards of geological chronology. But if each group contains a well-preserved suite of organic remains, it may not only be possible, but easy, to say exactly how much of the geological record has been left out between the two sets of formations. By comparing the fossils with those obtained from regions where the geological record is more complete, it may be ascertained perhaps that the lower rocks belong to a certain platform or stage in geological history which for our present purpose we may call D, and that the upper rocks can in like manner be paralleled with stage H. It would be then apparent that at this locality the chronicles of three great geological periods E, F, and G were wanting, which are elsewhere found to be intercalated between D and H. The lapse of time represented by this unconformability would thus be equivalent to that required for the accumulation of the three missing formations in those regions where sedimentation went on undisturbed.

But fossil evidence may be made to prove the existence of gaps which are not otherwise apparent. As has been already remarked, changes in organic forms must, on the whole, have been extremely slow in the geological past. The whole species of a sea floor could not pass entirely away, and be replaced by other forms, without the lapse of long periods of time. If then among the conformable stratified formations of former ages we encounter sudden and abrupt changes in the facies of the fossils, we may be certain that these must mark omissions in the record, which we may hope to fill in from a more perfect series elsewhere. The complete contrasts between unconformable strata are sufficiently explicable. It is not so easy to give a satisfactory account of those which occur where the beds are strictly conformable, and where no evidence can be observed of any considerable change of physical conditions at the time of deposit. A group of strata having the same general lithological characters throughout may be marked by a great discrepance between the fossils above and below a certain line. A few species may pass from the one into the other, or perhaps every species may be different. In cases of this kind, when proved to be not merely local but persistent over wide areas, we must admit, notwithstanding the apparently undisturbed and continuous character of the original deposition of the strata, that the abrupt transition from the one facies of fossils to the other must represent a long interval of time which has not been recorded by the deposit of strata. Professor Ramsay, who called attention to these gaps, termed them "breaks in the succession of organic remains." He showed that they occur abundantly among the Palæozoic and Secondary rocks of England. It is obvious, of course, that these breaks, even though traceable over wide regions, were not general over the whole globe. There have never been any universal interruptions in the continuity of the chain of being, so far as geological evidence can show. But the physical changes which caused the breaks may have been general over a zoological district or minor region. They no doubt often caused the complete extinction of genera and species which had a small geographical range.

From all these facts it is clear that the geological record, as it now exists, is at the best but an imperfect chronicle of geological history. In no country is it complete. The lacunæ of one region must be supplied from another. Yet in proportion to the geographical distance between the localities where the gaps occur and those whence the missing intervals are supplied, the element of uncertainty in our reading of the record is increased. The most desirable method of research is to exhaust the evidence for each area or province, and to compare the general order of its succession as a whole with that which can be established for other provinces. It is, therefore, only after long and patient observation and comparison that the geological history of different quarters of the globe can be correlated.

Subdivisions of the Geological Record by means of Fossils.— As fossil evidence furnishes a much more satisfactory and widely applicable means of subdividing the stratified rocks of the earth's crust than mere lithological characters, it is made the basis of the geological classification of these rocks. Thus we may find a particular stratum marked by the occurrence in it of various fossils, one or more of which may be distinctive, either from occurring in no other bed above and below, or from special abundance in that stratum. These species might therefore be used as a guide to the occurrence of the bed in question, which might be called by the name of the most abundant species. In this way a geological horizon or zone would be marked off, and geologists would thereafter recognize its exact position in the series of formations. But before such a generalization can be safely made, we must be sure that the species in question really never does appear on any other platform. This evidently demands wide experience over an extended field of observation. The assertion that a particular species occurs only on one horizon manifestly rests on negative evidence as much as on positive. The palæontologist who makes it cannot mean more than that he knows the fossil to lie on that horizon, and that, so far as his own experience and that of others goes, it has never been met with anywhere else. But a single example of the occurrence of the fossil on a different zone would greatly damage the value of his generalization, and a few such cases would demolish it altogether. Hence all such statements ought at first to be made tentatively. To establish a geological horizon on limited fossil evidence, and then to assume the identity of all strata containing the same fossils, is to reason in a circle and to introduce utter confusion into our interpretation of the geological record. The first and fundamental point is to determine accurately the order of superposition of the strata. Until this is done detailed palæontological classification may prove to be worthless. But when once the succession of the rocks has been fixed palæontological evidence may become paramount.

From what has been above advanced it must be evident that, even if the several groups in a formation or system of rocks in any district or country have been minutely subdivided by means of their characteristic fossils, and if, after the lapse of many years, no discovery has occurred to alter the established order of succession of these fossils, nevertheless the subdivisions can only be held good for the region in which they have been made. They must not be supposed to be strictly applicable everywhere. Advancing into another district or country where the petrographical characters of the same formation or system indicate that the original conditions of deposit must have been very different, we ought to be prepared to find a greater or less departure from the first observed or what might be regarded as the normal order of organic succession. There can be no doubt that the appearance of new organic forms in any locality has been in large measure connected with such physical changes as are indicated by diversities of sedimentary materials and arrangement. The Upper Silurian formations, for example, as studied by Murchison in Shropshire and the adjacent counties, present a clear sequence of strata well defined by characteristic fossils. But within a distance of 60 miles it becomes impossible to establish these subdivisions by fossil evidence. If we examine corresponding strata in Scotland, we find that they contain some fossils which never rise above the Lower Silurian formations in Wales and the west of England. Again, in Bohemia and in Russia we meet with still greater departures from the order of appearance in the original Silurian area, some of the most characteristic Upper Silurian organisms being there found far down beneath strata replete with records of Lower Silurian life. Nevertheless the general succession of life from Lower to Upper Silurian types remains distinctly traceable. Such facts warn us against the danger of being led astray by an artificial precision of palæontological detail. Even where the palæontological sequence is best established, it rests probably in most cases not merely upon the actual chronological succession of organic forms, but also, far more than is usually imagined, upon original accidental differences of local physical conditions. As these conditions have constantly varied from region to region, it must hardly ever happen that the same minute palæontological subdivisions, so important and instructive in themselves, can be identified and paralleled, except over comparatively limited geographical areas.

It cannot be too frequently stated, nor too prominently kept in view, that, although gaps occur in the succession of organic remains as recorded in the rocks, there have been no such blank intervals in the progress of plant and animal life upon the globe. The march of life has been unbroken, onward and upward. Geological history, therefore, if its records in the stratified formations were perfect, ought to show a blending and gradation of epoch with epoch, so that no sharp divisions of its events could be made. But the progress has been constantly interrupted; now by upheaval, now by volcanic outbursts, now by depression. These interruptions serve as natural divisions in the chronicle, and enable the geologist to arrange his history into periods. As the order of succession among stratified rocks was first made out in Europe, and as many of the gaps in that succession were found to be widespread over the European area, the divisions which experience established for that portion of the globe came to be regarded as typical, and the names adopted for them were applied to the rocks of other and far distant regions. This application has brought out the fact that some of the most marked breaks in the European series do not exist elsewhere, and, on the other hand, that some portions of that series are much more complete than in other regions. Hence, while the general similarity of succession may remain, different subdivisions and nomenclature are required as we pass from continent to continent.

A bed, or limited number of beds, characterized by one or more distinctive fossils, is termed a *zone* or *horizon*, and, as already mentioned, is often known by the name of a typical fossil, as the different zones in the Lias are by their special species of ammonite. A series of such zones, united by the occurrence among them of a number of the same species or genera, is called a *group*. A series of groups similarly related constitute a *formation*, and a number of formations may be united into a *system*. The terminology employed in this classification will be discussed in the following part.

PART VI.—STRATIGRAPHICAL GEOLOGY.

This branch of the science arranges the rocks of the earth's crust in the order of their appearance, and interprets the sequence of events of which they form the records. Its province is to cull from all the other departments of geology the facts which may be needed to show what has been the progress of our planet, and of each continent and country, from the earliest times of which the rocks have preserved any memorial. Thus from mineralogy and petrography it obtains information regarding the origin and subsequent mutations of minerals and rocks. From dynamical geology it learns by what agencies the materials of the earth's crust have been formed, altered, broken, upheaved, and melted. From structural geology it understands how these materials were put together so as to build up the complicated crust of the earth. From palæontological geology it receives in well-determined fossil remains a clue by which to discriminate the different stratified formations, and to trace the grand onward march of organized existence upon this planet. Stratigraphical geology thus gathers up the sum of all that is made known by the other departments of the science, and makes it subservient to the interpretation of the geological history of the earth.

The leading principles of stratigraphy may be summed up as follows:—

1. In every stratigraphical research the fundamental requisite is to establish the order of superposition of the strata. Until this is accomplished it is impossible to arrange the dates and make out the sequence of geological history.

2. The stratified portion of the earth's crust, or geological record, as it has been termed, may be subdivided into natural groups or formations of strata, each marked throughout by some common genera or species, or by a general resemblance in the type or character of its organic remains.

3. Many living species of plants and animals can be traced downward through the more recent geological formations; but they grow fewer in number as they are followed into more ancient deposits. With their disappearance we encounter other species and genera which are no longer living. These in turn may be traced backward into earlier formations, till they too cease, and their places are taken by yet older forms. It is thus shown that the stratified rocks contain the records of a gradual progression of organic forms. A species which has once died out does not seem ever to have reappeared. But as has been already pointed out in reference to Barrande's doctrine of colonies, a species may within a limited area appear in a formation older than that of which it is characteristic, having temporarily migrated into the district from some neighbouring region where it had already established itself.

4. When the order of succession of organic remains among the stratified rocks has been determined, they become an invaluable guide in the investigation of the relative age of rocks and the structure of the land. Each zone and formation, being characterized by its own species or genera, may be recognized by their means, and the true succession of strata may thus be confidently established even in a country which has been shattered by dislocation, or where the rocks have been folded and inverted.

5. The relative chronological value of the divisions of the geological record is not to be measured by mere depth of strata. While it may be reasonably assumed that a great thickness of stratified rock must mark the passage of a long period of time, it cannot safely be affirmed that a much less thickness elsewhere represents a correspondingly diminished period. This may sometimes be made evident by an unconformability between two sets of rocks, as has already been explained. The total depth of both groups together may be, say 1000 feet. Elsewhere we may find a single unbroken formation reaching a depth of 10,000 feet; but it would be utterly erroneous to conclude that the latter represents ten times the length of time shown by the two former. So far from this being the case, it might not be difficult to show that the minor thickness of rock really denoted by far the longer geological interval. If, for instance, it could be proved that the upper part of both the sections lay on one and the same geological platform, but that the lower unconformable series in the one locality belonged to a far lower and older system of rocks than the base of the thick conformable series in the other, then it would be clear that the gap marked by the unconformability really indicated a longer period than the massive succession of deposits.

6. Fossil evidence furnishes the chief means of comparing the relative value of formations and groups of rock. A break in the succession of organic remains marks an interval of time often unrepresented by strata at the place where the break is found. The relative importance of these breaks, and therefore, probably, the comparative intervals of time which they mark, may be estimated by the difference of the facies of the fossils on each side. If, for example, in one case we find every species to be dissimilar above and below a certain horizon, while in another locality only half of the species on each side are peculiar, we naturally infer, if the total number of species seems large enough to warrant the inference, that the interval marked by the former break was very much longer than that marked by the second. But we may go further and compare by means of fossil evidence the relation between breaks in the succession of organic remains and the depth of strata between them.

Three formations of fossiliferous strata, A, C, and H, may occur conformably above each other. By a comparison of the fossil contents of all parts of A, it may be ascertained that, while some species are peculiar to its lower, others to its higher portions, yet the majority extend throughout the formation. If now it is found that of the total number of species in the upper portion of A only one-third passes up into C, it may be inferred with some probability that the time represented by the break between A and C was really longer than that required for the accumulation of the whole of the formation A. It might even be possible to discover elsewhere a thick intermediate formation B filling up the gap between A and C. In like manner were it to be discovered that, while the whole of the formation C is characterized by a common suite of fossils, not one of the species and only one half of the genera pass up into H, the inference could hardly be resisted that the gap between the two formations marks the passage of a far longer interval than was needed for the deposition of the whole of C. And thus we reach the remarkable conclusion that, thick though the stratified formations of a country may be, in some cases they may not represent so long a total period of time as do the gaps in their succession,—in other words, that non-deposition was more frequent and prolonged than deposition, or that the intervals of time which have been recorded by strata have not been so long as those which have not been so recorded.

In all speculations of this nature, however, it is necessary to reason from as wide a basis of observation as possible, seeing that so much of the evidence is negative. Especially needful is it to bear in mind that the cessation of one or more species at a certain line among the rocks of a particular district may mean nothing more than that, owing to some change in the conditions of life or of deposition, these species were compelled to migrate or became locally extinct at the time marked by that line. They may have continued to flourish abundantly in neighbouring districts for a long period afterward. Many examples of this obvious truth might be cited. Thus in a great succession of mingled marine, brackish-water, and terrestrial strata, like that of the Carboniferous Limestone series of Scotland, corals, crinoids, and brachiopods abound in the limestones and accompanying shales, but disappear as the sandstones, ironstones, clays, coals, and bituminous shales supervene. An observer meeting for the first time with an instance of the disappearance, and remembering what he had read about "breaks in succession," might be tempted to speculate about the extinction of these organisms, and their replacement by other and later forms of life, such as the ferns, lycopods, ganoid fishes, and other fossils so abundant in the overlying strata. But further research would show him that high above the plant-bearing sandstones and coals other limestones and shales might be observed, once more charged with the same marine fossils as before, and still farther overlying groups of sandstones, coals, and carbonaceous beds followed by yet higher marine limestones. He would thus learn that the same organisms, after being locally exterminated, returned again and again to the same area. After such a lesson he would probably pause before too confidently asserting that the highest bed in which we can detect certain fossils marked really their final appearance in the history of life. A break in the succession may thus be extremely local, one set of organisms having been driven to a different part of the same region, while another set occupied their place until the first was enabled to return.

7. The geological record is at the best but an imperfect chronicle of the geological history of the earth. It abounds in gaps, some of which have been caused by the destruction of strata owing to metamorphism, denudation, or otherwise, some by original non-deposition, as above explained. Nevertheless from this record alone can the progress of the earth be traced. It contains the registers of the births and deaths of tribes of plants and animals which have from time to time lived on the earth. But a small proportion of the total number of species which have appeared in past time have been thus chronicled, yet by collecting the broken fragments of the record an outline at least of the history of life upon the earth can be deciphered.

The nomenclature adopted for the subdivisions of the geological record bears witness to the rapid growth of geology. It is a patch-work in which no system nor language has been adhered to, but where the influences by which the progress of the science has been moulded may be distinctly traced. Some of the earliest names are lithological, and remind us of the fact that mineralogy and petrography preceded geology in the order of birth—Chalk, Oolite, Greensand, Millstone Grit. Others are topographical, and often recall the labours of the early geologists of England—London Clay, Oxford Clay, Purbeck, Portland, Kimeridge beds. Others are taken from local English provincial names, and remind us of the debt we owe to William Smith, by whom so many of them were first used—Lias, Gault, Crag, Cornbrash. Others of later date recognize an order of superposition as already established among formations—Old Red Sandstone, New Red Sandstone. By common consent it is admitted that names taken from the region where a formation or group of rocks is typically developed, are best adapted for general use. Cambrian, Silurian, Devonian, Permian, Jurassic, are of this class, and have been adopted all over the globe.

But whatever be the name chosen to designate a particular group of strata, it soon comes to be used as a chronological or homotaxial term, apart altogether from the stratigraphical character of the strata to which it is applied. Thus we speak of the Chalk or Cretaceous system, and embrace under that term formations which may contain no chalk; and we may describe as Silurian a series of strata utterly unlike in lithological characters to the formations in the typical Silurian country. In using these terms we unconsciously allow the idea of relative date to arise prominently before us. Hence such a word as chalk or cretaceous does not suggest so much to us the group of strata so called, as the interval of geological history which these strata represent. We speak of the Cretaceous, Jurassic, and Cambrian periods, and of the Cretaceous fauna, the Jurassic flora, the Cambrian trilobites, as if these adjectives denoted simply epochs of geological time.

The geological record is classified into five main divisions: —(1) the Archæan, Azoic (lifeless), or Eozoic (dawn of life) Periods; (2) the Primary or Palæozoic (ancient life) Periods; (3) the Secondary or Mesozoic (middle life) Periods; (4) the Tertiary or Cainozoic (recent life); and (5) the Quaternary or Post-Tertiary Periods. These divisions are further ranged into systems, each system into formations, each formation into groups, and each group or series into single zones or horizons. The subjoined generalized table exhibits the order in which the chief subdivisions appear.

Order of Succession of the Stratified Formation of the Earth's Crust.

	Britain.	Continental Europe.	North America.
Post-Tertiary or Quaternary	Recent—Alluvium, peat, &c.	Alluvium.	Recent or Terrace.
	Pleistocene—*Cave deposits, Glacial drift.*	Diluvium.	Champlain.
			Glacial.
Tertiary or Cainozoic.	Pliocene—*Crag deposits of Norfolk and Suffolk.*	Pliocene—*Tegel, Dinotherium-Sand.*	Sumter.
	Miocene—*Lignite of Bovey Tracey, Mull, &c.*	Miocene—*Leithakalk, Upper Molasse.*	Yorktown.
		Oligocene—*Lower Molasse, Grès de Fontainebleau, &c.*	
	Eocene—*Tertiaries of Hampshire Basin, and Isle of Wight.*	Eocene—*Nummulite-limestone, Flysch.*	Alabama. Lignitic.
Secondary or Mesozoic.	Cretaceous. Upper	Senonian—*Craie blanche et tuffeau, Upper Quadersandstein.*	Fox-Hills group. (Upper Missouri Region.)
		Turonian—*Plänerkalk.*	Pierre group.
		Cenomanian—*Grès vert.*	Niobrara group.
		Gault.	Benton group.
	Cretaceous. Lower.	Neocomian.	Dakotah group.
	Jurassic. Oolitic. Upper.	Upper or White Jura (Malm).	Jurassic rocks appear to be but poorly developed in N. America.
	Jurassic. Oolitic. Lower.	Middle or Brown Jura (Dogger).	
	Jurassic. Liassic.	Lower or Black Jura (Lias).	
	Triassic. Upper.	Rhætic beds, Keuper.	
		Muschelkalk.	Triassic.
	Triassic. Lower.	Bunter.	
Primary or Palæozoic.	Permian.	Dyas or Permian { *Zechstein, Rothliegendes.*	Permian.
	Carboniferous. Coal-measures.	Terrain houiller, Steinkohlen.	Carboniferous.
	Carboniferous. Millstone Grit.	Flötzleerer Sandstein	Sub-Carboniferous.
	Carboniferous. Carboniferous Limestone.	Calcaire Carbonifère, Kohlenkalk, Kulm.	
	Devonian and Old Red Sandstone.	Devonian	Devonian.
	Silurian.	Silurian (Transition or Grauwacke system).	Silurian.
	Cambrian.	Primordial Silurian, older grauwacke and slate.	Primordial Silurian and Cambrian.
		Primitive schists.	Huronian.
Archæan or Azoic (Eozoic).	Fundamental gneiss.	Ur-gneiss.	Laurentian.

I. ARCHÆAN.

Underneath the oldest unaltered stratified and fossiliferous formations in Europe there occur masses of gneiss and other crystalline schistose rocks belonging perhaps to widely different geological periods, but, from want of satisfactory means of discrimination, necessarily united provisionally in one common series. That they are separated by a vast interval of time from the rocks which lie upon them is shown by the strong unconformability with which they are related to every formation of younger date than themselves. Everywhere thoroughly crystalline, they are disposed in rude, crumpled, often vertical beds, out of the ruins of which the overlying formations have been partly built.

Britain.—In no part of the European area are these ancient rocks better seen than in the north-west of Scotland. Their position there, previously indicated by MacCulloch and Hay Cunningham, was first definitely established by Murchison, who showed that they possess a dominant strike to N.N.W., and are unconformably overlaid by all the other rocks of the Scottish Highlands. They consist of a tough massive gneiss usually hornblendic, with bands of hornblende-rock, hornblende-schist, quartz-felsite, granite, and other crystalline rocks. In two or three places they enclose bands of limestone, but neither in these nor in any other parts of their mass has the least trace of any organic structure been detected. It is impossible at present to offer any conjecture as to their probable thickness. It must be many thousand feet; but its approximate amount, if ever ascertainable, will only be made out after the region where they occur has been mapped in detail. These gneisses and schists possess a massiveness and rudeness of bedding which strongly distinguishes them from all the other and younger metamorphic rocks of Britain. They form nearly the whole of the Outer Hebrides, and occupy a variable belt of the western parts of the counties of Sutherland and Ross. Murchison proposed to term them the Fundamental or Lewisian Gneiss from the isle of Lewis—the chief of the Hebrides. Afterwards he called them Laurentian, regarding them as the equivalent of some part of the great Laurentian system of Canada.

In recent years Mr Hicks and others have endeavoured to show that in Wales there exist here and there protrusions of an old crystalline group of rocks from beneath the Cambrian system, and they have described these "pre-Cambrian" masses as overlaid unconformably by younger formations, as in the north-west of Scotland. Professor Ramsay, however, who with his colleagues in the Geological Survey mapped the Welsh areas in detail, contends that the supposed older gneiss is merely a metamorphosed portion of the Cambrian rocks.

Continental Europe.—On the continent of Europe numerous areas of ancient gneiss rise from under the oldest fossiliferous formations. In Scandinavia the structure of part of the country resembles that of the north-west of Scotland: the fundamental-gneiss (*Urgneiss*), covering a large area, is overlaid unconformably by red sandstones which underlie the most ancient strata containing organic remains. The gneiss and its accompanying rocks range through Finland into the north-west of Russia, reappearing in the north-east of that vast empire in Petchora Land down to the White Sea, and rising in the nucleus of the chain of the Ural Mountains, and still further south in Podolia. In Central Europe they appear as islands in the midst of more recent formations. In the midst of the Carpathian Mountains they protrude at a number of points, but westwards in the Alpine chain they rise in a more continuous belt in the central portion of these crests, and show numerous mineralogical varieties, including protogine, mica-schist, and many other schists, as well as limestone and serpentine. But perhaps their most intelligible sections are those which they present in Bavaria and Bohemia between the valley of the Danube and the head-waters of the Elbe. They are there divided into two well-marked groups—(*a*) red gneiss, covered by (*b*) grey gneiss. According to Gümbel the former (called by him the Bojan gneiss) may be traced as a distinct formation associated with granite, but with very few other kinds of crystalline or schistose rocks, while the latter (termed the Hercynian gneiss) consists of gneiss with abundant interstratification of many other schistose rocks, graphitic limestone, and serpentine. The Hercynian gneiss is overlaid by mica-schist, above which comes a vast mass of argillaceous schists and shales. Gümbel some years ago found in the marbles associated with the younger gneiss what he considered to be an organism of the same genus as the *Eozoon* of Canada, to which reference will immediately be made. He named it *Eozoon Bavaricum*. More recently a similar substance was obtained in the Archæan series of Bohemia, and named by Fritsch *Eozoon Bohemicum*.

AMERICA.—In North America Archæan rocks cover a large part of the continent from the Arctic Circle southwards to the great lakes. They appear likewise, as in Europe, along the central parts of prominent mountain chains, as in the Rocky Mountain range and that of the Appalachians. They have been carefully studied in Canada, where the late Sir W. E. Logan, Director of the Geological Survey of the Dominion, estimated their depth at about 30,000 feet, but neither their top nor their base can there be found. He named them the Laurentian system from their abundant development along the shores of the St Lawrence. They have been divided into two series—(1) a lower formation more than 20,000 feet thick, consisting chiefly of granitic, orthoclase gneiss, with bands of quartz-rock, schists, iron-ore, and limestone; and (2) an upper formation fully 10,000 feet thick, composed also, for the most part, of gneiss, but marked by the occurrence of bands of Labrador felspar, as well as schist, iron-ore, and limestone. The upper division has been stated to lie unconformably on the lower. Mr Selwyn, however, has recently pointed out that this is almost certainly not the case, but that the limestone-bearing series rests conformably upon a massive granitoid gneiss, to which he would restrict the term Laurentian, classing the limestones in the next or Huronian system (*Nat. Hist. Soc. Montreal*, Feb. 1879).

In one of the Laurentian limestones of Canada, specimens have been found of a remarkable mixture of calcite and serpentine. These minerals are arranged in alternate layers, the calcite forming the main framework of the substance with the serpentine (sometimes loganite, pyroxene, &c.) disposed in thin, wavy, inconstant layers, as if filling up flattened cavities in the calcareous mass. So different from any ordinary mineral segregation with which he was acquainted did this arrangement appear to Logan, that he was led to regard the substance as probably of organic origin. This opinion was adopted, and the structure of the supposed fossil was worked out in elaborate detail by Dr Dawson of Montreal, who pronounced the organism to be the remains of a massive foraminifer which he called *Eozoon*, and which he believed must have grown in large thick sheets over the sea-bottom. This opinion was confirmed by Dr W. B. Carpenter, who from a large suite of additional and better preserved specimens, described a system of internal canals having the characters of those in true foraminiferal structures. (See FORAMINIFERA.) Other observers, notably Professors King and Rowney of Galway and Möbius of Kiel, have opposed the organic nature of *Eozoon*, and have endeavoured to show that the supposed canals and passages are merely infiltration veinings of serpentine in the calcite. In some cases, however, the "canal system" is not filled with serpentine but with dolomite, which seems to show that the cavities must have existed before either dolomite or serpentine were introduced into the substance. Dr Carpenter contends that the disposition of these passages in his decalcified specimens is very regular, and quite unlike any mineral infiltration with which he is acquainted.

The opinion of the organic nature of *Eozoon* has been supposed to receive support from the large quantity of graphite found throughout the Archæan rocks of Canada and the northern parts of the United States. This mineral occurs partly in veins, but chiefly disseminated in scales and laminæ in the limestones and as independent layers. Dr Dawson estimates the aggregate amount of it in one band of limestone in the Ottawa district as not less than from 20 to 30 feet, and he thinks it is hardly an exaggeration to say that there is as much carbon in the Laurentian as in equivalent areas of the Carboniferous system. He compares some of the pure bands of graphite to beds of coal, and maintains that no other source for their origin can be imagined than the deoxidation of carbonic acid by living plants. In the largest of three beds of graphite at St John he has found what he considers may be fibrous structure indicative of the existence of land-plants.

Still further evidence in favour of organized existence during Archæan time in the North American area has been adduced from the remarkably thick and abundant masses of iron ore associated with the Laurentian rocks of Canada and the United States. Dr Sterry Hunt has called attention to these ores as proving the precipitation of iron by decomposing vegetation during the Laurentian period on a more gigantic scale than at any subsequent geological epoch.[1] Some of the beds of magnetic iron ranged up to 200 feet in thickness. Large masses also of hæmatite and titaniferous iron, as well as of iron sulphides, occur in the Canadian Archæan series. These great bands of iron ore run southward, and form an important feature in the economic geology of the Northern States of the Union.

Above the Laurentian rocks in the region of Lake Huron lies a vast mass of slates, conglomerates, limestones, and quartz-rocks, attaining a depth of from 10,000 to 20,000 feet. They are termed Huronian. No fossils have yet been found in them; but they must be much younger than the Laurentian rocks, on which they rest unconformably, and from which they have been in part at least derived.

II. PALÆOZOIC.

Under the general term of Primary or Palæozoic are now included all the older sedimentary formations containing organic remains, up to the top of what is termed the Permian system. These rocks consist mainly of sandy and muddy sediment with occasional intercalated zones of limestone. They everywhere bear witness to comparatively shallow water and the proximity of land. Their frequent alternations of sandstone, shale, conglomerate, and other detrital materials, their abundant, rippled, and sun-cracked surfaces marked often with burrows and trails of worms, as well as the prevalent character of their organic remains, show that they must have been deposited in areas of slow subsidence, bordering continental or insular masses of land. As regards the organisms of which they have preserved the casts, the Palæozoic rocks, as far as the present evidence goes, may be grouped into two divisions—an older and a newer:—the former distinguished more especially by the abundance of its graptolitic, trilobitic, and brachiopodous fauna, and by the absence of vertebrate remains; the latter by the number and variety of its fishes and amphibians, the

[1] *Geology of Canada*, 1863, p. 573.

disappearance and extinction of graptolites and trilobites, and the abundance of its cryptogamic terrestrial flora.

Cambrian.

This name was applied by Sedgwick to the rocks of North Wales (Cambria), where he first investigated them. Their base is there nowhere seen, so that, though they attain a great depth, some part of their total mass must be concealed from view. They pass up continuously into the base of the Silurian system. Considerable diversity of opinion has existed, and still continues, as to the line where the upper limit of the Cambrian system should be drawn. Murchison contended that this line should be placed below the strata where a trilobitic and brachiopodous fauna begins, and that these strata cannot be separated from the overlying Silurian system. He therefore included in the Cambrian only the barren grits and slates of the Longmynd, Harlech, and Llanberis. Sedgwick, on the other hand, insisted on carrying the line up to the base of the Upper Silurian rocks. He thus left these formations as alone constituting the Silurian system, and massed all the Lower Silurian in his Cambrian system. Murchison worked out the stratigraphical order of succession from above, and chiefly by help of organic remains. He advanced from where the superposition of the rocks is clear and undoubted, and for the first time in the history of geology ascertained that the "transition-rocks" of the older geologists could be arranged into zones by means of characteristic fossils as satisfactorily as the Secondary formations had been classified in a similar manner by William Smith. Year by year, as he found his Silurian types of life descend farther and farther into lower deposits, he pushed backward the limits of his Silurian system. In this he was supported by the general consent of geologists and palæontologists all over the world. Sedgwick, on the other hand, attacked the problem rather from the point of stratigraphy and geological structure. Though he had collected fossils from many of the rocks of which he had made out the true order of succession in North Wales, he allowed them to lie for years unexamined. Meanwhile Murchison had studied the prolongations of some of the same rocks into South Wales, and had obtained from them the abundant suite of organic remains which characterized his Lower Silurian formations. Similar fossils were found abundantly on the continent of Europe, and in America. Naturally the classification proposed by Murchison was adopted all over the world. As he included in his Silurian system the oldest rocks containing a distinctive fauna of trilobites and brachiopods, the earliest fossiliferous rocks were everywhere classed as Silurian, and the name Cambrian was discarded by geologists of other countries as indicative of a more ancient series of deposits not characterized by peculiar organic remains, and therefore not capable of being elsewhere satisfactorily recognized. Barrande, investigating the most ancient fossiliferous rocks of Bohemia, distinguished by the name of the "Primordial Zone" a group of strata underlying the Lower Silurian rocks, and containing a peculiar and characteristic suite of trilobites. He classed it, however, with the Silurian system, and Murchison adopted the term, grouping under it the lowest dark slates which in Wales and the border English counties contained some of the same early forms of life.

Investigations during the last twelve years, however, chiefly by the late Mr Salter and Mr Hicks, have brought to light a much more abundant fauna from the so-called primordial rocks of Wales than they were supposed to possess. These fossils were found to be in large measure distinct from those in the undoubted Lower Silurian rocks. Thus the question of the proper base of the Silurian system was re-opened, and the claims of the Cambrian system to a great upward extension were more forcibly urged than ever. But these claims could now be urged on palæontological evidence such as had never before been produced. Accordingly there has arisen a general desire among the geologists of Britain to revise the nomenclature of the older rocks. Though as yet a common accord of opinion has not been reached, there seems a strong probability that ultimately the boundary line between the Cambrian and Silurian systems will be drawn above the primordial zone along the base of the great Arenig group or Lower Llandeilo rocks of Murchison. All his Silurian strata of older date than these rocks will be classed as Cambrian.

According to this classification, the Cambrian system, as developed in North Wales and the border English counties, consists of purple, reddish-grey, and green slates, grits, sandstones, and conglomerates. Its true base is nowhere seen, yet even the visible mass of strata has been estimated to reach the enormous thickness of 25,000 feet. By far the larger part of this vast depth of rock is unfossiliferous. Indeed it is only in some bands of the upper 6000 feet, or thereabouts, that fossils occur plentifully. By fossil evidence the Cambrian system may be divided into Lower and Upper, and each of these sections may be further subdivided into two groups, as in the following table:—

Cambrian of Wales.	Upper.	4. Tremadoc slates.
		3. Lingula flags.
	Lower.	2. Menevian group.
		1. Harlech and Longmynd group.

1. *Harlech and Longmynd Group.*—This includes purple, red, and grey flags, sandstones, and slates, with conglomerates. These strata attain a great thickness, estimated at 4000 feet in South Wales, but more than 8000 in North Wales. They were formerly supposed to be nearly barren of organic remains; but in recent years, chiefly through the researches of Mr Hicks at St Davids, they have yielded a tolerably abundant fauna, consisting of 30 species. Among these are 16 species of trilobite (*Paradoxides, Plutonia, Microdiscus, Palæopyge, Agnostus, Conocoryphe*), four annelides (*Arenicolites*), a sponge (*Protospongia*), five brachiopods (*Discina, Lingulella*), two pteropods (*Theca*), &c. Many of the surfaces of the strata in some parts of this group are marked with ripples, sun-cracks, and rain-pittings as well as with trails of worms—indicative of shallow-water and shore-conditions of deposit. 14 of the 30 species, according to Mr Etheridge, F.R.S., pass up into the Menevian group, and 7 continue into the Lingula flags.

2. *Menevian Group.*—This subdivision has been proposed for a series of sandstones and shales, with dark-blue slates and flags, dark-grey flags and grey grits, which are seen near St David's (Menevia), where they attain a depth of about 600 feet. They pass down conformably into the Harlech group with which, as just stated, they are connected by 14 species in common. The Menevian beds have yielded upwards of 50 species of fossils, of which 24 are confined to the Menevian, while 18 pass up into the lower Lingula flags. Among these the trilobites are specially prominent, Some of them attained a great size, *Paradoxides Davidis* being nearly two feet long. But with these were mingled others of diminutive size. It is noteworthy also, as Mr Hicks has pointed out, that while the trilobites had attained their maximum size at this early period, they are represented among the older Cambrian rocks by genera indicative of almost every stage of development, "from the little *Agnostus* with two rings in the thorax, and *Microdiscus* with four, to *Erinnys* with twenty-four," while blind genera occur together with those having the largest eyes.[1] Upwards of 30 species of trilobites have been obtained from the Menevian beds, the genera *Agnostus* (7 species), *Conocoryphe* (7 species), and *Paradoxides* being specially characteristic. Four species of sponges (*Protospongia*) and some annelide-tracks likewise occur. The mollusca are represented by 6 species of brachiopoda of the genera *Discina*, *Lingulella*, and *Obolella*; 5 pteropods (*Theca*) have been met with. The earliest entomostraca (*Entomis*) and the first cystidean (*Protocystites*) yet discovered occur in the Menevian fauna.

3. *Lingula Flags.*—These strata, consisting of bluish and black slates and flags, with bands of grey flags and sandstones, attain in some parts of Wales a thickness of more than 5000 feet. They received their name from the discovery by Mr E. Davis (1846) of vast numbers of a *Lingula* (*Lingulella Davisii*) in some of their layers. They rest conformably upon, and pass down into, the Menevian beds below them, and likewise graduate into the Tremadoc group above. They are distinguished by a characteristic

[1] Hicks, *Quart. Journ. Geol. Soc.*, xxviii. 174.

suite (78 species) of organic remains. The trilobites include the genera *Agnostus*, *Anapolenus*, *Conocoryphe*, *Dikelocephalus*, *Erinnys*, *Olenus*, and *Paradoxides*. The earliest phyllopods (*Hymenocaris*) and heteropods (*Bellerophon*) occur in these beds. The brachiopods include species of *Lingulella* (*L. Davisii*), *Discina*, *Obolella*, and *Orthis*. The pteropods are represented by three species of *Theca*. Several annelides (*Cruziana*) and polyzoa (*Fenestella*) likewise occur.

According to a careful census by Mr Etheridge, the Lingula flags may be grouped into three zones, each characterized by a peculiar assemblage of organic remains. The lower division contains 37 species, of which 9 are peculiar to it. The middle zone has yielded 5 species, 2 of which (*Conocoryphe bucephala* and *Lingulella Davisii*) pass down into the lower division, 1 (*Kutorgia cingulata*) into the upper, and 2 (*Lingula squamosa* and *Bellerophon Cambrensis*) are peculiar. The upper zone has yielded 40 species. Of these 9 pass up into the Tremadoc beds, while 2 (*Lingulella lepis* and *L. Davisii*) continue on into the Arenig group.

4. *Tremadoc Slates.*—This name was given by Sedgwick to a group of dark grey slates, about 1000 feet thick, found near Tremadoc in Carnarvonshire, and traceable thence to Dolgelly. Their importance as a geological formation was not recognized until the discovery of a remarkably abundant and varied fauna in them. They contain the earliest crinoids, star-fishes, lamellibranchs, and cephalopods yet found. The trilobites embrace 14 genera, among which, besides some, as *Agnostus*, *Conocoryphe*, and *Olenus*, found in the Lingula flags, we meet for the first time with *Angelina*, *Asaphus*, *Cheirurus*, *Neseuretus*, *Niobe*, *Ogygia*, *Psilocephalus*, &c. The same genera, and in some cases species, of brachiopods appear which occur in the Lingula flags, *Orthis Carausii* and *Lingulella Davisii* being common forms. Mr Hicks has described 12 species of lamellibranchs from the Tremadoc beds of Ramsay Island and St Davids, belonging to the genera *Ctenodonta*, *Palæarca*, *Glyptarca*, *Davidia*, and *Modiolopsis*. The cephalopods are represented by *Orthoceras sericeum* and *Cyrtoceras præcox*; the pteropods by *Theca Davidii*, *T. operculata*, and *Conularia Homfrayi*; the echinoderms by a beautiful star-fish (*Palasterina ramseyensis*) and by a crinoid (*Dendrocrinus Cambrensis*).[1]

Careful analysis of the fossils yielded by the Tremadoc beds suggests a division of this formation into two zones. According to a census by Mr Etheridge, the Lower Tremadoc rocks have yielded in all 56 species, of which 9 pass down into the Lingula flags and 10 ascend into the Upper Tremadoc zone, 31 being peculiar. The Upper Tremadoc beds contain, as at present ascertained, 33 species, of which 9 are peculiar, and 13 or possibly 15 pass up into the Arenig group. It is at the top of the Upper Tremadoc strata that the line between the Cambrian and Silurian systems is here drawn. According to Professor Ramsay, there is evidence of a physical break at the top of the Tremadoc beds of Wales, so that on a large scale the next succeeding or Arenig strata repose unconformably upon everything older than themselves. Mr Etheridge also shows that the palæontological break is nearly complete, only about 7 per cent. of the fossils of the one series passing over into the other. Out of 184 known Arenig species, not more than 13 are common to the Tremadoc beds underneath. Besides these important facts the character of the Arenig fauna strongly distinguishes it from that of the formations below, and further supports the line of division here adopted between the Cambrian and Silurian systems.

In the north-west of Scotland a mass of reddish-brown and chocolate-coloured sandstone and conglomerate (at least 8000 feet thick in the Loch Torridon district) lies unconformably upon the fundamental gneiss in nearly horizontal or gently inclined beds. It rises into picturesque groups of mountains which stand out as striking monuments of denudation, seeing that the truncated ends of their component flat strata can be traced even from a distance forming parallel bars along the slopes and precipices. The denudation must have been considerable even in early Silurian times, for the sandstones are unconformably overlaid by quartz-rocks and limestones containing Lower Silurian fossils. No trace of organic remains of any kind has been found in the red sandstones themselves. They were at one time regarded as Old Red Sandstone, though Macculloch, and afterwards Hay Cunningham, pointed out that they underlie parts of the schistose rocks of the northern Highlands. The discovery by Mr C. W. Peach of Lower Silurian shells in the overlying limestones showed that the massive red sandstones of western Ross and Sutherland could not be paralleled with those of the eastern tracts of those counties, but must be of older date than part of the Llandeilo rocks of the Lower Silurian period. Sir R. Murchison classed them as Cambrian—an identification which has much support in the lithological resemblance between these rocks of the north-west Highlands and much of the Lower Cambrian system of Wales.

In the south-east of Ireland masses of purplish, red, and green shales, slates, grits, quartz-rocks, and schists occupy a considerable area and attain a depth of 14,000 feet without revealing their base, while their top is covered by unconformable formations (Lower Silurian and Lower Carboniferous). They have yielded *Oldhamia*, described originally as a sertularian zoophyte, but now regarded by many palæontologists as an alga; also numerous burrows and trails of annelides (*Histioderma Hibernicum*, *Arenicolites didymus*, *A. sparsus*, *Haughtonia pœcila*). No Upper Cambrian forms have been met with in these Irish rocks, which are therefore placed with the Lower Cambrian, the unconformability at their top being regarded as equivalent to the interval required for the deposition of the intervening formations up to the time of the Llandeilo rocks, as in the north-west of Scotland. Some portions of the Irish Cambrian series have been intensely metamorphosed. Thus on the Howth coast they appear as schists and quartz-rocks; in Wexford they pass into gneiss and granite. In West Galway Mr Kinahan has described a vast mass of schists, quartz-rocks, and limestones (8000 feet and upwards) passing up into schistose, hornblendic, and unaltered rocks containing Llandeilo fossils, and he agrees with Griffith and King in regarding these as probably Cambrian. He suggests that they are Upper Cambrian, which would imply that Upper Cambrian rocks pass conformably into the Llandeilo formation without the occurrence of the thick Arenig rocks of Wales. In a difficult country, however, broken by faults and greatly metamorphosed, an unconformability might easily escape detection.

CONTINENTAL EUROPE.—According to the classification adopted by M. Barrande, the older Palæozoic rocks of Europe suggest an early division of the area of this continent into two regions or provinces,—a northern province, embracing the British Islands, and extending through North Germany into Scandinavia, on the one hand, and into Russia on the other, and a central-European province, including Bohemia, France, Spain, Portugal, and Sardinia.

Bohemia.—The classic researches of M. Barrande have given to the oldest fossiliferous rocks of Bohemia an extraordinary interest. He has made known the existence there of a remarkable suite of organic remains representative of those which characterize the Cambrian rocks of Britain. At the base of the geological formations of that region lie the Archæan gneisses already described. These are overlaid by vast masses of schists, conglomerates, quartzites, slates, and igneous rocks, which have been more or less metamorphosed, and are singularly barren of organic remains, though some of them have yielded traces of annelides. They pass up into certain grey and green fissile shales, in which the earliest well-marked fossils occur. The organic contents of this zone (Étage C) form what M. Barrande terms his primordial fauna, which contains 40 or more species, of which 27 are trilobites, belonging to the characteristic Cambrian genera—*Paradoxides* (12), *Agnostus* (5), *Conocoryphe* (4), *Ellipsocephalus* (2), *Hydrocephalus* (2), *Arionellus* (1), *Sao* (1). Not a single species of any one of these genera, save *Agnostus* (of which 4 species

[1] Hicks, *Quart. Journ. Geol. Soc.*, xxix. 39.

appear in the second fauna), has been found by M. Barrande higher than his primordial zone. Among other organisms in this primordial fauna, the brachiopods are represented by 2 species (*Orthis* and *Orbicula*), the pteropods by 5 (*Theca*), and the echinoderms by 5 cystideans.

Scandinavia.—In Norway the vast masses of Archæan gneiss (Tellemark) are overlaid by schists, red sandstones, and conglomerates. These are termed the Sparagmite formation, and have hitherto proved barren of fossils. They are covered, however, by beds containing *Dictyonema Norvegicum*, which may represent the primordial zone of Barrande. In Sweden the sparagmite formation has been more productive of organic remains. It is there represented by a sandy zone not more than 50 or 60 feet thick—a poor equivalent for the great mass of strata in the Cambrian system of Wales. It was originally termed the *Regio Fucoidarum* by Angelin, from the fucoids alone found in it. In more recent years, however, its list of organic remains has been considerably increased; 12 species of plants, chiefly fucoids, but including some (*Eophyton*) of higher grade, 9 species of annelides, 4 brachiopods, a pteropod, a bryozoan, a coral, a crinoid, and a sponge have been obtained. Above the strata containing these organisms comes a zone which has yielded 77 species of primordial trilobites, including the genera *Agnostus* (19 species), *Conocoryphe* (13), *Olenus* (21), *Paradoxides* (9).

North America.—Rocks corresponding in position and in the general character of their organic contents with the Cambrian formations of Britain have been recognized in different parts of the United States and Canada. They appear in Newfoundland, whence, ranging by Nova Scotia and New Brunswick, they enter Canada, the northern parts of New York, Vermont, and eastern Massachusetts. They rise again along the Appalachian ridge, in Wisconsin, Minnesota, Missouri, Arkansas, Texas, and Georgia. Westwards from the great valley of the Mississippi, where they have been found in many places, they reappear from under the Secondary and younger Palæozoic rocks of the Rocky Mountains. They have been divided by American geologists into two formations—(1) Acadian, a mass (2000 feet) of grey and dark shales and some sandstones; and (2) Potsdam (or Georgian), which attains in Newfoundland a depth of 5600 feet, but thins away westward and southward till in the valley of the St Lawrence, where it was studied by Logan and his associates of the Geological Survey of Canada, it is only from 300 to 600 feet thick.

Among the organic remains of the North American Cambrian rocks fucoid casts appear in many of the sandstones, but no traces of higher vegetation. The Acadian formation has yielded primordial trilobites of the genera *Paradoxides*, *Conocoryphe*, *Agnostus*, and some others; brachiopods of the genera *Lingulella*, *Discina*, *Obolella*, and *Orthis*; and several kinds of annelide-tracks. The Potsdam rocks contain a few sponges, the earliest forms of graptolite, some brachiopods, including, besides the genera in the Acadian beds, *Obolus*, *Camarella*, and *Orthisina*; some pteropods (*Hyolites* or *Theca*); two species of *Orthoceras*; annelide tracks; trilobites of the genera *Conocoryphe*, *Agnostus*, *Dikelocephalus*, *Olenellus*, *Ptychaspis*, *Chariocephalus*, *Aglaspis*, and *Illænurus*.

M. Barrande has called attention to the remarkable uniformity of character in the organic remains of his primordial zone over the continents of Europe and America. He published in 1871 the subjoined table, to show how close is the parallelism between the proportions in which the different classes of the animal kingdom are represented.[1]

[1] *Trilobites*, Prague, 1871, p. 196. Since the publication of this table the progress of research has increased the number of species from some localities; but the general facies of the primordial fauna has not been materially affected thereby.

Silurian.

The important system of rocks next to be described was first investigated by the late Sir R. Murchison in Wales and the bordering counties of England. He found it to be characteristically developed over the tract once inhabited by the Silures, an ancient British tribe, and he thence chose the name of Silurian as a convenient designation. It there passes down conformably into the Tremadoc slates at the top of the Cambrian series, and is covered conformably by the base of the Old Red Sandstone.

Great Britain.—In the typical area where Murchison's discoveries were first made he found the Silurian rocks divisible into two great and well-marked series, which he termed Lower and Upper. This classification has been found to hold good over a large part of the world. The subjoined table shows the present arrangement and nomenclature of the various subdivisions of the Silurian system.

		Feet.
B. Upper Silurian.	7. Ludlow group	1,950
	6. Wenlock group	1,600
	5. Upper Llandovery group	1,500
A. Lower Silurian.	4. Lower Llandovery group	1,000
	3. Bala and Caradoc group	6,000
	2. Llandeilo group	2,500
	1. Arenig or Stiper Stone group	4,000
	Approximate average thickness	=18,550

A. *Lower Silurian.*

1. *Arenig or Stiper Stone Group.*—These rocks consist of dark slates, shales, flags, and bands of sandstone. They are abundantly developed in the Arenig mountain, where, as originally described by Sedgwick, they contain masses of associated porphyry. Throughout that district they have been deposited at a time when streams of lava and showers of volcanic ashes were thrown out in great quantity from submarine vents. They contain an abundant suite of organic remains (184 species), of which only 13 species are common to the Tremadoc beds below. Trilobites occur of the genera *Æglina*, *Agnostus*, *Ampyx*, *Barrandea*, *Calymene*, *Cheirurus*, *Illænopsis*, *Illænus*, *Ogygia*, *Phacops*, and *Trinucleus*. Three species of pteropods (*Conularia*, *Theca*), 18 species of brachiopods (*Lingula*, *Lingulella*, *Obolella*, *Discina*, *Siphonotreta*, *Orthis*), 8 lamellibranchs, 3 gasteropods, and 5 cephalopods have been found; but the most abundant organisms are the graptolites, of which the Arenig rocks of St David's, in Pembrokeshire, have yielded 48 species, which belong to 20 genera, including *Didymograptus*, *Tetragraptus*, *Diplograptus*, *Dendrograptus*, and *Callograptus*.[2] Altogether

[2] Hicks, *Quart. Journ. Geol. Soc.*, xxxi. 167: Hopkinson and Lapworth, *ibid.*, p. 635.

78 species of hydrozoa have been obtained from the British Arenig rocks, but none from any older strata. This sudden and great development of these organisms gives a distinctive aspect to the Arenig rocks. It continues in the overlying Llandeilo group, so that the graptolites form in Britain a convenient character by which to mark off the Cambrian from the Lower Silurian fauna.

2. *Llandeilo Flag Group.*—Dark argillaceous flagstones, sandstones, and shales, some parts often calcareous. These beds were first described by Murchison as occurring at Llandeilo, in Carmarthenshire. They reappear on the coast of Pembrokeshire, and at Builth, in Radnorshire. Up to the present time they have yielded 227 species of fossils. Of these 13 are common to the Arenig below, 82 to the Caradoc or Bala above, while 145 are peculiar. The hydrozoa are still the most abundant forms, 94 species being here met with, no fewer than 81 of these being confined to Llandeilo rocks, and only 9 passing down into the Arenig group. Of crustacea 44 species have been obtained. These include the characteristic trilobites —*Ampyx nudus*, *Asaphus tyrannus*, *Barrandea Cordai*, *Calymene duplicata*, *C. Cambrensis*, *Cheirurus Sedgwickii*, *Ogygia Buchii*, *Trinucleus concentricus*, *T. Lloydii*. The brachiopods number 37 species, including the genera *Orthis*, *Leptæna*, *Strophomena*, *Lingula*, *Siphonotreta*. The lamellibranchs are represented by 6 species, the gasteropods by 10 (*Murchisonia*, *Cyclonema*, *Loxonema*), the heteropods by 7 (*Bellerophon*), the pteropods by 2 (*Conularia*, *Theca*), the cephalopods by 8 (*Orthoceras*, *Cyrtoceras*).

A remarkable feature in the history of the Llandeilo rocks in Britain was the outbreak of volcanic action abundantly in North Wales and in Cumberland. Vast piles of lava and ashes were thrown out, which even to this day remain in mass sufficient to form groups of important hills, as Cader Idris, Aran Mowddwy, the Arenigs, and the Moelwyns in Wales, and Helvellyn and Scaw Fell in Westmoreland and Cumberland.

3. *Caradoc or Bala Group.*—Under this name are placed the thick yellowish and grey sandstones of Caer Caradoc in Shropshire, and the grey and dark slates, grits, and sandstones round Bala in Merionethshire. In the Shropshire area some of the rocks are so shelly as to become strongly calcareous. In the Bala district the strata contain two limestones separated by a sandy and slaty group of rocks 1400 feet thick. The lower or Bala limestone (25 feet thick) has been traced as a variable band over a large area in North Wales. It is usually identified with the Coniston limestone of the Westmoreland region. The upper or Hirnant limestone (10 feet) is more local. Bands of volcanic tuff and large beds of various felsitic lavas occur among the Bala beds, and prove the contemporaneous ejection of volcanic products. These attain a thickness of several thousand feet in the Snowdon region.

A large suite of fossils has been obtained from this formation:—the sponges represented by *Sphærospongia* and other genera; the graptolites by *Diplograptus pristis*, *Graptolithus priodon*, and *G. Sedgwickii*, &c.; the corals by species of *Heliolites*, *Favosites*, *Monticulipora*, *Halysites*, *Petraia*; the echinoderms by encrinites of the genera *Cyathocrinus* and *Glyptocrinus*, by cystideans of the genera *Echinosphærites* and *Sphæronites*, and by star-fishes of the genera *Palæaster* and *Stenaster*; the annelides by *Serpulites*, *Tentaculites*, and numerous burrows and tracks; the trilobites by many species of the genera *Phacops*, *Cheirurus*, *Cybele*, *Lichas*, *Acidaspis*, *Calymene*, *Remopleurides*, *Asaphus*, *Illænus*, *Ampyx*, and *Trinucleus*; the polyzoa by *Fenestella*, *Glauconome*, and *Ptilodictya*; the brachiopods by *Atrypa*, *Rhynchonella*, *Leptæna*, *Orthis* (many species), *Strophomena*, *Discina*, and *Lingula*; the lamellibranchs by *Modiolopsis*, *Mytilus*, *Palæarca*, *Pterinea*, *Orthonota*, and *Ctenodonta*; the gasteropods by *Murchisonia*, *Pleurotomaria*, *Raphistoma*, *Cyclonema*, *Euomphalus*, *Maclurea*, *Holopea*; the pteropods by *Conularia*, *Theca*, and *Ecculiomphalus*; the heteropods by various species of *Bellerophon*; and the cephalopods by many species of *Orthoceras*, with forms of *Cyrtoceras* and *Lituites*.

4. *Lower Llandovery Group.*—In North Wales the Bala beds about 5 miles S.E. of Bala Lake begin to be covered with grey grits, which gradually expand southwards until they attain a thickness of 1000 feet in South Wales. These overlying rocks are well displayed near the town of Llandovery, where they contain some conglomerate bands, and where Mr Aveline detected an unconformability between them and the Bala group below them, so that the subterranean movements had already begun, which in Wales marked the close of the Lower Silurian period. Elsewhere they seem to graduate downwards conformably into that group. They cover a considerable breadth of country in Cardigan and Carmarthenshire, owing to the numerous undulations into which they have been thrown. Their chief interest lies in the transition which they present between the fauna of the Lower and Upper Silurian formations. They have yielded in all about 128 species of fossils, whereof 11 are peculiar, 93 are common to the Bala group below, and 83 pass up into Upper Llandovery rocks above. Some of the peculiar fossils are *Nidulites favus*, *Meristella crassa*, *M. angustifrons*, and *Murchisonia angulata*. Among the forms which come up from the Bala group and disappear here are the corals *Heliolites interstinctus*, *Petraia subduplicata*, and *Favosites aspera*; the trilobites *Lichas laxatus* and *Illænus Bowmanni*; the brachiopods *Orthis Actoniæ* and *O. insularis*; the gasteropods *Murchisonia gyrogonia* and *Cylonema crebristria*; and the cephalopod *Orthoceras tenuicinctum*. But many of the Lower Silurian forms continue on into the Upper Llandovery beds. From the abundance of the peculiar brachiopods termed *Pentamerus* in the Lower, but still more in the Upper Llandovery rocks, these strata were formerly grouped together under the name of "Pentamerus beds." Though the same species are found in both divisions, *Pentamerus oblongus* is chiefly characteristic of the upper group and comparatively infrequent in the lower, while *Stricklandinia* (*Pentamerus*) *lens* abounds in the lower but appears more sparingly in the upper.

The Lower Silurian rocks, typically developed in Wales, extend over nearly the whole of Britain, though largely buried under more recent formations. They rise into the hilly tracts of Westmoreland and Cumberland, where they consist of the following subdivisions in descending order:—

(Lower Llandovery not represented.)		
Coniston Limestone and Shale	=	Bala beds.
Volcanic series: tuffs and lavas without any intermixture of ordinary sedimentary strata except at the base, 12,000 ft.......	=	Part of Bala, whole of Llandeilo, and perhaps part of Arenig formation.
Skiddaw Slates, 10,000 or 12,000 ft. base not seen	=	Arenig, with perhaps Tremadoc and Lingula Flags.

Apart from the massive intercalation of volcanic rocks these strata present considerable lithological and palæontological differences from the typical subdivisions in Wales. The Skiddaw slates are black or dark-grey argillaceous, and in some beds sandy rocks, often much cleaved though seldom yielding workable slates, sometimes soft and black like Carboniferous shale. As a rule they are singularly unfossiliferous, but in some of their less cleaved and altered portions they have yielded about 40 species of graptolites (chiefly of the genera *Didymograptus*, *Diplograptus*, *Dichograptus*, *Tetragraptus*, *Phyllograptus*, and *Climacograptus*) *Lingula brevis*, traces of annelides, a few trilobites (*Æglina*, *Agnostus*, *Asaphus*, &c.), some phyllopods (*Caryocaris*), and remains of plants (*Buthotrephis*, &c.). In many places the slates have been metamorphosed, passing into chiastolite-slate, mica-schist, andalusite-schist, &c.

with protrusions of granite, syenite, and other crystalline rocks. Towards the close of the long period represented by the Skiddaw slates, volcanic action manifested itself, first by intermittent showers of ashes and streams of lava which were interstratified with the ordinary marine sediment, and then by a more powerful and continuous series of explosions, whereby a huge volcanic mountain or group of cones was piled up above the sea-level. The length of time occupied by this volcanic episode in Cumbrian geology may be inferred from the fact that all the Llandeilo and nearly all the Bala beds are absent here. The volcanic island slowly sank into a sea where Bala organisms flourished. Among these we find such familiar Bala species as *Favosites fibrosa*, *Heliolites interstinctus*, *Cybele verrucosa*, *Leptæna sericea*, *Orthis Actoniæ*, *O. biforata*, *O. calligramma*, *O. elegantula*, *O. porcata*, and *Strophomena rhomboidalis*. These organisms and their associates gathered on the submerged flanks of the sinking volcano into a bed of limestone—the Coniston limestone—which can still be traced for many miles through the Westmoreland hills, as the Bala limestone which it represents can be followed through the volcanic tracts of North Wales. The Coniston limestone is covered by certain flags and grits which from their organic remains are referred to the Upper Silurian series.

In the South of Scotland, according to the detailed researches of the Geological Survey, the Lower Silurian formations are represented by the subjoined groups of strata in descending order:—

Sandstones and conglomerates, Girvan valley	= Llandovery.
Conglomerates, grits, shales, and lenticular bands of limestone, Peeblesshire, Dumfriesshire, & W. Ayrshire, sometimes 2000 ft.	= Caradoc or Bala.
Carsphairn group, coarse pebbly grits and greywacke, 1200 ft.	= Llandeilo (14 000 ft.)
Upper Black Shale, with graptolites, 550 ft.	
Lowther group, olive, grey, and blue shales, and sandstones, 4000 ft.	
Dalveen group, greywacke and shale, with band of fine conglomerate, 3500 ft.	
Queensberry group, massive greywackes and grits, with occasional conglomerate bands and some shales, 4500 ft.	
Lower or Moffat Black Shale group, 200–400 ft.	
Ardwell group, brown flags, greywackes, and shales, sometimes purplish and red; base not seen	

As a whole these strata are singularly barren of organic remains. Most of the fossils which the Llandeilo groups contain lie in the bands of dark anthracitic shale which have been traced across nearly the whole breadth of the country. These shales are crowded with graptolites of recognizable Llandeilo forms, *Climacograptus teretiusculus*, *Diplograptus pristis*, and *Graptolithus sagittarius* being particularly abundant. Crustacea are exceedingly rare, but two phyllopods, *Discinocaris Browniana* and *Peltocharis aptychoides*, occur; while from Dumfriesshire two obscure trilobites are referred doubtfully to *Encrinurus* and *Phacops*. The vast thickness of sandy, gritty, and shaly unfossiliferous strata is the distinguishing feature of the Lower Silurian series in the south of Scotland. The Caradoc or Bala group lies unconformably upon the upper parts of the Llandeilo rocks. It contains in the eastern districts some calcareous conglomerates which here and there swell out into local masses of limestone. In the south-west of Ayrshire the limestones attain considerable dimensions. In these calcareous bands numerous Caradoc species have been found, among them *Cheirurus gelasinosus*, *Encrinurus punctatus*, with species of *Illænus* and *Asaphus*, *Orthis calligramma*, *O. confinis*, *Leptæna sericea*, *Maclurea*, and such corals as *Heliolites*, *Favosites*, *Omphyma*, and *Strephodes*. In the south-west of Ayrshire certain shales and sandstones full of Caradoc fossils are overlaid with sandstones, shales, and conglomerates containing *Pentamerus oblongus*, *Atrypa hemispherica*, *Meristella angustifrons*, *Lichas laxatus*, *Petraia elongata*, *Nidulites favus*, and numerous other fossils which indicate the horizon of the Llandovery rocks.

The Highlands of Scotland consist mainly of crystalline rocks—gneiss, mica-schist, chlorite-schist, clay-slate, quartz-rock, schistose flagstone, and many others, often much invaded by granite and other intrusive masses. It was at one time supposed that these rocks all belonged to the so-called primary or primitive series, older than any of the fossiliferous systems. But the discovery by Mr C. W. Peach, already referred to, that recognizable fossils occur in the limestone of Durness in Sutherlandshire, led Murchison to infer that the whole of the overlying gneissose and schistose masses are really metamorphosed Lower Silurian rocks—a generalization which has been completely confirmed by subsequent investigation. At the base of this great series of rocks masses of white quartz-rock are found lying with a marked unconformability upon the red sandstones described in a previous page. These quartzose beds are merely hardened and somewhat metamorphosed sandstones; they still show their original false-bedding, and the casts of sea-weeds and worm-burrows. They contain a band of limestone which in Assynt swells out to a thickness of 1000 feet or more, and can be traced almost continuously from the Kyles of Skye to the north coast of Sutherlandshire. Over these strata, in perfect conformable sequence, and with a complete lithological gradation, come quartzose flagstones dipping like the rocks below at gentle angles to the south-east. They become more schistose and crumpled as they are traced upwards, until, after a thickness of several thousand feet has been passed over, they begin to undulate in steep folds and pass into the ordinary schistose rocks which cover so much of the Highlands. The gradation from the comparatively unaltered lower quartz-rocks and limestones on the west to the intensely crumpled crystalline upper schists and flagstones on the east can be followed step by step in numerous fine natural sections from the north of Sutherland to the Kyles of Skye. The proof is thus complete that a vast mass of schists and other crystalline rocks overlies fossiliferous limestones in the Scottish Highlands. It therefore becomes of the utmost importance to determine the geological horizon of the fossils in the limestones. This was done by the late Mr Salter, who declared his conviction that they were unequivocally Lower Silurian, and bore a most remarkable resemblance to a group of fossils from the Lower Silurian rocks of North America. Five of the species he regarded as identical with known American forms (*Orthoceras arcuoliratum*, Hall; *Orthis striatula*, Emmons; *Ophileta compacta*, Salt.; *Murchisonia gracilis*, Hall; *M. bellicincta*, Hall), 4 as representative, 3 doubtful, and 1 new genus, found also in Canada. "That this truly North American assemblage," he remarks, "should be found in the extreme north of Scotland on the same parallel as the Canadian,—that species of *Maclurea* and *Raphistoma*, resembling those of the St Lawrence basin, and *Orthocerata*, bearing large siphuncles like those of North America, Scandinavia, and Russia, should occur in Scotland and yet be scarcely known further south, is at least suggestive of a geographical distribution—perhaps even of climatal conditions—not very unlike that of more modern times."[1] From this palæontological decision it follows that the overlying schistose series of the Scottish Highlands is a mass of metamorphosed Silurian strata. Examined in detail they show very unequal and sporadic metamorphism. Some portions are scarcely more changed than the ordinary greywackes and shales of unaltered districts. False-bedding, pebble-beds, and other common features of sedimentation occur abundantly throughout the whole vast series of schists. Here and there the metamorphism has become extreme, the rocks passing into coarsely crystalline schists full of garnets, with bands of hornblende-rock, actinolite-schist, and other metamorphic products, and passing even into granitic gneiss and true granite. No more convincing proof could be obtained that vast masses of schist do not necessarily belong to an azoic period of the earth's history, but may have been produced by the alteration of previously existing sediments.

It is not necessary to believe that the sediments so altered were in all cases mere ordinary marine sand and mud. The white quartz-rocks were no doubt at one time pure white siliceous sand, the rounded grains of which can still be readily detected in them. The quartzose flagstones were stratified sand with thin partings of clay or mud. The clay slates were evidently thick accumulations of mud. But the rocks containing a marked percentage of magnesia, such as chlorite-slate, actinolite-schist, hornblende-rock, &c., may have resulted from the alteration of volcanic sediments and submarine lavas. The evidence from Cumberland and Wales proves how voluminous and long continued were the volcanic eruptions of the Lower Silurian period in Britain. The abundant diffusion of volcanic detritus over the present sea-bottom is now well known. The "Challenger" researches have also shown us that, besides the glauconite previously known to be deposited from sea-water in the chambers of foraminifera and other dead organisms on the ocean-bottom, true magnesian silicates are now in the process of elimination from sea-water in some of the abysses of the ocean. It is quite possible therefore that some of the rocks of the metamorphic series rich in magnesian silicates may have arisen from the alteration of volcanic tuffs or submarine lavas, and that others may owe their distinctive composition to original chemical precipitation, as ably contended by Sterry Hunt, though their present crystalline structure must be regarded as a part of the general metamorphism by which the whole of the Lower Silurian rocks of the Highlands have been affected.

In the south-east of Ireland, grey, greenish, and purple grits, and grey and dark shales, lie uncomformably upon the Cambrian rocks, and contain a few fossils of Llandeilo age. They present interstratified beds of tuff and felsitic lavas indicating contemporaneous volcanic action. In the north-east of the island a broad

[1] *Quart. Jour. Geol. Soc.*, xx. 881.

belt of Lower Silurian rocks runs from the coast of Down into the heart of Roscommon and Longford. This belt is evidently a prolongation of that in the southern uplands of Scotland. It is marked by the occurrence of similar dark anthracitic shales crowded with graptolites. The richest fossiliferous localities among the Irish Lower Silurian rocks are found at the Chair of Kildare, Portrane near Dublin, Pomeroy in Tyrone, and Lisbellan in Fermanagh, where small protrusions of the older rocks rise as oases among the surrounding later formations. Portlock brought the northern and western localities to light, and Murchison pointed out that, while a number of the trilobites (*Trinucleus, Phacops, Calymene*, and *Illœnus*), as well as the simple plaited *Orthidæ, Leptænæ*, and *Strophomenæ*, some spiral shells, and many *Orthoccrata*, are specifically identical with those from the typical Caradoc and Bala beds of Shropshire and Wales, yet they are associated with peculiar forms, first discovered in Ireland, and very rare elsewhere in the British Islands. Among these distinctive fossils he cites the trilobites, *Remopleurides, Harpes, Amphion*, and *Bronteus*, with the smooth forms of *Asaphus* (*Isotelus*), which, though abundant in Ireland and America, seldom occur in Wales or England, and never on the Continent.[1]

In the north and west of Ireland a large area of surface is occupied by crystalline rocks—gneiss, schists, quartz-rocks, limestone, granite, &c.—which are manifestly a continuation of those of the Highlands of Scotland. They run south-westward parallel with the belt of unaltered Lower Silurian rocks from which, in some places, as in county Tyrone, they are only a few miles distant. The district of Pomeroy, so rich in Silurian fossils, promises to afford the greatest light on the interesting but difficult problem of the metamorphism of the Lower Silurian rocks of the Scottish Highlands and the north-west of Ireland. It will be seen from the evidence furnished by the sections in West Mayo (p. 337) that the metamorphism must have taken place prior to the deposition of the Upper Silurian formations of the west of Ireland.

B. *Upper Silurian.*

The formations which in the British Islands are classed as Upper Silurian occur in two very distinct types. So great indeed is the contrast between these types that it is only by a comparison of organic remains that the whole can be grouped together as the deposits of one great geological period. In the original region described by Murchison, and from which his type of the system was taken, the strata are comparatively flat, soft, unaltered, consisting mainly of somewhat incoherent sandy mud with occasional bands of limestone. But as these rocks are followed into North Wales, they are found to swell out into a vast series of grits and shales so like portions of the hard altered Lower Silurian rocks that, save for the evidence of fossils, they would naturally be grouped as part of that more ancient series. In Westmoreland and Cumberland, and still further north in the border counties of Scotland, also in the south-west of Ireland, it is the North Welsh type which prevails, so that in Britain the general lithological characters and minute palæontological subdivisions ascertained in the typical Silurian district are almost confined to that limited region, while over the rest of the British area for thousands of square miles the hard sandy and shaly type of North Wales is prevalent.

Taking first the Silurian tract of the south-west of England, and the east and south of Wales, we find a decided unconformability separating the Lower from the Upper Silurian formations. In some places the latter are found passing across the edges of the former, group after group, till they come to lie directly upon the Cambrian rocks. Indeed, in one district between the Longmynd and Wenlock edge, the base of the Upper Silurian rocks is found within a few miles to pass from the Caradoc group across to the Lower Cambrian rocks. It is evident, therefore, that in the Welsh region very great disturbance and extensive denudation preceded the commencement of the deposition of the Upper Silurian rocks. As Professor Ramsay has pointed out, the area of Wales, previously covered by a wide though shallow sea, was ridged up into a series of islands, round the margin of which the conglomerates at the base of the Upper Silurian series began to be laid down. This took place during a time of submergence, for these conglomeratic and sandy strata are found creeping up the slopes and even capping some of the heights, as at Bogmine, where they reach a height of 1150 feet above the sea.[2] The subsidence probably continued during the whole of the interval occupied by the deposition of the Upper Silurian strata, which thus were piled to a depth of from 3000 to 5000 feet over the disturbed and denuded platform of Lower Silurian rocks.

Arranged in tabular form, the subdivisions of the Upper Silurian rocks of Wales and the adjoining counties of England are in descending order as follows:—

	Base of Old Red Sandstone.		
3. Ludlow group	Tilestones. Upper Ludlow Rock. Aymestry Limestone. Lower Ludlow Rock.		
2. Wenlock group	Wenlock or Dudley Limestone .... Wenlock Shale .... Woolhope or Barr Limestone and Shale	=	Denbighshire Grits of North Wales.
1. Upper Llandovery group...	Tarannon Shale. May Hill Sandstones.		
	Lower Llandovery Rocks.		

1. *Upper Llandovery Group.*—(*a.*) *May Hill Sandstones.*—The position of these rocks as the true base of the Upper Silurian formations was first shown in 1853 by Sedgwick, who named them the May Hill Sandstones from the locality in Gloucestershire where they are so well displayed. Appearing on the coast of Pembrokeshire at Marloes Bay, they range across South Wales until they are overlapped by the Old Red Sandstone. They emerge again in Carmarthenshire, and trend north-eastward as a narrow strip at the base of the Upper Silurian series, from a few feet to 1000 feet or more in thickness, as far as the Longmynd, where as a marked conglomerate wrapping round that ancient Cambrian ridge they disappear. In the course of this long tract they pass successively and unconformably over Lower Llandovery, Caradoc, Llandeilo, and Cambrian rocks. They consist of yellow and brown ferruginous sandstones, often full of shells, which are apt to weather out and leave casts. Their lower parts are commonly conglomeratic, the pebbles being largely derived from older parts of the Silurian formations. Here and there, where the organic remains become extraordinarily abundant, the strata pass into a kind of sandy limestone, known as the "Pentamerus limestone," from the numbers of this brachiopod contained in it. The species of fossils found in the May Hill Sandstones number about 230.

Among these are some traces of fucoids; sponges (*Cliona, Ischadites*); the widely diffused *Graptolithus priodon*; a number of corals (*Petraia, Heliolites, Favosites, Halysites, Syringopora*, &c.); a few crinoids; some annelides, particularly the *Tentaculites anglicus*, which is abundant; a number of trilobites, of which *Phacops Stokesii, P. Weaveri, Encrinurus punctatus*, and *Calymene Blumenbachii* are common; numerous brachiopods, as *Atrypa hemispherica, A. reticularis, Pentamerus oblongus, Stricklandinia lirata* (*S. lens* also occurs), *Leptæna transversalis, Orthis calligramma, O. elegantula, O. reversa, Strophomena compressa, S. pecten*, and *Lingula parallela*; lamellibranchs of the mytiloid genera *Orthonota, Mytilus*, and *Modiolopsis*, with forms of *Pterinea, Ctenodonta*, and *Lyrodesma*; gasteropods, particularly the genera *Murchisonia, Pleurotomaria, Cyclonema, Holopella*; and cephalopods, chiefly *Orthocerata*, with some forms of *Actinoceras* and *Phragmoceras*, and the old species *Lituites cornu-arietis*.

(*b.*) *Tarannon Shale.*—Above the Upper Llandovery beds comes a very persistent zone of fine, smooth, light grey or blue slates, which has been traced down the whole length of Wales from the mouth of the Conway into Carmarthenshire. These rocks, termed the "paste-rock" by Sedgwick, have an extreme thickness of 1000 to 1500 feet. Barren in organic remains, their chief interest lies in the fact that

[1] *Siluria*, p. 174.

[2] *Physical Geology of Britain*, p. 91.

the persistence of so thick a band of rock between what were supposed to be continuous and conformable formations should have been unrecognized until it was proved by the detailed mapping of the Geological Survey.

2. *Wenlock Group.*—(*a.*) *Woolhope Limestone.*—In the original typical Upper Silurian tract of Shropshire and the adjacent counties, the Upper Llandovery rocks are overlaid by a local group of grey shales containing nodular limestone which here and there swells out into beds having an aggregate thickness of 30 or 40 feet. These strata are well displayed in the picturesque valley of Woolhope in Herefordshire, which lies upon a worn quaquaversal dome of Upper Silurian strata rising in the midst of the surrounding Old Red Sandstone. They are seen likewise to the northwest at Presteign, Nash Scar, and Old Radnor in Radnorshire, and to the east and south in the Malvern Hills (where they include a great thickness of shale below the limestone), and May Hill in Gloucestershire. These strata have yielded many characteristically Upper Silurian fossils, among which may be mentioned *Bumastus Barriensis, Homalonotus delphinocephalus, Phacops caudatus, Atrypa reticularis, Orthis calligramma, Strophomena imbrex, Rhynchonella borealis, R. Wilsoni, Euomphalus sculptus, Orthoceras annulatum.*

It is a characteristic of the older Palæozoic limestones to occur in a very lenticular form, swelling in some places to a great thickness and rapidly dying out, to reappear again perhaps some miles away with increased proportions. This local character is well exhibited by the Woolhope limestone. Where it dies out, the shales underneath and intercalated with it join on continuously to the overlying Wenlock shale, and no line for the Woolhope group can then be satisfactorily drawn. The same discontinuity is strikingly traceable in the Wenlock limestone to be immediately referred to.

(*b.*) *Wenlock Shale.*—This is a group of grey and black fine shales, traceable from the banks of the Severn near Coalbrook Dale across Radnorshire to near Carmarthen—a distance of about 90 miles. The same strata reappear in the protrusions of Upper Silurian rock which rise out of the Old Red Sandstone plains of Gloucestershire, Herefordshire, and Monmouthshire. In the Malvern Hills they were estimated by Professor Phillips to reach a thickness of 640 feet, but towards the north they thicken out to 1000 or even 1400 feet. On the whole the fossils are identical with those of the overlying limestone. The corals, however, so abundant in that rock are here comparatively rare. The brachiopods (of the genera *Leptæna, Orthis, Strophomena, Atrypa*, and *Rhynchonella*) are generally of small size—*Orthis biloba, O. hybrida*, and the large flat *O. rustica*, being characteristic. Of the higher mollusca thin-shelled forms of *Orthoceras* are specially abundant. Among the trilobites, *Encrinurus punctatus, E. variolaris, Calymene Blumenbachii, C. tuberculosa, Phacops caudatus*, and *P. longicaudatus* are common. The *Graptolithus priodon*, so frequent among the Bala beds of the Lower Silurian series, also occurs in the Wenlock shale. *Graptolithus Flemingii* is here a characteristic species.

(*c.*) *Wenlock Limestone* is a thick-bedded, sometimes flaggy, usually more or less concretionary limestone, grey or pale pink, often highly crystalline, occurring in some places as a single massive bed, in others as two or more strata separated by grey shales, the whole forming a thickness of rock ranging from 100 to 300 feet. As its name denotes, this stratum is typically developed along Wenlock Edge in Shropshire, where it runs as a prominent ridge for fully 20 miles, also between Aymestry and Ludlow. It likewise appears at the detached areas of Upper Silurian strata above referred to, being specially well seen near Dudley (whence it is often spoken of as the Dudley limestone), Woolhope, Malvern, May Hill, and Usk in Monmouthshire.

A distinguishing characteristic of the Wenlock limestone is the abundance and variety of its corals, of which 53 species have been described. The rock seems indeed to have been formed in part by massive sheets and bunches of coral. Among characteristic species are *Halysites catenularia, Heliolites interstinctus, H. tubulatus, Alveolites Labechei, Favosites aspera, F. fibrosa, F. Gothlandica, Cœnites juniperinus, Syringopora fascicularis*, and *Omphyma turbinatum.* The crinoids are also specially abundant, and are often beautifully preserved: *Periechocrinus moniliformis* is one of the most frequent species; others are *Crotalocrinus rugosus, Cyathocrinus goniodactylus*, and *Marsupiocrinus cœlatus*; with several cystideans, as *Pseudocrinites quadrifasciatus.* The crustaceans include numerous trilobites, among which we miss some of the persistent Lower Silurian genera, such as *Asaphus, Ogygia*, and *Trinucleus*, none of which ascend into the Wenlock group. The most abundant trilobite is the long-lived *Calymene Blumenbachii*, which ranges from the Llandeilo flags up to near the top of the Upper Silurian formations. It occurs abundantly at Dudley, where it received the name of the "Dudley Locust." Other common forms are *Encrinurus punctatus, E. variolaris, Phacops caudatus, P. Downingiæ, P. Stokesii, Bumastus Barriensis, Homalonotus delphinocephalus*, and *Cheirurus bimucronatus.* The brachiopods continue to be abundant; among typical species may be noted *Atrypa reticularis, Meristella tumida, Spirifer elevatus, S. plicatellus, Rhynchonella borealis* (very common), *R. cuneata, R. Wilsoni, Orthis elegantula, O. rustica, Strophomena rhomboidalis*, and *Pentamerus galeatus.* The lamellibranchs are not well represented; but several species of *Pterinea* are abundant, with *Grammysia cingulata*, and some species of *Modiolopsis* and *Ctenodonta.* The gasteropods are most characteristically marked by 8 or 9 species of *Euomphalus*, 3 or more of *Murchisonia*, with species of *Pleurotomaria, Acroculia*, and *Cyclonema.* The cephalopods are confined to few genera, *Lituites, Actinoceras, Cyrtoceras, Orthoceras*, and *Phragmoceras*; of these the orthoceratites are by far the most abundant both in species and individuals. *Orthoceras annulatum* is the most common form. The pteropods appear in the beautiful and very abundant *Conularia Sowerbyi*, and the heteropods in the common and characteristic *Bellerophon Wenlockensis.*

3. *Ludlow Group.*—This series of strata consists essentially of shales, with occasionally a calcareous band in the middle. It graduates downward into the Wenlock group, so that when the Wenlock limestone disappears the Wenlock and Ludlow shales form one continuous argillaceous formation. It is in this united form that the two groups stretch to the south-west through Brecon and Carmarthen. The Ludlow rocks are typically seen between Ludlow and Aymestry. They appear likewise at the detached Silurian areas from Dudley to the mouth of the Severn. They were grouped by Murchison into three zones.

(*a.*) *Lower Ludlow Rock.*—This is a group of soft dark-grey to pale greenish-brown or olive sandy shales, often with calcareous concretions. Much of the rock, however, presents so little fissile structure as to get the name of mudstone, weathering out into concretions which fall to angular fragments as the rock crumbles down. It becomes more sandy and flaggy towards the top. From the softness of the shales this zone of rock has been extensively denuded, and the Wenlock limestone rises up boldly from under it.

An abundant suite of fossils has been yielded by these shales. No fewer than 18 species of star-fishes, belonging to 6 genera, have been described (*Protaster*, like the brittle-stars of the British seas, *Palæocoma, Palasterina*). A few graptolites occur, particularly the persistent *Graptolithus priodon* (common), *G. colonus*, and *G. Flemingii.* A few of the Wenlock corals survive in the Lower Ludlow rock, but the conditions of deposit were evidently unfavourable for their growth. The trilobites are less numerous than in older beds; they include the venerable *Calymene Blumenbachii, Phacops caudatus*, and its still longer-tailed variety *P. longicaudatus*; also *Acidaspis Brightii, Homalonotus delphinocephalus*, and *Cyphaspis megalops.* But other forms of crustacean life occur in some number. As the trilobites begin to wane numerous phyllopods appear, the genus *Ceratiocaris* being represented by 10 or more species. Large eurypterids now make their entrance upon geological history — *Eurypterus, Pterygotus*, and *Hemiaspis.* Though brachiopods are not scarce, hardly any seem to be peculiar to the Lower Ludlow rock, the *Lingula lata*, which Murchison suggested might be peculiar, having been obtained from what is supposed to be representative of this group of strata in Westmoreland. *Rhynchonella Wilsoni, Spirifer exporrectus, Strophomena euglypha, Atrypa reticularis*, and *Chonetes minima* are not infrequent. Among the more frequently recurring species of lamellibranchs the following may be named—*Cardiola interrupta*, *C. striata*, *Orthonota rigida*, *O. semisulcata*, and a number of species of *Pterinea*. The orthoceratites are numerous, as *Orthoceras Ludense*, *O. subundulatum*, also species of *Phragmoceras* and *Lituites*. The numbers of these straight and curved cephalopods form one of the distinguishing features of the zone. At one locality, near Leintwardine in Shropshire, which has been prolific in Lower Ludlow fossils, particularly in star-fishes and eurypterid crustaceans, a fragment of the fish *Pteraspis* was discovered in 1859. This is the earliest trace of vertebrate life yet detected. It is interesting to note that the *Pteraspis* does not stand low in the scale of organization, but has affinities with our modern sturgeon.

(*b.*) *Aymestry Limestone* is a dark grey somewhat earthy concretionary limestone in beds from 1 to 5 feet thick. Where at its thickest it forms a conspicuous feature, rising above the soft and denuded Lower Ludlow shales and, owing to the easily removable nature of some fuller's earth on which it lies, it has here and there been dislocated by large landslips. It is still more inconstant than the Wenlock limestone. Though well developed at Aymestry it soon dies away into bands of calcareous nodules, which finally disappear, and the lower and upper divisions of the Ludlow group then come together. The most characteristic fossil is the *Pentamerus Knightii*; other common forms are *Rhynchonella Wilsoni*, *Lingula Lewisii*, *Strophomena euglypha*, *Bellerophon dilatatus*, *Pterinea Sowerbyi*, with many of the same shells, corals, and trilobites found in the Wenlock limestone. Indeed, as Murchison has pointed out, except in the less number of species and the occurrence of some of the shells more characteristic of the Upper Ludlow zone, there is not much palæontological distinction between the two limestones.[1]

(*c.*) *Upper Ludlow Rock.*—In the original Silurian district described by Murchison, the Aymestry limestone is covered by a calcareous shelly band full of *Rhynchonella navicula*, sometimes 30 or 40 feet thick. This layer is succeeded by grey sandy shale or mudstone, often weathering into concretions as in the Lower Ludlow zone, and assuming externally the same rusty-brown or greyish olive-green hue. Its harder beds are quarried for building-stone; but the general character of the deposit, like that of the argillaceous portions of the Upper Silurian formations as a whole in the typical district of Siluria, is soft, incoherent, and crumbling, easily decomposing once more into the original mud, and presenting in this respect a contrast to the hard fissile and often slaty shales of the Lower Silurian series. Many of the sandstone beds are crowded with ripple-marks, rill-marks, and annelid-trails, indicative of the shallow littoral waters in which they were deposited. One of the uppermost sandstones is termed the "Fucoid Bed," from the number of its cylindrical sea-weed-like stems. It likewise contains numerous inverted pyramidal bodies, which are believed to be casts of the cavities made in the muddy sand by the rotatory movement of crinoids rooted and half-buried in the micaceous mud.[2] At the top of the Upper Ludlow rock near the town of Ludlow, a brown layer occurs from a quarter of an inch to 3 or 4 inches in thickness, full of fragments of fish, *Pterygotus*, and shells. This layer, termed the "Ludlow Bone-bed," is the oldest from which any considerable number of vertebrate remains has been obtained. In spite of its insignificant thickness it has been detected at numerous localities from Ludlow as far as Pyrton passage, at the mouth of the Severn—a distance of 45 miles from north to south, and from Kington to Ledbury and Malvern—a distance of nearly 30 miles from west to east; so that it probably covers an area (now largely buried under Old Red Sandstone) not less than 1000 square miles in extent, yet it appears never to exceed and usually to fall short of a thickness of 1 foot. Fish remains, however, are not confined to this horizon. They have been detected in strata above the original bone-bed at Ludlow, together with some minute globular bodies believed to be the sporangia of a lycopod. These, with some other plant remains from the same district, are the earliest traces of land vegetation yet found. The higher parts of the Ludlow rock consist of fine yellow sandstone and harder grits known as the Downton sandstone. Originally the whole of these flaggy upper parts of the Ludlow group were called "Tilestones" by Murchison, and being often red in colour were included by him as the base of the Old Red Sandstone, into which they gradually and conformably ascend. Undoubtedly they show the gradual change of physical conditions which took place at the close of the Silurian period in the west of England, and brought in the deposits of the Old Red Sandstone. But as their organic contents are still unequivocally those of the Ludlow group, they are now classed as the uppermost zone of the Silurian system.

A considerable suite of organic remains has been obtained from the Upper Ludlow rock, which on the whole are the same as those in the zones underneath. Vegetable remains, some of which seem to be fucoids, but most of which are probably terrestrial and lycopodiaceous, abound in the Downton sandstone and passage-beds into the Old Red Sandstone. Corals, as might be supposed from the muddy character of the deposit, seldom occur, though Murchison mentions that the encrusting form *Alveolites fibrosus* may not infrequently be found enveloping shells, *Cyclonema corallii* and *Murchisonia corallii* being, as their names imply, its favourite habitats. Some annelides (*Serpulites longispinus*, *Cornulites serpularius*, *Tentaculites tenuis*, and *Trachyderma coriacea*) are not uncommon. The crustacea are represented chiefly by small ostracods (*Beyrichia Klœdeni*, *Leperditia marginata*, *Entomis tuberosa*), and by species of *Ceratiocaris*, *Dictyocaris*, *Eurypterus*, *Hemiaspis*, *Pterygotus*, and *Stylonurus*; the trilobites having still further waned, though *Homalonotus Knightii*, *Encrinurus punctatus*, *Phacops Downingiæ*, and a few others still occur, and even the persistent *Calymene Blumenbachii* may occasionally be found. Of the brachiopods the most abundant forms are *Rhynchonella nucula*, *Chonetes striatella*, *Discina rugata*, and *Lingula cornea*. The most characteristic lamellibranchs are *Orthonota amygdalina*, *Goniophora cymbæformis*, *Pterinea lineata*, *P. retroflexa*; some of the commonest gasteropods are *Murchisonia corallii*, *Platyschisma helicites*, and *Holopella obsoleta*. The orthoceratites are specifically identical with those of the Lower Ludlow rock, and are sometimes of large size, *Orthoceras bullatum* being specially abundant. The fish remains consist of bones, teeth, shagreen-like scales, plates, and fin-spines. They include some plagiostomous (placoid) forms (*Thelodus*, shagreen-scales, *Sphagodus*, skin, *Onchus*, spines) and some ostracosteans (*Cephalaspis*, *Auchenaspis*, and *Pteraspis*).

In the typical Silurian region of Shropshire and the adjacent counties, nothing can be more decided than the lithological evidence for the gradual disappearance of the Silurian sea, with its crowds of graptolites, trilobites, and brachiopods, and for the gradual introduction of those geographical conditions which brought about the deposit of the Old Red Sandstone. The fine grey and olive-coloured muds, with their occasional zones of limestone, are succeeded by bright red clays, sandstones, cornstones, and conglomerates. The evidence from fossils is equally explicit. Up to the top of the Ludlow rocks the abundant Silurian fauna continues in hardly diminished numbers. But as soon as the red strata begin the organic remains rapidly die out, until at last only the fish and the large eurypterid crustaceans continue to occur.

Turning now from the interesting and extremely important though limited area in which the original type of the Upper Silurian rocks is developed, we observe that whether we pass northwards or south-westwards the soft mudstones and thick limestones give way to hard slates, grits, and flagstones, among which it is scarcely possible sometimes even to discriminate what represents the Wenlock from what may be the equivalent of the Ludlow group. It is in Denbighshire and the adjacent counties that this change becomes most marked. The Tarannon shale above described passes into that region of North Wales, where it forms the base of the Upper Silurian formations. It is covered

[1] *Siluria*, p. 130.

[2] *Siluria*, p. 133.

by a series of grits or sandstones which in some places are at least 3000 feet thick. These are covered by and pass laterally into hard shales, which are believed to represent parts of the true Wenlock group, perhaps even some portion of the Ludlow rocks. It is evident, however, that in spite of the wide extent over which these Silurian rocks of North Wales are spread, and the great thickness which they attain, they do not present an adequate stratigraphical equivalent for the complete succession in the original Silurian district. Instead of passing up conformably into the base of the Old Red Sandstone, as at Ludlow, they are covered by that formation unconformably. In fact they have been upturned, crumpled, faulted, and cleaved before the deposition of those portions of the Old Red Sandstone which lie upon them. These great physical changes took place in Denbighshire when, so far as the evidence goes, there was entire quiescence in the Shropshire district; yet the distance between the two areas was not more than about 60 miles. These subterranean movements were doubtless the precursors of those more widely extended upheavals which converted the floor of the Silurian sea into a series of isolated basins, in which the Old Red Sandstone was laid down.

In Westmoreland and Cumberland a vast mass of hard slates, grits, and flags was identified by Sedgwick as of Upper Silurian age. These form the varied ranges of hills in the southern part of the lake district from near Shap to Duddon mouth. The following are the local subdivisions with the coujectural equivalents in Siluria.[1]

Hay Fell and Kirkby Moor Flags	Flaggy beds, with lamellibranchs abundant	=	(?) Tilestones.
	Massive greenish and grey sandstones, with bands of fossils, *Holopella* abundant	=	Upper Ludlow.
Bannisdale Slates	Calcareous beds, with *Rhynchonella navicula* abundant	=	Aymestry Limestone.
	Sandstone and shale, with starfish	=	Lower Ludlow.
	Dark blue flags and grits of great thickness	=	Upper Wenlock.
Coniston Grits	Flags and greywacke (*Orthoceras subundulatum*, *O. angulatum*, *Graptolithus Flemingii*, *G. colonus*, *Ceratiocaris Murchisoni*), upwards of 4000 feet	=	Lower Wenlock.
Coniston Flags	Dark grey coarse flags (*Cardiola interrupta*, *Orthoceras subundulatum*), 1000 feet ...		
Coniston Limestone (Lower Silurian)		=	Caradoc or Bala.

In the northern part of the Lake district a great anticlinal fold takes place. The Skiddaw slates arch over and are succeeded by the base of the volcanic series above described. But before more than a small portion of that series has appeared the whole Silurian area is overlapped unconformably by the Carboniferous Limestone series. It is necessary to cross the broad plains of Cumberland and the south of Dumfriesshire before Silurian rocks are again met with. In this intervening tract a synclinal fold must lie, for along the southern base of the uplands of the south of Scotland a belt of Upper Silurian rocks, dipping on the whole to the south-east, can be traced from the heart of the Cheviot Hills to the headlands of Wigtownshire. These rocks must reach a thickness of several thousand feet, but their top is nowhere seen. They repose on some of the older parts of the Llandeilo series, with so close a coincidence of dip and strike that no decided unconformability has yet been traced between them. They consist essentially of shales, with a considerable proportion of greywacke bands towards the base. At different horizons they contain lenticular bands of a calcareous pebbly grit. But their most characteristic feature, and one which at once distinguishes them locally from the adjoining Lower Silurian rocks, is the occurrence of a nearly black, highly fissile shale, composed of layers in most cases as thin as ordinary writing paper and usually crowded with graptolites. These peculiar bands occur throughout the whole series of rocks from bottom to top. They are sometimes so thin that 20 or 30 seams or ribs, each finely fissile, may be seen intercalated within the space of an inch of the ordinary shale or greywacke. Occasionally they form zones 80 to 100 feet thick, consisting entirely of finely leaved graptolitic shales. As a whole these Upper Silurian strata resemble lithologically the corresponding series in Westmoreland, though here and there they assume the character of mudstones not unlike those of Shropshire. The abundant fossils in them are simple graptolites (*Graptolithus Sedgwickii*, *G. Becki*, *G. Flemingii*, *G. colonus*, *G. Griestonensis*, *Retiolites Geinitzianus*, &c.). Orthoceratites come next in point of numbers (*Orthoceras annulatum*, *O. tenuicinctum*, &c.). In some of the shales crustacean fragments are numerous. They include large pieces of the carapace of *Dictyocaris*, with remains of *Pterygotus* and *Ceratiocaris*. The pebbly grits contain *Petraia* and crinoid stems. In the south of Kirkcudbright certain limestones and conglomerates intercalated among these shales have yielded a more varied fauna, having on the whole a decidedly Wenlock character. It includes *Favosites*, *Catenipora*, *Beyrichia tuberculata*, *Phacops caudatus*, *Meristella*, *Leptæna sericea*, *Atrypa reticularis*, *Strophomena imbrex*, *Murchisonia*, *Orthoceras tenuicinctum*, &c.

It is impossible in the south of Scotland to separate the Upper Silurian rocks into Wenlock and Ludlow groups. On the whole these rocks seem to be representative mainly of the older half of the Upper Silurian formations. They are covered unconformably by Lower Old Red Sandstone and later formations. In the counties of Edinburgh and Lanark, however, the base of the Lower Old Red Sandstone is found to graduate downward into a thick series of brown, olive, and grey shales, sandstones, and grits, containing undoubted Ludlow fossils. It is deserving of remark also that the peculiar lithological type so characteristic of the strata in the original Silurian area reappears in the centre of Scotland, many of the concretionary brown shales and olive-coloured mudstones being undistinguishable from those in the typical sections at Ludlow. Some of these beds are crowded with fossils. Among the most characteristic are *Leptæna transversalis*, *Orthonota amygdalina*, *Platyschisma helicites*, *Beyrichia Klœdeni*, *Orthoceras Maclareni*, with many crustaceans of the genera *Ceratiocaris*, *Eurypterus*, *Pterygotus*, *Slimonia*, and *Stylonurus*. In the Pentland Hills these strata are estimated to attain a thickness of 3500 to 4000 feet, but their base is nowhere reached; in Lanarkshire they are at least as thick. Their lower portions may represent some of the higher parts of the Wenlock group.

Ireland furnishes some interesting evidence regarding the geographical changes in the west of Europe between the close of the Lower Silurian and the beginning of the Upper Silurian period. It has already been pointed out that the metamorphosed Lower Silurian rocks of the Scottish Highlands are prolonged into the north of Ireland, whence they range south-westwards to Galway Bay. In the picturesque tract between Loch Mask and the mouth of Killary harbour these metamorphosed rocks are unconformably overlaid by masses of sandstones, conglomerates, and shales more than 7000 feet thick, and containing Llandovery and Wenlock fossils with a mixture of Caradoc forms. In the midst

[1] The arrangement and thicknesses here given are those in the Kendal district as mapped by Mr Aveline and Mr Hughes in the course of the Geological Survey (*Sheet* 98, S.E., *Explanation*, pp. 6-13, 1872).

of the greatly metamorphosed Lower Silurian platform, portions are to be found still little altered and full of fossils. The overlying Upper Silurian strata have not been metamorphosed, but contain pebbles of the altered rocks on the upturned edges of which they lie. It is evident therefore, as Mr Hull has remarked, that the metamorphism must have occurred between the close of the Lower and the commencement of the Upper Silurian period.[1] In connexion with this question it should be remarked that abundant volcanic activity accompanied the deposit of these Upper Silurian rocks in the west of Ireland, successive sheets of lava (eurite) and beds of tuff forming conspicuous bands among the stratified rocks, and reaching a collective thickness of 800 feet and upwards. Between Brandon Head and Dingle Bay a thick mass of strata on the coast, must, from the comparatively few fossils obtained from it, be held to represent Upper Silurian formations.

Continental Europe.—The broad hollow which, running from the mouth of the English Channel across the plains of northern Germany into the heart of Russia, divides the high grounds of the north and north-west of Europe from those of the centre and south, separates the European Silurian area into two distinct tracts. In the northern of these we find the Lower and Upper Silurian formations attaining an enormous development in Britain, but rapidly diminishing in thickness towards the north-east, until in the south of Scandinavia and the Gulf of Finland they reach only about $\frac{1}{25}$th of that depth. In these tracts, too, they have on the whole escaped so well from the dislocations, crumplings, and metamorphisms so conspicuous to the south-west, that to this day they remain over wide areas nearly as horizontal and soft as at first. In the southern tract Silurian rocks appear only here and there from amidst later formations, and almost everywhere present proofs of intense subterranean movement.

In the south of Scandinavia (Christiania, Mjösen See, Malmö, Gothland) the Lower and Upper Silurian rocks attain a united thickness of not more than about 1200 feet, yet are said to contain representatives of all the leading subdivisions of the British series. The following table exhibits the Silurian succession in the south of Norway and Sweden, with the supposed English equivalents:—

Sandy beds, with *Pterinea retroflexa*, *Rhynchonella nucula*, *Orthonota retusa*, *Beyrichia tuberculata*. S. Gothland	= Upper Ludlow.
Upper Malmö limestone .... Upper Graptolite marls, with *Graptolithus priodon* (*Ludense*) abundant.................... Lower Malmö or upper Orthoceratite limestone, with large *Orthocerata* having central siphuncles	= Lower Ludlow.
Encrinital schists with orthoceratites and *Gomphoceras pyriforme* .... Coral limestone (*Omphyma turbinatum* and other Wenlock corals)...........................	= Wenlock.
Pentamerus limestone, *Pentamerus oblongus*, *P. galeatus*, *Stricklandinia lens*, *Leptæna transversalis*, *Encrinurus punctatus*, &c. .... Lower argillaceous schists	= Llandovery.
Calcareous sandstones (containing a mixture of Llandovery forms, as *Meristella angustifrons*, and many large smooth *Pentameri*).......... Calcareous and argillaceous flagstones, *Orthis calligramma*, *O. testudinaria*, *O. pecten*, *Leptæna sericea*, *Conularia quadrisulcata*, *Asaphus expansus*, *Trinucleus concentricus*, &c. Orthoceratite limestone and lower Encrinital schists	= Caradoc.
Upper Graptolite schists, with *Diplograptus pristis*, *D. folium*, *D. teretiusculus*, and forms of *Asaphus*, *Ogygia*, *Trinucleus*, &c. .... Lower Orthoceratite limestone, with *Orthoceras duplex*, *O. annulatum*, *Lituites cornu-arietis*, *Orthis calligramma*, *O. elegantula*, *Bellerophon bilobatus*, &c.	= Llandeilo.
Lower Graptolite schists (with numerous graptolites)	= Arenig in part.
Alum schists, 150 feet (= Regiones A and B of Angelin), containing the fossils enumerated on p. 331 .... Quartzite (Fucoids)...	= Cambrian.

Though the general resemblance of the succession of fossils in Scandinavia and in Britain is singularly close, there are, as might have been anticipated, differences in the range of species, some forms having appeared earlier or having survived later in the one region than in the other. Thus the *Pentamerus oblongus* ascends in Scandinavia into rocks full of Wenlock corals, but does not occur in the Wenlock group of Britain. On the other hand, among Scandinavian strata containing such characteristically Lower Silurian genera of trilobites as *Asaphus*, *Trinucleus*, and *Ogygia*, there occur organisms which in Britain are typically Upper Silurian, such as *Orthoceras dimidiatum* and *O. distans*, two fossils of the Ludlow rocks. This is a point of considerable importance in its bearing upon the value of palæontological evidence in correlating the formations of different countries. It shows that the order of succession found to hold good in one region cannot be rigidly applied to others, and that in such cases it is not from individual species so much as from the general facies of the fossils that we must draw geological parallels. The first appearance and duration of a species have doubtless greatly varied in different regions.

In Russia Silurian rocks must occupy the whole vast breadth of territory between the Baltic and the flanks of the Ural Mountains, beyond which they spread eastwards into Asia. Throughout most of this extensive area they lie in horizontal undisturbed beds, covered over and concealed from view by later formations. Along the flanks of the Urals they have been upheaved, and placed on end or at a high angle against the central portions of that chain, and have been partially metamorphosed into chlorite-schist, mica-schist, quartz-rock, and other crystalline masses. But along the southern margin of the Gulf of Finland they appear at the surface as soft clays, sands, and unaltered strata, which, so far as their lithological characters go, might be supposed to be of late Tertiary date, so little have they been changed during the enormous lapse of ages since Lower Palæozoic time. The great plains between the Ural chain on the east and the rising grounds of Germany on the south-west have thus from a remote geological antiquity been exempted from the terrestrial corrugations which have affected so much of the rest of Europe. They have been alternately, but gently, depressed as a sea-floor, and elevated into steppes or plains. The following subdivisions have been established by F. Schmidt among the Silurian rocks of north-west Russia:—[2]

I. *Upper Silurian*—

Sandy variable limestone, with marly layers passing into sandstone (*Beyrichia tuberculata*, *Grammysia cingulata*, *Chonetes striatella*, and numerous fish remains, *Onchus*, &c.)	= Tilestones.
Upper Oesel group, yellow marly and sometimes dolomitic strata (*Rhynchonella Wilsoni*, *Chonetes striatella*, *Platyschisma helicites*, *Eurypterus remipes*, and fish remains, &c.)..	= Ludlow.
Lower Oesel group, dolomite, with marl and limestone below (*Propora tubulata*, *Halysites distans*, *Beyrichia Klödeni*, *Encrinurus punctatus*, *Proëtus concinnus*, *Meristella tumida*, *Spirifer crispus*, *Leptæna transversalis*, *Euomphalus funatus*, *Orthoceras annulatum*, &c.)	= Wenlock.

II. *Middle Silurian*—

Pentamerus band, with *P. estonus* (*oblongus*), *Alveolites Labechei*, *Bellerophon dilatatus*, *Bronteus signatus* (*laticauda*)... Compact limestone and dolomite with siliceous nodules (*Heliolites interstinctus*, *Ptilodictya scalpellum*, *Strophomena pecten*, *Orthis hybrida*, *Pentamerus linguifer*, *Leperditia marginata*) .... Pentamerus band, limestone, and dolomite, with *Pentamerus borealis*, &c.	= Llandovery.

[2] *Untersuchungen über die Silurische Formation von Estland, Nord-Livland, and Oesel*, Dorpat, 1858.

III. *Lower Silurian*—

(*c*) Borkholm limestones and marls (*Halysites labyrinthica, Heliolites megastoma, Syringophyllum organum, Lichas margaritifer, Pleurorhynchus dipterus, Orthoceras calamiteum*, &c.)	= Caradoc.
(*b*) Lyckholm, yellow or grey compact limestone and marls (*Orthis flabellulum, O. Actoniæ, O. insularis*, &c.)	
(*a*) Wesenberg limestone and marl (*Orthis testudinaria, Encrinurus multisegmentatus, Lichas Eichwaldi*, &c.)	
(*c*) Limestone usually somewhat bituminous, with partings of reddish yellow and brown very bituminous marl (*Beyrichia complicata, Asaphus acuminatus, Orthis calligramma, Leptæna sericea*, &c.)	= Llandeilo
(*b*) Orthoceratite limestone and marl bands, 15 to 40 feet thick (*Monticulipora petropolitana, Echinosphærites aurantium, Asaphus expansus, Orthis calligramma, Orthoceras vaginatum*, &c.)	
(*a*) Limestone, full of glauconite grains, especially towards the bottom (*Orthis calligramma, O. extensa*, abundant fragments of *Illænus* and *Asaphus*, &c.)	
(*d*) Glauconite sand (6 feet), with numerous Foraminifera in the glauconite grains (*Panderella, Cymbulia, Tiedemannia*, &c.) and the "Conodonts" of Pander	= Arenig.
(*c*) Alum-slate (10 feet), highly carbonaceous, with pyrite-nodules and abundant graptolites (*Dictyonema Hisingeri, Obolus*, &c.)	
(*b*) Ungulite sandstone (120 feet), yellow to white, with (in the upper part) abundant shells of *Obolus Apollinis* ("Ungulites" of Pander)	
(*a*) Blue clay, with sandstone bands, sparingly fossiliferous; bored at Revel to a depth of 800 feet without its bottom being reached	

In the centre and south of Europe by far the most important Silurian area is the basin of Bohemia, so admirably worked out by M. Barrande in his great work already cited (p. 323), wherein the formations are grouped as in the subjoined table:—

Upper Silurian.	3d Fauna.	Étage H Shales with coaly layers and beds of quartzite (*Phacops fecundus, Tentaculites elegans*) with species of *Leptæna, Orthoceras, Lituites, Goniatitis*, &c.	850 ft.
		,, G Argillaceous limestones with chert, shales, and calcareous nodules. Numerous trilobites of the genera *Dalmanites, Bronteus, Phacops, Proëtus Harpes*, and *Calymene*; *Atrypa reticularis, Pentamerus linguifer.*	1000 ,,
		,, F Pale and dark limestone with chert. *Harpes, Lichas, Phacops, Atrypa reticularis, Pentamerus galeatus, Favosites Gothlandica, F. fibrosa, Tentaculites.*	
		,, E Shales with calcareous nodules, and shales resting on sheets of igneous rock (300 ft.). A very rich Upper Silurian fauna, abundant cephalopods, trilobites, &c.; *Halysites catenularius*, graptolites many species.	450–900 ,,
Lower Silurian.	2d Fauna.	,, D Yellow, grey, and black shales, with quartzite and conglomerate at base. Abundant trilobites of genera *Trinucleus, Ogygia, Asaphus, Illænus, Remopleurides*, &c.	3000 ,,
Cambrian.	Primordial Fauna.	,, C Shales or "schists," sometimes with porphyries and conglomerates. *Paradoxides, Ellipsocephalus, Agnostus*, and other genera of trilobites referred to above (*ante*, p. 330).	900–1200 ,,
Azoic.		,, B } Schists wholly unfossiliferous resting ,, A } on bottom gneiss.	

The lower two *étages* (A, B) correspond probably to some of the older parts of the British Cambrian series, and perhaps in part to still older rocks. Étage C, or the Primordial Zone, is the equivalent of the Upper Cambrian rocks of Wales, possibly also partly of the Arenig series. Étage D, subdivided into five groups (*d1, d2, d3, d4*, and *d5*), appears to be, on the whole, representative of the Lower Silurian formations of the British area, though it is impossible to make the minor subdivisions in the two countries agree. The remaining four formations answer to the English and Welsh Upper Silurian series,—the highest zone of all (H) indicating by its organic remains the approach of the Devonian series.

Small though the area of the Silurian basin of Bohemia is (for it measures only 100 miles in extreme length by 44 miles in its greatest breadth), it has proved extraordinarily rich in organic remains. M. Barrande has named and described above 2000 species from that basin alone, the greater number being peculiar to it. Some aspects of its organic facies are truly remarkable. One of these is the extraordinary variety and abundance of its straight and curved cephalopods. M. Barrande has determined 18 genera and 2 sub-genera, comprising in all no fewer than 1127 distinct species. The genus *Orthoceras* alone contains 554 species, and *Cyrtoceras* has 230.[1] The trilobites likewise appear in great numbers, the same indefatigable explorer having detected as many as 42 distinct genera, comprising 350 species. Of these the most prolific genus is *Bronteus*, which includes 46 species entirely confined to the 3d fauna or Upper Silurian; *Acidaspis* has 40 species, of which 6 occur in the 2d and 34 in the 3d fauna. *Proëtus* also numbers 40 species, which all belong to the 3d fauna, save 2 found in the 2d. Other less prolific but still abundant genera are *Dalmanites, Phacops*, and *Illænus*. The 2d fauna, or Lower Silurian rocks, contain in all 32 genera and 127 species of trilobites, while the 3d fauna, or Upper Silurian formations, contain 17 genera and 205 species, so that generic types are more abundant in the earlier and specific varieties in the later rocks.[2]

In Germany Silurian rocks appear in a few detached areas, but present a great contrast to those of Bohemia in their comparatively unfossiliferous character, and the absence of any one continuous succession of the whole Silurian system. They occur in the Thuringer Wald, where a series of fucoidal-schists (perhaps Cambrian) passes up into slates, greywackes, &c., with *Lingula, Discina, Calymene*, numerous graptolites, and other fossils. These strata (from 1600 to 2000 feet thick) may represent the Lower Silurian formations. They are covered by some graptolitic alum-slates, shales, flinty slates, and limestones (*Favosites Gothlandica*, &c.), which no doubt represent the Upper Silurian, and pass into the base of the Devonian formations. Among the Harz Mountains certain greywackes and shales containing land-plants (lycopods, &c.), trilobites (*Dalmanites*, &c.), graptolites, &c., are regarded as of intermediate age between true Upper Silurian and Lower Devonian rocks. In the north-west of France an impoverished series of sandstones and slates represents the succession of formations up to the top of the Silurian or base of the Devonian system, and contains a suite of trilobites which indicate more analogy with the Silurian fauna of Bohemia and of Spain than with that of the British Islands. In the western half of the Spanish peninsula Silurian rocks are found flanking the older schists and crystalline masses, and spreading over a vast area of the tableland. They appear to belong chiefly if not wholly to the lower division of the system, and they include representatives of Barrande's primordial zone, containing 19 species of organisms, of which 9 are primordial trilobites.

North America.—In the United States and Canada the Silurian formations spread continuously over a vast territory, from the mouth of the St Lawrence south-westwards into Alabama and westwards by the great lakes. They almost encircle and certainly underlie all the later Palæozoic deposits of the great interior basin. The rocks are most typically developed in the state of New York, where they have been arranged as in the subjoined table.

B. Upper Silurian.

IV. Oriskany Formation.	Oriskany sandstone (*Spirifer arenosus*).	Ludlow.
III. Lower Helderberg Formation.	(4) Upper Pentamerus limestone (*Pentamerus pseudogaleatus*)	
	(3) Delthyris limestone (*Meristella lævis*)	
	(2) Lower Pentamerus limestone (*Pentamerus galeatus*)	
	(1) Water-lime (*Tentaculites, Eurypterus*, and *Pterygotus*)	
II. Salina Formation.	Onendago salt group, nearly barren of fossils	
I. Niagara Formation.	(3) Niagara shale and limestone (*Halysites, Favosites, Calymene Blumenbachii, Homalonotus delphinocephalus, Leptæna tranversalis*, &c.)	Wenlock.
	(2) Clinton group (*Pentamerus oblongus, Atrypa reticularis*, &c.)	Upper Llandovery.
	(1) Medina group with Oneida conglomerate (*Modiolopsis orthonota*)

A. Lower Silurian.

Formation	Group		
II. Trenton Formation.	(3) Cincinnati (Hudson River) group (*Syringopora, Halysites, Diplograptus pristis, Pterinea demissa, Leptæna sericea*).		
	(2) Utica group—Utica shale.		
	(1) Trenton group	Trenton limestone. Black River limestone. Birdseye limestone.	*Graptolithus amplexicaulis, Trinucleus concentricus, Orthis testudinaria, Murchisonia, Conularia, Orthoceras, Cyrtoceras*, &c.
I. Canadian Formation.	(3) Chazy group—Chazy limestone (*Maclurea magna, M. Logani, Orthoceras, Illænus, Asaphus*).		
	(2) Quebec group (upwards of 100 species of trilobites of genera *Agnostus, Ampyx, Amphion, Conocoryphe, Dikelocephalus, Illænus, Asaphus*, &c., more than 50 species of graptolites).		
	(1) Calciferous group (graptolites, *Lingulella acuminata, Leptæna, Conocardium, Ophileta compacta, Orthoceras primigenium*, 14 species of trilobites of the genera *Amphion, Bathyurus, Asaphus, Conocoryphe*).		
	Potsdam formation, representing Cambrian (see *ante*, p. 331).		

The most recent researches of Mr Selwyn and his colleagues of the Geological Survey of Canada have shown that in the so-called Quebec group have been included a number of formations of very different stratigraphical positions. He recognizes in it three distinct groups:—(1) at the base a group of crystalline schists; (2) a group of sandstones and slates with abundant volcanic rocks, probably Cambrian; and (3) Lower Silurian slates, shales, limestones, quartzites, sandstones, and conglomerates. He objects to the introduction of new names to denote systems of rocks, and thinks that Laurentian, Huronian, Cambrian, and Silurian meet all present requirements.

Devonian and Old Red Sandstone.

In Wales and the adjoining counties of England, where so full a development of the Silurian system was originally discovered and worked out by Murchison, the abundant marine fauna comes to an abrupt close when the red rocks set in at the top of the Ludlow group. From that horizon upwards in the geological series we have to pass through some 10,000 feet or more of barren red sandstones and marls, until we again encounter a copious marine fauna in the Carboniferous Limestone. It is evident that between the disappearance of the Silurian and the arrival of the Carboniferous fauna very great geographical changes must have occurred over the area of Wales and the west of England. The sea must have been excluded from the area, or at least must have been rendered unfit for the existence and development of marine life over the area in question. From the striking contrast between the general facies of life in the Silurian and that in the Carboniferous system it is manifest that the interval between them must have been of long duration.

The geological records of this vast interval are still only very partially unravelled and interpreted. At present the general belief among geologists is that, while in the west and north-west of Europe the Silurian sea-bed was upraised into land in such a way as to enclose large inland basins, in the centre and south-west the geographical changes did not suffice to exclude the sea, which continued to cover more or less completely that region. In the isolated basins of the north-west a peculiar type of deposits termed the Old Red Sandstone is believed to have accumulated, while in the shallow seas to the south and east a series of marine sediments and limestones was formed to which the name of Devonian has been given. It is thus supposed that the Old Red Sandstone and the Devonian represent different geographical areas, with different phases of sedimentation and of life, during the long lapse of time between the Silurian and Carboniferous periods.

That the Old Red Sandstone does really represent this prolonged interval can be demonstrated by innumerable sections in Britain, where its lowest strata are found graduating downward into the top of the Ludlow group and its highest beds are seen to pass up into the base of the Carboniferous system. But the evidence is not everywhere so clear in regard to the true position of the Devonian rocks. That these rocks lie between Silurian and Carboniferous formations is indeed sufficiently clear. But it is a curious fact that where the Lower Devonian beds are best developed the Upper Silurian formations are scarcely to be recognized, or if they occur, they can hardly be separated from the so-called Devonian rocks. It is therefore quite possible that the lower portions of what has been termed the Devonian series may in certain regions to some extent represent what are elsewhere recognized as undoubted Ludlow or even perhaps Wenlock rocks. We cannot suppose that the rich Silurian fauna died out abruptly at the close of the Ludlow epoch. We should be prepared for the discovery of younger Silurian rocks than the latest of those in Britain, such as M. Barrande has shown to exist in his Étage H. The rocks termed Lower Devonian may partly represent some of these later phases of Silurian life, if they do not also mark peculiar geographical conditions of a still older period in Upper Silurian time. On the other hand, the upper parts of the Devonian system might in several respects be claimed as fairly belonging to the Carboniferous system above.

The late Mr Jukes proposed a solution of the Devonian problem, the effect of which would be to turn the whole of the Devonian rocks into Lower Carboniferous, and to place them above the Old Red Sandstone, which would thus become the sole representative in Europe of the interval between Silurian and Carboniferous time.[1] In the following descriptions an account will first be given of the Devonian type and then of the Old Red Sandstone.

A. Devonian.

This name was first applied by Sedgwick and Murchison to the rocks of North and South Devon and Cornwall, whence a suite of fossils was obtained which Lonsdale pronounced to be intermediate in character between Silurian and Carboniferous. The relations of these strata to Silurian rocks cannot be determined from any section. They pass upward into Carboniferous strata. They have been arranged into three divisions, as in the subjoined table.

Upper....	Pilton and Pickwell-Down Group.—Grey slate with courses of impure limestone (Pilton) passing down into yellow, brown, and red sandstones (Baggy Point, Marwood), and a series of hard grey and red sandstones and micaceous flagstones at the base (Pickwell-Down, Dulverton, Morte Bay).
Middle..	Ilfracombe Group.—Grey unfossiliferous slates (Morte Hoe, Woolacombe, and Lee Bay) passing down into calcareous fossiliferous slates and limestones (Ilfracombe, Combe Martin, Torquay, Plymouth) resting on hard green, grey, and red grits, sandstones, and conglomerates (Hangman Hill).
Lower....	Lynton Group.—Soft slates with thin limestone and sandstone bands (Lynton) resting on lowest schists and red and grey micaceous sandstones (Lynton, Lynmouth, Foreland, &c.).

The total fauna of the British Devonian rocks numbers about 400 species. The middle group is the chief repository of fossils.

Lower.—Among the lower gritty slates and limestone bands of North Devon there are found, according to the detailed census compiled by Mr Etheridge, 18 species of fossils, comprising *Favosites cervicornis, Fenestella antiqua, Orthis arenata, Spirifer canaliferus, S. lævicostus*, &c. Of these organisms 7 species are also found among the Devonian rocks of the Rhine, Belgium, or France. Mr Etheridge re-

[1] See his papers in *Journ. Roy. Geol. Soc. Ireland* (1865), i. pt. 1, new ser., and *Quart. Journ. Geol. Soc.*, xxii. (1866), and his pamphlet on *Additional Notes on Rocks of North Devon, &c.*, 1867.

marks that it is singular that the British Lower Devonian rocks should only have yielded 1 gasteropod (*Pleurotomaria aspera*), 4 lamellibranchs, 1 cephalopod (*Orthoceras gracile*), and 1 nucleobranch (*Bellerophon bisulcatus*). They have furnished only 10 brachiopods. Traces of fish remains have been obtained among them in the form of bones and coprolitic debris. So far as observation has gone not a single Silurian species has been certainly detected in the Devonian rocks of Britain, with, according to Mr Etheridge, the sole exception of the long-lived and universally diffused *Atrypa reticularis*, which occurs in the Ilfracombe group. There can be no doubt, however, from the meagre list of fossils from the Lower Devonian rocks of Devon and Cornwall, that either the conditions for the existence or those for the fossilization of the early Devonian fauna must have been singularly unfavourable in the south-west of England. It would be exceedingly rash to argue as to the extinction of the Silurian fauna from the unsatisfactory evidence of these rocks.

Middle.—As above remarked, this is the great storehouse of Devonian fossils in the south-west of England. In this fauna, as tabulated by Mr Etheridge, there are 8 amorphozoans, including 5 species of *Stromatopora*; 23 genera and 50 species of cœlenterates, among which the corals *Acervularia, Alveolites, Cyathophyllum, Favosites, Pleurodictyum,* and *Petraia* are conspicuous; 4 genera and 8 species of crinoids (*Hexacrinus, Cyathocrinus,* &c.); 1 annelide (*Tentaculites annulatus*); 5 genera and 13 species of crustaceans, which are all trilobites (*Phacops granulatus, P. latifrons, P. punctatus, Bronteus flabellifer, Cheirurus articulatus, Harpes macrocephalus,* &c.); and 12 species of polyzoans. The brachiopods are abundant; 68 species have been yielded by the rocks of South Devon, including *Athyris concentrica, A. lachryma, Atrypa reticularis, A. desquamata, Camarophoria rhomboidea, Cyrtina Lemarlii, Orthis striatula, Rhynchonella acuminata, R. pugnus, Pentamerus brevirostris, Spirifer disjunctus, Stringocephalus Burtini, Uncites gryphus,* &c. The lamellibranchs are poorly represented, 11 genera only occurring, and many of them represented by only 1 species. The gasteropods are likewise present in but small numbers and variety; 12 genera and 36 species have been enumerated. Of these species, 4 (*Acroculia vetusta, Euomphalus lævis, Macrocheilus imbricatus,* and *Murchisonia spinosa*) survived into the Carboniferous period. The cephalopods are represented by 5 genera, the most abundant specifically being *Cyrtoceras* and *Orthoceras*; *Goniatites, Clymenia,* and *Nautilus* also occur. Of the total list of fossils a large proportion is found in the Middle Devonian rocks of the continent of Europe. Very few species agree with those of the Silurian or with those of the Carboniferous system.

Upper.—From the calcareous portions of the Petherwin and Pilton beds of Cornwall and Devon a considerable number of fossils has been obtained. Among the more characteristic of these we find 11 species of the coiled cephalopod *Clymenia* (*C. undulata, C. lævigata, C. striata*), the trilobites *Phacops granulatus* and *P. latifrons*, the small ostracod *Cypridina serrato-striata*, the brachiopods *Spirifer disjunctus* or *Verneullii, Strophomena rhomboidalis, Chonetes Hardrensis, Productus subaculeatus,* and the lamellibranch *Cuculæa Hardingii.* The Marwood and Baggy Point beds have also yielded traces of land plants, such as *Knorria dichotoma* and *Adiantites Hibernicus*, the latter fern being common in some parts of the Upper Old Red Sandstone of Ireland.

The higher red and yellow sandy portions of the Upper Devonian rocks shade up insensibly at Barnstaple in North Devon into strata which by their fossils are placed at the base of the Carboniferous Limestone series. But in no other series save the south-western district of Britain can such a passage be observed. In all other places the Carboniferous system, where its true base can be seen, passes down into the red sandy and marly strata of the Upper Old Red Sandstone without marine fossils.

CONTINENTAL EUROPE.—Devonian rocks occupy a large area in the centre of Europe, extending from the Ardennes through the south of Belgium across Rhenish Prussia to Darmstadt. They are best known from the picturesque gorges which have been cut through them by the Rhine below Bingen and by the Moselle below Treves. They have been arranged into the following groups in the Eifel region, where their true geological position was first indicated by Sedgwick and Murchison.

III. *Upper Devonian*—
- (c) Cypridina shales (*Cypridina serrato-striata*).
- (b) Goniatite shales (*Goniatites retrorsus, G. primordialis, Orthoceras subflexuosum, Cardiola retrostriata,* &c.).
- (a) Nodular crumbling limestone (Kramenzelkalk), dolomitic marl, and shaly limestone (*Spirifer disjunctus* or *Verneuilli, Atrypa reticularis, Rhynchonella cuboides, Productus subaculeatus,* &c.).

II. *Middle Devonian*—
- (b) Stringocephalus group, consisting of the great Eifel limestone with underlying crinoidal beds (*Stringocephalus Burtini, Spirifer undatus, Productus subaculeatus, Pentamerus galeatus, Atrypa reticularis, Calceola sandalina.* and many corals and crinoids).
- (a) Calceola group,—marly limestones full of *Calceola sandalina, Spirifer concentricus, Camarophoria microrhyncha,* &c., esting upon impure shaly ferruginous limestone and greywacke, marked by an abundance of *Spirifer cultrijugatus, Rhynchonella Orbignyana Atryva reticularis, Phacops latifrons,* &c.

I. *Lower Devonian*—
- (c) Upper greywacke and shale (Vichter-Schichten), with a mixture of Lower and Middle Devonian fossils.
- (b) Ahr group,—greywacke-shales with *Chonetes sarcinulata, C. dilatata, Rhynchonella Livonica, Spirifer paradoxus, S. speciosus,* many species of *Pterinea, Pleurotomaria,* and *Murchisonia.*
- (a) Coblentz group, greywacke and clay-slate (*Leptæna laticosta, Chonetes sarcinulata, Rhynchonella Livonica, Pleurodictyum problematicum,* &c.).

This threefold subdivision, with a central mass of calcareous strata, is traceable westwards through Belgium (where the Calcaire de Givet represents the Stringocephalus limestone of the Eifel) and eastwards into the Harz. The rocks reappear with local petrographical modifications, but with a remarkable persistence of general palæontological characters, in Eastern Thuringia, Franconia, Saxony, Silesia, the north of Moravia, and East Galicia. Devonian rocks have been detected among the crumpled rocks of the Styrian Alps by means of the evidence of abundant corals, clymenias, gasteropods, lamellibranchs, and other organic remains. Perhaps in other tracts of the Alps, as well as in the Carpathian range, similar shales, limestones, and dolomites, though as yet unfossiliferous, but containing ores of silver, lead, mercury, zinc, cobalt, and other metals, may be referable to the Devonian system.

In the centre of Europe, therefore, the Devonian rocks consist of a vast thickness of dark-grey sandy and shaly rocks, with occasional seams of limestone, and in particular with one thick central calcareous zone. These rocks are characterized in the lower zones by numerous broad-winged spirifers and by peculiar trilobites (*Phacops, Homalonotus,* &c.), which, though generically like those of the Silurian system, are specifically distinct. The central calcareous zone abounds in corals and crinoids as well as in numerous brachiopods. In the highest bands a profusion of coiled cephalopods (*Clymenia*) occurs in some of the limestones, while the shales are crowded with a small but characteristic ostracod crustacean (*Cypridina*). Here and there traces of fishes have been found, more especially in the Eifel, but seldom in such a state of preservation as to warrant their being assigned to any definite place in the zoological scale. More recently, however, E. Beyrich has described from Gerolstein in the Eifel an undoubted species of *Pterichthys*, which, as it cannot be certainly identified with any known form, he names *P. Rhenanus.* A *Coccosteus* has been described by F. A. Roemer from the Harz, and more recently one has been cited from Bicken near Herborn by V. Koenen; but, as Beyrich points out, there may be some doubt as to whether the latter is not a *Pterichthys.*[1] A *Ctenacanthus*, seemingly undistinguishable from the *C. Bohemicus* of Barrande's Étage G, has also been obtained from the Lower Devonian "Nereitenschichten" of

[1] *Zeitschrift der Deutsch. Geol. Gesell.*, xxix. 751.

Thuringia.[1] The characteristic *Holoptychius nobilissimus* has recently been detected in the Psammite de Condroz, which in Belgium forms a characteristic sandy portion of the Upper Devonian rocks. These are interesting facts, as helping to link the Devonian and Old Red Sandstone types together. But they are as yet too few and unsupported to warrant any large deduction as to the correlations between these types.

It is in the north-east of Europe that the Devonian and Old Red Sandstone appear to be united into one system, where the limestones and marine organisms of the one are interstratified with the fish-bearing sandstones and shales of the other. In Russia, as was shown in the great work *Russia and the Ural Mountains* by Murchison, De Verneuil, and Keyserling, rocks intermediate between the Upper Silurian and Carboniferous Limestone formations cover an extent of surface larger than the British Islands. This wide development arises not from the thickness but from the undisturbed horizontal character of the strata. Like the Silurian formations above described, they remain to this day nearly as flat and unaltered as they were originally laid down. Judged by mere vertical depth, they present but a meagre representative of the massive Devonian greywacke and limestone of Germany, or of the Old Red Sandstone of Britain. Yet vast though the area is over which they form the surface rock, it is probably only a small portion of their total extent; for they are found turned up from under the newer formations along the flank of the Ural chain. It would thus seem that they spread continuously across the whole breadth of Russia in Europe. Though almost everywhere undisturbed, they afford evidence of some terrestrial oscillation between the time of their formation and that of the Silurian rocks on which they rest, for they are found gradually to overlap Upper and Lower Silurian formations.

The chief interest of the Russian rocks of this age lies in the fact, first signalized by Murchison and his associates, that they unite within themselves the characters of the Devonian and the Old Red Sandstone types. In some districts they consist largely of limestones, in others of red sandstones and marls. In the former they present mollusks and other marine organisms of known Devonian species; in the latter they afford remains of fishes, some of which are specifically identical with those of the Old Red Sandstone of Scotland. The distribution of these two palæontological types in Russia is traced by Murchison to the lithological characters of the rocks, and consequent original diversities of physical conditions, rather than to differences of age. Indeed cases occur where in the same band of rock Devonian shells and Old Red Sandstone fishes lie commingled. In the belt of the formation which extends southwards from Archangel and the White Sea, the strata consist of sands and marls, and contain only fish remains. Traced through the Baltic provinces, they are found to pass into red and green marls, clays, thin limestones, and sandstones, with beds of gypsum. In some of the calcareous bands such fossils occur as *Orthis striatula*, *Spiriferina prisca*, *Leptæna productoides*, *Spirifer calcaratus*, *Spirorbis omphaloides*, and *Orthoceras subfusiforme*. In the higher beds *Holoptychius* and other well-known fishes of the Old Red Sandstone occur. Followed still further to the south, as far as the watershed between Orel and Woronesch, the Devonian rocks lose their red colour and sandy character, and become thin-bedded yellow limestones, and dolomites with soft green and blue marls. Traces of salt deposits are indicated by occasional saline springs. It is evident that the geographical conditions of the Russian area during the Devonian period must have closely resembled those of the Rhine basin and central England during the Triassic period.

The Russian Devonian rocks have been classified as follows:—

Upper....	Red and white sandstone and green marls,—numerous fish remains, particularly *Holoptychius nobilissimus*, *Glyptosteus favosus*, *Diplopterus macrocephalus*.
Middle..	Limestones, clays, marls, dolomite, and gypsum,—numerous characteristic Devonian shells and crinoids, also *Holoptychius nobilissimus*.
Lower....	In some districts red and green limestones with red marls and Middle Devonian fossils; in others (North Livonia) sandstones and clays, with numerous fish remains of the genera *Osteolepis*, *Dipterus*, *Diplopterus*, *Asterolepis*, and others found also in the Caithness flags of Scotland.

There is an unquestionable passage of the uppermost Devonian rocks of Russia into the base of the Carboniferous system. The Devonian rocks of North America are noticed at the end of the next section.

B. *Old Red Sandstone.*

Under this name is comprised a vast and still imperfectly described series of red sandstones, shales, and conglomerates, intermediate in age between the Ludlow rocks of the Upper Silurian formations and the base of the Carboniferous system in Britain. These rocks were termed "Old" to distinguish them from a somewhat similar series overlying the Coal-measures, to which the name New Red Sandstone was applied. When the term Devonian was adopted, it speedily supplanted that of Old Red Sandstone, inasmuch as it was founded on a type of marine strata of wide geographical extent, whereas the latter term described what appeared to be merely a British and local development. For the reasons already given, however, it is desirable to retain the title Old Red Sandstone as descriptive of a remarkable suite of formations to which there is nothing analogous in typical Devonian rocks. It is in Great Britain that the Old Red Sandstone of Europe is almost entirely developed. This interesting series of deposits must from the first have been deposited in separate areas or basins, the sites of some of which can still be traced. Their diversities of sediment and discrepance of organic contents point to the want of any direct communication between them. It was maintained many years ago by Mr Godwin Austen, and has been more recently enforced by Professor Ramsay, that these basins were lakes or inland seas. The character of the strata, the absence of unequivocally marine fossils, the presence of land-plants and of numerous ganoid fishes which have their modern representatives in rivers and lakes, suggest and support this opinion, which has been generally adopted by geologists. The red arenaceous and marly beds which, with their fish remains and land-plants, occupy a depth of many thousand feet between the top of the Upper Silurian and the base of the Lower Carboniferous formations, are regarded as the deposits of a series of lakes or inland seas formed by the uprise of portions of the Silurian sea-floor. The length of time during which these lacustrine basins must have existed is shown, not only by the thickness of the deposits formed in them, but by the complete change which took place in the marine fauna between the close of the Silurian and the commencement of the Carboniferous period. The prolific fauna of the Wenlock and Ludlow rocks was extirpated over the British area by the physical changes which produced the lake-basins of the Old Red Sandstone. When a marine population—crinoids, corals, and shells—once more overspreads the area it is found to be completely different. So thorough a change must have demanded a long interval of time.

Murchison, who strongly advocated the opinion that the Old Red Sandstone and Devonian rocks represented different geographical conditions of the same period, and who had with satisfaction seen the adoption of the Devonian classification by Continental geologists, endeavoured to trace in the Old Red Sandstone of Britain a threefold division like that which had been accepted for the Devonian system. He accordingly arranged the formations as in the subjoined table.

Old Red Sandstone as classified by Murchison.		
	Upper.	Yellow and red sandstones and conglomerates (*Pterichthys major*, *Holoptychius nobilissimus*, &c.) = Dura Den beds.
	Middle.	Grey and blue calcareous and bitumenous flagstones, limestones, and red sandstones, and conglomerates (*Dipterus*, *Osteolepis*, *Asterolepis*, *Acanthodes*, *Pterichthys*, &c.) = Caithness flags.
	Lower.	Red and purple sandstones, grey flagstones, and coarse conglomerates (*Cephalaspis*. *Pteraspis*. *Pterygotus*) = Arbroath flags.

It is important to observe that in no district can these three subdivisions be found together, and that the so-called "middle" formation occurs only in one region—the north of Scotland. The classification, therefore, does not rest upon any actually ascertained stratigraphical sequence, but on an inference from the organic remains. The value of this inference will be estimated a little further on. All that can be affirmed from stratigraphical evidence in any Old Red Sandstone district in Britain is that a great physical and

[1] *Op. cit.*, 423.

palæontological break can generally be traced in the Old Red Sandstone, dividing it into two completely distinct series—a Lower, which graduates downward into the Upper Silurian, and an Upper, which passes upward into the base of the Carboniferous system.

As a whole, the Old Red Sandstone, where its strata are really red, is like other masses of red deposits, singularly barren of organic remains. The physical conditions under which the precipitation of iron oxide took place were evidently unfavourable for the development of animal life in the same waters. Professor Ramsay has connected the occurrence of such red formations with the existence of salt lakes, from the bitter waters of which not only iron-oxide but often rock-salt, magnesian limestone, and gypsum were thrown down. He points also to the presence of land-plants, footprints of amphibia, and other indications of terrestrial surfaces, while truly marine organisms are either found in a stunted condition or are absent altogether. Where the strata of the Old Red Sandstone, losing their red colour and ferruginous character, assume grey or yellow tints and pass into a calcareous or argillaceous condition, they not infrequently become fossiliferous. At the same time it is not unworthy of remark that some of the red conglomerates, which might be supposed little likely to contain organic remains, are occasionally found to be full of detached scales, plates, and bones of fishes.

Along the border of the Silurian region from Shropshire into South Wales the uppermost parts of the Silurian system graduate into a mass of red strata not less than 10,000 feet thick, which in turn pass up conformably into the base of the Carboniferous system. This vast accumulation of red rocks, termed the Old Red Sandstone, consists in its lower portions of red and green shales and flagstones, with some white sandstones and thin cornstones; in the central and chief division, of red and green spotted sandy marls and clays, with red sandstones and cornstones; in the higher parts of grey, red, chocolate-coloured, and yellow sandstones, with bands of conglomerate. No unconformability has yet been detected in any part of this series of rocks, though, from the observations of De la Beche, it may be suspected that the higher strata which graduate upward into the Carboniferous formations are separated from the underlying portions of the Old Red Sandstone by a distinct discordance.

Although, as a whole, barren of organic remains, these red rocks have here and there, more particularly in the calcareous zones, yielded fragments of fishes and crustaceans. In their lower and central portions remains of the ganoids *Cephalaspis*, *Didymaspis*, *Scaphaspis*, *Pteraspis*, and *Cyathaspis* have been found, together with crustaceans of the genera *Stylonurus*, *Pterygotus*, and *Prearcturus*, and obscure traces of plants. The upper yellow and red sandstones contain none of the cephalaspid fishes, which are there replaced by *Pterichthys* and *Holoptychius*, associated with distinct impressions of land-plants. In some of the higher parts of the Old Red Sandstone of South Wales and Shropshire, *Serpula* and *Conularia* occur; but these are exceptional cases, and point to the advent of the Carboniferous marine fauna, which doubtless existed outside the British area before it spread over the Old Red Sandstone basins.

It is in Scotland that the Old Red Sandstone shows the most complete and varied development, alike in physical structure and in organic contents. Throughout that country the system is found everywhere to present a division into two well-marked groups of strata, separated from each other by a strong unconformability and a complete break in the succession of organic remains. It occurs in distinct areas which appear to mark the site of separate basins of deposit. One of these occupies the central valley between the base of the Highland mountains and the uplands of the southern counties. On the north-east it is cut off by the present coast-line from Stonehaven to the mouth of the Tay. On the south-west it ranges by the island of Arran across St George's Channel into Ireland, where it runs almost to the western sea-board, flanked on the north, as in Scotland, by hills of crystalline rocks and on the south chiefly by a Lower Silurian belt. Another distinct and still larger basin lies on the north side of the Highlands, but only a portion of it comes within the present area of Scotland. It skirts the slopes of the mountains along the Moray Firth and the east of Ross and Sutherland, and stretches through Caithness and the Orkney Islands as far as the south of the Shetland group. It may possibly have been at one time continued as far as the Sognefjord and Dalsfjord in Norway, where red conglomerates like those of the north of Scotland occur. There is even reason to infer that it may have ranged eastwards into Russia, for some of its most characteristic organisms are found also among the red sandstones of that country. A third minor area of deposit lay on the south side of the southern uplands over the east of Berwickshire and the north of Northumberland, including the area of the Cheviot Hills. A fourth occupied a basin on the flanks of the south-west Highlands, which is now partly marked by the terraced hills of Lorne. There is sufficient diversity of lithological and palæontological characters to show that these several areas were distinct basins, separated both from each other and from the sea.

In the central basin of Scotland between the Highlands and the southern uplands, the twofold division of the Old Red Sandstone is typically seen. The lower series of deposits attains a maximum depth of upwards of 20,000 feet. In Lanarkshire it is found to pass down conformably into the Upper Silurian rocks; elsewhere its base is concealed by later formations, or by the unconformability with which different horizons rest upon the older rocks. It is covered unconformably by every formation younger than itself. It consists of reddish-brown or chocolate-coloured, grey, and yellow sandstones, red shales, grey flagstones, coarse conglomerates, and occasional bands of limestone and cornstone. The grey flagstones and thin grey and olive shales and "calmstones" are almost confined to Forfarshire, in the north-east part of the basin, and are known as the Arbroath flags. One of the most marked lithological features in this central Scottish basin is the prodigious masses of interbedded volcanic rocks. These, consisting of porphyrite-lavas, felsites, and tuffs, attain a thickness of more than 6000 feet, and form important chains of hills, as in the Pentland, Ochil, and Sidlaw ranges. They lie several thousand feet above the base of the system, and are regularly interstratified here and there with bands of the ordinary sedimentary strata. They point to the outburst of numerous volcanic vents along the lake or inland sea in which the Lower Old Red Sandstone of central Scotland was laid down; and their disposition shows that these vents ranged themselves in lines or linear groups parallel with the general trend of the great central valley. The fact that the igneous rocks are succeeded by thousands of feet of sandstones, shales, and conglomerates, without any intercalation of lava or tuff, proves that the volcanic episode in the history of the lake came to a close long before the lake itself disappeared.

As a rule the deposits of this lake are singularly unfossiliferous, though some portions of them, particularly in the Forfarshire flagstone group, have proved rich in fish remains. In Lanarkshire about 5000 feet above the base of the system a thin band of shale occurs, containing a graptolite, *Spirorbis Lewisii*, and *Orthoceras dimidiatum*,—undoubtedly Upper Silurian forms. This interesting fact serves to indicate that, though geographical changes had elevated the Upper Silurian sea-floor partly into land and partly into isolated inland water-basins, the sea outside still contained an Upper Silurian fauna, which was ready on any favourable opportunity to re-enter the tracts from which it had been excluded. The interval of its reappearance seems to have been very brief, however, for the band of shale containing these Upper Silurian marine organisms is only a few inches thick, and the fossils have not been detected on any other horizon. With these exceptions, the fauna of the formation consists entirely of fishes and crustaceans. Nine or more species of crustaceans have been obtained, chiefly eurypterids, but including one or two phyllopods. The large pterygotus (*P. Anglicus*) is especially characteristic, and must have attained a great size, for some of the individuals indicate a length of 6 feet with a breadth of 1½ feet. There occur also a smaller species (*P. minor*), two *Eurypteri*, three species of *Stylonurus*, and abundant clusters of crustacean egg-packets termed *Parkia decipiens*. Seventeen species of fishes have been obtained, chiefly from the Arbroath flags. They belong to the suborders *Acanthodidæ* and *Ostracostei*. One of the most abundant forms is the little *Acanthodes Mitchelli*. Another common fish is *Diplacanthus gracilis*. There occur also *Climatius scutiger*, *C. reticulatus*, and *C. uncinatus*, *Parexus incurvus*, *Euthacanthus* (four species), *Cephalaspis Lyellii*, and *Pteraspis Mitchelli*. Some of the sandstones and shales are crowded with indistinctly preserved vegetation, occasionally in sufficient quantity to form thin laminæ of coal. In Forfarshire the surfaces of the shaly flagstones are now and then covered with linear grass-like plants like the sedgy vegetation of a lake or marsh. In Perthshire certain layers occur chiefly made up of compressed stems of *Psilophyton*. The adjoining land was doubtless clothed with a flora in large measure lycopodiaceous.

The Old Red Sandstone of the northern basin is typically developed in Caithness, where it consists chiefly of the well-known dark-grey bituminous and calcareous flagstones of commerce. It rests unconformably upon the metamorphosed Lower Silurian schists, and must have been deposited on the very uneven bottom of a sinking basin, seeing that occasionally even some of the higher platforms are found resting against the schists and granites. The lower zones consist of red sandstones and conglomerates which graduate upward into the flagstones. Other red sandstones, however, supervene in the higher parts of the system. The total depth of the series in Caithness has been estimated at upwards of 16,000 feet.

Murchison was the first to attempt the correlation of the Caithness flagstones with the Old Red Sandstone of the rest of Britain. Founding upon the absence from these northern rocks of the characteristic cephalaspidean fishes of the admitted Lower Old Red Sandstone of the south of Scotland and of Wales and Shropshire, upon the presence of numerous genera of fishes not known to occur in the true Lower Old Red Sandstone, and upon the discovery of a *Pterygotus* in the basement red sandy group of strata, he concluded that the massive flagstone series of Caithness could not be classed with the Lower Old Red Sandstone, but must be of younger date. He supposed the red sandstones, conglomerates, and shales at the base, with their *Pterygotus*, to represent the true Lower Old Red Sandstone, while the great flagstone series with its distinctive fishes was made into a middle division answering in some of its ichthyolitic contents to the Middle Devonian rocks of the Continent. This view has been accepted everywhere by geologists. Recently, however, it has been called in question by Professor Geikie, who gives reasons for maintaining the Caithness flagstones to be Lower Old Red Sandstone, and for denying the existence of any middle division. He shows that the discrepance in organic contents between the Caithness and the Arbroath flags is by no means so strong as Murchison supposed, but that several species are common to both. In particular, he finds that the characteristically Lower Old Red Sandstone and Upper Silurian crustacean genus *Pterygotus* occurs, not merely in the basement zone of the Caithness flags, but also high up in the series. The genera *Acanthodes* and *Diplacanthus* are abundant both in Caithness and in Forfarshire. *Parexus incurvus* occurs in the northern as well as the southern basin. It is contended that the palæontological distinctions are not greater than the striking lithological differences between the strata of the two regions would account for, or than the contrast between the ichthyic faunas of contiguous water-basins at the present time.

Somewhere about 60 species of fishes have been obtained from the Old Red Sandstone of the north of Scotland. Among these the genera *Acanthodes*, *Asterolepis*, *Cheiracanthus*, *Cheirolepis*, *Coccosteus*, *Diplacanthus*, *Diplopterus*, *Dipterus*, *Glyptolepis*, *Osteolepis*, and *Pterichthys* are specially characteristic. Some of the shales are crowded with the little ostracod crustacean *Estheria membranacea*. Land-plants abound, especially in the higher groups of the flagstones, where forms of *Psilophyton*, *Lepidodendron*, *Stigmaria*, *Sigillaria*, *Calamite*, and *Cyclopteris*, as well as other genera, occur. In the Shetland Islands traces of abundant contemporaneous volcanic rocks have been observed, which, with the exception of two trifling examples in the region of the Moray Firth, are the only known instances of volcanic action in the Lower Old Red Sandstone of the north of Scotland. In the other two Scottish basins, those of the Cheviot Hills and of Lorne, volcanic action continued long vigorous, and produced thick piles of lava like those of the central basin above referred to.

The Upper Old Red Sandstone consists in Scotland of red sandstones, clays or marls, conglomerates, and breccias, the sandstones sometimes becoming yellow or even white. These strata, wherever their stratigraphical relations can be distinctly traced, lie unconformably upon the lower division of the system, and pass up conformably into the Carboniferous rocks above. If they are studied from the side of the underlying formation, they seem naturally to form part of the Old Red Sandstone, since they agree with it in general lithological character and also in containing some distinctively Old Red Sandstone genera of fishes, such as *Pterichthys* and *Holoptychius*. But, approached from the upper or Carboniferous direction, they appear rather to form the natural sandy base of that system into which they insensibly graduate. On the whole, they are remarkably barren of organic remains, though in one locality—Dura Den in Fife—they have yielded a number of genera and species of fishes, crowded profusely through the pale sandstone as if the individuals had been suddenly killed and rapidly covered over with sediment. Among the characteristic organisms of the Scottish Upper Old Red Sandstone are *Pterichthys major*, *Holoptychius nobilissimus*, *H. Andersoni*, *Glyptopomus*, *Glyptolæmus*, and *Phaneropleuron*.

An interesting fact deserves mention here as a corollary to what has been stated above regarding the survival for some time of an Upper Silurian fauna outside the area of the British Old Red Sandstone lakes. In the Upper Old Red Sandstone of the basin of the Firth of Clyde, *Pterichthys major* and *Holoptychius* occur at the Heads of Ayr, while a band of marine limestone lying in the heart of the red sandstone series in Arran is crowded with ordinary Carboniferous Limestone shells, such as *Productus giganteus*, *P. semireticulatus*, *P. punctatus*, *Chonetes Hardrensis*, *Spirifer lineatus*, &c. None of these fossils has been detected in the great series of red sandstones overlying the limestone. They do not reappear till the limestones at the base of the Carboniferous series; yet the organisms must have been living during all that long interval outside of the Upper Old Red Sandstone area. Not only so, but they must have been in existence long before the formation of the thick Arran limestone, though it was only during the comparatively brief interval represented by that limestone that geographical changes permitted them to enter the Old Red Sandstone basin and settle for a while on its floor. Thus we see that while, on the one hand, the older parts of the Lower Old Red Sandstone were coeval with an Upper Silurian fauna which, having disappeared from the area of Britain, survived outside of that area, on the other hand, the higher parts of the Upper Old Red Sandstone were contemporaneous with a Carboniferous Limestone fauna which, having appeared beyond the British area, was ready to spread over it as soon as the conditions became favourable for the invasion. It is, of course, obvious that such an abundant and varied fauna as that of the Carboniferous Limestone cannot have come suddenly into existence at the period marked by the base of that formation. It must have had a long previous existence outside the present area of the deposits. But it is seldom that we obtain such clear evidence of the fact as in these instances from the Scottish Old Red Sandstone.

In the north of Scotland, on the lowlands bordering the Moray Firth, and again in the island of Hoy, one of the Orkney group, yellow and red sandstones, sometimes containing characteristic Upper Old Red Sandstone fishes, are found lying unconformably upon the Caithness flags. In these northern tracts the same relation is thus traceable as in the central counties between the two divisions of the system.

Turning southward across the border districts, we trace the red sandstones and conglomerates of the Upper Old Red Sandstone lying unconformably on Silurian rocks and Lower Old Red Sandstone. Some of the brecciated conglomerates have much resemblance to glacial detritus, and it has been suggested that they have been connected with contemporaneous ice-action. Such are the breccias of the Lammermuir Hills, and those which show themselves here and there from under the overlying mass of Carboniferous strata which flanks the Silurian hills of Cumberland and Westmoreland. Red conglomerates and sandstones appear interruptedly at the base of the Carboniferous rocks even as far as Flintshire and Anglesea. They are commonly classed as Old Red Sandstone, but merely from their position and lithological character. No organic remains have been found in them. They may therefore, in part at least, be taken as the basement beds of the Carboniferous system.

In Devonshire, at Barnstaple, Pilton, Marwood, and Baggy Point, certain sandstones, shales, and limestones (already referred to in the account of the Devonian rocks) graduate upward into the base of the Carboniferous system, and appear to represent the Upper Old Red Sandstone of the rest of Britain. They contain land plants and also many marine fossils, some of which are common Carboniferous forms. They thus indicate a transition into the geographical conditions of the Carboniferous period, as is still more clearly illustrated by the corresponding strata in Scotland.

North America.—The Devonian system, as developed in the northern States, and eastern Canada and Nova Scotia, presents much geological interest in the union which it contains of the same two distinct petrographical and biological types found in Europe. If we trace the range of these rocks along the Alleghany chain through Pennsylvania into New York, we find them to contain a characteristic suite of marine organisms comparable with those of the Devonian system of Europe. But on the eastern side of the great range of Silurian hills in the north-eastern States, we encounter in New Brunswick and Nova Scotia a succession of red and yellow sandstones, limestones, and shales nearly devoid of marine organisms, yet full of land-plants, and with occasional traces of fish remains.

The marine or Devonian type has been grouped in the following subdivisions by the geologists of New York:—

Upper Devonian.	Catskill Red Sandstone. Chemung group. Portage group. Genesee group. Hamilton group. Marcellus group.
Lower Devonian.	Corniferous or Upper Helderberg group. Schoharie Grit. Cauda-galli Grit.

In the Lower Devonian series traces of terrestrial plants (*Psilophyton, Caulopteris*, &c.) have been detected even as far west as Ohio. Corals (cyathophylloid forms, with *Favosites, Syringopora*, &c.) abound, especially in the Corniferous Limestone, which is perhaps the most remarkable mass of coral-rock in the American Palæozoic series. Among the brachiopods are species of *Pentamerus, Stricklandinia, Rhynchonella*, and others, with the characteristic European form *Spirifer cultrijugatus*, and the world-wide *Atrypa reticularis*. The trilobites include the genera *Dalmanites, Proëtus*, and *Phacops*. The earliest known traces of American fishes occur in the Corniferous group. They consist of ichthyodorulites, and teeth of cestraciont and hybodont placoids, and plates, bones, and teeth of some peculiar ganoids (*Macropetalichthys, Onychodus*).

In the Hamilton formation (embracing the Marcellus shale, the Hamilton beds, and the Genesee shale) remains of land-plants occur, but much less abundantly than among the rocks of New Brunswick. Brachiopods are especially abundant among the sandy beds in the centre of the formation. They comprise, as in Europe, many broad-winged spirifers (*S. mucronatus*, &c.), with species of *Productus, Chonetes, Athyris*, &c. The earliest American goniatites have been noticed in these beds. Newberry has described a gigantic fish (*Dinichthys*) from the Black Shale of Ohio.

The Portage and Chemung groups have yielded land-plants and fucoids, also some crinoids, numerous broad-winged spirifers, with *Aviculæ*, and a few other lamellibranchs. These strata consist in the New York region of shales and laminated sandstones, which attain a maximum thickness there of upwards of 2000 feet, but die out entirely towards the interior. They are covered by a mass of red sandstones and conglomerates—the Catskill group, which is 2000 or 3000 feet deep in the Catskill Mountains, and thickens along the Appalachian region to 5000 or 6000 feet. Those red arenaceous rocks bear a striking similarity in their lithological and biological characters to the Upper Old Red Sandstone of Europe. As a whole they are unfossiliferous, but they have yielded some ferns like those of the Upper Old Red Sandstone of Ireland and Scotland (*Cyclopteris*), and some characteristic genera of fish, as *Holoptychius* and *Bothriolepis*.

Turning now to the eastern side of the ancient Laurentian and Silurian ridge, which, stretching southwards from Canada, separated in later Palæozoic time the great interior basin from the Atlantic slopes, we find the Devonian rocks of New York, Pennsylvania, and the interior represented in New Brunswick and Nova Scotia by a totally different series of deposits. The contrast strikingly recalls that presented by the Old Red Sandstone of the north of Scotland and the Devonian rocks of North Germany. On the south side of the St Lawrence the coast of Gaspé shows rocks of the Quebec group unconformably overlaid by grey limestones with green and red shales, attaining, according to Logan, a total thickness of about 2000 feet,[1] and replete in some bands with Upper Silurian fossils. They are conformably followed by a vast arenaceous series of deposits termed the Gaspé Sandstones, to which the careful measurements of Logan and his colleagues of the Canadian Geological Survey assign a depth of 7036 feet. This formation consists of grey and drab-coloured sandstones, with occasional grey shales and bands of massive conglomerate. Similar rocks reappear along the southern coast of New Brunswick, where they attain a depth of 9500 feet, and again on the opposite side of the Bay of Fundy. The researches chiefly of Dr J. W. Dawson have shown that these strata contain an abundant terrestrial flora —the oldest of which any relics have yet been recovered, for the few Upper Silurian land-plants at present known hardly deserve to be reckoned as a known flora. In his recent census he enumerates no fewer than 118 species of land-plants. They are almost all acrogens, the lycopods and ferns being largely predominant. Among the distinctive forms the following may be mentioned—*Psilophyton, Arthrostigma, Leptophleum*, and *Prototaxites*. Forty-nine ferns are given, including the genera *Cyclopteris, Neuropteris, Sphenopteris*, and some treeferns (*Psaronius, Caulopteris*). Lepidodendroid and sigillaroid plants abound, as well as calamites. Higher forms of vegetation are represented by a few conifers (*Dadoxylon, Ormoxylon, Prototaxites*, &c.). From a locality on Lake Erie, Dr Dawson describes a fragment of dicotyledonous wood, not unlike that of some modern trees—the most ancient

[1] *Geology of Canada*, p. 393.

fragment of an angiospermous exogen yet discovered. So abundant are these vegetable remains that in some layers they actually form thin seams of coal.

The interest of these remains of the most venerable American forests is heightened by the discovery of the fact that they were not without the hum of insect life. The most ancient known relics of insect forms have been recovered from the Devonian strata of New Brunswick. They are all neuropterous wings, and have been referred by Mr Scudder of Boston to four species combining a remarkable union of characters now found in distinct orders of insects. In one fragment he observed a structure which he could only compare to the stridulating organ of some male *Orthoptera*. Another wing indicates the existence of a gigantic *Ephemera*, with a spread of wing extending to 5 inches. In the shallow pools of the period some small crustaceans lived, the remains of which have been partially preserved. Among these is a minute, shrimp-like *Eurypterus*, and a more highly organized form named *Amphipeltis*. That the sea had at least occasional access to the inland basins into which this abundant terrestrial vegetation was washed is proved by the occurrence of marine organisms, such as a small annelid (*Spirorbis*) adhering to the leaves of the plants, and (in Gaspé and Nova Scotia) by the occasional appearance of brachiopods, especially *Lingula*, *Spirifer*, and *Chonetes*.[1]

CARBONIFEROUS.

This great system of rocks has received its name from the seams of coal which form one of its distinguishing features both in Europe and in North America. In Europe it is most completely developed in the British Islands. Elsewhere on that continent it occurs in patches, either lying in hollows of older rocks, or exposed by the removal of overlying formations.

GREAT BRITAIN.—The area within which the Carboniferous rocks of Britain occur is sufficiently extensive to contain more than one type of the system, and thus to cast much light on the varied geographical conditions under which these rocks were accumulated. In prosecuting the study of this part of British geology, it is soon discovered, and it is essential to bear in mind, that, during the Carboniferous period, the land whence the chief supplies of sediment were derived rose mainly to the north and north-west, as it seems to have done from very early geological time. While therefore the centre and south of England lay under clear water of moderate depth, the north of the country and the south of Scotland were covered by shallow water, which was continually receiving sand and mud from the adjacent northern land. Hence vertical sections of the Carboniferous formations of Britain differ greatly according to the districts in which they are taken. The subjoined table may be regarded as expressing the typical subdivisions which can be recognized, with modifications, in all parts of the country.

Coal-measures	Red and grey sandstones, clays, and sometimes breccias, with occasional seams and streaks of coal and spirorbis limestone (*Cythere inflata*, *Spirorbis carbonarius*). Middle or chief coal-bearing series of yellow sandstones, clays, and shales, with numerous workable coals (*Anthracosia*, *Anthracomya*, *Beyrichia*, *Estheria*, *Spirorbis*, &c.). Gannister beds, flagstones, scales, and thin coals, with hard siliceous (gannister) pavements (*Orthoceras*, *Goniatites*, *Posidonia*, *Aviculopecten*, *Lingula*, &c.).
Millstone Grit	Grits, flagstones, and shales, with thin seams of coal.
Carboniferous Limestone series......	Yoredale group of shales and grits passing down into dark shales and limestones (*Goniatites*, *Aviculopecten*, *Posidonomya*, *Lingula*, *Discina*, &c.). Thick limestone in south and centre of England and Ireland, passing northwards into sandstones, shales, and coals (abundant corals, polyzoans, brachiopods, lamellibranchs, &c.). Lower Limestone Shale of south and centre of England (marine fossils like those of overlying limestone), passing northward into the Calciferous Sandstone group of Scotland (marine, estuarine, and terrestrial organisms).

In the article COAL (vol. vi. p. 49) an account has been given of the principal coal-fields of the world; likewise a diagram (p. 48) representing the chief subdivisions of the Carboniferous system in Britain, as the rocks are traced from north to south.

Base of the System.—In the south-west of England, and in South Wales, the Carboniferous system passes down conformably into the Old Red Sandstone. The passage beds consist of yellow, green, and reddish sandstones, of green, grey, red, blue, and variegated marls and shales, sometimes full of terrestrial plants. They are well exposed on the Pembrokeshire coasts, marine fossils being there found even among the argillaceous beds at the top of the Red Sandstone series. They occur with a thickness of about 500 feet in the gorge of the Avon near Bristol, but show less than half that depth about the Forest of Dean. At their base there lies a bone-bed containing abundant palatal teeth. Not far above this horizon plant-bearing strata are found. Hence these rocks bring before us a mingling of terrestrial and marine conditions. In Yorkshire, near Lowther Castle, Brough, and in Ravenstonedale, alternations of red sandstones, shales, and clays, containing *Stigmaria* and other plants, occur in the lower part of the Carboniferous Limestone. Along the eastern edge of the Silurian hills of the Lake district the Old Red Sandstone appears here and there, and passes up through a succession of red and grey sandstones, and green and red shales and marls, with plants, into the base of the Carboniferous Limestone.

It is in Scotland, however, that this peculiar type of the basement Carboniferous rocks is best seen. In that country the lowest subdivision of the Carboniferous system, known as the Calciferous Sandstones, consists of red, white, and yellow sandstones, blue, grey, green, and red marls or clays, blue and black shales, thin coals, seams of limestone and cement-stone, and abundant volcanic rocks. The red sandstones lie at the base, and pass down into the Upper Old Red Sandstone, in which, as has been already pointed out (*ante*, p. 344), true Upper Old Red Sandstone fishes are found, while there occur also bands of limestone full of true Carboniferous Limestone corals and brachiopods. Hence it is evident that the Carboniferous Limestone fauna had already appeared outside the British area before the close of the Old Red Sandstone period. It was when the peculiar geographical conditions which prevailed during that period finally ceased, and the sea began to spread over the ancient lakes and land of Britain, that the abundant Carboniferous fauna invaded the area. The Calciferous Sandstones of Scotland may therefore represent a portion of the Carboniferous Limestone of England.

Over the greater part of the south and centre of Scotland the lower red sandstones are surmounted by a series of contemporaneous volcanic rocks. Successive sheets of porphyrites and tuffs form long ranges of hills from Arran and Bute on the west to the mouth of the estuary of the Forth on the east, and from the Campsie Fells on the north to the heights of Liddesdale and the English border. These volcanic sheets sometimes reach a thickness of 1500 feet. That they belong to the Carboniferous system is shown by the occurrence of shales and sandstones (with Carboniferous plants) at their base. They show that the early part of the Carboniferous period in Scotland was marked by a prodigious volcanic activity, which, on its cessation, was followed by the prolonged subsidence required for the accumulation of the Carboniferous system. The rocks succeeding the volcanic zone are termed the cement-stone group. In Berwickshire and the west of Scotland they consist of thin bedded white, yellow, and green sandstones, grey, green, blue, and red clays and shales, with thin bands of a pale argillaceous limestone or cement-stone. Seams of gypsum occasionally appear. These strata are, on the whole,

[1] Dawson's *Acadian Geology*, chaps. xxi. and xxii.

singularly barren of organic remains. They seem to have been laid down with great slowness, and without disturbance, in enclosed basins, which were not well fitted for the support of animal life, though fragmentary plants serve to show that the adjoining slopes were covered with vegetation.

In the basin of the Firth of Forth, however, the group presents a different lithological aspect and is abundantly fossiliferous. It there usually consists of yellow, grey, and white sandstones, with blue and black shales, clay-ironstones, limestones, "cement-stones," and occasional seams of coal. The sandstones form excellent building stones, the city of Edinburgh having been built of them. Some of the shales are so bituminous as to yield, on distillation, from 30 to 40 gallons of crude petroleum to the ton of shale; they are consequently largely worked for the manufacture of mineral oils. The limestones are usually dull, yellow, and close grained, in seams seldom more than a few inches thick, and graduate by addition of carbonate of iron into cement-stone; but occasionally they swell out into thick lenticular masses like the well-known limestone of Burdie House, so long noted for its remarkable fossil fishes. This limestone appears to be mainly made up of the crowded cases of a small ostracod crustacean (*Leperditia Okeni*, var. *Scoto-Burdigalensis*). The coal-seams are few and commonly too thin to be workable, though one of them, known as the Houston coal, has been mined to some extent in Linlithgowshire. The fossils of the cement-stone group indicate an alternation of fresh or brackish-water and marine conditions. They include numerous plants, of which the most abundant are *Sphenopteris affinis*, *Lepidodendron* (two or three species), *Lepidostrobus variabilis*, *Araucarioxylon*. Some of the shales near Edinburgh have afforded a few specimens of a true monocotyledon allied to the modern Pothos (*Pothocites Grantoni*). Ostracod crustaceans, chiefly the *Leperditia* above mentioned, crowd many of the shales. With these are usually associated abundant traces of the presence of fish, either in the form of coprolites or of scales, bones, plates, and teeth. The following are characteristic species: *Elonichthys striolatus*, *E. Robisoni*, *Rhadinichthys ornatissimus*, *Nematoptychius Greenockii*, *Eurynotus crenatus*, *Rhizodus Hibberti*, *Megalichthys* sp., *Gyracanthus tuberculatus*, *Ctenoptychius pectinatus*. At intervals throughout the group marine horizons occur, usually as shale bands marked by the presence of such distinctively Carboniferous Limestone species as *Spirorbis carbonarius*, *Discina nitida*, *Lingula squamiformis*, *Bellerophon decussatus*, and *Orthoceras cylindraceum*.

One of the most interesting features in the cement-stone group of the basin of the Firth of Forth is the prodigious number and variety of the associated volcanic masses, and the proofs which they exhibit that, at the time when that group of strata was accumulating, the region of shallow lagoons, islets, and coal-growths was dotted over with innumerable active volcanic vents. The eruptions continued into the time of the Carboniferous Limestone, but ceased before the deposition of the Millstone Grit. The lavas are chiefly varieties of basalt-rocks, sometimes coarsely crystalline and even granitoid in texture, and graduating through intermediate stages to true close-grained compact basalts, which neither externally nor in microscopic structure differ from basalt of Tertiary date

The basement group of the Carboniferous system in Ireland is evidently a prolongation of the Scottish cement-stone group. In the south of this island, however, a very distinct and peculiar development of the Lower Carboniferous rocks is to be remarked. Between the top of the Old Red Sandstone and the base of the Carboniferous Limestone there occurs in the county of Cork an enormous mass (fully 5000 feet) of black and dark-grey shales, impure limestones, and grey and green grits and true cleaved slates. To these rocks the name of Carboniferous Slate was given by Griffith. They contain numerous Carboniferous Limestone species of brachiopods, echinoderms, &c., as well as traces of land-plants in the grit bands. Great though their thickness is in Cork, they rapidly change their lithological character, and diminish in mass as they are traced away from that district. In the almost incredibly short space of 15 miles, the whole of the 5000 feet of Carboniferous Slate of Bantry Bay have disappeared, and at Kenmare the Old Red Sandstone is followed immediately and conformably by the Limestone with its underlying shale. Mr Jukes held that the Carboniferous Slate is the equivalent of part of the Devonian rocks of Devon and Cornwall.

Carboniferous Limestone.—The Lower Limestone shale is overlaid conformably by a thick mass of limestone, one of the most distinctive members of the British Carboniferous system. On referring to a geological map of England it will be seen that from Northumberland southwards to the low plains in the centre of England there runs a ridge of high ground, formed by a great anticline, along which the Carboniferous Limestone appears at intervals from underneath higher members of the system. In this northern Carboniferous area, of which the axis is known as the Pennine Chain, the limestone attains its maximum development. In one portion of the district it reaches a depth of 4000 feet, and yet its actual base is nowhere seen. This Pennine region appears to have been the area of maximum depression during the early part of the Carboniferous period in Britain. Traced towards the south west, the limestone diminishes to sometimes not more than 500 feet in South Wales. Northwards, losing its character as a massive calcareous formation, it is split up by intercalations of sandstone, shale, coal, &c., until actual limestone becomes a very subordinate member of the series in central Scotland.

In the Carboniferous areas of the south-west of England and South Wales, the limits of the Carboniferous Limestone are well defined by the Limestone Shale below, and by the Farewell Rock or Millstone Grit above. In the Pennine area, however, the massive limestone is succeeded by a series of shales, limestones, and sandstones, known as the Yoredale group. These cover a large area and attain a great thickness. In North Staffordshire they are 2300 feet, which, added to the 4000 feet of limestone below, gives a depth of 6300 feet for the whole Carboniferous Limestone series of that region. In Lancashire the Yoredale rocks attain still more stupendous dimensions, Mr Hull having found them to be no less than 4500 feet thick. Both the lower or main (Scaur) limestone and the Yoredale group pass northwards into sandstones and shales, with coal-seams, and diminish in thickness. It is not impossible, as already suggested, that the cement-stone group of the Calciferous Sandstones of Scotland may represent, not only the thin Lower Limestone shale, but also some of the older parts of the English Carboniferous Limestone.

Where typically developed, the Carboniferous Limestone is a massive well-bedded limestone, chiefly light bluish-grey in colour, varying from a compact homogeneous to a distinctly crystalline texture, and rising into ranges of hills, whence its original name "Mountain Limestone." It contains occasional scattered irregular nodules and nodular beds of dark chert. It is abundantly fossiliferous. The fossils commonly stand out on weathered surfaces of the rock, but microscopic investigation shows that even those portions of the mass which appear most structureless consist of the crowded remains of marine organisms. The limestone may be regarded as derived entirely from the organic debris of a sea-floor. Diversities of colour and lithological character occur, whereby the bedding of the thick calcareous mass can be distinctly seen. Here and there a more marked crystalline structure has been superinduced; but the most distinct examples of metamorphic change are those where the rock has been converted into what is termed "dun-stone." This alteration is frequent in the mining districts of Yorkshire and the neighbouring counties. It consists in the dolomitization of the rock along either the lines of bedding or the joints. Thus changed, it becomes a yellowish or brown crystalline dolomite, which runs vertically through the mass of the limestone along some definite joint, in courses of 20 or 30 fathoms in width. Such a metamorphism must have been effected by water percolating along the line of the joint, and affecting the rock for some distance on either side. In

Derbyshire sheets of contemporaneous lava, locally termed "toadstone," are interpolated in the Carboniferous Limestone.

The fauna of the Carboniferous Limestone of England is abundant and characteristic. Numerous foraminifers occur, *Saccamina Carteri* being often very characteristic. The corals are numerous, embracing upwards of 30 genera and about 100 species. These include both simple cup corals, as *Zaphrentis*, *Clisiophyllum*, and compound forms, like *Alveolites* and *Phillipsastræa*. Crinoids are individually in enormous numbers, many beds of limestone appearing to consist of little else than their fragmentary stems and cups; *Actinocrinus*, *Platycrinus*, *Poteriocrinus*, *Cyathocrinus*, are common genera. Three species of sea-urchins are known. Of the trilobites, so characteristic of the older Palæozoic rocks, the last lingering forms are here found in three small genera —*Brachymetopus*, *Phillipsia*, and *Griffithides*. Polyzoa abound, some portions of the limestone being almost entirely composed of them, the genera *Fenestella*, *Sulcoretepora*, *Vincularia*, *Polypora*, *Diastopora*, and *Glauconome* being frequent. The brachiopods comprise 18 genera and 160 species, some of the most common forms being *Productus*, *Spirifer*, *Rhynchonella*, *Athyris*, *Chonetes*, *Orthis*, *Lingula*, and *Discina*. But the higher mollusks now begin to preponderate over the brachiopods. The lamellibranchs number 49 genera and 334 species, including forms of *Aviculopecten*, *Leda*, *Nucula*, *Sanguinolites*, *Leptodomus*, *Schizodus*, *Edmondia*, *Modiola*, and *Conocardium*. The gasteropods amount to 206 species belonging to 29 genera, among which *Euomphalus*, *Natica*, *Pleurotomaria*, *Macrocheilus*, and *Loxonema* are frequent. The genus *Bellerophon* is represented by 23 species, among which *B. Urei* and *B. decussatus* are frequent. The cephalopods number 148 species, belonging among other genera to *Orthoceras*, *Nautilus*, *Discites*, and *Goniatites*. About 100 genera of fishes, chiefly from teeth and spines, have been described, as *Psammodus*, *Cochliodus*, *Cladodus*, *Petalodus*, *Rhizodus*, *Ctenoptychius*, &c. Some of these were no doubt placoids which lived solely in the sea, but many, if not all of the ganoids, probably migrated between salt and fresh water; at least their remains are found in Scotland in strata full of land-plants, cyprids, and other indications of estuarine or fluviatile conditions.

The Carboniferous Limestone series of Scotland presents a striking contrast to that of the typical formation in England. It consists mainly of sandstones, shales, fire-clays, and coal-seams, with a few comparatively thin seams of encrinal limestone. Its lower portions include the chief limestone bands. The thickest of these seams, known as the Hurlet or main limestone, is usually about 6 feet in thickness, but in the north of Ayrshire swells out to 100 feet, which is the most massive bed of limestone in any part of the Scottish Carboniferous system. It lies upon a seam of coal, and is in some places associated with pyritous shales, which have been largely worked as a source of alum. This superposition of a bed of marine limestone on a seam of coal is of frequent occurrence in the Carboniferous Limestone series of Scotland. Above the group of Lower Limestones comes a thick mass of strata containing many valuable coal-seams and ironstones. Some of these strata are full of terrestrial plants (*Lepidodendron*, *Sigillaria*, *Stigmaria*, *Sphenopteris*, *Alethopteris*); others, particularly the ironstones, contain marine shells, such as *Lingula*, *Discina*, *Leda*, *Myalina*, *Euomphalus*. Numerous remains of fishes have been obtained, more especially from some of the ironstones and coals (*Gyracanthus formosus* and other placoid fin-spines, *Megalichthys Hibberti*, *Rhizodus Hibberti*, with species of *Elonichthys*, *Acanthodes*, *Ctenoptychius*, &c.). Remains of labyrinthodonts have also been found in this group of strata, and have been detected even down in the Burdie House limestone. The highest division of the Carboniferous Limestone series consists of a group of sandstones and shales, with a few coal-seams, and three, sometimes more, bands of marine limestone. Although these limestones are each seldom more than 3 or 4 feet thick, they have a wonderful persistence throughout the coal-fields of central Scotland. As already mentioned, they can be traced over an area of at least 1000 square miles, and they probably extended originally over a considerably greater region. The Hurlet limestone with its underlying coal can also be followed across a similar extent of country. Hence it is evident that during certain epochs of the Carboniferous period a singular uniformity of conditions prevailed over a large region of deposit in the centre of Scotland.

The difference between the lithological characters of the Carboniferous Limestone series, in its typical development, as a great marine formation, and in its arenaceous and argillaceous prolongation into the north of England and Scotland, has long been a familiar example of the nature and application of the evidence furnished by strata as to former geographical conditions. It shows that the deeper and clearer water of the Carboniferous sea spread over the site of Yorkshire, Derbyshire, and Lancashire; that the land lay to the north; and that, while the whole area was undergoing subsidence, the maximum movement took place over the area of deeper water. It was from the northern land that the sand and mud were derived, but the sediment during the time of the Carboniferous Limestone seems to have sunk to the bottom before it could reach the great basin in which foraminifers, corals, crinoids, and mollusks were building up the great calcareous deposit. Yet the thin limestone bands, which run so persistently among the Lower Carboniferous rocks in Scotland, prove that there were occasional episodes during which the sediment ceased to arrive, and when the same species of shells, corals, and crinoids spread northwards towards the land, forming for a time over the sea-bottom a continuous sheet of calcareous ooze like that of the deeper water further south. These intervals of limestone growth no doubt point to times of more rapid submergence, perhaps also to other geographical changes whereby the sediment was for a time prevented from spreading so far.

Viewed as a whole, therefore, the Carboniferous Limestone series of Northumberland and Scotland contains the records of a long-continued but intermittent process of subsidence. The numerous coal-seams with their underclays were undoubtedly surfaces of vegetation that grew in rank luxuriance on the wide marine mud-flats, and mark pauses in the subsidence. Perhaps we may infer the relative length of these pauses by the comparative thicknesses of the coal-seams. The overlying and intervening sandstones and shales indicate a renewal of the downward movement, and the gradual infilling of the depressed area with sediment, until the water once more shoaled, and the vegetation from adjacent swamps spread over the muddy flats as before. The occasional limestones serve to indicate the epochs of more prolonged or more rapid subsidence, when marine life was enabled to flourish over the site of the submerged forests. But that the sea, even though tenanted in these northern parts by a limestone-making fauna, was not so clear and well suited for the development of animal life during some of these submergences as it was further south, seems to be proved by the paucity and dwarfed forms of the fossils in the thin limestones, as well as by the admixture of clay in the stone.

In Ireland the Carboniferous Limestone swells out to a vast thickness, and covers a large part of the island. It attains a maximum in the west and south-west, where, according to Kinahan,[1] it consists in Limerick of the following subdivisions:—

		Feet.
Upper (Burren) Limestone	Bedded limestone	240
	Cherty zone	20
Upper (Calp) Limestone	Limestones and shales	1000
	Cherty zone	40
Lower Limestone	*Fenestella* limestone	1900
	Lower cherty zone	20
	Lower shaly limestones	280
Lower Limestone Shale		100
		3600

[1] *Geology of Ireland*, p. 72.

The chert bands which form such marked horizons among these limestones are counterparts of others found abundantly in the Carboniferous Limestone of England and Scotland. They have been recently studied by Hull and Hardman, who have found them full of siliceous replacements of calcareous foraminifers, crinoids, &c., and who regard them as due to a chemical alteration on the floor of the Carboniferous sea. Portions of the limestone have a dolomitic character, and sometimes are oolitic. Great sheets of melaphyre, felstone, and tuff, representing volcanic eruptions of contemporaneous date, are interpolated in the Carboniferous Limestone of Limerick and other parts of Ireland. As the limestone is traced northwards it shows a similar change to that which takes place in the north of England, becoming more and more split up with sandstone, shale, and coal-seams, until, at Ballycastle, it presents exactly the characters of the coal-bearing part of the formation in Scotland.

Millstone Grit.—This name is given to a group of sandstones and grits, with shales and clays, which runs persistently through the centre of the Carboniferous system from South Wales into the middle of Scotland. In South Wales it has a depth of 400 to 1000 feet; in the Bristol coal-field, of about 1200 feet. Traced northwards it is found to be intercalated with shales, fire-clays, and thin coals, and, like the lower members of the Carboniferous system, to swell out to enormous dimensions in the Pennine region. In North Staffordshire, according to Mr Hull, it attains a thickness of 4000 feet, which in Lancashire increases to 5500 feet. These massive accumulations of sediment were deposited on the north side of a barrier of Silurian and Cambrian rocks, which, during all the earlier part of the Carboniferous period, seems to have extended across central England, and which was not submerged until part of the Coal-measures had been laid down. North of this great area of deposit the Millstone Grit thins away to not more than 400 or 500 feet. It continues a comparatively insignificant formation in Scotland, attaining its greatest thickness in Lanarkshire and Stirlingshire, where it is known as the Moor Rock. In Ayrshire it does not exist, unless its place be represented by a few beds of sandstone at the base of the Coal-measures.

The Millstone Grit is generally barren of fossils. When they occur they are either plants like those in the coal-bearing strata above and below, or marine organisms of Carboniferous Limestone species. In Northumberland, indeed, it contains a band of limestone undistinguishable from some of those in the Yoredale group and Scaur limestone.

Coal-Measures.—This division of the Carboniferous system consists of numerous alternations of grey, white, yellow, sometimes reddish sandstone, dark-grey and black shales, clay-ironstones, fire-clays, and coal-seams. In South Wales it attains a maximum depth of about 12,000 feet; in the Bristol coal-field it is 5090 feet. But in these districts, as in the rest of the Carboniferous areas of Britain, we cannot be sure that all the Coal-measures originally deposited now remain, for they are always unconformably covered by later formations. In some localities, indeed, the denudation must have been very great, for the next overlying system of deposits (Permian) is found resting even on the Carboniferous Limestone. In North Staffordshire the depth of the Coal-measures is about 5000 feet, which in South Lancashire increases to 8000. These great masses of strata diminish as we trace them eastwards and northwards. In Derbyshire they are about 2500 feet thick, in Northumberland and Durham about 2000 feet, and about the same thickness on the west side of the island in the Whitehaven coal-field. In Scotland they attain a maximum of about 2000 feet.

The Coal-measures are susceptible of local subdivisions indicative of different and variable conditions of deposit. The following tables show the more important of these:—

GLAMORGANSHIRE.

Upper series, more than 3400 feet	Sandstones, shales, &c., with 26 coal-seams.
Pennant Grit, 3246 feet	Hard thick-bedded sandstones &c., 15 coal-seams.
Lower series, 450 to 850 feet	Shales, ironstones, and 34 coal-seams.
	Millstone Grit.

SOUTH LANCASHIRE.

Upper, 1680 to 2000 feet	Shales, *Spirorbis* limestone, ironstone, sandstone, and thin coal-seams.
Middle, 3000 to 4000..	A great series of strata, with numerous valuable coals.
Lower or Gannister, 1400 to 2000 feet ...	Flags, shales, and three or four thin coals, with floors of "gannister."
	Millstone Grit.

CENTRAL SCOTLAND.

150 feet and upwards..	Red sandstones and clays, with occasional thin coals and *Spirorbis* limestone.
Upwards of 2000 feet in Lanarkshire	Sandstones, shales, and fire-clays, with ironstones and coals.
	Moor-rock or Millstone Grit.

The numerous beds of compressed vegetation form the most remarkable feature of the Coal-measures. Each of them is usually underlaid by a seam of fire-clay, representing the soil on which the plants grew. Hence they mark successive terrestrial surfaces, which, after enduring for a longer or shorter period, were carried down beneath the water and covered over with sand and silt. There is no modern formation that affords a close parallel to that of the ancient coal-growths. The nearest analogy is furnished by the mangrove swamps alluded to already on p. 290. These masses of arborescent vegetation grow out into the sea as a belt or fringe on low shores, and form a matted soil which adds to the breadth of the land. Their roots spread in the salt water where marine organisms are abundant. The coal-growths no doubt also flourished in salt or at least brackish water; for such shells as *Aviculopecten*, *Anthracosia*, and *Goniatites* are found lying on the coal or in the shales attached to it.

The vegetation of the Carboniferous period must have been luxuriant and varied. Upwards of 500 species of plants have been obtained from the Carboniferous rocks of Britain, yet these must represent but a small portion of the original flora.

The most abundant forms were ferns and lycopods. Numerous reed-like plants likewise played a conspicuous part in the general vegetation of the low grounds, while apparently on the drier and more elevated tracts (for their remains are less frequently met with) large coniferous trees flourished. The ferns strikingly resemble many modern forms. Among the more frequent genera were *Sphenopteris*, *Pecopteris*, *Alethopteris*, *Neuropteris*, and *Cyclopteris*. The lycopodiaceous plants attained the size of forest trees. Among the more typical forms were many species of *Lepidodendron*, the stems and seed-cones of which are scattered through the Carboniferous strata. Some of the coal-seams are largely composed of the spores of these plants. *Sigillaria*, regarded by some as allied to the cycads, by others as more akin to the lycopods, is represented by numerous species. The roots known as *Stigmaria* abound in most fire-clays, showing how largely the coal consists of trees having roots of this kind. The *Equisetaceæ* show themselves in the form of numerous *Calamites* which, though resembling in general aspect our modern horse-tails, differed in many points of structure, and notably in their gigantic size. Coniferous trees occur chiefly in the form of stems and branches. They include the genera *Dadoxylon*, *Araucarioxylon*, and *Pinites*. Small nut-like fruits (*Trigonocarpum*) abound in some beds, and are now believed to be the fruits of yew-like conifers. The presence of monocotyledonous plants is proved by the *Pothocites* referred to above (p. 347)

The animal remains of the Coal-measures are comparatively few. In certain bands, particularly of ironstone, numerous mollusca occur, and similar forms are to be occasionally met with in the shales.

Among the more frequent species are *Anthracomya modiolaris*, *Anthracosia ovalis*, *A. robusta*, *A. acuta*, *Anthracoptera Browniana*, *Aviculopecten papyraceus*, and *Goniatites Listeri*. But at the top of the Middle Coal-measures, near Manchester, a band of true marine shells occurs, including *Ctenodonta*, *Nautilus*, *Discites*, *Goniatites*, and *Orthoceras*. The little *Spirorbis carbonarius* abounds in some shales. The crustaceans are chiefly represented by *Beyrichia* and *Estheria*, but large eurypterid forms likewise occur. Fishes occur frequently, remains of the larger kinds usually appearing as scales, teeth, fin-spines, or bones, while the smaller ganoids are often preserved entire. Common species are *Megalichthys Hibberti* (?), *Rhizodus granulatus*, *Cœlacanthus lepturus*, *Palæoniscus Egertoni*, *Pleuracanthus gibbosus*. The British Carboniferous rocks have yielded 13 genera of labyrinthodonts (*Anthracosaurus*, *Loxomma*, *Ophiderpeton*, *Pholiderpeton*, *Pteroplax*, *Urocordylus*, &c.). These were probably fluviatile animals of predaceous habits, living on fish, crustacea, and other organisms of the fresh or salt waters of the coal lagoons. The larger forms are believed to have measured 7 or 8 feet in length; some of the smaller examples, though adult and perfect, do not exceed as many inches.[1] That the woods of the Carboniferous period were not devoid of insect life is known from the discovery of some beetles and neuroptera at Coalbrookdale.

CONTINENTAL EUROPE.—As in Britain so on the Continent the Carboniferous system occupies many detached areas or basins—the result partly of original deposition, partly of denudation, and partly of the spread and overlap of more recent formations. There can be no doubt that the English Carboniferous Limestone once extended continuously eastward across the north of France, along the base of the Ardennes, through Belgium, and across the present valley of the Rhine into Westphalia. From the western headlands of Ireland this calcareous formation can thus be traced eastward for a distance of 750 English miles into the heart of Europe. It then begins to pass into a series of shales and sandstones, which no doubt represent the same proximity to shore as the similar strata in the north of England and Scotland. In Silesia, and still much further eastwards in central and southern Russia, representatives of the Carboniferous Limestone appear, but interstratified, as in Scotland, with coal-bearing strata. Traces of the same blending of marine and terrestrial conditions are found also in the north of Spain. But over central France, and eastwards through Bohemia and Moravia into the region of the Carpathians, the Coal-measures rest directly upon the older formations, most commonly upon gneiss and other crystalline rocks. It would appear that these tracts had remained above water during the time of the Carboniferous Limestone, but were gradually depressed during that of the Coal-measures.

In the north of France and Belgium the British type of the Carboniferous system is well shown. At the base lies a group of green, grey, and reddish shales and yellow sandstones, precisely similar in lithological character to parts of the Calciferous Sandstones of Scotland. They are well seen in some recent railway cuttings to the north of Boulogne, and also in the valley of the Meuse above Namur, lying upon the Psammites de Condroz or Upper Devonian beds. They are succeeded by the Carboniferous Limestone, which is subdivided into eight formations, having an aggregate thickness of 800 metres, and each characterized by its own assemblage of fossils. The horizon of the Millstone Grit is marked by the occurrence of certain alum-schists. The Coal-measures of this area have been referred to in the article COAL.[2]

The Saarbruck coal-field furnishes a good example of that type of the Carboniferous system where the lower marine series is absent. It lies unconformably on Devonian rocks, and attains a thickness of more than 10,000 feet. It is divided into the following groups of strata:—

2. Upper series, consisting at the top of red sandstones, below which come shales, sandstones, &c., with a few coal-seams—*Anthracosia*, *Estheria*.
1. Lower series, consisting of an upper group of red conglomerates, sandstones, clays, resting upon the great coal-bearing division. Abundant plants, with labyrinthodonts and insect remains.

Geinitz, drawing attention to the distribution of plants in the Saxon Coal-measures, remarks that a certain order can be observed in their appearance. He divides the strata accordingly into three zones, each marked by a characteristic assemblage of plants, and he believes that the classification can be applied in other countries.

3. The Fern Zone, marked by the profusion of its ferns (*Sphenopteris*, *Hymenophyllites*, *Schizopteris*, *Odontopteris*, *Neuropteris*, *Cyclopteris*, *Alethopteris*, *Caulopteris*). This is underlaid by
2. The Sigillaria Zone, containing many species of *Sigillaria*, also *Lepidodendron*, *Calamites*, *Asterophallites*, and a few ferns.
1. The Lycopod Zone, abounding in *Sagenaria Veltheimiana*, with *Sphenopteris distans*, *Calamites transitionis*, &c.

The lowest of these zones (1) is compared by Geinitz with the Culm, that is, the sandy, shaly, and coal-bearing representative of the Carboniferous Limestone. To the east of the Rhine valley, as already mentioned, the true Carboniferous Limestone loses its normal character and assumes that of the Culm—a series of shales, sandstones, greywackes, and conglomerates, in which the abundant fauna of the limestone is reduced to a few mollusks (*Productus antiquus*, *P. latissimus*, *P. semireticulatus*, *Posidonomya Becheri*, *Goniatites sphæricus*, *Orthoceras striatulum*, &c.). The *Posidonomya* particularly characterizes certain dark shales known as Posidonia schists. About 50 species of plants have been obtained from the Culm, typical species being *Calamites transitionis*, *Sagenaria Veltheimiana*, *Stigmaria ficoides*, *Sphenopteris distans*, *Cyclopteris tenuifolia*. This flora bears a strong resemblance to that of the Calciferous Sandstones of Scotland.

NORTH AMERICA.—Rocks corresponding in geological position and the general aspect of their organic contents with the Carboniferous system of Europe are said to cover an area of more than 200,000 square miles in the United States and British North America. The following table shows the subdivisions which have been established among them:—

Carboniferous.	Coal-measures,—a series of sandstones, shales, ironstones, coals, &c., varying from 100 feet in the interior continental area to 4000 feet in Pennsylvania, and more than 8000 feet in Nova Scotia. The plant remains include forms of *Lepidodendron*, *Sigillaria*, *Stigmaria*, *Calamites*, ferns, and coniferous leaves and fruits. The animal forms embrace in the marine bands species of *Spirifer*, *Productus*, *Bellerophon*, *Nautilus*, &c. Among the shales and carbonaceous beds numerous traces of insect life have been obtained, comprising species related to the may-fly and cockroach. Spiders, scorpions, centipedes, limuloid crabs, and land snails like the modern *Pupa* have also been met with. The fish remains comprise teeth and ichthyodorulites of placoid genera, and a number of ganoids (*Eurylepis*, *Cœlacanthus*, *Megalichthys*, *Rhizodus*, &c.). Several labyrinthodonts occur, and true reptiles are represented by one saurian genus found in Nova Scotia, the *Eosaurus*.
	Millstone Grit,—a group of arenaceous and sometimes conglomeratic strata, with occasional coal-seams, only 25 feet thick in some parts of New York, but swelling out to 1500 feet in Pennsylvania.
Sub-Carboniferous.	Chester group.—Limestones, shales and sandstones, sometimes 600 feet.
	St Louis group.—Limestones with shale, in places 250 feet.
	Keokuk group.—Limestone with chert layers and nodules.
	Burlington group.—Limestone, in places with chert and hornstone, 25 to 200 feet.
	Kinderhook group.—Sandstones, shales, and thin limestones, 100 to 200 feet, resting on the Devonian black shale.
	The sub-Carboniferous groups are mainly marine limestones, but contain here and there remains of the characteristic Carboniferous land vegetation. Crinoids of many forms abound in the limestones. A remarkable polyzoon, *Archimedes*, occurs in some of the bands. The brachiopods are chiefly represented by species of *Spirifer* and *Productus*; the lamellibranchs by *Myalina*, *Schizodus*, *Aviculopecten*, *Nucula*, *Pinna*, and others, the cephalopods by *Orthoceras*, *Nautilus*, *Goniatites*, *Gyroceras*, &c. The European genus of trilobite, *Phillipsia*, occurs. Numerous teeth and fin-spines of selachian fishes give a further point of resemblance to the European Carboniferous Limestone. Some of the rippled rain-pitted beds contain amphibian footprints—the earliest American forms yet known.

[1] Miall, *Brit. Assoc. Rep.*, 1873, p. 216.

[2] [In the article COAL, vol. vi. p. 56, the coal basin of Hardinghem is said to be of Carboniferous Limestone age. This, which appeared to be the most probable view of a very obscure point, has been proved to be a mistake, as the strata are actually Coal-measures inverted in position, the same disturbance being characteristic of the south side of the basin of the Pas-de-Calais for a considerable distance. This is now so generally recognized that borings for coal in that basin through the Tertiary and Cretaceous formations are not necessarily stopped on reaching Devonian strata, as coal-seams have been discovered vertically below the older strata at considerable depths, *e.g.*, at Auchy au Bois. In another pit, at Courrières, the fact that the measures on the upper levels are inverted in position has been recently proved by the sinkings traversing the same seams in reverse order, *i.e.*, in their normal position in the lower workings. These facts have an important bearing on the question of the probable extension of the Coal-measures in the south-east of England. The discovery (in 1878) of Devonian strata at the moderate depth of 1400 feet in the centre of London, at Messrs Meux's brewery, is another interesting fact that bears out the views previously put forward by Mr Godwin Austen. (H. B.)]

Permian.

Britain.—In England the Coal-measures are unconformably overlaid by a series of red sandstones, conglomerates, breccias, and marls, which at one time were grouped in one great formation as the New Red Sandstone, in contradistinction to the *Old* Red Sandstone lying below the Carboniferous system. They were likewise known as the Poikilitic series, from their mottled or variegated colours. They are now divided into two systems or groups of formations, the lower half being included in the Palæozoic series under the name of Permian (after Perm, a Russian province where they are well displayed), and the upper half being relegated to the Secondary series, and termed Trias.

The Permian system in England consists of the following subdivisions :—

		W. of England.	E. of England.
3. Upper...	Red sandstones, clays, and gypsum	600 ft.	50–100 ft.
2. Middle..	Magnesian limestone; Marl slate	10–30 ,,	600 ,,
1. Lower...	Red and variegated sandstone; Reddish-brown and purple sandstones and marls, with calcareous conglomerates and breccias of volcanic rocks	3000 ,,	100–250 ,,

From the thicknesses here given, it is evident that the Permian rocks have a very different development on the two sides of England. On the east side, from the coast of Northumberland southwards to the plains of the Trent, they consist chiefly of a great central mass of limestone. But on the west side of the Pennine Chain, and extending southwards into the central counties, the calcareous zone disappears, and we have a great accumulation of red, arenaceous, and gravelly rocks.

Lower.—This subdivision attains its greatest development in the vale of the Eden, where it consists of brick-red sandstones, with some beds of calcareous conglomerate or breccia, locally known as "brockram," derived from the waste of the Carboniferous Limestone. These red rocks extend across the Solway into the valleys of the Nith and Annan, in the south of Scotland, where they lie unconformably on the Lower Silurian rocks. Their breccias consist of fragments of the adjacent Silurian greywackes and shales, but near Dumfries some calcareous breccias or "brockrams" occur. These brecciated masses have evidently accumulated in small lakes or narrow fjords. Much further south, in Staffordshire, and in the districts of the Clent and Abberley Hills, the brecciated conglomerates in the Permian series attain a thickness of 400 feet. They have been shown by Ramsay to consist in large measure of volcanic rocks, grits, slates, and limestones, which can be identified with rocks on the borders of Wales. Some of the stones are 3 feet in diameter and show distinct striation. The same writer has pointed out that these Permian drift-beds cannot be distinguished by any essential character from modern glacial drifts, and he has no doubt that they were ice-borne, and, consequently, that there was a glacial period during the accumulation of the Lower Permian deposits of the centre of England.

Like red rocks in general the Lower Permian beds are almost barren of organic remains. Such as occur are indicative chiefly of terrestrial surfaces. Plant remains occasionally appear, such as *Caulerpites* (supposed to be of marine growth), *Lepidodendron dilatatum*, *Calamites*, *Sternbergia*, and fragments of coniferous wood. The cranium of a labyrinthodont (*Dasyceps*) has been obtained from the Lower Permian rocks at Kenilworth. Footprints referred to members of the same extinct order have been observed abundantly on the surfaces of the sandstones of Dumfriesshire, and also in the vale of the Eden.

Middle.—This subdivision is the chief repository of fossils in the Permian system. Its strata are not red, but consist of a lower zone of hard brown shale with occasional thin limestone bands (Marl Slate) and an upper thick mass of dolomite (Magnesian Limestone). The latter is the chief feature in the Permian development of the east of England. It corresponds with the Zechstein of Germany, as the Marl Slate does with the Kupfer-schiefer. It is a very variable rock in its lithological characters, being sometimes dull, earthy, fine-grained, and fossiliferous, in other places quite crystalline, and composed of globular, reniform, botryoidal, or other irregular concretions of crystalline and frequently internally radiated dolomite. Though the Magnesian Limestone runs as a thick persistent zone down the east of England it is represented on the Lancashire and Cheshire side by bright red and variegated sandstone covered by a thin group of red marls, with numerous thin courses of limestone, containing *Schizodus*, *Bakevellia*, and other characteristic fossils of the Magnesian Limestone.

The middle Permian division has yielded about 100 species belonging to 46 genera of fossils—a singularly poor fauna when contrasted with that of the Carboniferous system below. The brachiopods (9 genera, 21 species) include *Productus horridus*, *Camarophoria multiplicata*, *C. Schlotheimi*, *Strophalosia Goldfussi*, *Lingula Credneri*, and *Terebratula elongata*. The lamellibranchs number 16 genera and 31 species, among which *Schizodus Schlotheimii*, *Bakevellia tumida*, *B. antiqua*, *B. ceratophaga*, *Mytilus squamosus*, and *Arca striata* are characteristic. The univalves are represented by 11 genera and 26 species, including *Pleurotomaria* and *Turbo* as common genera. Fishes have been obtained chiefly in the marl slate to the number of 21 species belonging to 8 genera, of which *Palæoniscus* is the chief. These small ganoids are closely related to some which haunted the lagoons of the Carboniferous period.

Upper.—Murchison and Harkness have classed as Upper Permian certain red sandstones with thin partings of red shale, and an underlying band of red and green marls and gypsum. These rocks, seen at St Bees, near Whitehaven, resting on a magnesian limestone, have not yet yielded any fossils.

Continental Europe.—The two types of the Permian system presented by the east and west sides of England reappear in different areas on the mainland of Europe. The eastern or Durham type is found in enormous masses of strata flanking the Harz Mountains, also in Thuringia, in Saxony, and in Bohemia. The western or Salopian type is found over many thousands of square miles in the north and east of Russia.

The German geologists, recognizing the remarkable two-fold character of its rocks, have called this system "Dyas," and have proposed to retain the term Permian to express the more simple type, such as is found in Russia and western England. They group the members of their Dyas as follows :—

Zechstein Group.	Anhydrite, gypsum, rock-salt, marl, dolomite, fetid shale and limestone. The amorphous gypsum is the chief member of this group; the limestone is sometimes full of bitumen.
	Crystalline granular (*Rauchwacke*) and fine sandy (*Asche*) dolomite (6 to 65 feet).
	Zechstein, an argillaceous thin-bedded compact limestone 15 to 30 (sometimes even 90) feet thick.
	Kupfer-schiefer—a black bituminous shale not more than about 2 feet thick.
	Zechstein, conglomerate, and calcareous sandstone.
Rothliegende Group.	Upper.—Conglomerates (quartz-porphyry conglomerate) and sandstone, with associated melaphyres and tuffs.
	Middle.—Red clays, shales, and fine shaly sandstones, with bands of quartz-conglomerate and earthy limestone. Melaphyre and porphyrite masses intercalated.
	Lower.—Shaly sandstones, shales (with bituminous bands), and conglomerates.

The name "Rothliegende" or "Rothtodtliegende" (red-layer or red-dead-layer) was given by the miners because their ores disappeared in the red rocks below the copper-bearing Kupfer-schiefer. The coarse conglomerates have been referred by Ramsay to a glacial origin, like those of the Abberley Hills. One of the most interesting features of the formation is the evidence of the contemporaneous outpouring of great sheets of quartz-porphyry, granite-porphyry, porphyrite, and melaphyre, with abundant interstratifications of various tuffs, not infrequently enclosing organic remains. From the very nature of its component materials, the Rothliegende is comparatively barren of fossils, a few ferns, calamites, and remains of coniferous trees are found in it, particularly towards the base, where indeed they form, in the Mansfeld district, a coal-seam about 5 feet thick.

The plants, all of terrestrial growth, on the whole resemble generically the Carboniferous flora, but seem to be nearly all specifically distinct. They include forms of *Calamites* (*C. gigas*), *Asterophyllites*, and ferns of the genera *Sphenopteris*, *Alethopteris*, *Neuropteris*, *Odontopteris*, with well-preserved silicified stems of tree-ferns (*Psaronius*, *Tubicaulis*). The conifer *Walchia* (*W. piniformis*) is specially characteristic. Fish remains occur sparingly (*Amblypterus*, *Palæoniscus*, *Acanthodes*), and traces of labyrinthodonts (*Archegosaurus Decheni*) have been met with.

The Zechstein group is characterized by a suite of fossils like those of the Middle Permian of England. The Kupfer-schiefer contains numerous fish (*Palæoniscus Freislebeni*, *Platysomus gibbosus*, &c.) and remains of plants (coniferous leaves and fruits and sea-weeds). This deposit is believed to have been laid down in some enclosed sea-basin, the waters of which, probably from the rise of mineral springs connected with some of the volcanic foci of the time, were so charged with metallic salts in solution as to become unfit for the continued existence of animal life. The dead fish, plants, &c., by their decay, gave rise to reduction and precipitation of these salts as sulphides, which thereupon enclosed and replaced the organic forms, and permeated the mud at the bottom. This old sea-floor is now the widely extended band of copper-slate which has so long and so extensively been worked along the flanks of the Harz. After the formation of the Kupfer-schiefer the area must have been once more covered by clearer water, for the Zechstein contains a number of organisms of which *Productus horridus*, *Spirifer undulatus*, *Strophalosia Goldfussi*, *Schizodus obscurus*, and *Fenestella retiformis* are common. Renewed unfavourable conditions are indicated by the dolomite, gypsum, and rock-salt which succeed. Professor Ramsay, reasoning upon such phenomena as developed in England, has connected them with the abundant labyrinthodont footprints and other evidences of shores and land, as well as the small number and dwarfed forms of the shells in the Magnesian Limestone, and has speculated on the occurrence of a long continental period in Europe, during one epoch of which a number of salt inland seas existed wherein the Permian rocks were accumulated. He compares these deposits to what may be supposed to be forming now in parts of the Caspian Sea.

North America.—The Permian system is hardly represented at all in this part of the globe. In Kansas certain red and green clays, sandstones, limestones, conglomerates, and beds of gypsum lie conformably on the Carboniferous syste , and contain a few genera and species of molluscs (*Bakevellia*, *Myalina*, &c,), which occur in the European Permian rocks.

III. SECONDARY OR MESOZOIC.

Triassic.

It has been already mentioned that the great mass of red rocks, which in England overlie the Carboniferous system, were formerly classed together as New Red Sandstone, but are now ranged in two systems. We have considered the lower of these under the name of Permian. The general facies of organic remains in that division is still decidedly Palæozoic. Its brachiopods and its plants connect it with the Carboniferous rocks below. Hence it is placed at the close of the long series of Palæozoic formations. When, however, we enter the upper division of the red rocks, though the general lithological characters remain very much as in the lower group, the fossils bring before us the advent of the great Mesozoic flora and fauna. This group therefore is put at the base of the Mesozoic or Secondary series. It is called Trias, because in Germany it consists of three well-marked subdivisions. But the old name, New Red Sandstone, is familiarly retained for it by many geologists in England. The term Trias, like Dyas, is unfortunately chosen, for it elevates a mere local character into an importance which it does not deserve. The threefold subdivision, though so distinct in Germany, disappears elsewhere.

Great Britain.—Triassic rocks occupy a large area of the low plains in the centre of England, ranging thence northwards along the flanks of the Carboniferous tracts to Lancaster Bay, and southwards by the head of the Bristol Channel to the south-east coast of Devonshire. They have been arranged in the following subdivisions:—

Rhætic	Penarth beds.—Red, green, and grey marls, and "White Lias."
Upper Trias or Keuper.	New Red Marl.—Red and grey shales and marls, with beds of rock-salt and gypsum (*Estheria* and *Foraminifera*).
	Lower Keuper Sandstone.—Thinly laminated micaceous sandstones and marls (waterstones) passing downwards into white, brown, or reddish sandstones, with a base of calcareous conglomerate or breccia.
Middle	Wanting in England (Muschelkalk of Germany).
Lower Trias or Bunter.	Upper Mottled Sandstone.—Soft bright-red and variegated sandstones, without pebbles.
	Pebble beds.—Harder reddish-brown sandstones with quartzose pebbles, passing into conglomerate; with a base of calcareous breccia.
	Lower Mottled Sandstone.—Soft bright-red and variegated sandstone, without pebbles.

Like the Permian red rocks below, the sandstones and marls of the Triassic series are almost barren of organic remains. Hence the subdivisions in the foregoing table are based on mineral characters, and could not therefore be relied on as a guide in districts outside of the English area. Indeed, extraordinary differences in the development of the different members of the series occur, even within that area, as may be seen from the subjoined table, which shows the variations in thickness from north-west to south-east:—

		Lancashire and W. Cheshire.	Stafford-shire.	Leicester-shire and Warwick-shire.
		Feet.	Feet.	Feet.
Keuper.	Red marl	3000	800	700
	Lower Keuper sandstone	450	200	150
Bunter.	Upper mottled sandstone	500	50–200	absent
	Pebble beds	500–750	100–300	0–100
	Lower mottled sandstone	200–500	0–100	absent

Hence we observe that, while towards the north-west the Triassic rocks attain a maximum depth of 5200 feet, they rapidly come down to a fifth or a sixth of that thickness as they pass towards the south-east. Recent borings in the south-eastern counties show that the Triassic rocks are there absent altogether. It is evident that the source of supply of the sediment lay towards the north. This is further borne out by the character of the pebble-beds. These are coarsest towards the north, and, besides local materials, contain abundant rolled pebbles of quartz which have evidently been derived from some previous conglomerate, probably from some of the Old Red Sandstone masses now removed or concealed The Trias everywhere rests unconformably on the rocks underneath it, so that, although the general physical conditions as regards climate, geography, and sedimentation, which prevailed in the Permian period still continued, great terrestrial movements had, in the meanwhile, taken place, whereby the Permian sediments were upraised and exposed to denudation. Hence the Trias rests now on Permian, now on Carboniferous, and sometimes even on Cambrian rocks. Moreover, the upper parts of the Triassic series overlap the lower, so that the Keuper groups come to rest directly on Permian or Carboniferous rocks.

One of the most interesting features in the English Trias is the occurrence of beds of rock-salt which have long been profitably worked. The uppermost subdivision of the Keuper, consisting of red marls, has a wide distribution, for it can be traced from the coast of Lancashire to the Bristol Channel, and covers a larger area of surface in the central counties than the rest of the Trias and the whole of the Permian sandstones combined. Even as far south as the coast of Devonshire, it contains casts of the cubical spaces once occupied by crystals of common salt. But in Cheshire the salt occurs in two or more beds, of which the lower is sometimes upwards of 100 feet thick. It is a crystalline substance, usually tinged yellow or red from intermixture of clay and peroxide of iron, but is tolerably pure in the best part of the beds, where the proportion of chloride of sodium is as much as 98 per cent. Through the bright red marls with which the salt is interstratified there run bands of gypsum, somewhat irregular in their mode of occurrence, sometimes reaching a thickness of 40 feet and upwards. Thin seams of rock-salt likewise occur among the red marls. These facts point to the concentration and evaporation of salt lakes or inland seas.

The organic remains of the Trias are comparatively few, as the conditions for at least animal life must have been extremely unfavourable in the waters of the ancient Dead Sea wherein these red rocks were accumulated. The land possessed a vegetation which, from the few fragments yet known, seems to have consisted in large measure of cypress-like coniferous trees (*Voltzia*, *Walchia*), with calamites on the lower more marshy grounds. The red marl group contains in some of its layers numerous valves of the little crustacean *Estheria minuta*, and a solitary species of lamellibranch, *Pullastra arenicola*. A number of teeth, spines, and sometimes entire skeletons of fish have been obtained (*Dipteronotus cyphus*, *Palæoniscus superstes*, *Hybodus Keuperi*, *Acrodus minimus*, *Sphenonchus minimus*, *Lophodus*, &c.). The bones, and still more frequently the footprints, of labyrinthodont and even of saurian reptiles occur in the Keuper beds—*Labyrinthodon* (4 species), *Cladyodon Lloydii*, *Hyperodapedon*, *Palæosaurus*, *Teratosaurus*, *Thecodontosaurus*, *Rhyncosaurus*, and footprints of *Cheirotherium*. The remains of a small marsupial (*Microlestes*) have likewise been discovered.

Rhætic.—At the top of the Red Marl certain thin-bedded strata form a gradation upwards into the base of the Jurassic system. As their colours are grey and blue, and contrast with the red marls on which they repose conformably, they were formerly classed without hesitation in the Jurassic series. Egerton, however, showed that, from the character of their included fish remains, they had more palæontological affinity with the Trias than with the Lias. Subsequent research, particularly among the Rhætic Alps and elsewhere on the Continent, brought to light a great series of strata of intermediate characters between the Trias and Lias. These results led to renewed examination of the so-called beds of passage in England, which were found to be truly representative of the massive formations of the Tyrolese and Swiss Alps. They are therefore now classed as Rhætic, and considered as the uppermost member of the Trias, but offering evidence of the gradual approach of the physical geography and characteristic fauna and flora of the Jurassic period.

The Rhætic beds extend as a continuous though very thin band at the top of the Trias, from the coast of Yorkshire across England to Lyme Regis on the Dorsetshire shores. They occur in scattered patches even up as far as Carlisle, and westwards on both sides of the Bristol Channel. Their thickness, on the average, is probably not more than 50 feet, though it rarely increases to 150 feet. They consist of thin-bedded grey and dark shales and clays, with bands of light-coloured limestone. One of their most important subdivisions is the so-called Bone-bed—a pyritous, micaceous, and occasionally rippled sandstone, sometimes in several bands, abounding in fish bones, teeth, coprolites, and other organic remains. The grey marly beds in the lower portion of the series have yielded remains of the *Microlestes Rhæticus*. Among the reptilian fossils are some precursors of the great forms which distinguished the Jurassic period (*Ichthyosaurus* and *Plesiosaurus*). The fishes include *Acrodus minimus*, *Ceratodus altus*, *Hybodus minor*, *Nemacanthus monilifer*, &c. Some of the lamellibranchs are specially characteristic; such are *Cardium Rhæticum*, *Avicula contorta*, *Pecten Valoniensis*, and *Pullastra arenicola*.

Professor Ramsay has drawn attention to the probable geographical changes recorded by the Triassic rocks of England. Connecting them with the earlier and similar Permian sandstones and marls he points out that the great Continental period which began with the Old Red Sandstone closed with the New Red Marl, and was characterized by the existence of great lakes, many of which must have been salt, and by the abundance of labyrinthodont life. The Triassic rocks were, doubtless, laid down in one of these salt lakes round the margins of which the labyrinthodonts left their footprints on the soft sand. In the Rhætic series we see how these inland basins were gradually invaded by the sea, which brought into the region of Britain the rich fauna of the Jurassic period.

CONTINENTAL EUROPE.—The Trias is the most compactly distributed of all the geological formations of Europe. Its main area extends as a great basin from Basel down to the plains of Hanover, traversed along its centre by the course of the Rhine, and stretching from the flanks of the old high grounds of Saxony and Bohemia on the east across the Vosges mountains into France. This must have been a great inland sea, out of which the Harz mountains, and the high grounds of the Eifel, Hundsruck, and Taunus probably rose as islands. It may have extended up to the base of the Alps, for enormous masses of Triassic rocks now form part of these mountains. Traces of what were probably other basins occur eastward in the Carpathian district, along the southern front of the Alps, in the west and south of France, and over the eastern half of the Spanish peninsula. But these areas have been considerably obscured, sometimes by dislocation and denudation, sometimes by the overlap of more recent formations.

In the great German Triassic basin the deposits are as shown in the subjoined table.

Keuper.	Upper or Rhætic.—Grey sandy clays and fine-grained sandstones, containing *Equisetum*, *Asplenites*, and cycads (*Zamites*, *Pterophyllum*), sometimes forming thin seams of coal—*Cardium Rhæticum*, *Avicula contorta*, *Estheria minuta*, *Nothosaurus*, *Termatosaurus*, *Belodon*, and *Microlestes antiquus*.
	Middle (Bunte Keupermergel, Gypskeuper).—Bright red and mottled marls, with beds of gypsum and rock-salt. In some places where sandstones appear they contain numerous plants (*Equisetum columnare*, *Tæniopteris vittata*, *Pterophyllum*, &c.), and labyrinthodont and fish remains. 300 to 1000 feet.
	Lower (Lettenkohle, Kohlenkeuper).—Grey sandstones and dark marls and clays, with abundant plants, sometimes forming thin seams of an earthy hardly workable coal (Lettenkohle). The plants include, besides those above mentioned, the conifers *Araucaroxylon Thuringicum*, *Voltzia heterophylla*, &c Some of the shales are crowded with small ostracod crustacea (*Estheria minuta*). Remains of fish (*Ceratodus*) and of the *Mastodonsaurus Jægeri* have been obtained. About 230 feet.
Muschelkalk.	Upper Limestone in thick beds with argillaceous partings.—It abounds in organic remains among which *Ceratites nodosus*, *Nautilus bidorsatus*, *Lima striata*, *Myophoria vulgaris*, *Trigonodus Sandbergeri*, *Terebratula vulgaris*, and *Encrinus liliiformis* are specially characteristic. It is a thoroughly marine formation, sometimes almost wholly made up of crinoid stems. 200 to 400 feet.
	Middle Limestone and Anhydrite, consisting of dolomites with anhydrite, gypsum, and rock-salt. Nearly devoid of organic remains, though bones and teeth of saurians have been found. 200 to 400 feet.
	Lower Limestone, consisting of limestones and dolomites, but on the whole poor in fossils, save in the limestone bands, some of which are full of *Terebratula vulgaris* and *Encrinus liliiformis*. 160 to 500 feet.
Bunter.	Upper (Röth).—Red and green marls, with gypsum in the lower part. 250 to 300 feet.
	Middle.—Coarse-grained sandstones, sometimes incoherent, with wayboards of *Estheria* shale.
	Lower.—Fine reddish argillaceous sandstone, often micaceous and fissile, with occasional interstratifications of dolomite and of the marly oolitic limestone called "Rogenstein."
	The Bunter division is usually barren of organic remains. The plants already known include *Equisetum arenaceum*, one or two ferns, and a few conifers (*Albertia* and *Voltzia*). The lamellibranch *Myophoria costata* is found in the upper division all over Germany. Numerous footprints occur on the sandstones, and the bones of labyrinthodonts as well as of fish have been obtained.

The Trias attains an enormous development in the eastern Alps, where it bears evidence of having been accumulated under very different conditions from those of the Trias in Germany. The great thickness of its limestones, and their unequivocally marine organisms, show that it must have accumulated in opener water, which remained clear and comparatively free from inroads of sandy and muddy sediment. It possesses, moreover, a high interest as being a massive formation of marine origin formed between Permian and Jurassic times, and containing a remarkable blending of true Palæozoic organisms with others as characteristically Mesozoic. It is divided into two great series:—(1) Lower Trias, consisting of (*a*) Werfen Shales and Guttenstein Limestone, and (*b*) Virgloria Limestone or alpine Muschelkalk; and (2) Upper Trias,—a varied series of strata in three leading groups, having a united thickness sometimes of thousands of feet.

North America.—Rocks which are regarded as equivalent to the European Trias cover a large area in North America. On the Atlantic coast they are found on Prince Edward's Island, New Brunswick, and Nova Scotia, in Connecticut, New York, Pennsylvania, and North Carolina. Spreading over an enormous extent of the western territories, they cross the Rocky Mountains into California and British Columbia. They consist mainly of red sandstones, passing sometimes into conglomerates, and often including shales and impure limestones. On the Pacific slope they contain distinctly marine organisms, which include a mingling of such Palæozoic genera as *Spirifer*, *Orthoceras*, and *Goniatites*, with the characteristically Secondary genus *Ammonites*. In the centre and east of the continent they are marked by the occurrence of terrestrial plants, and in Connecticut by abundant footprints of land animals. The fossil plants present a general facies like that of the European Triassic flora, among them cycads, including some of the European species of *Pterophyllum*. Ferns (*Pecopteris*, *Neuropteris*, *Clathropteris*), calamites, and conifers are the predominant forms. The fauna is remarkable chiefly for the number and variety of its vertebrates. The labyrinthodonts are represented by footprints, from which upwards of fifty species have been described. Saurian footprints have likewise been recognized, but in a few cases their bones also have been found. These saurians had some bird-like characteristics, among others that of three-toed hind feet, which produced impressions exactly like those of birds. It is by no means certain, therefore, that what have been described as ornithichnites were not really made by dinosaurs. A small insectivorous marsupial (*Dromatherium*), found in the Trias of North Carolina, is the oldest American mammal yet known.

Jurassic.

The next great period of geological time is termed the Jurassic, from the Jura Mountains, where the deposits of that age are well developed. It was in England, however, that they were first studied by William Smith, in whose hands they were made to lay the foundations of stratigraphical geology. The names adopted by him for the subdivisions he traced across the country have passed into universal use, and though some of them are uncouth English provincial names, they are as familiar to the geologists of France, Switzerland, and Germany as to those of England.

The Jurassic formations stretch across England in a varying band from the mouth of the Tees to the coast of Dorsetshire. They consist of harder sandstones and limestones interstratified with softer clays and shales. Hence they give rise to a characteristic type of scenery,—the more durable beds standing out as long ridges, sometimes even with low cliffs, while the clays underlie the level spaces between. Arranged in descending order, the following subdivisions of the English Jurassic system are recognized:—

			Maximum thicknesses. Feet.
Upper or Portland Oolites.	Purbeck.	Upper fresh-water beds ... Middle marine beds .... Lower fresh-water beds ..	360
	Portland.	Portland Stone	70
		Portland Sands	150
		Kimeridge Clay	600
Middle or Oxford Oolites.	Coralline Oolite.	Coral Rag and Calcareous Grit	250
	Oxford clay.	Oxford Clay and Kellaways Rock	600
Lower or Bath Oolites.	Great Oolite.	Cornbrash, Bradford Clay	40
		and Forest Marble (in Dorsetshire 450 ft.)	30
		Great or Bath Oolite with Stonesfield slate (part of Northampton Sand)	130
	Fuller's Earth.	Fuller's Earth group	150
	Inferior Oolite.	Cheltenham beds	270
		Midford Sands (and perhaps part of Northampton Sands), "Dogger" of Yorkshire	160
Lias.		Upper Lias	400
		Marlstone	200
		Lower Lias	900

Although these names appear in tabular order as expressive of what is the predominant or normal succession of the beds, considerable differences occur when the rocks are traced across the country. Thus the Forest Marble attains a thickness of 450 feet in Dorsetshire, but dwindles down to only 15 feet at Blenheim Park. The Inferior Oolite consists of marine limestones and shales in Gloucestershire, but chiefly of massive estuarine sandstones and shales in Yorkshire. These differences help to bring before us some of the geographical features of the British area during the Jurassic period.

The Lias consists of three formations, well marked by physical and palæontological characters. In the lower member numerous thin blue and brown limestones with partings of dark shale are surmounted by similar shales with occasional nodular limestone bands, the whole being divided into seven zones, each characterized by the presence of one or more distinctive species of ammonite. From this point of the geological series up to the close of the Mesozoic formations, the ammonites play a chief part among the mollusks. The Middle Lias, consisting of argillaceous limestones (marlstones) with micaceous sands and clays, is divided into five ammonite zones. In its Yorkshire development this subdivision is remarkable for containing a bed of earthy carbonate of iron 15 to 20 feet thick, which has been extensively worked in the Cleveland district. The upper division is composed chiefly of clays and shales with nodules of limestones, among which three ammonite zones have been noted in Yorkshire.

The organic remains of the Lias comprise leaves and other remains of cycads (*Palæozamia*), conifers (*Pinites*, *Cupressus*, *Peuce*), ferns (*Otopteris*, *Alethopteris*, &c.), and reeds (*Equisetites*). These fossils serve to indicate the general character of the flora, which seems now to have been mainly cycadaceous and coniferous, and to have presented a great contrast to the lycopodiaceous vegetation of Palæozoic times. The occurrence of land-plants dispersedly throughout the English Lias shows also that the strata, though chiefly marine were deposited within such short distance from shore, as to receive from time to time leaves, seeds, fruits, twigs, and stems from the land. Further evidence in the same direction is supplied by the numerous insect remains, which have been obtained principally from the Lower Lias. These were, no doubt, blown off the land and fell into shallow water, where they were preserved in the silt on the bottom. The *Neuroptera* are numerous, and include several species of *Libellula*. The coleopterous forms comprise a number of beetles. There were likewise representatives of the orthopterous, hemipterous, and dipterous orders. These relics of insect-life are so abundant in some of the calcareous bands that the latter are known as insect-beds. With them are associated remains of terrestrial plants, cyprids, and mollusks, sometimes marine, sometimes apparently brackish-water. The marine life of the period has been abundantly preserved, so far at least as regards the comparatively shallow and juxta-littoral waters in which the Liassic strata were accumulated. Corals, though on the whole scarce, abound on some horizons (*Isastræa*, *Montlivaltia*, *Septastræa*, &c.). The crinoids were represented by thick growths of *Extracrinus* and *Pentacrinus*. There were several kinds of star-fishes, and also of sea-urchins (*Cidaris*, *Diadema*, *Acrosalenia*)—all generically distinct from those of the Palæozoic periods. The contrast between the Liassic crustacea and those of the older systems, as Phillips has pointed out, is very decided, the ancient trilobites having entirely disappeared, and having been succeeded by tribes of long-tailed ten-footed lobsters and prawns. There is a similar striking difference between the mollusks of the Lias and those of the Palæozoic rocks, bearing witness to the great biological changes which had taken place in the long interval. The brachiopods are chiefly species of *Rhynchonella* and *Terebratula*—genera which, though occurring in Palæozoic rocks, play there a comparatively subordinate part. They include the last *Spiriferi* and *Leptænæ*. Of the lamellibranchs, a few of the most characteristic genera are *Gryphæa*, *Lima*, *Pecten*, *Monotis*, *Cardinia*, *Hippopodium*, *Myacites*, and *Pholadomya*. Gasteropods, though usually rare in such muddy strata as the greater part of the Lias, occasionally occur, but most frequently in the calcareous zones. Altogether 89 species are at present known, the chief genera being *Pleurotomaria*, *Turbo*, *Eucyclus*, *Cerithium*, and *Chemnitzia*. The cephalopods, however, are the most abundant and characteristic shells of the Lias; the family of the ammonites numbers in Yorkshire at least 113 species. As already stated, some species are so distinctive of special horizons that the whole of the Lias has been subdivided into zones, each denoted by the name of its characteristic ammonite. In ascending order, these zones are named as follows:—In the Lower Lias,—1st, *Ammonites planorbis*; 2d, *A. angulatus*; 3d, *A. Bucklandi*; 4th, *A. tuberculatus*; 5th, *A. obtusus*; 6th, *A. oxynotus*; 7th, *A. varicostatus*. In the Middle Lias,—1st, *A. Jamesoni* and *armatus*; 2d, *A. capricornus*; 3d, *A. margaritatus*; 4th, *A. spinatus*; 5th, *A. annulatus*. In the Upper Lias,—1st, *A. serpentinus*; 2d, *A. communis*; 3d, *A. jurensis*. The genus *Nautilus* is also present. The dibranchiate cephalopods are represented by upwards of 40 species of the genus *Belemnites*. Numerous species of fishes have been obtained from the Lias. Some of these are placoids, known only by their teeth (*Acrodus*, *Ceratodus*), others only by their spines (*Nemacanthus*), and some by both teeth and spines (*Hybodus*). The ganoids are frequently found entire, the genera *Dapedius*, *Pholidophorus*, *Æchmodus*, *Lepidotus*, *Pachycormus*, and *Leptolepis* being among the most frequent. But undoubtedly the most important palæontological feature of the Lias is the number and extraordinary interest of its reptilian remains. These include the extinct order of enaliosaurs or sea-lizards, uniting characters which are not found together in any living forms. Among these are the genus *Ichthyosaurus*, a creature with a fish-like body, two pairs of strong swimming paddles, and probably a vertical tail-fin. The head, joined to the body without any distinct neck, was furnished with two large eyes, having a ring of bony plates round the eyeball, and with teeth that had no distinct sockets. Some of the skeletons of this creature exceed 24 feet in length. Contemporaneous with it was the *Plesiosaurus*, distinguished by its long neck, the larger size of its paddles, the smaller size of its head, and the insertion of its teeth in special sockets, as in the higher saurians. These creatures seem to have haunted the shallow seas of the Liassic time. There were also huge winged bat-like reptiles (*Dimorphodon*), with large heads, having teeth in distinct sockets, eyes like the *Ichthyosaurus*, and one finger of each fore foot prolonged to a great length, for the purpose of supporting a membrane for flight. The bones, like those of birds, were hollow and air-filled. Gigantic deinosaurs were likewise among the inhabitants of Britain during Liassic time. These were true reptiles, yet with peculiarities of structure, particularly in the hinder part of the skeleton, linking them with birds like the ostrich. To this order belongs the *Megalosaurus* from the Lias of Lyme Regis. Lastly, the true crocodiles had representatives in the Liassic waters and shores, in the genera *Teleosaurus* and *Steneosaurus*.

The Lower or Bath Oolites lie conformably upon the top of the Lias, with which they are connected by a general similarity of organic remains. Out of the 312 known species in the Upper Lias, about 39 or 40 pass up into the overlying formation. The lowest of the three subdivisions of the English Oolites consists in the south-west and centre of England of shelly marine limestones, with clays and sandstones; but, as these strata are traced northwards into Northampton, Rutland, and Lincolnshire, they pass into a series of strata indicative of deposit in the estuary of some river descending from the north, for, instead of the abundant cephalopods of the truly marine and typical series, we meet with fresh-water genera such as *Cyrena* and *Unio*, with marine forms such as *Ostrea* and *Modiola*, thin seams of lignite, and remains of terrestrial plants. These indications of the proximity of land become still more marked in Yorkshire, where the strata (800 feet thick) consist chiefly of sandstones, shales with seams of ironstone and coal, and occasional horizons containing marine shells. It is deserving of notice that the Cornbrash, which forms the top of the Lower Oolite in the typical Gloucestershire district, occurs likewise in the same position in Yorkshire. Though rarely more than 8 feet thick, it runs across the country from Devonshire to Yorkshire. Thus a distinctly defined series of beds of an estuarine character, exactly representative of the marine formations of the south-west, shows us that at the close of the Lower Oolitic period the estuary of the northern tract was submerged, and a continuous sea-floor stretched across the whole of the south-east of England.

Thanks to the deposits of the Yorkshire estuarine series our knowledge of the Oolitic is much more ample than of the Liassic flora. With the exception of a few littoral fucoids all the plants are of terrestrial forms. They comprise about 60 species of ferns, among which the genera *Pecopteris*, *Sphenopteris*, *Phlebopteris*, and *Tæniopteris* are characteristic. Next in abundance come the cycads, of which more than 20 species are known, belonging to the genera *Otozamites*, *Zamites*, *Pterophyllum*, and *Cycadites*. Coniferous remains are not infrequent in the form of stems or fragments of wood, as well as in occasional twigs with attached leaves; the genera *Araucarites*, *Brachyphyllum*, *Thuytes*, *Peuce*, *Walchia*, *Cryptomerites*, and *Taxites* have been recognized. The Inferior Oolite presents a tolerably copious suite of invertebrate remains, which resemble generically those of the Lias. The predominance of *Rhynchonella* and *Terebratula* over the rest of the brachiopods becomes still more marked. *Gryphæa*, *Lima*, *Pecten*, *Cardium*, *Myacites*, *Mytilus*, *Pholadomya*, *Trigonia* are frequent shells, while ammonites and belemnites also occur, though much more sparingly than in the Lias below, and in some of the later subdivisions of the Oolitic series. The Fuller's Earth, though well-marked in the Bath district, where it is about 200 feet thick, dies out in Oxfordshire, and contains only a few distinctive fossils, most of its forms being also found in the Inferior Oolite.

The Great or Bath Oolite consists, in Gloucestershire and Oxfordshire, of three groups of strata. At the base comes a series of thin-bedded limestones with sands, known as the Stonesfield Slate; in the centre lies a mass of shelly and yellow or cream-coloured often Oolitic limestones, with partings of marl or clay—the Great Oolite; while at the top lies a set of clays and shelly limestones, including the Bradford Clay, Forest Marble, and Cornbrash. The Stonesfield Slate, the lowest of these three zones, is a local but exceedingly important subdivision, which has furnished a large number of reptilian and some mammalian remains. It must have been deposited in shallow water close to thickly wooded shores.

About a dozen species of ferns have been found in the Stonesfield Slate, the genera *Pecopteris*, *Sphenopteris*, and *Tæniopteris* being still the prevalent forms. The cycads are chiefly species of *Palæozamia*, the conifers of *Thuytes*. With these drifted fragments of a terrestrial vegetation there occur remains of beetles, dragon-flies, and other insects which had been blown or washed off the land. The waters were tenanted by a few brachiopods (*Rhynchonella* and *Terebratula*), by lamellibranchs (*Gervillia*, *Lima*, *Ostrea*, *Pecten*, *Astarte*, *Modiola*, *Trigonia*, &c.), by gasteropods (*Natica*, *Nerita*, *Patella*, *Trochus*, &c.), by a few ammonites and belemnites, and by placoid and ganoid fishes, of which about 50 species are known. The reptiles comprise representatives of turtles, with peculiar species of *Ichthyosaurus* and *Plesiosaurus*. The genus *Teleosaurus*, which occurs in the Yorkshire Lias, is among the organisms of the Stonesfield Slate. It was a true carnivorous crocodile, measuring about 18 feet in length, and is judged by Phillips to have been in the habit of venturing more freely to sea than the gavial of the Ganges and the crocodile of the Nile. The huge deinosaur *Megalosaurus* frequented the shores of the Stonesfield lagoons, walking probably on its massive hind legs, and feeding on the mollusks, fishes, and perhaps the small mammals of the district. It is estimated to have had a length of 25 feet, and to have weighed 2 or 3 tons. The flying reptiles were likewise represented by the *Rhamphorynchus*,—a harpy-like creature which was able to fly, to shuffle on land, or perch on rocks, perhaps even to dive in search of its prey. But the most important organic remains of the Stonesfield Slate are undoubtedly its mammalia, of which three genera *Amphitherium*, *Phascolotherium*, and *Stereognathus* have been determined. Only portions of lower jaws have yet been found, pointing doubtless to the fact that, as the animals were drifted from land, the lower jaws, unprotected by outer skin, were separated in decomposition from the rest of the body. These interesting relics were the first traces of mammalian life found in strata of such high antiquity. They are regarded as having belonged to small marsupial animals, to which living analogues exist in Australia. In the Great Oolite the remains of a gigantic saurian *Cetiosaurus* have been found. According to Phillips it was probably, when standing, not less than 10 feet in height and 50 feet in length, a marsh-loving or river-side animal, living on the ferns, cycads, and conifers among which it dwelt.

In the MIDDLE or OXFORD OOLITES, the Oxford Clay, so called from the name of the county through which it passes in its course from the coast of Dorsetshire to that of Yorkshire, consists mainly of layers of stiff blue and brown clay. In its lower portion lies a marked zone of calcareous abundantly fossiliferous sandstone, known, from a place in Wiltshire, as the Kelaways Rock, which, after dying out in the midland counties, reappears on the Yorkshire coast. This zone contains about 150 species of fossils, of which nearly a half are found in lower parts of the Jurassic series, and about the same number pass upward into higher zones.

Among its characteristic forms is *Ammonites Calloviensis.* The Oxford clay, from the nature of its material and the conditions of its deposit, is deficient in some forms of life which were no doubt abundant in neighbouring areas of clearer water. Thus there are hardly any corals, few echinoderms, polyzoa, or brachiopods. Some lamellibranchs are abundant, particularly *Gryphæa* and *Ostrea* (both forming sometimes wide oyster-beds), *Lima, Avicula, Pecten, Astarte, Trigonia*—the whole having a great similarity to the assemblages in the Lower Oolite formations. The gasteropods are not so numerous as in the calcareous beds below, but belong mostly to the same genera. The ammonites are numerous,—*A. Duncani, A. Jason, A. Lamberti,* and *A. oculatus* being characteristic. Of the belemnites, which also are frequent, *B. hastatus* is found all the way from Dorsetshire to Yorkshire. Spines and teeth of placoid fishes and entire specimens of *Lepidotus* are occasionally to be met with. The reptiles, besides *Ichthyosaurus, Megalosaurus, Plesiosaurus* (4 species), *Steneosaurus,* and *Rhamphorhynchus,* comprise also *Pleiosaurus*—a marine saurian with large head, short neck, paddles similar to those of Plesiosaurus, approaching the type of the ichthyosaurians, but even surpassing them in size.

The Coralline Oolite can likewise be traced, with local modifications and partial interruptions, across England from Yorkshire to Dorsetshire. It is named from its beds full of masses of coral. It consists of three zones,—a lower calcareous grit, a central rubbly limestone with corals (the true "coral rag" of William Smith), and an upper calcareous grit, which, though feebly represented further south, attains importance in Yorkshire. It is frequently entirely made up of comminuted shells, urchins, corals, and other marine organisms. The corals include the genera *Isastræa, Thamnastræa,* and *Thecosmilia.* The urchins belong to *Cidaris, Hemicidaris, Pigurus, Pigaster,* and other genera. There are likewise *Ammonites, Belemnites,* and *Nautili.*

The UPPER or PORTLAND OOLITES bring before us the closing epochs of the long Jurassic period in England, with the records of some of the physical revolutions which led to this change. At their base lies the Kimeridge Clay, so named from the locality on the coast of Dorsetshire where it is so well exhibited, and whence it is traceable continuously, save where covered by the Chalk, into Yorkshire. Like the Oxford Clay below, it is distinguished by its thickness, persistence, and peculiar organic remains.

Mollusca appear in greatly diminished variety; *Gryphæa virgula, Ostræa deltoidea, Astarte Hartwellensis,* and *Cardium striatulum* are characteristic species. The reptiles are the most important of the palæontological contents of this zone. They include remains of turtles, 5 species of *Ichthyosaurus,* 5 of *Pleiosaurus,* 8 of *Plesiosaurus, Cœteosaurus, Megalosaurus,* and the crocodilians *Steneosaurus, Teleosaurus,* and *Goniopholis.*

The Portland beds are so named from the isle of Portland, where they directly succeed the Kimeridge Clay. A feeble representative of them is believed to overlie that clay on the Yorkshire coast, but it is in the southern counties that they attain their chief development. They consist, at Portland, of a lower sandy set of beds about 150 feet thick, and of an upper calcareous zone (containing the well-known limestone so largely used for building purposes under the name of Portland stone) about 70 feet thick.

The fossils, which very commonly occur as mere empty casts, include as characteristic species *Isastræa oblonga, Cardium dissimile, Trigonia gibbosa,* and *Terebra Portlandica.* There occur also remains of some of the great Oolitic saurians.

The Purbeck beds, so named from the Isle of Purbeck, where they are best developed, are usually connected with the foregoing formations as the highest zone of the Jurassic series of England. But they are certainly separated from the rest of that series by many peculiarities, which show that they were accumulated at a time when the physical geography and the animal and vegetable life of the region were undergoing a remarkable change.

They have been arranged in three groups. The lowest consists of fresh-water limestones and clays, with layers of ancient soil containing stumps of the trees which grew in them. The middle group comprises about 130 feet of strata with marine fossils, while the highest division shows a return of fresh-water conditions. Among the indications of the presence of the sea is an oyster bed (*Ostrea distorta*) 12 feet thick, with *Pecten, Modiola, Avicula, Thracia,* &c. The fresh-water bands contain still living genera of lacustrine and fluviatile shells—*Paludina, Limnæa, Planorbis, Physa, Valvata, Unio,* and *Cyclas.* Numerous fishes, both placoid and ganoid, haunted these Purbeck waters. Many insects, blown off from the adjacent land, sank and were entombed and preserved in the calcareous mud. These include coleopterous, orthopterous, hemipterous, neuropterous, and dipterous forms. Remains of several reptiles, chiefly chelonian, but including the Jurassic crocodile *Goniopholis,* have also been discovered. But the most remarkable organic remains of the Purbeck beds are those of 10 genera and 25 species of marsupial mammals, from the size of a mole to that of a polecat. They are believed to have been mostly insectivorous. One of them (*Triconodon major*) is regarded by Owen as carnivorous, and probably about the size of the existing *Dasyurus maugei* of Australia. These mammalian remains occur, almost wholly as lower jaws, in a stratum about 5 inches thick lying near the base of the Middle Purbeck group.

CONTINENTAL EUROPE.—Jurassic rocks cover a vast area in central Europe. They rise from under the Cretaceous formations in the north-east of France, whence they range southwards down the valleys of the Saone and Rhone to the Mediterranean. They appear as a broken border round the old crystalline nucleus of Auvergne. Eastwards they range through the Jura Mountains up to the high grounds of Bohemia. They appear in the outer chains of the Alps on both sides, and on the south they rise along the centre of the Apennines, and here and there over the Spanish peninsula. Covered by more recent formations they underlie the great plain of northern Germany, whence they range eastwards and occupy large tracts in central and eastern Russia. According to Neumayr, three distinct geographical regions of deposit can be made out among the Jurassic rocks of Europe. (1.) The Mediterranean province, embracing the Pyrenees, Alps, and Carpathians, with all the tracts lying to the south. One of the biological characters of this area was the great abundance of ammonites belonging to the groups of *Heterophylli* (*Phylloceras*) and *Fimbriati* (*Lytoceras*). (2.) The central European province, comprising the tracts lying to the north of the Alpine ridge, and marked by the comparative rarity of the ammonites just mentioned, which are replaced by others of the groups *Inflati* (*Aspidoceras*) and *Oppellia,* and by abundant reefs and masses of coral. (3.) The boreal or Russian province, comprising the middle and north of Russia, Spitzbergen, and Greenland. The life in this area was much less varied than in the others, showing that in Jurassic times there was a perceptible diminution of temperature towards the north. The ammonites of the more southern tracts here disappear, together with the corals.

In France the following arrangement has been made of the Jurassic rocks, the subdivisions nearly corresponding to those first proposed in England:—

(Purbeck beds not recognized.)
Terrain Portlandien (Calcaire tacheté de Boulogne).
,, Kimeridgien (Argile de Honfleur).
,, Corallien (Calcaire Corallien).
,, Oxfordien (Oolithe de Trouville).
,, Callovien (Argiles de Dives = Kelaways Rock).
,, Bathonien (Oolithe de Caen = Cornbrash, Terre à foulon).
,, Bajocien ou Oolithe Inférieure (Oolithe de Bayeux).
,, Toarcien (Marnes Liasiques supérieure = Upper Lias).
,, Liasien (Marnes et calcaires à Belemnites = Middle Lias).
,, Sinémurien (Calcaire à Gryphées = Lower Lias).

In north-western Germany the subjoined classification has been adopted.

Upper or White Jura (Malm).		Purbeck group (Serpulit, Münder Mergel, and Eimbeckhäuser Plattenkalk).
		Kimeridge group (Upper, with *Ammonites gigas* and *Exogyra virgula*; Lower or Nerinceu-Schichten).
		Oxford group (Upper, with *Cidaris florigemma*: Lower, with *Gryphæa dilatata*).
Middle or Brown Jura (Dogger).	Upper	Clays with *Ammonites ornatus.*
		Shales with *Amm. macrocephalus.*
		Cornbrash with *Avicula echinata, Amm. posterus.*
		Shales with *Ostrea Knorri, Amm. ferrugineus.*
		Zone of *Amm. Parkinsoni.*
	Middle	Coronaten-Schichten, clays with *Belemnites giganteus, Amm. Humphresianus, Amm. Braikenridgi.*
	Lower	Shales with *Inoceramus polyplocus, Amm. Murchisonæ.*
		Clays and limestones with *Amm. opalinus.*
Lower or Black Jura (Lias).	Upper	Grey marls with *Ammonites jurensis.*
		Bituminous shales (Posidonien-schiefer) with *Amm. lythensis, A. communis, A. bifrons, Posidonia Bronni.*
	Middle	Clays with *Amm. amalthea.*
		Marls and limestones with *Amm. capricornus.*
		Dark clays and ferruginous marls with *Amm. brevispina.*
	Lower	Clays with *Amm. planicosta.*
		Blue grey clays with *Amm. Bucklandi* (Arieten-schichten).
		Dark clays with *Amm. angulatus.*
		Dark clays and sandy layers with *Amm. planorbis* (*psilonotus*).

North America.—So far as yet known rocks of Jurassic age play but a very subordinate part in North Amercian geology. Perhaps some of the red strata of the Trias belong to this division, for it is difficult, owing to paucity of fossil evidence, to draw a satisfactory line between the two systems. Strata containing fossils believed to represent those of the European Jurassic series have been met with in recent years during the explorations in the western domains of the United States. They occur among some of the eastern ranges of the Rocky Mountains, as well as on the western side of the watershed. They have been recognized also far to the north beyond the great region of Azoic and Palæozoic rocks in the arctic portion of the continent. They consist of limestones and marls, which appear seldom to exceed a few hundred feet in thickness. The fossils include species of *Pentacrinus, Monotis, Trigonia, Lima, Ammonites,* and *Belemnites.*

Cretaceous.

The next great series of geological formations is termed the Cretaceous system, from the fact that in England and western Europe one of its most important members is a thick band of white chalk (*creta*).

Britain.—The Purbeck beds bring before us evidence of a great change in the geography of England towards the close of the Jurassic period. They show how the floor of the sea in which the thick and varied formations of that period were deposited came to be gradually elevated, and how into pools of fresh and brackish water the leaves, insects, and small marsupials of the adjacent land were washed down.

These evidences of terrestrial conditions are followed in the same region by a vast delta-formation, that of the Weald, which accumulated over the south of England, while the older parts of the Cretaceous system were being deposited in the north. Hence there are two types of that system, one where the strata are fluviatile or estuarine, termed the Wealden type, the other where they are marine, known as the Neocomian type. Arranged in descending order the following are the subdivisions of the English Cretaceous rocks:—

Upper Cretaceous.	Chalk	Upper Chalk with flints ... Lower Chalk without flints; Chalk Marl (Grey Chalk); Chloritic Marl	..........600 to 1200 ft.
	Upper Greensand	Greenish-grey sandstones and sands	40 ,, 150 ,,
	Gault.	Stiff blue clay with calcareous and pyritous nodules......	100 ,, 150 ,,

Lower Cretaceous or Neocomian. Fluviatile Type.	Marine Type.		
Weald Clay, 1000 ft.	Upper.	Lower Greensand. Folkstone beds.	70 to 100 ft
Hastings beds consisting of—Tunbridge Wells Sand (140-380 ft);		Sandgate beds ..	75 ,, 100 ,,
Wadhurst Clay (120-180 ft);		Hythe beds......	80 ,, 300 ,,
Ashdown Sand (400 or 500 ft).		Atherfield clay.	20 ,, 60 ,,
		Upper part of Speeton Clay......	150 ,,
	Middle.	Punfield beds, Tealby beds, and middle part of Speeton Clay............	150 ,,
	Lower.	Lower part of Speeton Clay......	200 ,,

Lower Cretaceous or Neocomian.—The fluviatile development of this series in the south of England consists of a great depth of sands and clays known generally as the Wealden series, from the Weald of Sussex and Kent, where they are best displayed.

They precisely resemble the deposits of a delta, and this is borne out by their organic remains, which consist partly of terrestrial plants (*Equisetum, Sphenopteris, Alethopteris, Thuytes,* cycads, and conifers), and fresh-water shells (*Unio,* 10 species; *Cyrena,* 5 species; with *Cyclas, Paludina, Melania,* &c.), with a few estuarine or marine forms as *Ostrea* and *Mytilus,* and ganoid fishes (*Lepidotus*) like the gar of American rivers. Among the spoils of the land floated down by this river were the carcases of huge deinosaurian reptiles (*Iguanodon, Hylæosaurus, Megalosaurus*), of the long necked plesiosaurs, and of winged pterodactyles. The deltoid formation in which these remains occur extends in an east and west direction for at least 200 miles, and from north to south for at least 100. Hence the delta must have been not less than 20,000 square miles in area. It has been compared with that of the Quorra; in reality, however, its extent must have been greater than its present visible area, for it has suffered from denudation, and is to a large extent concealed under more recent formations. The river probably descended from the north-west, draining a vast area, of which the existing mountain groups of Britain are perhaps merely fragments.

The marine type of the Lower Cretaceous rocks is now commonly termed Neocomian, from Neufchâtel (*Neocomum*), where it is well developed. In the south of England only the upper division appears, overlying conformably the Wealden series, and showing the gradual depression of the old delta and the advance of the sea. In Yorkshire, however, a thick deposit known as the Speeton Clay has been ascertained by Mr Judd to pass down into the Jurassic system, and to contain a representation of the upper parts of the Neocomian of the Continent.

The lower division of the Speeton Clay contains, among other fossils, *Ammonites Noricus.* The central zone is marked by *Pecten cinctus, Ancyloceras Duvallii,* and *Meyeria ornata.* The upper division is characterized by *Perna Mulleti, Ammonites Deshayesii, Pecten orbicularis.* It is the fossils of this upper division which occur in the Lower Greensand of Kent. They amount to about 300 species, of which only 18 or 20 per cent. pass up into the Upper Cretaceous. This marked palæontological break, taken in connexion with traces of unconformability between the Lower Greensand and the Gault, shows that a definite geological boundary-line can be drawn between the lower and upper parts of the Cretaceous system.

Upper Cretaceous.—At the base of this series lies the Gault—a dark blue stiff clay or marl, sometimes sandy and calcareous. It overlaps the older parts of the Cretaceous series, and in Wiltshire lies on Kimeridge Clay. Among the characteristics fossils of this division are *Cyclocyathus Fittoni, Caryophilia Bowerbankii, Nucula pectinata, Inoceramus sulcatus, Natica Gaultina, Rostellaria carinata, Ammonites dentatus,* and *Hamites attenuatus.* In all, about 200 species of fossils occur, of which about 46 per cent. pass into up into the Upper Greensand.

The Gault is overlaid by a group of sands and sandstones often of a greenish tint from the presence of glauconite grains. Hence the name Upper Greensand which is applied to them. These strata can be traced westwards into Devonshire, and eastwards to the headlands of Kent, but they die out towards the north. Their mineralogical characters and variable thickness seem to point to them as deposits of the shore of the sea in which the chalk was subsequently laid down upon them.

Among their characteristic fossils are the sponges *Siphonia pyriformis* and *S. costata*; urchins of the genera *Cidaris*, *Echinus* and *Salenia*; numerous *Terebratulæ* and *Rhynchonellæ*; many lamellibranchs, particularly of the genera *Exogyra*, *Ostrea*, *Gryphæa*, *Lima*, *Pecten*, and *Trigonia*; and gasteropods of the genera *Natica*, *Turritella*, and others. The cephalopods abound and comprise many forms of *Ammonites* (40 species), *Hamites*, *Scaphites*, *Baculites*, *Nautilus*, and *Belemnites*.

Chalk.—This conspicuous member of the Cretaceous system has at its base a white or pale yellow marl with green grains of glauconite, phosphatic nodules, and iron pyrites (Chloritic Marl), which is succeeded sometimes by a kind of argillaceous chalk (Chalk Marl) forming the base of the true Chalk. It can be traced from Flamborough Head in Yorkshire across the south-eastern counties to the coast of Dorset. Throughout this long course its western edge usually rises somewhat abruptly from the plains as a long winding escarpment, which from a distance often reminds one of an old coast-line. The upper half of the Chalk is generally distinguished by the presence of many nodular layers of flint. With the exception of these enclosures, however, the whole formation is a remarkably pure white pulverulent dull limestone, meagre to the touch, and soiling the fingers. It is composed mainly of crumbled foraminifera, with the mingled debris of urchins, corals, and mollusks. It must have been accumulated in a sea of some depth and tolerably free from sediment, like some of the foraminiferal ooze of the existing sea-bed. There is, however, no evidence that the depth of the water at all approached that of the abysses in which the present Atlantic globigerina-ooze is being laid down. Indeed, the character of the foraminifera, and the variety and association of the other organic remains, are not like those which have been found to obtain now on the deep floor of the Atlantic.

Somewhere about 800 species of fossils are known from the English Chalk. Occasional rare fragments of terrestrial wood occur, perforated by the teredo, and telling of a transport of some distance from land. Sponges are numerous. They have usually been silicified and preserved in the flint nodules. Among the more characteristic genera are *Choanites*, *Cliona*, *Ventriculites*, *Brachiolites*, *Spongia*, and *Siphonia*. Careful preparation of a fragment of chalk usually brings to light remains, sometimes well preserved, of foraminifera (*Rotalina ornata*, *Cristellaria rotulata*, *Globigerina bulloides*). Corals are represented by about 15 species (*Parasmilia*, *Cœlosmilia*, *Caryophyllia*, &c.). The echini form one of the most conspicuous features among the Chalk fossils, from their individual numbers and their variety of forms. Among the more common genera the following may be named—*Ananchytes*, *Echinoconus* (*Galerites*), *Cardiaster*, *Micraster*, *Cyphosoma*, *Cidaris*, *Pseudodiadema*, *Discoidea*, and *Salenia*. Among other star-fishes the genus *Goniaster* occurs in numerous species in the upper division of the Chalk. The crinoids were represented in the sea of the period by a *Comatula*, one or two *Pentacrinites*, *Marsupites*, and *Bourgueticrinus*. Polyzoa abound in the Upper Chalk (*Homæosolen*, *Pustulopora*, *Holostoma*, &c.). The brachiopods appear in the form of great numbers of *Rhynchonella*, *Terebratula*, and *Terebratulina*, with *Crania*, *Thecidea*, and *Kingena*. Among the lamellibranchs the genera *Ostrea*, *Pecten*, *Inoceramus*, and *Lima* are particularly frequent. Gasteropods are comapratively few, *Pleurotomaria perspectiva* being one of the few forms found both in the lower and upper division of the Chalk. Cephalopods however, abound; characteristic species are *Belemnitella plena*, *B. mucronata*, *Nautilus Deslongchampsianus*, *Ammonites navicularis*, *A. varians*, *A. Rothomagensis*, *Turrilites costatus*, *Baculites baculoides*. *Scaphites æqualis*, and *Hamites armatus*. Upwards of 80 species of fish have been discovered. These include chimæroids (*Edaphodon*, *Ischyodus*), sharks (*Hybodus*, *Ptychodus*, *Lamna*, *Otodus*), ganoids (*Macropoma*, *Pycnodus*), and teleosteous or bony fishes (*Beryx*, *Enchodus*, *Saurocephalus*). Numerous reptilian remains have been found, more particularly in a bed about 1 foot thick lying at the base of the Chalk of Cambridge, and largely worked for phosphate of lime derived from reptilian coprolites and bones. Among the known forms are several chelonians, the great deinosaur *Acanthopholis*, several species of *Plesiosaurus*, 5 or 6 species of *Ichthyosaurus*, 10 species of *Pterodactylus* from the size of a pigeon upwards, one of them having a spread of wing amounting perhaps to 25 feet, 3 species of *Mosasaurus*, a crocodilian (*Polyptychodon*), and some others. At Cambridge also the bones of one or two species of birds have been found, probably belonging to *Natatores* allied to the living gulls.

CONTINENTAL EUROPE.—The Cretaceous system in many detached areas covers a large extent of the Continent. From the south of England it spreads southward across the north of France up to the base of the ancient central plateau of that country. Eastwards it ranges beneath the Tertiary and post-Tertiary deposits of the great plain, appearing on the north side at the southern end of Scandinavia and in Denmark, on the south side in Belgium and Hanover, round the flanks of the Harz, in Bohemia and Poland, eastwards into Russia, where it covers many thousand square miles up to the southern end of the Ural chain. To the south of the central axis in France, it underlies the great basin of the Garonne, flanks the chain of the Pyrenees on both sides, spreads out largely over the eastern side of the Spanish table-land, and reappears on the west side of the crystalline axis of that region along the coast of Portugal. It is seen at intervals along the north and south fronts of the Alps, extending down the valley of the Rhone to the Mediterranean, ranging along the chain of the Apennines into Sicily and the north of Africa, and widening out from the eastern shores of the Adriatic through Greece, and along the northern base of the Balkans to the Black Sea, round the southern shores of which it ranges in its progress into Asia, where it again covers an enormous area.

A series of rocks covering so vast an extent of surface must needs present many differences of type, alike in their lithological characters and in their organic contents. They bring before us the records of a time when one continuous sea stretched over all the centre with most of the south of Europe, covered the north of Africa, and swept eastwards to the far east of Asia. There were doubtless many islands and ridges in this wide expanse of water, whereby its areas of deposit and biological provinces must have been more or less sharply defined. Some of these barriers can still be traced, as will be immediately pointed out.

The accompanying table contains the subdivisions of the Cretaceous system which have been adopted in a few of the more important areas of Continental Europe.

It will be seen from this table that while there is sufficient palæontological similarity to allow a general parallelism to be drawn among the Cretaceous rocks of western Europe, there are yet strongly marked differences pointing to very distinct conditions of life, and probably, in many cases, to disconnected areas of deposit. Nowhere can these contrasts be more strikingly seen than in crossing from the Cretaceous basin of the Loire to that of the Garonne. In the north of France the Upper Cretaceous beds are precisely like those of England, the soft white Chalk forming a conspicuous feature in both countries; but, on the south side of the great axis of crystalline rocks, the soft chalk is replaced by hard limestones. There is a prevalence of calcareous matter, often sparry, throughout the whole series of formations, with comparatively few sandy or clayey beds. This mass of limestone attains its greatest development in the southern part of the department of the Dordogne, where it is said to be about 800 feet thick. But the lithological differences are not greater than those of the fossils. In the north of France, Belgium, and England, the singular molluscan family of the *Hippuritidæ* or *Rudistes* appears only occasionally and sporadically in the Cretaceous rocks, as if a stray individual had from time to time found its way into the region, but without being able to establish a colony there. In the south of France, however, the hippurites occur in prodigious quantity. They often mainly compose the limestones, hence called hippurite limestones (Rudisten-Kalke). They attained a great size, and seem to have grown on immense banks like our modern oyster. They appear in successive species on the different stages of the Cretaceous system, and can be used for marking palæontological horizons, as the cephalopods are elsewhere. But while these lamellibranchs played so important a part throughout the Cretaceous period in the south of France, the numerous ammonites and belemnites, so characteristic of the Chalk in England, were absent from that region. This very distinctive type of hippurite limestone has so much wider an extension than the English type of the Cretaceous system that it should be regarded as really the normal development. It ranges through the Alps into Dalmatia, and round the great Mediterranean basin far into Asia. Gümbel has proposed to group the European Cretaceous rocks into three great regions :—(1) the northern province, or area of white chalk with *Belemnitella*,

Table showing the Subdivisions of the Cretaceous System in the West of Europe.

	England.	Northern France.	North-West Germany and Denmark.	Southern France.
Senonian.		Danien, Craie supérieure et calcaire pisolitique (p. 360).	Faxoe chalk. Maestricht chalk (p. 360).	
Senonian.	Upper Chalk with flints.	Craie blanche (*Belemnitella mucronata*). Craie (*Belemnitella quadratas*).	Oberquadersandstein (*Belemnitella mucronata, &c.*)	Calcaires à rudistes (*Radiolites*)
Senonian.	Lower Chalk without flints.	Craie (*Micraster cor-anguinum*).	Oberquadersandstein (*Micraster cor-anguinum*).	
Turonian.	Chalk Marl.	Craie marneuse.	Mittelquader. Mittelpläner (*Inoceramus Cuvieri* and *I. labiatus*)	Calcaires à *Hippurites cornu-vaccinum*, et à *Radiolites cornu-pastoris*.
Turonian.	Chloritic Marl	Craie glauconieuse		Calcaires marneux (*Inoceramus labiatus*).
Cenomanian.	Upper Greensand.	Grès vert supérieur	Unterquader, Unterpläner (*Ammonites Rotomagensis*, *A. varians*).	Calcaires à *Caprotina triangularis*, et à *Ammonites Rotomagensis*
Gault.	Gault.	Albien, argile marneuse ou sableuse. Aptien, argiles à plicatules. Urgonien.	Flammenmergel (*Avicula gryphæoides*). Clay (*Belemnites minimus*). Marls, &c. *Ammonites tardefurcatus*, *Belemnites Ewaldi*) Clays (*Belemnites Brunsvicensis*). *Ancyloceras* beds.	Albien, sables et grès verts ou ferrugineux à *Turrilites*. Aptien (*Orbitulina lenticularis*). Calcaire à caprotines
Neocomian or Hils.	Lower Greensand.	Argiles ostréennes (*Exogyra subplicata*, *Ostrea Leymerii*).	Hils clay (Hilsthon) with *Ammonites Noricus*, &c.	Néocomien supérieur (*Toxoceras complanatus*), calcaire à *Spatangus*.
Neocomian or Hils.	Weald Clay and Hastings Sand. — Punfield and Tealby beds and middle part of Speeton Clay.	Calcaires néocomiens et marnes bleues (*Toxaster complanatus*).	Hils conglomerate (*Toxoceras complanatus*, *Rhynchonella depressa*). — Weald clay (*Melania*, *Cyrena*).	Néocomien moyen, calcaire à *Aptychus*.
Neocomian or Hils.	Weald Clay and Hastings Sand. — Lower part of Speeton Clay.	Sable blanc et ferrugineux.	Deistersandstein with coal seams.	Néocomien inférieur (*Toxoceras Campechei*).

comprising England, northern France, Belgium, Denmark, Westphalia; (2) the Hercynian province, or area of *Exogyra columba*, embracing Bohemia, Moravia, Saxony, Silesia, and central Bavaria; and (3) the southern province, or area of hippurites, including the regions south of the crystalline axis of France, the Alps, and southern Europe.

The Wealden beds, with the Hastings Sands and Weald Clay, are found in north-west Germany. They contain abundant remains of terrestrial vegetation, which is sometimes aggregated into thin seams of black glancing coal, occasionally even as much as 6½ feet thick. The marine or typical Neocomian series attains a great development among the eastern Alps, where it consists mainly of massive white and grey limestones, divided into zones according to their characteristic fossils. Some geologists place in it a part of the massive Vienna sandstone (Wiener Sandstein) which enters so largely into the structure of the outer Alps. The massive arenaceous formation formerly massed together under the general name of Quader-sandstein, but now found to be the equivalent of the calcareous bands of other regions, and capable of subdivision into the chief normal groups, forms a conspicuous feature in Saxony and Bohemia, as in the great gorge of the Elbe and the picturesque crags and pinnacles of Saxon Switzerland. From the Upper Cretaceous beds, in the neighbourhood of Aix-la-Chapelle, consisting of white sands and laminated clays 400 feet thick, a large number of terrestrial plants have been obtained. The number of species is estimated at more than 400. Of these 70 or 80 are cryptogams, chiefly ferns (*Gleichenia*, *Lygodium*, *Asplenium*, &c.); there are numerous conifers (some akin to *Sequoia*), and three or four kinds of screw-pine (*Pandanus*). This flora has a much more modern aspect than any other yet found in Secondary formations. But its most important feature is the occurrence of numerous true exogenous plants—the earliest yet found in Europe. The prevalent forms are *Proteaceæ*, many of them being referred to genera still living in Australia or at the Cape of Good Hope. There occur also species of oak, bog-myrtle, &c. These interesting fragments serve to indicate the modern character of the flora of Europe towards the close of the Cretaceous period, and to show that the climate, doubtless greatly warmer than that which now prevails, nourished a vegetation like that of some parts of Australia or the Cape. Further information has been afforded regarding the extension of this flora by the discovery in North Greenland of a remarkable series of fossil plants. From certain Lower Cretaceous beds of that Arctic region Heer has described 30 species of ferns, 9 cycads, and 17 conifers while, from the Upper Cretaceous rocks of Noursoak, he enumerate species of poplar, fig, sassafras, credneria, and magnolia.

North America.—The recent surveys of the western territories of the United States have greatly increased our knowledge of the Cretaceous system on the American continent, where it is now known to cover a vast expanse of surface, and to reach a thickness of sometimes 10,000 feet. Sparingly developed in the eastern States, from New Jersey into South Carolina, it spreads out over a wide area in the south, stretching round the end of the long Palæozoic ridge from Georgia through Alabama and Tennessee to the Ohio; and reappearing from under the Tertiary formations on the west side of the Mississippi over a large space in Texas and the south-west. Its maximum development is reached in the western States and Territories of the Rocky Mountain region—Wyoming, Utah, and Colorado. Cretaceous rocks have likewise been detected in Arctic America near the mouth of the Mackenzie River.

Much controversy has been carried on among American geologists regarding the upper limit of the Cretaceous system, some maintaining, from the character of the plants and of the shells, that the great plant-bearing series termed the Lignitic is of Tertiary age, others insisting, from the occurrence of true Cretaceous shells in and above the Lignitic series, that it must belong to the Cretaceous system. In the Upper Missouri region Hayden and Meek established the following subdivisions :—

5. Fox Hills group.—Sandstones and sandy clays (*Belemnitella*, *Nautilus*, *Ammonites*, *Baculites*, *Mosasaurus*, &c.) .... 500 ft.
4. Fort Pierre group.—Plastic clays (*Ammonites*, *Scaphites*, *Inoceramus*, &c.) .... 700 ,,
3. Niobrara group.—Calcareous marl (*Ostrea congesta*, *Inoceramus problematicus*, fish remains), ... 200 ,,
2. Fort Benton group.—Clays and limestones (*Scaphites*, *Ammonites*, *Pholadomya*, &c.) .... 800 ,,
1. Dakotah group.—Sandstones, clays, and seams of lignite, with vast numbers of dicotyledonous leaves; a few marine shells. This is the great repository of the Cretaceous flora .... 400 ,,

American Cretaceous fossils include the earliest dicotyledonous plants yet found on this continent, upwards of 100 species having been found, of which one-half were allied to living American forms. Among them are species of oak, willow, poplar, beech, maple, hickory, fig, tulip-tree, sassafras, sequoia, American palm (*Sabal*), and cycads. The more characteristic mollusca are species of *Terebratula*, *Ostrea*, *Gryphæa*, *Inoceramus*, *Hippurites*, *Radiolites*, *Ammonites*, *Scaphites*, *Hamites*, *Baculites*, *Belemnites*, *Ancyloceras*, and *Turrilites*. Of the fishes of the Cretaceous seas 97 species are known, comprising large predaceous representatives of modern or osseous types like the salmon and saury, though cestracionts and ganoids still flourished. But the most remarkable feature in the American Cretaceous fauna, as at present known, is the great number, variety, and size of the reptiles. According to the enumeration of Cope, who includes, however, in his list the Lignitic group here placed among the Tertiary formations, there are known at present 18 species of deinosaurs, 4 pterosaurs, 14 crocodilians, 13 sauropterygians or sea-saurians, 48 testudinates (turtles, &c.), and 50 pythonomorphs or sea-serpents. One of the most extraordinary of these reptilian forms was the *Elasmosaurus*—a huge snake-like form 40 feet long, with slim arrow-shaped head on a swan-like neck rising 20 feet out of the water. This formidable sea-monster "probably often swam many feet below the surface, raising the head to the distant air for a breath, then withdrawing it and exploring the depths 40 feet below without altering the position of its body. It must have wandered far from land, and that many kinds of fishes formed its food is shown by the teeth and scales found in the position of its stomach" (Cope). But the real rulers of the American Cretaceous waters were the pythonomorphic saurians or sea-serpents. Some of them attained a length of 75 feet or more. They possessed a remarkable elongation of form, particularly in the tail; their heads were large, flat, and conic, with eyes directed partly upwards. They swam by means of two pairs of paddles, like the flippers of the whale, and the eel-like strokes of their flattened tail. Like snakes they had four rows of formidable teeth on the roof of the mouth, which served as weapons for seizing their prey. But the most remarkable feature in these creatures was the unique arrangement for permitting them to swallow their prey entire, in the manner of snakes. Each half of the lower jaw was articulated at a point nearly midway between the ear and the chin, so as greatly to widen the space between the jaws, and the throat must, consequently, have been loose and baggy like a pelican's. Nine species of birds have been obtained from the American Cretaceous rocks. Three of these belonged to the order of Natatores or swimmers, which includes our modern gulls, ducks, and geese; four were *Grallæ* or waders; while two belonged to a long extinct order, and united certain ichthyic and reptilian characters with those of birds. (See Cope, *Report of U.S. Geol. Surv. of Territories*, vol. ii., 1875; Marsh, *American Journ. Science*, 3d ser., i. to iv.; Leidy, *Smithsonian Contributions*, 1865, No. 192; Lesquereux, *Cretaceous Flora*, *Report of U.S. Geol. Surv. of Territories*, vol. vi.)

IV. TERTIARY OR CAINOZOIC.

The close of the Secondary periods was marked in the west of Europe by great geographical changes, during which the floor of the Cretaceous sea was raised partly into land and partly into shallow marine and estuarine waters. These events must have occupied a vast period of time, so that, when sedimentation once more began in the region, the organic remains of the Secondary ages had (save in a few low forms of life) entirely disappeared and given place to others of a distinctly more modern type. In England, the interval between the Cretaceous and the next geological period represented there by sedimentary formations is marked by the abrupt line which separates the top of the Chalk from all later accumulations, and by the evidence that the Chalk seems to have been in some places extensively denuded before even the oldest of what are called the Tertiary beds were deposited upon its surface. There is evidently here a considerable gap in the geological record. We have no data for ascertaining what was the general march of events in the south of England between the eras chronicled respectively by the Upper Chalk and the overlying Thanet beds.

Here and there on the Continent a few scraps of evidence are obtainable which help to fill up this gap. Thus, on the banks of the Meuse at Maestricht, a series of shelly and polyzoan limestones with a conglomeratic base (*Système Maestrichtien* of Dumont, who places it above his Senonian system in the Upper Cretaceous series) contains a mingling of true Cretaceous organisms with others which are characteristic of the older Tertiary formations. It contains, for example, the characteristic Upper Chalk crinoid, *Bourgeticrinus ellipticus*, in great numbers; also *Ostrea vesicularis*, *Baculites Faujasii*, *Belemnitella mucronata*, and the great reptile *Mosasaurus*; but with these occur such Tertiary genera as *Voluta*, *Fasciolaria*, and others. At Faxoe, on the Danish island of Seeland, the uppermost member of the Senonian series contains in like manner a blending of well-known Upper Chalk organisms with the Tertiary genera *Cypræa*, *Oliva*, and *Mitra*. In the neighbourhood of Paris also, and in scattered patches over the north of France, a formation known as the pisolitic limestone occurs, which was formerly classed with the Tertiary formations, seeing that its fossils had more affinities with later than with older rocks. But the discovery in it of numerous distinctively Upper Cretaceous forms has led to its being placed at the top of the Senonian series, from which, however, it is marked off by a decided unconformability, for it rests on a denuded surface of the White Chalk. These fragmentary formations are interesting, in so far as they help to show that, though in western Europe there is a tolerably abrupt separation between Cretaceous and Tertiary deposits, there was nevertheless no real break between the two periods. The one merged insensibly into the other; but the chronicles of the intervening ages have been in great measure destroyed.

In entering upon the Tertiary series of formations, we find ourselves upon the threshold of the modern type of life. The ages of lycopods, ferns, cycads, and yew-like conifers have passed away, and that of the dicotyledonous angiosperms—the hard-wood trees and evergreens of to-day—now succeeds them, but not by any sudden extinction and re-creation, for, as we have seen (*ante*, p. 359), some of these trees had already begun to make their appearance even in Cretaceous times. The ammonites, baculites, and other cephalopods, which had played so large a part in the molluscan life of the Secondary periods, now cease. The great reptiles, too, which in such wonderful variety of type were the dominant animals of the earth's surface, alike on land and sea, ever since the commencement of the Lias, now wane before the increase of the mammalia, which advance in ever-augmenting diversity of type until man appears at their head.

The name Tertiary, given in the early days of geology before much was known regarding fossils and their history, has retained its hold on the literature of the science. It is sometimes replaced by the term Cainozoic (*recent life*), which expresses the great fact that it is in the series of strata comprised under this designation that most recent species and genera have their earliest representatives. Taking as the basis of classification the percentage of living species of mollusca found in the different groups of the Tertiary series, Lyell proposed a scheme of arrangement which has been generally adopted. The older Tertiary formations, in which the number of still living species of shells is very small, where, in fact, we seem to see as it were the first beginnings of the modern life, he named *Eocene* (*dawn of the recent*), including under that title those parts of the Tertiary series of the London and Paris basins wherein the proportion of existing species of shells was only 3½ per cent. The middle Tertiary beds in the valleys of the Loire, Garonne, and Dordogne, containing 17 per cent. of living species, were termed *Miocene* (*less recent*). The younger Tertiary formations of Italy were included under the designation *Pliocene* (*more recent*), because they contained a majority or from 35 to 95 per cent. of living species. This newest series, however, was further subdivided into Older Pliocene (35 to 50 per cent. of living species) and Newer Pliocene (90 to 95 per cent.). This classification, with various modifications and amplifications, has been adopted for the Tertiary group not of Europe only but of the whole globe.

As the North American development of the Tertiary series differs in so many respects from that of Europe, it will be most conveniently considered by itself after the European classification has been described.

EOCENE.

GREAT BRITAIN.—The Eocene rocks of Britain are entirely confined to the south-east of the island, where they occupy two great depressions of the chalk, known respectively as the London and Hampshire basins. They have been arranged into the groups shown in the subjoined table.

Upper	Upper fresh-water and estuarine series	Hempstead beds	170 ft.
		Bembridge ,,	115 ,,
		Osborne ,,	70 ,,
		Headon ,,	200 ,,

Middle	Middle marine series.	Upper Bagshot Sand	250 to 300 ft.
		Middle Bagshot beds, including Barton Clay (300 feet) and Bracklesham beds (100 feet).	
		Lower Bagshot beds	100 ,, 150 ,,
		London Clay	50 ,, 500 ,,
Lower	Lower fresh-water, estuarine, and marine series.	Oldhaven beds	20 ,, 30 ,,
		Woolwich and Reading beds	15 ,, 163 ,,
		Thanet Sand	20 ,, 60 ,,

Grouped in relation to the physical changes which they record, these strata naturally stand in three divisions. At the base lies a series of beds laid down in fresh, estuarine, and sea-water, on an upraised denuded surface of Chalk. Then comes a central group bearing witness to the deepening of these shallow waters, and to the advance of the sea far up the former estuary. The upper group brings before us proof of the eventual retreat of the sea, and the conversion of the area once more into fresh-water lakes and rivers. This arrangement does not quite tally with that which is based on a comparison of the fossils with existing forms, and with those of other Tertiary districts, for it places the London Clay in the middle series, though the fossil evidence distinctly shows that formation to belong to the older Eocene groups.

Lower Eocene.—The Thanet Sand at the base of the London Tertiary basin consists of pale yellow and greenish sand, sometimes clayey, and containing at its bottom a layer of green-coated flints resting directly on the Chalk. According to Mr Whitaker, it is doubtful if any proof of actual erosion of the chalk can anywhere be seen under the Tertiary deposits in England, and he states that the Thanet Sands everywhere lie upon an even surface of chalk with no visible unconformability. Professor Philips, on the other hand, describes the chalk at Reading as having been "literally ground down to a plain or undulated surface, as it is this day on some parts of the Yorkshire coast," and having likewise been abundantly bored by lithodomous shells. The fossils of the Thanet Sand comprise about 70 known species (all marine, except a few fragments of terrestrial vegetation). Among them are several foraminifera, numerous lamellibranchs (*Astarte tenera*, *Cyprina Morrisii*, *Ostrea Bellovacina*, &c.), a few species of gasteropods (*Natica subdepressa*, *Aporrhais Sowerbii*, &c.), a nautilus, and the teeth or palatal bones of fishes (*Lamna*, *Pisodus*).

The Woolwich and Reading beds, or Plastic Clay of the older geologists, consist of lenticular sheets of plastic clay, loam, sand, and pebble beds. The organic remains show that the sea of the Thanet Sand era gradually shallowed into an estuary. They amount to more than 100 species, and include a few plants of terrestrial growth such as *Ficus Forbesi*, *Grevillea Heeri*, and *Laurus Hookeri*. The lamellibranchs are partly estuarine or fresh-water (*Cyclas*, *Cyrena*, *Dreissena*, *Unio*), partly marine. Of the latter a characteristic species is *Ostrea Bellovacina*, which forms a thick oyster bed at the base of the series. *Ostrea tenera* is likewise abundant. The gasteropods include a similar mixture of marine with fluviatile species (*Cerithium funatum*, *Melania inquinata*, *Natica subdepressa*, *Fusus latus*, *Paludina lenta*, &c.) The fish are chiefly sharks (*Lamna*). Bones of turtles and scutes of crocodiles have been found. The highest organisms are bones of mammalia, one of which, the *Coryphodon*, was allied to the modern tapir.

The Oldhaven beds forming the base of the London Clay, though of trifling thickness, have yielded upwards of 150 species of fossils. Traces of *Ficus*, *Cinnamomum*, and *Coniferæ* have been obtained from them; but the organisms are chiefly marine and partly estuarine shells, the gasteropods being particularly abundant. The London Clay, as its name implies, is a mass of clay, stiff, brown, or bluish-grey, with septarian nodules. It extends through both the London and Hampshire basins, attaining a maximum thickness in the south of Essex. It has yielded a long and varied suite of organic remains, from which we can see that it must have been laid down in the sea beyond the mouth of a large estuary, into which abundant relics of the vegetation, and even sometimes of the fauna of the adjacent land were swept. Its fossils are mainly marine mollusca, and, taken in connexion with the flora, indicate that the climate was somewhat tropical in character. The plants include the fruits or other remains of palms (*Nipadites*), custard-apple, acacia, gourds, melons, *Proteaceæ*, and *Coniferæ*. Crustacea abound (*Xanthopsis*, *Hoploparia*). Gasteropods are the prevalent mollusks, the common genera being *Pleurotoma* (45 species), *Fusus* (15 species), *Cypræa*, *Murex*, *Cassidaria*, *Pyrula*, and *Voluta*. The cephalopods are represented by 6 or more species of *Nautilus*, by *Belosepia sepioidea*, and *Beloptera Levesquei*. Nearly 100 species of fishes occur in this formation, the rays (*Myliobates*, 14 species) and sharks (*Lamna*, *Otodus*, &c.) being specially numerous. A sword-fish (*Tetrapterus priscus*), and a saw-fish (*Pristis bisulcatus*) about 10 feet long, have been described by Agassiz from the London Clay of Sheppey, whence almost the whole of the fish remains have been obtained. The reptiles were numerous, but markedly unlike, as a whole, to those of Secondary times. Among them are numerous turtles and tortoises, two species of crocodile, and a sea-snake (*Palæophis*), estimated to have been 13 feet long. Remains of birds have also been met with; one of these (*Lithornis vulturinus*) appears to have been allied to the vulture, another (*Halcyornis toliapicus*) to our modern king-fisher, besides waders and other types. The mammals numbered among their species a hog (*Hyracotherium*), several tapirs (*Coryphodon*, &c.), an opossum (*Didelphys*), and a bat. The carcases of these animals must have been borne seawards by the great river which transported so much of the vegetation of the neighbouring land.

Middle.—The Bagshot group consists of sand and bands of clay which, in the Hampshire basin, are tolerably fossiliferous. As developed in the Isle of Wight and at Bournemouth, their lower members have yielded a large number of terrestrial plants, among which the *Proteaceæ* are still numerous, together with species of fig, cinnamon, fan-palm (*Sabal*), oak, yew, cypress, laurel, lime, senna, and many more. Crocodilian forms still haunted the waters, and have left their bones with those of sea-snakes and turtles and of the tapirs and other denizens of the land, which still, as in the time of the London Clay, continued to be washed out to sea. Among these strata we now find one of the most typical organisms of the Eocene rocks of the Mediterranean basin, a foraminifer termed *Nummulites* (*N. lævigata*, *N. scabra*, *N. variolaria*). Characteristic fossils are *Voluta athleta*, *V. luctatrix*, *Murex asper*, *Fusus longævus*, *Cardita planicosta*, and *Chama squamosa*.

Upper.—The strata of this division of the English Eocene formations are entirely confined to Hampshire and the Isle of Wight. They consist of sands, clays, marls, and limestones, in thin-bedded alternations. These strata were accumulated partly in the sea, partly in brackish, and partly in fresh water. They were hence named by Edward Forbes the fluvio-marine series. Among the marine fossils are—*Fusus porrectus*, *Oliva Branderi*, *Natica labellata*, *Ostrea callifera*, and *Nummulites lævigata*. The genera *Cerithium*, *Potamomya*, *Paludina*, *Planorbis*, *Limnæa*, and *Cyclas* are abundant, showing the brackish and fresh-water conditions in which many of the strata were deposited. Remains of turtles, snakes, crocodiles, and alligators continue to occur in these Upper Eocene beds. With these are found the bones of several very characteristic mammals also met with in the Paris basin,—the three-toed *Palæotherium*, resembling the living tapir; *Anoplotherium*, a more graceful animal with long tail), and two-toed feet, forming a kind of intermediate type between a hog and a deer or antelope; *Dichobune*, allied to the last named; also *Dichodon*, *Hyopotamus*, *Chœropotamus*, *Hyænodon*, &c. The top of the Eocene series in the Isle of Wight has been removed by denudation, so that we have no evidence in Britain of what took place after the close of the Eocene period.

CONTINENTAL EUROPE.—Geologists on the continent of Europe, finding it impossible to carry out the principle of percentage of recent species, as originally formulated by Lyell in his terminology of the Tertiary series, have made various modifications of this nomenclature. By some the three terms Eocene, Miocene, and Pliocene are retained, but, following Beyrich, they subdivide the Miocene into two, keeping that term for the upper half and calling the lower Oligocene, which corresponds with Lyell's Lower Miocene. Others would consider the whole Tertiary and post-Tertiary series as divisible into three groups, the Eocene or Older Tertiary, corresponding pretty closely to the Lyellian use of the term, the Neogene or Younger Tertiary, embracing both Miocene and Pliocene, and the Diluvial and Alluvial.

In the Paris basin the Eocene formations assume a somewhat different type from that which they present in England, though the occurrence of a number of the same species of fossils in both allows of their being paralleled in a general way. The lower Eocene consists there of sand and clay answering in lithological character to the Thanet Sand and Plastic Clay of the London basin. The common species in that basin (*Ostrea Bellovacina*) occurs there in great numbers, while the brackish water-beds contain some of the common species at Woolwich, such as *Cyrena cuneiformis* and *Melania inquinata*. Beds of lignite occur in this division, likewise bones of *Coryphodon Eocænus*, *Viverra gigantea*, and the bird *Gastornis*. The Middle Eocene is made up of the characteristic "Calcaire grossier"—a mass of limestone, sometimes tender and crumbling, in other places so compact as to be largely quarried as a building stone. Some portions are entirely composed of minute foraminifera (miliolitic limestone). Among the characteristic fossils of this division are *Nummulites*, *Cerithium giganteum*, with bones of *Dichobune*, *Lophiodon*, *Paloplotherium*, &c. The Upper Eocene consists of sand (Sables moyens) overlaid by the great gypsum and gypseous marl group of Montmartre. This is the deposit from which so many of the mammals of the Eocene period have been recovered. It is divided into three zones, and among its fossils are upwards of 50 species of quadrupeds, including many Palæotheres, Anoplotheres, Paloplotheres, with *Xiphodon*, *Dichobune*, *Adapis*, *Chœropotamus*, *Myoxus*, *Canis Parisiensis*, *Viverra Parisiensis*, *Vespertilio*, *Didelphys Cuvieri*, and about 17 species of birds.

The Eocene formations of the north-west of Europe occupy but a few detached basins, and consist for the most part of soft clays, sands, marls, and thin limestones. They were laid down partly in estuaries, rivers, or lakes, partly in shallow seas near land. They contain abundantly the vegetation, with some remains of the quadrupeds and birds, of that land, and show that still in older Tertiary times, as during the long Palæozoic and Secondary ages, the chief area of land lay to the north-west. But when we turn to the corresponding formations in central and southern Europe, they present a totally different aspect. In the first place, they at once impress us with the idea of their antiquity, for they consist chiefly of massive, hard, crystalline, and sometimes even marble-like limestones, which suggest some of the Palæozoic rocks rather than those of so modern a date as the London Clay and Calcaire Grossier. Again, instead of being confined to a few local basins, they cover an enormous geographical area and play a notable part in the structure of some of the great mountain chains of the globe. Crowded as they are with nummulites, they must have been deposited not in estuaries and shallow bays but in a wide and clear sea, which, traced by the area of these limestones, must have ranged across the whole of the south of Europe and north of Africa, through Greece, Turkey, Asia Minor, and the heart of Asia, to the far shores of China and Japan. Since the time when this wide channel connected the Atlantic and the Pacific across the heart of the Old World, the great mountain ranges of the Pyrenees, Alps, Apennines, Carpathians, and of Central Asia, have been upheaved to their present altitude. Some of the prominent peaks along their flanks consist of the hardened and crumpled calcareous mud of the Eocene sea.

In the northern and southern Alps the Eocene formations consist of nummulitic limestone—a grey, yellow, sometimes reddish compact rock, usually containing and often made up of nummulites; nummulite sandstone; Vienna sandstone—an enormous mass of arenaceous rock almost destitute of organic remains, and referred partly to the Cretaceous and partly to the Eocene series; and Flysch—a massive development of dark shales or schists, sandstones, and argillaceous limestone, sometimes charged with the remains of fucoids and (at Matt, Glarus) of fish. The nummulitic series of southern Europe is divided into zones characterized by fossils, and brought into a kind of broad parallelism with the subdivisions of the English and French Eocene basins. In the eastern Alps, near Vienna and elsewhere, some of the nummulitic sandstones contain enormous blocks of granite, gneiss, and other crystalline rocks, which are believed to have been ice-borne, and therefore to prove the existence of Alpine glaciers even in Eocene times. These mountains already existed, as it were, in embryo, even far back in the Secondary and Palæozoic ages. During the later part of the Eocene period they seem to have been clothed with an abundant flora, among which the fan-palm, *Banksia*, *Dryandria*, and other plants remind one of the living vegetation of tropical America, the East Indies, and Australia. Out of these plants the important coal-seams of Häring in Tyrol were formed.

MIOCENE.

According to the original nomenclature proposed by Lyell, this subdivision of the Tertiary series was meant to include those strata in which 17 per cent. or thereabouts of the shells belong to still living species. As the system of nomenclature was adopted at a time when our knowledge both of living and fossil species was still very defective, it could not but require modification with the progress of science. Some strata, classed at one time as Miocene from their proportion of recent forms, might, on more extended research, prove to contain a much larger percentage, and therefore to be referable to a later part of the Tertiary series. The term, however, is used as a convenient and long-established designation for a series of strata younger than the Eocene, which they seem to have succeeded, though in some parts of the European area after enormous geographical changes.

GREAT BRITAIN.—Miocene formations, in the ordinary sense of the term, are almost entirely absent from the British Islands. In Devonshire, at Bovey Tracey, a small but interesting group of sand, clay, and lignite beds, from 200 to 300 feet thick, lies between the granite of Dartmoor and the Greensand hills, in what was evidently the hollow of a Miocene lake. From these beds Heer of Zurich, who has thrown so much light on the Miocene flora of both the Old World and the New, has described about 50 species of plants, which, he says, place this Devonshire group of strata on the same geological horizon with some part of the Lower Miocene formations of Switzerland. Among the species are a number of ferns (*Lastræa stiriaca*, *Pecopteris lignitum*, &c.); some conifers, particularly a *Wellingtonia* called the *Sequoia Couttsiæ*, the debris of which forms one of the lignite beds; a few grasses, water-lilies, and a palm. Leaves of oaks, figs, laurels, willows, and seeds of grapes have also been detected—the whole vegetation implying a subtropical climate. In the north of Ireland lies a great plateau of basalt, presenting along the coast of Antrim a magnificent range of mural escarpments. The basalt-beds mark successive outpourings of lava, which took place on a prodigious scale from the Antrim region northwards through the Western Islands and the Faroe Islands into Iceland, and even far up into Arctic Greenland. In Ireland the basalts attain a maximum thickness of 900 feet; in Mull about 3000 feet. They are associated with tuffs, pitchstones, trachytes, and granitoid rocks, which mark the position of the main vents of eruption. It is evident that long-continued and vigorous volcanic action took place in these north-western regions. The geological date of this activity can be approximately fixed by the fossil plants here and there to be found in leaf-beds between the sheets of basalt. They agree generally with species found in the Older Miocene beds of Switzerland; and hence the date of this marked volcanic era in the north-west of Europe and in Greenland is placed in the older part of the

Miocene period. With these exceptions there are no Miocene rocks in Britain.

CONTINENTAL EUROPE.—The records of the Miocene period in Europe bring before us a scene very different from that which the region presented during the Eocene ages. The least amount of change took place in the north-west and north. It consisted chiefly in the upraising of the floor of the shallow sea which had stretched eastwards across the north of France, and the formation of numerous fresh-water lakes, lagoons, and morasses. But over the Alpine region a vast revolution took place. The Eocene sea had its bed elevated, and the Alps rose many thousand feet above their previous height, carrying up on their flanks the hardened, upturned, crumpled, and crystallized nummulite limestone. These vast corrugations of the earth's crust were general over the whole globe about the same geological period. Subterranean movements appear to have continued during Miocene times in the Alpine area; large lake-basins were formed over a great part of what is now Switzerland, and in these the deposits of the period took place. Hence the Miocene formations of Europe are in great measure of lacustrine and terrestrial formation. The sea, however, was allowed to pass across the south of France between the central axis and the Pyrenees. It likewise covered a wide area in eastern Europe, sweeping far up into the Vienna basin and the foot of the Austrian Alps. Traces of the occasional presence of the sea can likewise be followed across Belgium and North Germany, and even on the south side of the Eifel and Westphalian high grounds in the basin of Mainz.

In France, on the north side of the axis of old rocks, the upper parts of the Eocene series are covered by certain marls, clays, and limestones, containing *Ostrea cyathula*, and passing up into the thick sandstone of Fontainebleau, well known for its picturesque scenery. These are considered as the base of the Miocene (or Oligocene) series. They contain *Fusus elongatus*, *Aporrhais speciosa*, *Pectunculus obovatus*, *Cyrena semistriata*, *Cerithium plicatum*, &c. They are succeeded by some fresh-water limestones (Calcaire de Beauce) full of *Paludina*, *Planorbis*, *Limnæa*, and *Helix*. These strata show very instructively the gradual shallowing of the sea in the north of France, and its conversion into fresh-water lakes and land. Further to the south a subsequent depression took place, in which the shelly sands and marls (faluns) of Touraine were accumulated. These strata lie in scattered patches, and seldom exceed 50 feet in thickness. They contain chiefly marine shells (*Cypræa*, *Oliva*, *Mitra*, *Terebra*, *Fasciolaria*, *Conus*, &c.), also remains of the *Dichobune* and *Chæropotamus*, with some of the huge early pachyderms,—*Mastodon*, *Dinotherium*, rhinoceros, hippopotamus, and species of dolphin, morse, &c.

In North Germany the older Miocene rocks are marine where they pass westwards into the Belgian area, but as they are followed southwards they bear evidence of increasing proximity to land, till at last they contain abundant seams of lignite, and hence have been termed the Brown-coal series. They appear to underlie most of the great north Germanic plain, on the south side of which they rise up into the Rhine valley, Thuringia, Saxony, and Silesia. The Brown-coal series consists of sandstones, conglomerates, and clays, with leaf-beds and seams of lignite. The last, which have been largely worked as fuel, are mainly composed of remains of conifera, (*Taxites*, *Taxoxylon*, *Cupressinoxylon*, *Sequoia*), but with them are associated, in the neighbouring strata, leaves and other fragments of oak, beech, maple, fig, laurel, cinnamomum, magnolia, sassafras, palmacites, &c. These strata are overlaid by marine beds containing *Ostrea*, *Cardita*, *Pleurotoma*, *Voluta*, and numerous corals. The subterranean movements above referred to as having long affected the Alpine region were felt likewise in North Germany, for we find these marine beds succeeded by a second lignitic formation, seen at Grosser Hubenecken, on the eastern horn of the Gulf of Dantzic. But this could only have been a local uplift, for marine sands and clays are next found with a wide diffusion over the plains of northern Germany.

Nowhere in Europe do the Miocene formations play so important a part in the scenery of the land, or present on the whole so interesting and full a picture of the state of Europe when they were deposited, as in Switzerland. Rising into massive mountains, as in the well-known Righi and Rossberg, they attain a thickness of more than 6000 feet. While they include indications of the presence of the sea, they have preserved with marvellous perfection a large number of the plants which clothed the Alps, and of the insects which flitted through the woodlands. They are termed "Molasse" by the Swiss geologists, and have been divided into the following groups:—

Upper fresh-water Molasse and brown-coal, consisting of sandstones, marls, and limestones, with a few lignite-seams and fresh-water shells, and including the remarkable group of plant and insect-bearing beds of Oeningen.

Upper marine Molasse (Helvetian stage)—sandstones and calcareous conglomerates, with 37 per cent. of shells, which are to be found living partly in the Mediterranean, and partly in tropical seas.

Lower fresh-water Molasse (Mainz stage)—sandstones with abundant remains of terrestrial vegetation, and containing also an intercalated marine band with *Cerithium*, *Venus*, &c.

Lower brown-coal or red Molasse (Aquitanian stage)—the most massive member of the whole series, consisting of red sandstones, marls, and conglomerates (Nagelfluh), resting upon variegated red marls. It contains seams of lignite, and a vast abundance of the remains of terrestrial vegetation.

Lower marine Molasse (Tongrian stage)—sandstone containing marine and brackish-water shells, among which is the *Ostrea cyathula*, above mentioned as a characteristic shell, at the base of the Miocene series in the north of France.

By far the larger portion of these strata is of lacustrine origin. They must have been formed in a large lake, the area of which probably underwent gradual subsidence during the period of deposition, so that the sea gained occasional admission into it. We may form some idea of the importance of the lake from the fact already stated, that the deposits formed in its waters are upwards of 6000 feet thick. Thanks to the untiring labours of Professor Heer, we know more of the vegetation of the mountains round that lake than we do of that of any other ancient geological period. The woods were marked by the predominance of an arborescent vegetation, among which evergreen forms were conspicuous, the whole having a decidedly American aspect. Among the plants were palms of American type, the Californian coniferous genus *Sequoia*, a great variety of maples, oaks, hornbeams, poplars, planes, willows, laurels, evergreen oaks, with vines, clematis, cypresses, and many more. In the Oeningen beds, so gently have the leaves, flowers, and fruits fallen, and so well have they been preserved, that we may actually trace the alternation of the seasons by the succession of different conditions of the plants. Selecting 482 of those plants which admit of comparison, Heer remarks that 131 might be referred to a temperate, 266 to a sub-tropical, and 85 to a tropical zone. American types are most frequent among them; European types stand next in number, followed in order of abundance by Asiatic, African, and Australian. Great numbers of insects (between 800 and 900 species) have been obtained from Oeningen. Judging from the proportions of species found there, the total insect fauna may be presumed to have been then richer in some respects than it now is in any part of Europe. The wood-beetles were specially numerous and large. Nor did the large animals of the land escape preservation in the silt of the lake. We know, from bones found in the Molasse, that among the inhabitants of that land were species of tapir, mastodon, rhinoceros, and deer. The woods were haunted by musk-deer, apes, opossums, three-toed horses, and some of the strange, long-extinct Tertiary ruminants, akin to those of Eocene times. There were also frogs, toads, lizards, snakes, squirrels, hares, beavers, and a number of small carnivores. On the lake the huge *Dinotherium* floated, mooring himself perhaps to its banks by the two strong tusks in his under jaws. The waters were likewise tenanted by numerous fishes (of which 32 species have been described, all save one referable to existing genera), crocodiles, and chelonians.

Contemporaneously with the existence of the great Swiss Miocene lake, one or more large sheets of fresh water lay in the heart of France. In these basins a series of marls and limestones (1500 feet thick) accumulated, from which have been obtained the remains of nearly 100 species of mammals, including some palæotheres, like those of the Paris Eocene basin, a few genera found also in the Lower Miocene beds of Mainz, crocodiles, snakes, and birds. This water basin appears to have been destroyed by volcanic explosions, which afterwards poured out the great sheets of lava, and formed the numerous cones and *puys* so conspicuous on the plateau of Auvergne.

The sea which during the later part of the Miocene period stretched across the south of France ran also up the present valley of the Danube to the foot of the Alps and the high grounds of Bohemia and Moravia. In this wide eastern bay or Vienna basin a series of deposits was laid down, which have been grouped in four divisions,—the two lower classed as Miocene, and the two upper as Pliocene. The lowest group (Mediterranean stage or Marine Tegel) has yielded more than 1000 species of mollusca (*Conus*, *Ancillaria*, *Pyrula*, *Murex*, *Cardium*, &c.), with remains of *Mastodon*, *Dino-*

therium, and other mammals. The second group (Sarmatian stage) consists of brackish-water beds showing the partial uprise of the bottom of the Vienna basin. It contains *Cerithium*, *Paludina*, *Rissoa*, with bones of dolphins, seals, turtles, and fish. The two uppermost divisions (Congeria stage and Belvedere stage), referred to the Pliocene series, are fresh-water formations, showing the final freshening and disappearance of the Miocene sea in the south-east of Europe.

In Styria and Carinthia the lower Aquitanian or Mediterranean stage bears witness in its plants and lignites to the proximity of land during its formation, while its shells are of fresh and brackish water genera. It has subsequently been upheaved, and the later Miocene strata lie unconformably on its edges. The subterranean movements east of the Alps culminated in the outpouring of enormous sheets of trachyte, andesite, propylite, and basalt in Hungary and along the flanks of the Carpathian chain into Transylvania. In Croatia the older Miocene marls, with their abundant land-plants, insects, &c., contain two beds of sulphur (the upper 4 to 16 inches thick, the under 10 to 15 inches), which have been worked at Radoboj. At Hrastreigg, Buchberg, and elsewhere, coal is worked in the Aquitanian stage in a bed sometimes 65 feet thick. In Transylvania, and along the base of the Carpathian mountains, extensive masses of rock-salt and gypsum are interstratified in the Tertiary formations. The largest of these, that of Parajd, has a maximum length of about 2500 yards, a breadth of 1800 yards, and a depth nearly 200 yards, and is estimated to contain 3500 millions of cubic feet of salt.

Greenland.—One of the most remarkable geological discoveries of recent times has been that of Miocene plant beds in North Greenland. Heer has described a flora extending at least up to 70° N. lat., containing 137 species, of which 46 are found also in the central European Miocene basins. More than half of the plants are trees, including 30 species of conifers (*Sequoia*, *Thujopsis*, *Salisburia*, &c.), besides beeches, oaks, planes, poplars, maples, walnuts, limes, magnolias, and many more. These plants grew on the spot, for their fruits in various stages of growth have been obtained from the beds. From Spitzbergen (78° 56′ N. lat.) 136 species of fossil plants have been named by Heer. But the latest English Arctic expedition brought to light a bed of coal, black and lustrous like one of the Palæozoic fuels, from 81° 45′ lat. It is from 25 to 30 feet thick, and is covered by black shales and sandstones full of land-plants. Heer notices 26 species, 18 of which had already been found in the Arctic Miocene zone. As in Spitzbergen, the conifers are most numerous (pines, firs, spruces, and cypresses), but there occur also the arctic poplar, two species of birch, two of hazel, an elm, and a viburnum. In addition to these terrestrial trees and shrubs the stagnant waters of the time bore water-lilies, while their banks were clothed with reeds and sedges. When we remember that this vegetation grew luxuriantly within 8° 15′ of the North Pole, in a region which is now in darkness for half of the year, and is almost continuously buried under snow and ice, we can realize the difficulty of the problem in the distribution of climate which these facts present to the geologist.

Pliocene.

Great Britain.—The Miocene period seems to have passed away without any notable portion of the British Islands being depressed under the sea. Save the great outpouring of lava in the north-west, and the rise of hundreds of "dykes" of basalt along cracks of the crust in the north of England and throughout Scotland, the area of Britain seems to have remained as a part of the mainland of Europe, little affected by the subterranean movements which, as we have seen, were so potent among the Alps and in eastern Europe. At length the south-eastern counties began to subside, and on their submerged surface some sandbanks and shelly deposits were laid down, very much as similar accumulations now take place at the bottom of the North Sea. These formations are termed the Crag, and are subdivided, according to their proportion of living species of shells, into the following groups:—

Chillesford beds	Chillesford Clay	1 to 8 ft.
	Chillesford Sand with shells	5 ,, 8 ,,
Norwich (fluvio-marine, mammaliferous) Crag		5 ,, 10 ,,
Red Crag		25 ,,
White (Suffolk, coralline) Crag		40 ,, 60 ,,

The White Crag consists of shelly sands and marls. It contains 316 species of shells, of which 84 per cent. are still living. Among these are *Terebratula grandis*, *Lingula Dumortieri*, *Pecten opercularis*, *Pholadomya histerna*, *Pyrula reticulata*. The name coralline was given to the formation from the immense number of coral-like polyzoa which it contains, no fewer than 130 species having been described. The Red Crag is also a thin and local formation, consisting of a dark-red or brown ferruginous shelly sand. Of its mollusks, 92 per cent are believed to be still living species, and, out of 25 species of corals, 14 are still natives of British seas. Some of the typical shells of this subdivision are *Trophon antiquum* (*Fusus contrarius*), *Voluta Lamberti*, *Purpura tetragona*, *Pecten opercularis*, *Pectunculus glycimeris*, and *Cyprina rustica*. Numerous mammalian remains have been obtained from these sands, including bones of *Mastodon Arvernensis* and *M. tapiroides*, *Elephas meridionalis*, *Rhinoceros Schleiermacheri*, *Tapirus priscus*, *Sus antiquus*, *Equus plicideus*, *Hipparion*, *Hyæna antiqua*, *Felis pardoides*, and *Cervus anoceros*. The Norwich or Fluvio-marine or Mammaliferous Crag consists of a few feet of shelly sand and gravel, containing, so far as known, 139 species of shells, of which 93 per cent. are still living. About 20 of the species are land or fresh-water shells. The name of mammaliferous was given from the large number of bones, chiefly of extinct species of elephant, recovered from this deposit. These fossils comprise *Mastodon Arvernensis*, *Elephas meridionalis*, *E. antiquus*, a hippopotamus, horse, and deer, likewise the living species of otter and beaver. One interesting feature in this formation is the decided mixture in it of *northern* species of shells, such as *Rhynchonella psittacea*, *Scalaria Grœnlandica*, and *Astarte borealis*. These may be regarded as the forerunners of the great invasion of Arctic plants and animals which, in the beginning of the Quaternary ages, came southward into Europe, together with the severe climate of the north. The Chillesford beds occur likewise as a thin local deposit in Suffolk and Norfolk. Of the shells which they contain, about two-thirds still live in Arctic waters. It is evident that, in these fragmentary accumulations of the Crag series, we have merely the remnants of some thin sheets of shelly sands and gravels laid down in the shallow waters of the North Sea, while that great lowering of the European climate was beginning which culminated in the succeeding or Glacial period.

Continental Europe.—Marine strata, sometimes of considerable thickness, were laid down over different portions of the European area during the Pliocene period. The most extensive of these occur in Italy and Sicily; in the latter island they have since been upheaved to a height of 3000 feet above the sea. They have likewise been raised into the chain of heights flanking the Apennine Mountains, where they are known as the Subapennine series. In the shore waters and estuaries of that ancient Italy some of the same huge mammals lived as were contemporaneously denizens of England,—the Auvergne mastodon. *Rhinoceros Etruscus Elephas meridionalis*. *Hippopotamus major*, with bears and hyænas.

Eastwards we obtain evidence of the gradual exclusion of the sea from the areas of the European continent which it had covered during the Miocene period. The Congeria stage (above referred to) of the Vienna basin brings before us the picture of an isolated gulf gradually freshening by the inpouring of rivers like the modern Caspian, but with bays nearly cut off from the main body of water, and undergoing so copious an evaporation without counterbalancing inflow that their salt was deposited over the bottom as in the Karaboghaz of the Caspian (*ante*, p. 279).

Tertiary Series of North America.

Tertiary formations of marine origin extend in a strip of low land along the Atlantic border of the United States.

from the coast of New Jersey southward round the margin of the Gulf of Mexico, whence they run up the valley of the Mississippi to beyond the mouth of the Ohio. On the western sea-board they also occur in the coast ranges of California and Oregon, where they sometimes have a thickness of 3000 or 4000 feet, and reach a height of 3000 feet above the sea. Over the Rocky Mountain region Tertiary strata cover an extensive area, but are chiefly of fresh-water origin, though containing marine interstratifications. The following are the subdivisions into which they have been grouped, together with their supposed European equivalents:—

4. Sumter series = Pliocene.
3. Yorktown ,, = Miocene, with perhaps part of Pliocene.
2. Alabama ,, = Middle and Upper Eocene.
1. Lignitic ,, = Lower Eocene.

1. *Lignitic.*—As already mentioned, it is still matter of dispute whether this formation should not be included wholly or in large measure in the Cretaceous system below. It consists mainly of lacustrine strata, with occasional brackish water and marine bands. Its name is derived from the beds of fossil fuel which it contains. The mollusca in some of the shell-bearing beds comprise species of *Inoceramus*, *Anchura*, *Gyrodes*, *Cardium*, *Cyrena*, *Melampus*, *Ostrea*, and *Anomia*. Other strata contain the modern lacustrine and fluviatile genera *Physa*, *Valvata*, *Cyrena*, *Corbula*, and *Unio*. An abundant terrestrial flora has been disinterred from the Lignitic strata. It resembles in many respects the present flora of North America, comprising as it does species of oak, poplar, maple, elm, dogwood, beech, hickory, ilex, plane, fig, cinnamon, laurel, magnolia, smilax, thuja, sequoia, and several palms. A few of the species are common to the Middle Tertiary flora of Europe, and a number of them have been met with in the Tertiary beds of the Arctic regions. Some of the seams of vegetable matter are true bituminous coals and even anthracites.

It was stated in the account of the North American Cretaceous rocks that considerable difference of opinion exists as to the line to be drawn between these rocks and those of Tertiary age. According to Cope, the Vertebrate remains of the Lignitic series bind it indissolubly to the Mesozoic formations. Lesquereux, on the other hand, insists that the vegetation is unequivocally Tertiary. The former writer, admitting the force of the evidence furnished by the fossil plants, concludes, that "there is no alternative but to accept the result that a Tertiary flora was contemporaneous with a Cretaceous fauna, establishing an uninterrupted succession of life across what is generally regarded as one of the greatest breaks in geologic time." The Lignitic series was disturbed along the Rocky Mountain region before the deposition of the succeeding Tertiary formations, for these lie uncomformably upon it. So great have been the changes in some regions that the strata have assumed the character of hard slates like those of Palæozoic date, if indeed they have not become in California thoroughly crystalline masses.

2. *Alabama Group.*—The strata included in this group are believed to represent the Middle and Upper Eocene of Europe. As their name implies, they are well developed in the State of Alabama, where they consist of two sub-groups,—(1) the Clayborne beds—clays, marls, limestones, lignite, and sands, and (2) the Vicksburg beds—lignitic clays, limestones, and marls,—the whole attaining a thickness of nearly 250 feet. But the strata thicken into South Carolina. Towards the west the marine fossils give place to leaf-beds and lignites. In the Green River basin the strata attain a thickness of more than 2000 feet, lying on the disturbed Lignitic group, and containing beds of coal, with remains of fish and of tapiroid pachyderms. The fossils of the Alabama group in the eastern States comprise numerous sharks, some of which are specifically, and more are generically, the same as some of the English Eocene forms, such as *Lamna elegans*, and *Carcharodon megalodon*; also bones of several crocodiles and snakes. In the lacustrine and fluviatile deposits of the west there have been found also the remains of several birds, and a large number of mammals, including marsupials, numerous representatives of the tapirs, with double pairs of nasal horns, an early form of horse (*Orohippus*) not larger than a fox, and with four toes in the fore foot, rodents, insectivores, bats, carnivores, and a number of forms allied to the living lemurs and marmosets. The richness of this fauna is remarkable, particularly in the mammals.

3. *Yorktown Group.*—Under this name are classed strata of sand and clay, which extend over a large area in the seaward part of the eastern States. Their organic remains (comprising mollusks, with remains of sharks, seals, walruses, whales, &c.) show them to have been chiefly laid down in a shallow sea in Miocene time. Westward, in the Upper Missouri region, and across the Rocky Mountains into California and Oregon, strata assigned to the same geological period were laid down in great lakes, and attain thicknesses of 1000 to 4000 or 5000 feet. The organic remains of these ancient lakes embrace examples of three-toed horses (*Anchitherium*), of horned tapir-like animals (*Titanotherium*), of forms related to the hog, rhinoceros, camel, lama, deer, musk-ox, hare, squirrel, beaver, hyæna, wolf, panther, and tiger. The intermediate types indicated by Cuvier among the Paris Tertiary beds have been greatly increased from the American Tertiary groups by the researches of Marsh and Leidy.

4. *Sumter Group* or *Pliocene.*—In the Carolina States beds of loam, clay, or sand, lying in hollows of the older Tertiary deposits, and containing from 40 to 60 per cent. of living marine shells, are referred to the Pliocene age. In the Upper Missouri region, the Yorktown group is overlaid by other fresh-water beds, which are believed to be Pliocene. These strata contain land and fresh-water shells, probably of existing species. But their most remarkable organic remains are the mammalia, which continue the wonderful series in the strata underneath. Dana thus summarizes the facts:—"Leidy has determined a large number of Pliocene mammals, all now extinct. They include three species of camel (*Procamelus*); a rhinoceros as large as the Indian species; a mastodon smaller than *M. Americanus*, L., of the Quaternary; an elephant (*E. Americanus*), occurring also in the Quaternary; four or five species of the horse family, one of which was closely like the modern horse; a species of deer (*Cervus Warreni*, L.); others near the musk-deer of Asia; species of *Merychyus*, allied to *Oreodon* (a genius intermediate between deer, camel, and hog); a wolf larger than any living species; a small fox; a tiger (*Felis augustus*, L.) as large as the Bengal tiger, besides other carnivores; a small beaver; a porcupine. The collection of animals has a strikingly Oriental character, except in the preponderance of herbivores."

V. POST-TERTIARY OR QUATERNARY.

Under this division are included the various superficial deposits in which all the mollusca are of still living species. It is usually subdivided into two series—(1) an older group of deposits in which many of the mammals are of extinct species,—to this group the names of Pleistocene, Post-Pliocene, or Diluvial have been given; and (2) a later series, wherein the mammals are all of still living species, to which the name of Recent or Alluvial has been assigned. These subdivisions, however, are confessedly very artificial, and it is often exceedingly difficult to draw any line between them.

In Europe and North America a tolerably sharp demarcation can usually be made between the Pliocene formations and those now to be described. The Crag deposits of the south-east of England show traces of a gradual lowering of the temperature during later Pliocene times. This change of climate continued to augment until at last thoroughly arctic conditions prevailed, under which the oldest of the Post-Tertiary or Pleistocene deposits were accumulated.

It is hardly possible to arrange these deposits in a strict chronological order, because we have no means of deciding, in many cases, their relative antiquity. The following table is rather an enumeration of the more important of them than an arrangement in their exact sequence:—

Recent......	River alluvia, peat mosses, lake deposits, blown sand, marine deposits, raised beaches.
Pleistocene or Glacial.	Brick-earth, valley-gravels, old marine terraces, cavern-deposits.
	Moraine-stuff, Kame or Esker series, Clyde-beds, Upper Boulder clays, Interglacial beds, Lower Till, ice-worn rock-surfaces.
	Pre-glacial forests and land surfac

Pleistocene or Glacial.

Under the name of the Glacial Period or Ice Age, a remarkable geological episode in the history of the northern hemisphere is denoted. We have seen in the foregoing section on the Crag deposits that there is evidence of a gradual refrigeration of the climate at the close of the Tertiary ages. This change of temperature affected the higher latitudes alike of the Old and the New World. It reached such a height that the whole of the north of Europe was buried under snow and ice, extending southwards even as far as Saxony. The Alps and Pyrenees were loaded with vast snow-fields, from which enormous glaciers descended into the plains, overriding ranges of minor hills on their way. The greater portion of Britain was similarly ice-covered.

The effect of the movement of the ice was necessarily to remove the soils and superficial deposits of the land surface. Hence in the areas of country so affected, the ground having been scraped and smoothed, the glacial accumulations laid down upon it rest abruptly, and without any connexion, on whatever underlies them. Considerable local differences may be observed in the nature and succession of the different deposits of the glacial period, as they are traced from district to district. It is hardly possible to determine, in some cases, whether certain portions of the series are coeval or belong to different epochs. But the following are the leading facts which have been established for the North-European area. First, there was a gradual increase of the cold, though with warm intervals, until the conditions of modern North Greenland extended as far south as Middlesex, Wales, the south-west of Ireland, and 50° N. lat. in central Europe. This was the culmination of the Glacial period. Then followed a considerable depression of the land and the spread of cold arctic water over the submerged tracts, with abundant floating ice; next came a re-elevation, with renewed augmentation of the snow-fields and glaciers. Very gradually, and after intervals of increase and diminution, the ice retired towards the north, and with it the arctic flora and fauna that had peopled the European plains. The existing snow-fields and glaciers of the Pyrenees, Switzerland, and Norway are remnants of the great ice-sheets of the glacial period, while the arctic plants of the mountains are relics of the northern vegetation which was universal from Norway to Spain.

Ice-worn Rocks.—Beginning at the base of the deposits from which this interesting history is compiled, we find the solid rocks over the whole of northern Europe to present the characteristic smoothed flowing outlines which can be produced only by the grinding action of land-ice (*ante*, p. 282). Where they have been long exposed, this peculiar surface is apt to be effaced by the disintegrating action of the weather, though it retains its hold with extraordinary pertinacity. Along the fjords of Norway and the sea-lochs of the west of Scotland, it may be seen slipping into the water, smooth, bare, polished, and grooved as if the ice had only recently retreated. But where the protecting cover of clay or other superficial deposits has been newly removed, the peculiar ice-worn surface is as fresh as that by the side of a modern glacier. Observations of the directions of the striæ have shown that on the whole these markings diverge from the main masses of high ground. In Scandinavia they run westwards and south-westwards on the Norwegian coasts, and eastwards or south-eastwards across the lower grounds of Sweden. When the ice descended into the basin of the Baltic and the plains of northern Germany, it moved southwards and south-westwards, but seems to have slightly changed its direction in different areas and at different times. Its movements can be made out partly from the striæ on the solid rock, but more generally from the glacial drift which it has left behind. Thus it can be shown to have moved down the Baltic into the North Sea. At Berlin its movement must have been from east to west. But at Leipsic, as recently ascertained by Credner, it came from N.N.W. to S.S.E., being doubtless shed off in that direction by the high grounds of the Harz mountains. Its southern limit can be traced with tolerable clearness from Jevennaar in Holland eastwards across the Rhine valley, along the base of the Westphalian hills, round the projecting promontory of the Harz, and then southwards through Saxony to the roots of the Erzgebirge. Passing next south-eastwards along the flanks of the Riesen and Sudeten chain, it sweeps across Poland into Russia, circling round by Kieff, and northwards by Nijni Novgorod towards the Urals.

It has been estimated that, excluding Finland, Scandinavia, and the British Isles, the ice must have covered not less than 1,700,000 square kilometres of the present lowlands of Europe. Its influence on the solid rocks over which it passed has not been everywhere equal. Over much of the north German plain, indeed, the rocks are concealed under drift. But in the more undulating hilly ground, particularly in the north and north-west, the ice has effected the most extraordinary abrasion. It is hardly possible, indeed, to describe adequately in words these regions of most intense glaciation. The old gneiss of Norway and Sutherlandshire, for example, has been so eroded, smoothed, and polished, that it stands up in endless rounded hummocks, many of them still smooth and flowing like dolphins' backs, with little pools, tarns, and larger lakes lying between them. Seen from a height the ground appears like a billowy sea of cold grey stone. The lakes, every one of them lying in a hollow of erosion, seem scattered broadcast over the landscape. So enduring is the rock, that even after the lapse of so long an interval, it retains its ice-worn aspect almost as unimpaired as if the work of the glacier had been done only a few generations since.

Some idea of the massiveness of the ice-sheet is obtainable from a consideration of the way in which the striæ run across important hill ranges, and athwart what might seem to be their natural direction. Whilst there was a general southward movement from the great snow-fields of Scandinavia, the high grounds of Britain were important enough to have their own independent ice, which, as the striæ show, radiated outward, some of it passing westwards into the Atlantic and some of it eastward into the North Sea. So thick must it have been as it moved off the Scottish Highlands that it went across the broad plains of Perthshire, filling them up to a depth of at least 2000 feet, and passing across the range of the Ochil Hills, which at a distance of 12 miles runs parallel with the Highland mountains, and reaches a height of 2352 feet. In such cases it has been observed that the striæ along the lower slopes of the hill barrier run either parallel with the trend of the ground or slant up obliquely, while those on the summits may cross the ridge at right angles to its course. This shows that there must have been a differential movement in the great ice-sheet, the lower parts, as in a river, becoming embayed, and being forced to move in a direction sometimes even at a right angle to that of the general advance. On the lower grounds, also, the striæ, converging from different sides, unite at last in one general trend as the various ice-sheets must have done, as they descended from the high grounds on either side and coalesced into one common mass. This is well seen in the great central valley of Scotland. Still more marked is the deflexion of the striæ in Caithness and the Orkney and Shetland Islands. In these districts the general direction of the striation is from S.S.E., which, in Caithness, is nearly at right angles to what might have been anticipated. This deflexion has been attributed to the coalescence of the ice from Norway and from the northern Highlands in the basin of the North Sea, and its subsequent progress along the resultant line into the Atlantic. But it may have been due to the fan-shaped spreading out of the vast mass of ice descending into the Moray Firth; for the striæ on the south side of that inlet run E. by S., and at last S.E., on the north-east of Aberdeenshire, showing that the ice, on the one hand, turned southwards into the North Sea, until it met the N.E. stream from Kincardineshire and the valleys of the Dee and Don, while, on the other, it moved northward so as no doubt to join the Scandinavian sheet, and march with it into the Atlantic. The basin of the North Sea must have been choked up with ice in its northern parts, if not entirely. At that time England and the north-west of France were united, so that any portion of the North Sea basin not invaded by land-ice must have formed a lake, with its outlet by the hollow through which the Strait of Dover has since been opened. It has been suggested that during such a condition of things the widespread fresh-water deposit termed Loess was formed, which covers so large a space in the lower plains of the Rhine and the north of Belgium, and appears in the valleys of the south-east of England.

The ice is computed to have been at least between 6000 and 7000 feet thick in Norway, measured from the present sea-level. From the height at which its transported debris has been observed on the Harz, it is believed to have been at least 1470 feet thick there, and to have gradually risen in elevation as one vast plateau, like that which at the present time covers the interior of Greenland. Among the Alps it attained almost incredible dimensions. The present snowfields and glaciers of these mountains, large though they are, form no more than the mere shrunken remnants of the great mantle of snow and ice which then over-spread Switzerland. In the Bernese Oberland, for example, the valleys were filled to the brim with ice, which, moving northwards, crossed the great plain, and actually overrode a part of the Jura mountains. Huge fragments of granite and other rocks from the central chain of the Alps are found high on the slopes of that range of heights.

Boulder-clay or Till.—Under this name is included the debris which accumulated and was pushed onward under the ice-sheet, the "grund moräne" or "moraine profonde" (*ante*, p. 282). All over the low grounds of North Germany, Denmark, and Holland lies a stony or earthy clay passing into sand or gravel, in which, together with locally derived debris, there is a greater or less proportion of fragments from the north. Some of the rocks of Scandinavia, Finland, and the Upper Baltic are of so distinctive a kind that they can be recognized in small pieces in the boulder-clay. Thus the peculiar syenite of Laurwig in the south of Norway has been recognized abundantly in the drift of Denmark; it occurs in that of Hamburg, and in the boulder-clay of the Holderness cliffs in Yorkshire. The well-known Rhomben-porphyr of southern Norway has likewise been recognized at Holderness. Fragments of the Silurian rocks from Gothland, or from the Russian islands Dago or Oesel, have been met with as far as the north of Holland. These transported fragments, so abundant within the line of demarcation just traced, are an impressive testimony to the movements of the northern ice-sheet and floating ice.

The boulder-clay is not spread as a uniform sheet over the ground, but varies greatly in thickness and in irregularity of surface. Round the mountainous centres of dispersion it is apt to occur in long ridges or "drums" which run in the general direction of the rock-striation.

In those areas which served as independent centres of dispersion for the ice-sheet, the boulder-clay partakes largely of the local character of the rocks of each district where it occurs. Thus in Scotland the clay varies in colour and composition as it is traced from district to district. Over the Carboniferous rocks it is dark, over the red sandstones it is red, over the Silurian rocks it is fawn-coloured. The great majority of the stones also are of local origin, not always from the immediately adjacent rocks, but from points within a distance of a few miles. Evidence of transport, however, can be gathered from the stones, for they are found in almost every case to include a proportion of fragments which have come from beyond the district. The direction indicated by the percentage of travelled stones is always the same for each region. Thus, in the lower part of the valley of the Firth of Forth, while most of the fragments are from the surrounding Carboniferous formations, from 5 to 20 per cent. is found to have come eastward from the Old Red Sandstone range of the Ochil Hills—a distance of 25 or 30 miles, while 2 to 5 per cent. are pieces of the Highland rocks, which must have come from the high grounds at least 50 miles to the north-west. The evidence of dispersion revealed by the stones in the boulder-clay harmonizes with that of the striæ on the rocks. Every main mass of elevated ground in Britain seems to have caused the ice to move outward from it for a certain distance, until the stream coalesced with that descending from some other height. In Scotland the ice was massive enough to move out into the basin of the North Sea (then doubtless in great part usurped by the glaciers) until it met that which was streaming down from Scandinavia. Hence no Scandinavian blocks have ever been found in Scotland. But the Norwegian ice which crept southwards across Denmark, may once have extended across the North Sea to the Yorkshire coast, if the Scandinavian stones of Holderness were not carried on floating ice.

The stones in the boulder-clay have a characteristic form and surface. They are usually oblong, have one or more flat sides or "soles," are smoothed or polished, and have their edges worn round. Where they consist of a fine-grained enduring rock, they are almost invariably found to be striated, the striæ running with the long axis of the stone. These markings are precisely similar to those on the solid rocks underneath the boulder clay, and like them have manifestly been produced by the friction of stones and grains of sand as the whole mass of debris was being steadily pushed on in one given direction by the resistless advance of the ice (*ante*, p. 282).

Interglacial Beds.—The boulder-clay is not one uniform mass of material. In a limited section, indeed, it usually appears as an unstratified mass of stiff stony clay. But it is found on further examination to be split up with various inconstant and local interstratifications. Beds of sand, gravel, fine clay, and peaty layers occur in this way in different platforms in the boulder clay. In Scotland and elsewhere these interpolated beds bear witness to intervals when the ice retired from the area, and the land, so far as uncovered, was clothed with vegetation and traversed by herds of the hairy mammoth, reindeer, and musk-ox. Hence the long glacial period must have been interrupted by episodes probably of considerable duration when a milder climate prevailed. Such an alternation of conditions is explained on the hypothesis discussed in previous pages (*ante*, pp. 218–220).

Evidences of Submergence.—After the ice had attained its greatest development, the land, which perhaps in north-western Europe stood at a higher level above the sea than it has done since, began to subside. The ice-fields were carried down below the sea-level, where they broke up and cumbered the sea with floating bergs. The heaps of loose debris which had gathered under the ice, being now exposed to waves, ground-swell, and marine currents, were thereby more or less washed down and reassorted. Coast-ice, no doubt, still formed along the shores, and was broken up into moving floes, as happens every year now in northern Greenland. The proofs of this phase of the long glacial period are contained in the sands, gravels, erratic blocks, and stratified clays which overlie the coarse older till. It is difficult to determine the extent of the submergence, for when the land rose the more elevated portions continued to be the seats of glaciers, which, moving over the surface, destroyed the deposits which would otherwise have remained as witnesses of the presence of the sea. The most satisfactory evidence is undoubtedly that supplied by beds of marine shells. These have been observed on Moel Tryfan, in North Wales, at a height of no less than 1350 feet, but as the same kind of deposits in which they occur extend to a much greater height, the submergence probably considerably exceeded the limit at which the shells occur. In Cheshire beds of shells have been met with at a height of

1200 feet. In Scotland the highest level from which they have yet been obtained is 524 feet; and in this instance they lie in one of the interstratifications in the boulder-clay. The coast of Scotland is fringed by a succession of raised beaches which, up to that at 100 feet above the present mean tide-level, are often remarkably fresh. The 100-feet terrace forms a wide plateau in the estuary of the Forth, and the 50-feet terrace is as conspicuous on the Clyde. The elevation of the land has brought up within tide-marks some of the clays deposited over the sea-floor during the time of the submergence. In the Clyde basin and some of the western fjords these clays (Clyde beds) are full of shells. Comparing the species with those of the adjacent seas, we find them to be more boreal in character; nearly the whole of the species still live in Scottish seas, though a few are extremely rare. Some of the more characteristic northern shells in these deposits are *Pecten Islandicus*, *Tellina calcarea*, *Leda truncata*, *L. lanceolata*, *Saxicava rugosa*, *Panopæa Norvegica*, *Trophon clathratum*, and *Natica clausa*.

That ice continued to float about in these waters is shown by the striated stones contained in the fine clays, and by the remarkably contorted structure which these clays occasionally display. Sections may be seen where, upon perfectly undisturbed horizontal strata of clay and sand, other similar strata have been violently crumpled, while horizontal beds lie directly upon them. These contortions must have been produced by the horizontal pressure of some heavy body moving upon the originally flat beds. No doubt the agent was ice in the form of large stranding masses which were driven aground in the fjords or shallow waters where the clays accumulated. Another indication of the presence of floating ice is furnished by large boulders scattered over the country, and lying sometimes on the stratified sands and gravels, though no doubt many of the so-called erratics belong to the time of the chief glaciation.

One of the most puzzling members of the Drift is the series of sands and gravels which cover the low grounds in many places, and rise up to heights of 1000 feet and more. These deposits are sometimes spread out in undulating sheets, which, in the lower districts, seem to merge insensibly into the marine terraces and raised beaches. But they are also very commonly disposed in remarkable mounds and in ridges which run across valleys, along hill-sides, and even over watersheds. These ridges are known in Scotland as kames, in Ireland as eskers, and in Scandinavia as osar. They consist sometimes of coarse gravel or earthy detritus, but more usually of clean, well-stratified sand and gravel, the stratification towards the surface corresponding with the external slopes of the ground, in such a manner as to prove that the ridges are original forms of deposit, and not the result of the irregular erosion of a general bed of sand and gravel. Some writers have compared these features to the submarine banks formed in the pathway of tidal currents near the shore. Others have supposed them rather to be of terrestrial origin, due to the melting of the great snow-fields and glaciers, and the consequent discharge of large quantities of water over the country. But no very satisfactory explanation has yet been given.

Re-emergence.—Later Glaciers.—When the land began to rise again, the temperature all over central and northern Europe was still severe. Vast sheets of ice still held sway over the mountains, and continued to descend into the lower tracts and to go out to sea. To this period are ascribed certain terraces or "parallel-roads" which run along the sides of valleys in the Scottish Highlands. It is believed that the mass of ice descending from some of the loftier snow-fields of this time was so great as to accumulate in front of lateral valleys, and to so choke them up as to cause the water to accumulate in them and flow out in an opposite direction by the *col* at the head. In these natural reservoirs the level at which the water stood for a time was marked by a horizontal ledge or platform due partly to erosion of the hill-side and partly to the arrest of the descending debris when it entered the water.

Every group of mountains nourished its own glaciers; even small islands, such as Arran in Scotland, had their snowfields, whence glaciers crept down into the valleys and shed their moraines. It would appear indeed that some of the northern glaciers of Scotland continued to reach the sea-level even when the land had risen to within 50 feet or less of its present elevation. On the east side of Sutherlandshire the moraines descend to the 50-feet raised beach; on the west side of the same county they come down still lower. The higher mountains of Europe still show the descendants of these later glaciers, but the ice has retreated from the lower elevations. In the Vosges the glaciers have long disappeared, but their moraines remain still fresh. In Wales, Cumberland, and the southern uplands and Highlands of Scotland, moraines, perched blocks, and *roches moutonnées* attest the abundance and persistence of the last glaciers. It is sometimes possible to trace the stages in the gradual retreat of the ice towards its parent snow-fields, for the crescent-shaped moraine mounds lie one behind another until they finally die out about the head of the valley, near what must have been the edge of the snow-field.

We know as yet very little of the fauna and flora of the land during the Glacial Period in Europe. The vegetation was doubtless in great measure the same as that of arctic Norway at the present day. The animals included the musk-ox, lemming, rein-deer, and other still living arctic forms, but included some which have become extinct, such as the hairy mammoth and woolly rhinoceros. During the milder inter-glacial periods denizens of warmer regions found their way northwards into Europe. Thus the hippopotamus haunted the rivers of the south of England. By degrees, as the climate ameliorated, the arctic vegetation was finally extirpated from the lower grounds of central and western Europe, and plants loving a milder temperature, which had doubtless been natives of Europe before the period of great cold, were enabled to reoccupy the sites whence they had been driven. On the higher mountains, where the climate is still not wholly uncongenial for them, colonies of this once general arctic flora still survive. The arctic animals have also been driven away to their northern homes, or have become wholly extinct. And thus, as imperceptibly as it began, the long and varied Ice Age came to an end as it merged into the next succeeding geological period.

Recent or Human Period.

That long succession of ages to which the name of the Glacial Period has been given shaded without abrupt change of any kind into what is termed the Human or Recent Period. Indeed it may be said with truth that the Glacial Period still exists in Europe. The snow-fields and glaciers have disappeared from Britain, but they still linger among the Pyrenees, remain in larger mass among the Alps, and spread over wide areas in northern Scandinavia. This dovetailing or overlapping of geological periods has been the rule from the beginning of time, the apparently abrupt transitions in the geological record being due to imperfections in the chronicle.

The question has often been asked whether man was coeval with the Ice Age. To give an answer, we must know within what limits the term Ice Age is used, and to what particular country or district the question refers. For it is evident that even to-day man is contemporary with the Ice Age in the Alpine valleys and in Finmark. There can be no doubt that he inhabited Europe after the greatest extension of the ice, but while the rivers were still larger than now from the melting snow, and flowed at higher levels.

The proofs of the existence of man in former geological periods are not to be sought for in the occurrence of his own bodily remains, as in the case of other animals. His bones are indeed now and then to be found, but in the vast majority of cases his former presence is revealed by the implements he has left behind him, formed of stone, metal, or bone. Many years ago the archæologists of Denmark, adopting the subdivisions of the Latin poets, classified the prehistoric traces of man in three great divisions—those of (1) the Stone Age, (2) the Bronze Age, and (3) the Iron Age. There can be no doubt that, on the whole, this has been the general order of succession. Men used stone and bone before they had discovered the use of metal. Nevertheless, the use of stone long survived the introduction of bronze and iron. In fact, in many European countries where metal has been known for many centuries, there are districts where stone implements are still employed, or where they were in use until quite recently. It is obvious also that, as there are still barbarous tribes unacquainted with the fabrication of metal, the Stone Age is not yet extinct in many parts of the world. In this instance we again see how geological periods run into each other. The nature or shape of the implement cannot therefore be always a very satisfactory proof of antiquity. We must judge of it by the circumstances under which it was found. From the fact that in north-western Europe the ruder kind of stone weapons occurs in what are certainly the older deposits, while others of more highly finished workmanship are found in later accumulations, the Stone Age has been subdivided into an early or Palæolithic and a later or Neolithic epoch. There can be no doubt, however, that the later was in great measure coeval with the age of bronze, and even to some extent of iron.

The deposits which contain the history of the human period are cavern-loam, river-alluvia, lake-bottoms, peat-mosses, sand-dunes, and other superficial accumulations.

Most calcareous districts abound in underground tunnels and caverns which have been dissolved by the passage of water from the surface (*ante*, p. 271). In a large number of cases these cavities have communicated with the outer surface, so that terrestrial animals, including man himself, have made use of them as places of retreat, or have fallen or been washed into them. The floors of some of them are covered with loam or cave-earth, resulting from the deposit of the silt carried in the water which formerly flowed through them. Very commonly also, a deposit of stalagmite has formed from the drip of the roof. Hence any organic remains which may have found their way to these floors have been sealed up and admirably preserved.

Above the present levels of the rivers there lie platforms or terraces of alluvium, sometimes to a height of 80 or 100 feet. These deposits are fragments of the river gravels and loams laid down when the streams flowed at that elevation, and therefore before the valleys were widened and deepened to their present form. River action is at the best but slow. To erode the valleys to so great a depth beneath the level of the upper alluvia, must have demanded a period of many centuries. There can therefore be no doubt of the high antiquity of these deposits. They have yielded the remains of many mammals, some of them extinct, together with the flint flakes made by man. From the nature and structure of some of the high-lying gravels, there can be little doubt that they were formed at a time when the rivers were larger than now, and were liable to be frozen and to be obstructed by large accumulations of ice. We are thus able to connect the formations of the human period with some of the later phases of the Ice Age in the west of Europe.

From the evidence of caverns and river-alluvia of Britain, Germany, and France, Dawkins enumerates about fifty mammals as among the chief inhabitants of Europe during the early human period. They include many of the animals still found wild in Europe, Asia, or Africa, such as the marmot, hare, beaver, lemming, leopard, lynx, wild cat, otter, brown bear, wolf, fox, African elephant, musk sheep, chamois, wild boar, horse, reindeer, and hippopotamus. It will be observed what a remarkable mixture there is in this list of forms now found in alpine or arctic regions, on the one hand, with others only now to be seen in warm latitudes. Probably there continued to be great alternations of climate and changes in the distribution of food, so that migrations successively from opposite quarters took place into central and western Europe. But among the denizens of these regions were some that have been long extinct, such as the mammoth, *Elephas antiquus*, *Machairodus latidens*, the woolly rhinoceros, the Irish elk, and others. That man was the contemporary of these extinct forms is shown both by the association of his flint weapons with their remains, and by the discovery of a tusk of the mammoth with an admirable outline of the animal carved upon it. This valuable relic, with bones of the reindeer and stag admirably sculptured into likenesses of these animals, was found in one of the caves of Perigord in central France.

From the beds of lakes, and from peat-mosses, evidences of more advanced civilization have been obtained. In Switzerland and elsewhere, remains of wooden pile-dwellings have been observed during times when the water has been low. Associated with these are weapons and implements of stone, in other cases of bronze and of iron, pottery, rude kinds of cloth, seeds of different cereals, and bones of domesticated animals. The dog, swine, goat, horned sheep, and other familiar animals appear as the companions of man. But there is evidence that some of the creatures which he tamed to his use were not natives of Europe, but had their original stocks in central Asia, and that some of his grains must likewise have been introduced. Hence we have glimpses into some of the early human migrations from that eastern centre whence so many successive waves of population have invaded Europe.

The later chronicles of the geologist merge insensibly into those of the archæologist. The latter claims as his field whatever belongs to the history of man on the globe; the former includes the history of man in that larger history of the earth of which a brief outline has been given in the foregoing pages.

Post-Tertiary Series in North America.

The general succession of events in post-Tertiary times appears to have been nearly the same over the northern hemisphere both in the New and the Old World. In North America we have the same sharply-defined line between the older post-Tertiary deposits and previous formations, due to the glacial conditions which, overspreading these regions, in great measure destroyed the superficial accumulations of the immediately preceding eras. The Quaternary or post-Tertiary formations are grouped by American geologists in the following subdivisions:—

4. Recent and Prehistoric	Peat, alluvium, blown sand, "alkali" deposits, geyser deposits, cave deposits, artificial mounds.
3. Terrace	River-terraces, loess. Raised beaches.
2. Champlain ...	*Saxicava* sand, Champlain clays, *Leda* clay.
1. Glacial	Boulder clays, unstratified clays, sands, and gravels.

1. *Glacial.*—As in Europe, the glacial deposits increase in thickness and variety from south to north. The southern limit of the unstratified drift lies somewhere in the neighbourhood of the 39th parallel of north latitude, and the deposit ranges from the Atlantic westward to the meridian of 98°. It spreads, therefore, across British North America, and is found over a considerable area of the north-eastern States. It rises to a height of 5800 feet among

the White Mountains. The absence of any true boulder-drift on the Rocky Mountain slopes, where it might have been looked for, is remarkable.

Underneath the boulder-clay the solid rocks, as in Europe, are often well striated. The direction of the striæ is generally southward, varying to south-east and south-west according to the form of the ground. In recent years extensive ice-worn rock-surfaces have been observed among the Rocky Mountains by Hayden, King, and others, proving that these elevations formerly possessed their glaciers, if they were not buried under the great ice-sheet.

The drift bears witness to a general southerly transport of material, and, in conjunction with the striated rocks, shows that the great ice-sheet moved from north to south at least as far as about the latitude of Washington. Logan mentions that in some parts of Canada the glacial drift and boulders run in ridges north and south, thus corresponding with the general direction of transport, like the "drums" in Britain. As in Europe, the coarse boulder-clay at the base of the Quaternary deposits is essentially unfossiliferous.

2. *Champlain.*—Under this name American geologists class the sands, gravels, and clays which overlie the lower boulder-drift. These deposits include coarse unstratified gravels, as well as finely-stratified clays. In eastern Canada they are well developed, and show the following subdivisions :—

Upper.	St Maurice and Sorel sands; *Saxicava* sand of Montreal; upper sand and gravel of Beauport; upper Champlain clay and sand of Vermont.
Lower.	*Leda* clay of the St Lawrence and Ottawa; lower shell-sand of Beauport; lower Champlain clay of Vermont.

The lower subdivisions consist chiefly of clays, which rise to a height of 600 feet above the sea. They have some interstratified beds of siliceous sand, but few boulders. They contain marine organisms, such as *Leda truncata*, *Saxicava rugosa*, *Tellina Grœnlandica*, bones of seals, whales, &c. On the banks of the Ottawa, in Gloucester, the clays contain numerous nodules which have been formed round organic bodies, particularly the fish *Mallotus villosus* or capeling of the Lower St Lawrence. Dawson also obtained numerous remains of terrestrial marsh plants, grasses, carices, mosses, and algæ. This writer states that about 100 species of marine invertebrates have been obtained from the clays of the St Lawrence valley. All except four or five species in the older part of the deposits are shells of the boreal or Arctic regions of the Atlantic; and about half are found also in the glacial clays of Britain. The great majority are now living in the Gulf of St Lawrence and neighbouring coasts, especially off Labrador.[1]

3. *Terrace.*—This division includes the terraced deposits of alluvial material so marked along the river valleys and lake margins in the northern part of the United States and in Canada, and found also in some degree along the sea-coast. These deposits occur in successive platforms or terraces, marking the contraction in volume of the lakes and rivers, consequent, probably, upon intermittent upheavals of the land. They are well developed round the great lakes. Thus in the basin of Lake Huron deposits of fine sand and clay containing fresh-water shells rise to a height of 40 feet or more above the present level of the water, and run back from the shore sometimes for 20 miles. Regular terraces, corresponding to former water-levels of the lake, run for miles along the shores at heights of 120, 150, and 200 feet. Shingle beaches and mounds or ridges, exactly like those now in course of formation along the exposed shores of Lake Huron, can be recognized at heights of 60, 70, and 100 feet. Unfossiliferous terraces occur abundantly on the margin of Lake Superior. At one point mentioned by Logan, no fewer than seven of these ancient beaches occur at intervals up to a height of 331 feet above the present level of the lake.[2] Most of the rivers are bordered with lines of terraces, as in the well-known example of the Connecticut valley described by Hitchcock. The rivers are believed to have had their maximum volume at the beginning of the Terrace epoch, swollen doubtless by the melting of the still existing ice-sheets and snow-fields. Their work consisted partly in depositing fine alluvium or loess over their flood-plains, partly in scouring their channels out of the Champlain formations. Greater elevation towards the interior, by augmenting their slope, increased their excavating power.

Terraces of marine origin likewise occur both on the coast and far inland. On the coast of Maine they occur at heights of 150 to 200 feet, round Lake Champlain at least as high as 300 feet, and at Montreal nearly 500 feet above the present level of the sea. In the absence of organic remains, however, it is not always possible to distinguish between terraces of marine origin marking former sea-margins, and those left by the retirement of rivers and lakes. In the Bay of Fundy evidence has been cited by Dawson to prove subsidence, for he has observed there a submerged forest of pine and beech lying 25 feet below high-water mark.[3]

4. *Recent and Prehistoric.*—The deposits in this group are essentially the same with those in Europe; and, as in that continent so in America, no definite lines can be drawn within which they should be confined. They cannot be sharply separated from the Terrace series, on the one hand, nor from modern accumulations, on the other. Besides the marshes, peat-bogs, and other organic deposits which belong to an early period in the human occupation of America, some of the younger alluvia of the river-valleys and lakes can no doubt claim a high antiquity, though they have not supplied the same copious evidence of early man which gives so much interest to the corresponding European formations. Heaps of shells of edible species occur on the coasts of Nova Scotia, Maine, &c. The large mounds of artificial origin in the Mississippi valley have excited much attention.

PART VII.—PHYSIOGRAPHICAL GEOLOGY.

In the investigation of the geological history of any country, two questions present themselves. We have first to consider the nature and arrangement of the rocks which underlie the surface, and to ascertain from them what has been the march of events, what changes in geography have successively taken place, and what races of plants and animals have come and gone. The gradual geological evolution of the earth has been sketched in the foregoing part of this article. But besides the history of the solid rocks beneath the surface of the land, there is that of the surface itself. Mountains and plains, valleys and ravines, cliffs, peaks, passes, lakes, and the many other features of a country demand attention. By what processes have these varied outlines been impressed upon the surface of the globe? Are they of different ages, and if so, how can their history be ascertained?

The branch of geological inquiry which endeavours to answer these questions has been termed Physiography or Physiographical Geology. Its investigations evidently demand an acquaintance with Stratigraphical Geology. We must be able to trace out the former geographical conditions of the globe before we can adequately reason on the origin of those now existing. Hence the consideration of this branch of the subject has necessarily been reserved for this concluding section.

The stratified formations, of which the succession and history have been traced in the previous pages, were chiefly laid down on the sea-floor in wide horizontal or gently inclined sheets. They have since been upraised into land; their horizontality has been in great part destroyed; and they have been enormously wasted by denuding agents. In considering therefore how they have acquired their present external forms, we have to deal with the effects of two kinds of forces, one acting from below, the other on the surface.

These stratified rocks were, on the whole, deposited in shallow water, and have been repeatedly upraised and denuded, so that the younger have been formed out of the waste of the older. They have their modern counterparts, not in the deposits of the great ocean-basins, but in those of comparatively shallow seas. The inference to be drawn from these facts is that the present continental regions, through many local oscillations, have existed as terrestrial ridges from a remote geological antiquity, and that the ocean basins in like manner have, on the whole, retained their identity. When the geologist asks himself how the present distribution of sea and land is to be accounted for, he finds that the answer to the question goes back to early Palæozoic times, whence he can in some cases trace the gradual growth of a continent downward through the long cycles of geological time. But there still remains the problem to account for the original wrinkling of the surface of the globe, whereby the present great ridges and hollows were produced.

It is now generally agreed that these inequalities have been produced by unequal contraction of the earth's mass, the interior contracting more than the outer crust, which must therefore have accommodated itself to this diminution of diameter by undergoing corrugation. But there seems

[1] *Acadian Geology*, p. 76. [2] *Geology of Canada*, p. 910.
[3] *Acadian Geology*, p. 28.

to have been some original distribution of materials in the globe that initiated the depressions on the areas which they have retained. It has been already pointed out (*ante*, p. 223) that the matter underlying the oceans is more dense than that beneath the continents, and that, partly at least, to this cause must the present position of the oceans be attributed. The early and persistent subsidence of these areas, with the consequent increase of density, seems to have determined the main contours of the earth's surface.

From what has been stated in part iv., the reader will understand that rocks which were originally horizontal, or nearly so, have been crumpled over tracts thousands of square miles in extent, so as to occupy now a superficial area greatly less than that which they originally covered. It is evident that they have been horizontally compressed, and that this result can only have been achieved as a consequence of the subsidence of such a curved surface as that of our globe. The difficulty of explaining these corrugations on the hypothesis of the contraction of a solid globe is undoubtedly great. Mr O. Fisher, indeed, believes that the present inequalities of contour on the earth's surface are from sixty-six to eleven and a half times as great as they would have been had they resulted from the contraction of a solid globe; and he has suggested that the earth need not have become solid throughout simultaneously, and consequently may have been considerably larger than it is now at the time when a solid crust was first formed.[1]

The geological phenomena long ago led to a belief in the liquidity of the earth's interior. Since this belief has been so weightily opposed by the physical arguments already adduced (*ante*, p. 225), geologists have endeavoured to modify it in such a way as, if possible, to satisfy the requirements of physics, while at the same time providing an adequate explanation of the corrugation of the earth's crust. Mr Hopkins, Professor Dana, Professor Shaler, and Mr Fisher have, on different grounds, advocated the existence of a fluid or viscous substratum beneath the crust, the contraction and consolidation of which produce the corrugations of the rocks and of the surface. "The increase of temperature," says Mr Fisher, "though rapid near the surface, becomes less and less as we descend, so that, if the earth were once wholly melted, the temperature near the centre is not very greatly above what it is at a depth which, compared to the earth's radius, is small. Consequently, if it requires great pressure to solidify the materials at such a temperature, it is probable that the melting temperature may be reached before the pressure is sufficient to solidify." The crust, of course, must be able to sustain itself on the corrugated surface of the supposed viscous layer without breaking up and sinking. The same writer has even suggested that the observed amount of corrugation is more than can be accounted for even on this hypothesis, and that the shrinkage may have been due not merely to cooling, but to the escape of water from the interior in the form of the superheated steam of volcanic vents.[2] More recently Herr Siemens has been led, from observations made in May 1878 at Vesuvius, to conclude that vast quantities of hydrogen gas, or combustible compounds of hydrogen, exist in the earth's interior, and that these, rising and exploding in the funnels of volcanoes, give rise to the detonations and clouds of steam.[3]

Leaving the vexed question of the condition of the earth's interior, the hypothesis of secular cooling and contraction furnishes a natural explanation of the origin of the dominant elevations and depressions of the surface, and of the intense crumpling which the rocks in many regions have undergone. Taking 0·09 as the coefficient of contraction for a supposed stratum 500 miles thick, lying beneath 25 miles of crust, and passing from a fused into a solid state, Mr Fisher found that every 100 miles measured along a great circle on the surface would have been one mile larger before the contraction, and that this might produce a triangular elevation of "25 square miles on a base of 100 miles, which would give a range of mountains half a mile high. If only 50 miles out of the hundred were disturbed, the range would be a mile high, and so on."[4]

The effects of this lateral pressure may show themselves either in broad dome-like elevations, or in narrower and loftier ridges of mountain. The structure of the crust is so complex, and the resistance offered by it to the pressure is consequently so varied, that abundant cause is furnished for almost any diversity in the forms and distribution of the wrinkles into which it is thrown. It is evident, however, that the folds have tended to follow a linear direction. In North America, from early geological times, they have kept on the whole on the lines of meridians. In the Old World, on the contrary, they have chosen diverse trends, but the last great crumplings—those of the Alps, Caucasus, and the great mountain ranges of central Asia—have risen along parallels of latitude.

Mountain chains must therefore be regarded as evidence of the shrinkage of the earth's mass. They may be the result of one movement, or of a long succession of such movements. Formed on lines of weakness in the crust, they have again and again given relief from the strain of compression by undergoing fresh crumpling and upheaval. The successive stages of uplift are usually not difficult to trace. The chief guide is supplied by unconformability, as explained on p. 318. Let us suppose, for example, that a mountain range consists of upraised Lower Silurian rocks, upon the upturned and denuded edges of which the Carboniferous Limestone lies transgressively. The original upheaval of that range must have taken place at the period of geological time represented by the interval between the Lower Silurian and the Carboniferous Limestone formations. If, in following the range along its course, we found at last the Carboniferous Limestone also highly inclined and covered unconformably by the Upper Coal-measures, we should know that a second uplift of that portion of the ground had taken place between the time of the Limestone and that of the Upper Coal-measures. By this simple and obvious kind of evidence the relative ages of different mountain chains may be compared. In most great mountain-chains, however, the rocks have been so intensely crumpled, and even inverted, that much labour may be required before their true relations can be determined.

The Alps offer an instructive example of a great mountain chain formed by repeated movements during a long succession of geological periods. As has been already stated, the central portions of the chain consist of gneiss, schists, granite, and other crystalline rocks, partly referable to the Archæan series, but many of which appear to be metamorphosed formations of Palæozoic, Secondary, and even of older Tertiary age.

It would appear therefore that the first outlines of the Alps were traced out even in Archæan times, and that after submergence, and the deposit of Palæozoic formations along their flanks, if not over most of their site, they were re-elevated into land. From the relations of the Mesozoic rocks to each other, we may infer that several renewed uplifts after successive denudations took place before the beginning of the Tertiary formations. A large part of the range was, as we have seen, submerged during the Eocene period under the waters of that wide sea which spread across the centre of the Old World, and in which the Nummulitic Limestone and Flysch were deposited. But about the close of that period the grand upheaval took place to which the present magnitude of the mountains is chiefly due. The older Tertiary rocks, previously horizontal under the sea, were raised up into land, crumpled, dislocated, inverted, together with all the older formations of the chain. So intense was the compression to which the Eocene clays and sands were subjected

[4] *Cambridge Phil. Trans.*, vol. xi. pt. iii.

that they were converted into rocks as hard and crystalline as many of the Palæozoic masses. It is strange to reflect that the enduring materials out of which so many of the mountains, cliffs, and pinnacles of the Alps have been formed are of no higher geological antiquity than the London Clay and other soft Eocene deposits of the south of England. After the paroxysm of elevation had ended, one or more large lakes were formed along the northern base of the mountains. In these hollows the Swiss molasse accumulated to a depth of more than 6000 feet—a great pile of slowly formed gravels, sands, and clays. That the sea gained occasional access to the region is shown by the interpolation of bands containing marine organisms, as already stated (*ante*, p. 363). Not improbably a gradual subsidence of the region was going on during the formation of the molasse. But towards the close of the Miocene period another great epoch of mountain-making was ushered in. The lakes disappeared, and their thick sediments were thrust up into large, broken, mountain masses. The Righi, Rossberg, and other prominent heights along the northern flank of the Alps are formed of these upturned lacustrine deposits. Since that great movement no paroxysm seems to have affected the Alpine region. Ceaseless changes, indeed, have been in progress, but they have been due not so much to subterranean causes as to those subaerial forces which are still so active.

The gradual evolution of a continent during a long succession of geological periods has been admirably worked out for North America by Dana, King, Hayden, Newberry, Powell, Dawson, and others. The general character of the structure is extreme simplicity, as compared with that of the Old World. In the Rocky Mountain region, for example, while the Palæozoic formations lie unconformably upon the Archæan gneiss, there is, according to King, a regular conformable sequence from the Lower Silurian to the Jurassic rocks. During the enormous interval of time represented by these massive formations what is now the axis of the continent remained undisturbed save by a gentle and protracted subsidence. In the great depression thus produced all the Palæozoic and a great part of the Mesozoic rocks were accumulated. At the close of the Jurassic period the first great upheavals took place. Two lofty ranges of mountains,—the Sierra Nevada (now with summits more than 14,000 feet high, and the Wahsatch,—400 miles apart, were pushed up from the great subsiding area. These movements were followed by a prolonged subsidence, during which Cretaceous sediments accumulated over the Rocky Mountain region to a depth of 9000 feet or more. Then came another vast uplift, whereby the Cretaceous sediments were elevated into the crest of the mountains, and a parallel coast-range was formed fronting the Pacific. Intense metamorphism of the Cretaceous rocks is stated to have taken place. During the Tertiary ages the Rocky Mountains were permanently raised above the sea, and gradually elevated to their present height. Vast lakes existed among them, in which, as in the Miocene basins of the Alps, enormous masses of sediment accumulated. The slopes of the land were clothed with an abundant vegetation, in which, as already stated (*ante*, p. 365), we may trace the ancestors of many of the living trees of North America. One of the most striking features in the later phases of this history was the outpouring of great floods of trachyte and other lavas from many points and fissures over a vast space of the Rocky Mountains. In the Snake River region these lavas have a depth of 700 to 1000 feet, over an area 300 miles in breadth.

These examples show that the elevation of mountains has been occasional and, so to speak, paroxysmal. Long intervals elapsed when a slow subsidence took place, but at last a point was reached when the descending crust, unable any longer to withstand the accumulated lateral pressure, was forced to find relief by rising into mountain ridges. With this effort the elevatory movements ceased. They were followed either by a stationary period, or more usually by a renewal of the gradual depression, until eventually relief was again obtained by upheaval, sometimes along new lines, but often on those which had previously been used.

We see also how, by such enormous compression, the rocks should have acquired a cleavage structure (*ante*, p. 306). Soft clays have been squeezed and folded till they have become hard fissile slates. So intense have been the corrugation and compression that the strata have undergone a chemical rearrangement of their particles; they have been "metamorphosed" or changed into schists and gneisses, if indeed some portions of them have not been actually fused and intruded into the surrounding masses as igneous rocks.

The consideration of these changes enables us to realize why the strata of a great mountain chain should rise into steeper folds as they are traced away from the plains, until they are found at last folded back upon themselves, and the older are made to overlie the younger. Instead of overlying the central and more ancient masses of the range, they seem really to dip into and under them, so that a section across the region might convey the impression of a great syncline instead of a great and complicated anticline. This fan-shaped arrangement of the rocks may be observed even in the single mountains of a great chain. Mount Blanc is a familiar example.

Another piece of geological structure is sometimes brought vividly before us by the examination of these regions of disturbance. Not only have the rocks been crumpled and inverted; they have likewise been traversed by great dislocations. Those on one side of a fissure have been pushed bodily over those on the other side, or they have experienced a vertical displacement of hundreds or even thousands of feet. As a rule, however, dislocations are more easily traced, if they are not also larger and more numerous, among the low grounds than among the mountains. One of the most remarkable and important faults in Europe is that which bounds the southern edge of the Belgian coal-field. It can be traced across Belgium, has recently been detected in the Boulonnais (*ante*, p. 350, *note*), and may not improbably run beneath the Secondary and Tertiary rocks of the south of England. It is a remarkable fact that faults which have a vertical displacement of many thousands of feet produce little or no effect upon the surface. The great Belgian fault, for example, is crossed by the valleys of the Meuse, and other northerly-flowing streams. Yet so indistinctly is it marked in the Meuse valley that no one would suspect its existence from any peculiarity in the general form of the ground, and even an experienced geologist, until he had learned the structure of the district, would scarcely detect any fault at all.

With the fractures along mountain chains we may connect the hot springs so frequently to be met with in these regions. But the most important connexion with the heated interior is that established by volcanic vents. The theory of secular contraction, while affording a rational explanation of the origin of the great terrestrial ridges, serves at the same time to show why volcanoes should so frequently rise along these ridges (*ante*, p. 254). The elevation of the crust, by diminishing the pressure on the parts beneath the upraised tracts, permits them to assume a liquid condition, and to rise within reach of the surface when, driven upwards by the expansion of superheated vapours, they are ejected in the form of lava or ashes.

It appears therefore that the present contours of the earth's surface must be due in large measure to the effects of the contraction of a cooling globe. The crust has been repeatedly corrugated, sometimes suffering sudden and paroxysmal shocks, at other times undergoing slow and long-continued upheaval and depression.

But these subterranean movements form only one phase of the operations by which the outlines of the land have been produced. They have ridged up the solid crust above the sea-level, and have thus given rise to land, but the land as we now see it has acquired its features from the prolonged and varied action of the epigene agents upon rocks of very varied heights and powers of resistance.

It is evident that, as a whole, the land suffers ceaseless erosion from the time that it appears above water. It is likewise clear, from the nature of the materials composing most of the rocks of the land, that they have been derived from old denudations of the same kind. And thus, side by side with the various upheavals and subsidences, there has been a continuous removal of materials from the land, and an equally persistent deposit of these materials under water, and consequent growth of new rocks.

This degradation of the surface may be aptly compared to a process of sculpturing, which begins as soon as the land emerges from the sea, and never ceases so long as any portion of the land remains above water. The implements employed by nature in this great work are those epigene forces whose operations have already been described. Each of them, like a special kind of graving tool, produces its own characteristic impress on the land. The work of rain, of frost, of rivers, of glaciers, can be readily discriminated, though they all combine harmoniously towards the achievement of their one common task. Hence the present contours of the land must depend partly (1) on the vigour with which the several epigene agents perform their work of erosion, (2) on the original configuration of the ground, and the influence it may have had in guiding the operations of these agents, and (3) on the varying structure and powers of resistance possessed by the rocks.

1. Taking a broad view of denudation, we may conveniently group together the action of air, frost, springs, rivers, glaciers, and the other agents which wear down the surface of the land, under the one common designation of subaerial, and that of the sea as marine. The general results of subaerial action are—to furrow and channel the land, to erode valleys, to sharpen and splinter the ridges of mountains, and thus, while roughening, to lower the general surface and carry out the detritus to the sea. The action of the sea, on the other hand, is to plane down the land to the level at which the influence of breakers and ground-swell ceases to have any erosive effect; the flat platform, so often visible between tide-marks on a rocky exposed coast-line, is an impressive illustration of the tendency of marine denudation. The combined result of subaerial and marine action, if unimpeded by any subterranean movement, would evidently be to reduce the land to one general level under the sea. For, except in that upper marginal zone where the waves and tidal currents play, the waters of the ocean protect the solid rocks which they cover. And the rocks indeed can find no permanent protection anywhere else. But to reduce a large area of land such as a continent to the condition of a submarine plain, would require a longer period of time than seems to have elapsed between two epochs of upheaval. Traces of ancient plains of marine denudation are to be met with in Scandinavia and in Scotland, on but a comparatively small scale, as if there had been time for only a narrow platform to be formed before the next paroxysm of contraction and uplift completely renovated the geography of the region.

Instead of trying to estimate how much work is done by each of the subaerial agents in eroding the land, we gain a much more impressive idea of the reality and magnitude of their work as a whole by treating their operations as one great process, the effects of which can be actually measured. The true gauge of the present yearly waste of the surface of the land is furnished by the amount of mineral matter carried every year into the sea by rivers. This mineral matter is partly in mechanical suspension, partly in chemical solution, and is to no small extent pushed in the form of shingle and sand along the bottoms of the streams. Some data respecting its amount have been already given (*ante*, pp. 274, 278). If we take the ratios furnished by the Mississippi as a fair average, which, from the vast area and varied climatal and geographical characters of the region drained by that river, they probably are, then we learn that $\frac{1}{6000}$th of a foot is worn away from the general surface of the land every year. At this rate, if the present erosion could be sustained, the whole American continent, of which, according to Humboldt, the mean height is 748 feet, would be worn down to the sea-level in about $4\frac{1}{2}$ millions of years —a comparatively short period in geological chronology. It is obvious, however, that the denudation is not equally distributed over the whole surface of the land. If $\frac{1}{6000}$th of a foot is the mean rate from the whole surface, then some parts, including the more level grounds, must lose very much less than that amount, while other parts, such as the slopes and valleys, must lose very much more. The proportions between these extremes must continually vary throughout every country, according to angle of declivity, nature of surface, amount and distribution of rainfall, and whether the rain is spread over the year or concentrated into a short period.

The proportion between the area covered by the more level ground of a country, where the rate of deundation is least, and that of the declivities, valleys, and stream channels, where that rate is greatest, may be assumed as nine to one. The extent of the annual waste may be further taken to be nine times greater over the latter than over the former, so that, while the more level parts of the surface have been lowered 1 foot, the valleys have lost 9 feet. Taking the mean rates of waste over the whole area to be $\frac{1}{6000}$th of a foot per annum we find that on these data the annual loss amounts to $\frac{5}{9}$ths of a foot from the flatter grounds and 5 feet from the valleys in 6000 years. This is equal to a loss of 1 foot from the former in 10,800 years and from the later in 1200 years, or to $\frac{1}{12}$th of an inch from the one in 75 and from the other in $8\frac{1}{2}$ years. At this rate of erosion, a valley 1000 feet deep may be excavated in 1,200,000 years. These estimates are only approximations to the truth, but they are valuable in directing attention to the real efficacy of the apparently insignificant subaerial denudation now in progress. Any other estimates of the relative amount of material worn away from the different parts of the surface may be taken, but the mean annual loss from the whole area, as ascertained by the river discharge, remains unaffected. If we represent too large an amount as removed from the valleys we diminish the loss from the open country, or if we make the contingent derived from the latter too great we lessen that from the former.

2. From this reasoning it follows that, apart altogether from irregularities of surface due to inequalities of upheaval, every area of land exposed to ordinary subaerial action must, in the end, be channeled into a system of valleys. Even a smooth featureless tract elevated uniformly above the sea would eventually be widely and deeply eroded. Nor would this require a long geological period, for, at the present rate of waste in the Mississippi basin, valleys 800 feet might be carved out in a million years. Undoubtedly the original features superinduced by subterranean action would guide and modify the operations of running water, though their influence would certainly wane as the features themselves slowly disappeared. In no case probably would the aboriginal contour remain through a succession of geological periods. Traces of it might still be discernible, but they would be well-nigh effaced by the new outlines produced by the superficial agents. In the vast tablelands of Colorado and the other western territories of the United States an impressive picture is visible of the results of mere subaerial erosion on undisturbed and nearly level strata. Systems of stream-courses and valleys, river gorges unexampled elsewhere in the world for depth and length, vast winding lines of escarpment, like ranges of sea-cliffs, terraced slopes rising from plateau to plateau, huge buttresses and solitary stacks standing like islands out of the plains, great mountain masses towering into picturesque peaks and pinnacles cleft by innumerable gullies, yet everywhere marked by the parallel bars of the horizontal strata out of which they have been carved—these are the orderly symmetrical characteristics of a country where the scenery is due entirely to the action of subaerial agents on the one hand and the varying resistance of perfectly regular stratified rocks on the other. The Alps, on the contrary, present an

instructive example of the kind of scenery that arises where a mass of high ground has resulted from the intense corrugation and upheaval of a complicated series of stratified and crystalline rocks, subsequently for a vast period carved by rain, frost, springs, and glaciers. We see how, on the outer flanks of those mountains among the ridges of the Jura, the strata begin to undulate in long wave-like ridges, and how, as we enter the main chain, the undulations assume a more gigantic tumultuous character, until, along the central heights, the mountains lift themselves towards the sky like the storm-swept crests of vast earth billows. The whole aspect of the ground suggests intense commotion. Where the strata appear along the cliffs or slopes they may often be seen twisted and crumpled on the most gigantic scale. Out of this complicated mass of material the subaerial forces have been ceaselessly at work since its first elevation. They have cut out valleys, sometimes along the original depressions, sometimes down the slopes. They have eroded lake-basins, dug out corries or *cirques*, notched and furrowed the ridges, splintered the crests, and have left no part of the original surface unmodified. But they have not effaced all traces of the convulsions by which the Alps were upheaved.

3. The details of the sculpture of the land have mainly depended on the nature of the materials on which nature's erosive tools have been employed. The joints by which all rocks are traversed have served as dominant lines along which the rain has filtered, and the springs have risen, and the frost wedges have been driven. On the high bare scarps of a high mountain the inner structure of the mass is laid open, and there the system of joints is seen to have determined the lines of crest, the vertical walls of cliff and precipice, the forms of buttress and recess, the position of cleft and chasm, the outline of spire and pinnacle. On the lower slopes, even under the tapestry of verdure which nature delights to hang where she can over her naked rocks, we may detect the same pervading influence of the joints upon the forms assumed by ravines and crags. Each kind of rock, too, gives rise to its own characteristic form of scenery. The massive crystalline rocks, such as granite, yield each in its own fashion to the resistless attacks of the denuding forces. They are broadly marked off from the stratified rocks in which the parallel bands of the bedding form a leading feature in every cliff and bare mountain slope. Among the latter rocks also very distinctive types of surface may be observed. A range of sandstone hills, for example, presents a marked contrast to one of limestone.

In the physiography of any region, the mountains are the dominant features. A true mountain chain consists of rocks which have been crumpled and pushed up in the manner already described. But ranges of hills almost mountainous in their bulk may be formed by the gradual erosion of valleys out of a mass of original high ground. In this way some ancient tablelands, those of Norway and of the Highlands of Scotland, for example, have been so channeled by deep fjords and glens that they now consist of massive rugged hills, either isolated or connected along the flanks. The forms of the valleys thus eroded have been governed partly by the structure and composition of the rocks, and partly by the relative potency of the different denuding agents. Where the influence of rain and frost has been slight, and the streams, supplied from distant sources, have had sufficient declivity, deep, narrow, precipitous ravines or gorges have been excavated. The cañons of the Colorado are a magnificent example of this result. Where, on the other hand, ordinary atmospheric action has been more rapid, the sides of the river channels have been attacked, and open sloping glens and valleys have been hollowed out. A gorge or defile is usually due to the action of a waterfall, which, beginning with some abrupt declivity or precipice in the course of the river when it first commenced to flow, or caused by some hard rock crossing the channel, has eaten its way backward, as already explained (p. 276).

Lakes may have been formed in several ways. 1. By subterranean movements as, for example, during those which gave rise to mountain chains. But these hollows, unless continually deepened by subsequent movements of a similar nature would be filled up by the sediment continually washed into them from the adjoining slopes. The numerous lakes in such a mountain system as the Alps cannot be due merely to this cause, unless we suppose the upheaval of the mountains to have been geologically quite recent, or that subsidence must take place continuously or periodically below each independent basin. But there is evidence that the upheaval of the lakes is not of recent date, while the idea of perpetuating lakes by continual subsidence would demand, not in the Alps merely, but all over the northern hemisphere where lakes are so abundant, an amount of subterranean movement of which, if it really existed, there would assuredly be plenty of other evidence. 2. By irregularities in the deposition of superficial accumulations prior to the elevation of the land or during the disappearance of the ice-sheet. The numerous tarns and lakes enclosed within mounds and ridges of drift-clay and gravel are examples. 3. By the acccumulation of a barrier across the channel of a stream and the consequent ponding back of the water. This may be done, for instance, by a landslip, by the advance of a glacier across a valley, or by the throwing up of a bank by the sea across the mouth of a river. 4. By erosion. The only agent capable of excavating hollows out of the solid rock such as might form lake-basins is glacier-ice (*ante*, p. 282). It is a remarkable fact, of which the significance may now be seen, that the innumerable lake-basins of the northern hemisphere lie on surfaces of intensely ice-worn rock. The striæ can be seen on the smoother rock-surfaces slipping into the water on all sides. These striæ were produced by ice moving over the rock. If the ice could, as the striæ prove, descend into the rock-basins and mount up the farther side, smoothing and striating the rock as it went, it could erode the basins. It is hardly possible to convey in words an adequate conception of the enormous extent to which the north of Europe and North America has had its surface ground down by ice. The ordinary rough surfaces produced by atmospheric disintegration have been replaced by a peculiar flowing contour which is traceable even to below the sea-level.

In the general subaerial denudation of a country, innumerable minor features are worked out as the structure of the rocks controls the operations of the eroding agents. Thus, among comparatively undisturbed strata, a hard bed resting upon others of a softer kind is apt to form along its outcrop a line of cliff or escarpment. Though a long range of such cliffs resembles a coast that has been worn by the sea, it may be entirely due to mere atmospheric waste. Again, the more resisting portions of a rock may be seen projecting as crags or knolls. An igneous mass will stand out as a bold hill from amidst the more decomposable strata through which it has risen. These features, often so marked on the lower grounds, attain their most conspicuous development among the higher and barer parts of the mountains, where subaerial disintegration is most rapid. The torrents tear out deep gullies from the sides of the declivities. Corries are scooped out on the one hand, and naked precipices are left on the other. The harder bands of rock project as massive ribs down the slopes, shoot up into prominent *aiguilles*, or give to the summits the notched saw-like outlines they so often present.

Tablelands may sometimes arise from the abrasion of hard rocks and the production of a level plain by the action of the sea, or rather of that action combined with the previous degradation of the land by subaerial waste. But most of the great tablelands of the globe seem to be platforms of little-disturbed strata which have been upraised bodily to a considerable elevation. No sooner, however, are they placed in that position than they are attacked by running water, and begin to be hollowed out into systems of valleys. As the valleys sink, the platforms between them grow into narrower and more definite ridges, until eventually the level tableland is converted into a complicated network of hills and valleys, wherein, nevertheless, the key to the whole arrangement is furnished by a knowledge of the disposition and effects of the flow of water. The examples of this process brought to light in Colorado, Wyoming, Nevada, and the other western territories, by Newberry, King, Hayden, Powell, and other explorers, are among the most striking monuments of geological operations in the world.

The materials worn from the surface of the higher are spread out over the lower grounds. We have already traced how streams at once begin to drop their freight of sediment when, by the lessening of their declivity, their carrying power is diminished (p. 276–7). The great plains of the earth's surface are due to this deposit of gravel, sand, and loam. They are thus monuments at once of the destructive and reproductive processes which have been in progress unceasingly since the first land rose above the sea and the first shower of rain fell. Every pebble and particle of their soil, once part of the distant mountains, has travelled slowly and fitfully downward. Again and again have these materials been shifted, ever moving downward and sea-ward. For centuries, perhaps, they have taken their share in the fertility of the plains and have ministered to the necessities of flower and tree, of the bird of the air, the beast of the field, and of man himself. But their destiny is still the great ocean. In that bourne alone can they find undisturbed repose, and there, slowly accumulating in massive beds, they will remain until, in the course of ages, renewed upheaval shall raise them into future land, there once more to pass through the same cycle of change. (A. GE.)

INDEX.

GEOMETRY

PART I.—PURE GEOMETRY.

GEOMETRY has been divided since the time of Euclid into an "elementary" and a "higher" part. The contents and limits of the former have been fixed by Euclid's *Elements*. The latter included at the time of the Greek mathematicians principally the properties of the conic sections and of a few other curves. The methods used in both were essentially the same. These began to be replaced during the 17th century by more powerful methods, invented by Roberval, Pascal, Desargues, and others. But the impetus which higher geometry received in their works was soon arrested, in consequence of the discoveries of Descartes,—the new calculus to which these gave rise absorbing the attention of mathematicians almost exclusively, until Monge, at the end of the 18th century, re-established "pure" as distinguished from Descartes's "coordinate" (or analytical) geometry. Since then the purely geometrical methods have been continuously extended, especially by Poncelet, Steiner, Von Staudt, and Cremona, and in England by Hirst and Henry Smith, to mention only a few of the leading names.

Whilst higher geometry thus made most rapid progress, the elementary part remained almost unaltered. It has been taught up to the present day on the basis of Euclid's *Elements*, the latter being either used directly as a text-book (in England), or being replaced (in most parts of the Continent) by text-books which are essentially Euclid's *Elements* rewritten, with a few additions about the mensuration of the circle, cone, cylinder, and sphere. Only within a very recent period have attempts been made to change the character of the elementary part by introducing some of the modern methods.

We shall give in this article—first, a survey of elementary geometry as contained in Euclid's *Elements*, and then, in form of an independent treatise, an introduction to higher geometry, based on modern methods. In the former part we shall suppose that a copy of Euclid's *Elements* is in the hands of the reader, so that we may dispense, as a rule, with giving proofs or drawing figures. We thus shall give only the contents of his propositions grouped together in such a way as to show their connexion, and often expressed in words which differ from the verbal translation in order to make their meaning clear. It will make little difference which of the many English editions of Euclid's *Elements* the reader takes. Of these we may mention Simson's, Potts's, and Todhunter's.

SECTION I.—ELEMENTARY OR EUCLIDIAN GEOMETRY.

The Axioms.

§ 1. The object of geometry is to investigate the properties of space. The first step must consist in establishing those fundamental properties from which all others follow by processes of deductive reasoning. They are laid down in the Axioms, and these ought to form such a system that nothing need be added to them in order fully to characterize space, and that nothing may be left out without making the system incomplete. They must, in fact, completely "define" space. Several such systems are conceivable. Euclid has given one, others have been put forward in recent times by Riemann (*Abhandl. der königl. Gesellsch. zu Göttingen*, vol. xiii.), by Helmholz (*Göttinger Nachrichten*, June 1868), and by Grassmann (*Ausdehnungslehre von* 1844). How many axioms the system ought to contain, and which system is the simplest, may be said to be still an open question. We shall consider only Euclid's system.

§ 2. The axioms are obtained from inspection of space and of solids in space,—hence from experience. The same source gives us the notions of the geometrical entities to which the axioms relate, viz., solids, surfaces, lines or curves, and points. A solid is directly given by experience; we have only to abstract all material from it in order to gain the notion of a geometrical solid. This has shape, size, position, and may be moved. Its boundary or boundaries are called surfaces. They separate one part of space from another, and are said to have no thickness. Their boundaries are curves or lines, and these have length only. Their boundaries, again, are points, which have no magnitude but only position. We thus come in three steps from solids to points which have no magnitude; in each step we lose one extension. Hence we say a solid has three dimensions, a surface two, a line one, and a point none. Space itself, of which a solid forms only a part, is also said to be of three dimensions. The same thing is intended to be expressed by saying that a solid has length, breadth, and thickness, a surface length and breadth, a line length only, and a point no extension whatsoever.

Euclid gives the essence of these statements as definitions:—

Def. 1, I. *A point is that which has no parts, or which has no magnitude.*
Def. 2, I. *A line is length without breadth.*
Def. 5, I. *A superficies is that which has only length and breadth.*
Def. 1, XI. *A solid is that which has length, breadth, and thickness.*

If we allow motion in geometry,—and it seems impossible to avoid it,—we may generate these entities by moving a point, a line, or a surface, thus:—

The path of a moving point is a line.
The path of a moving line is, in general, a surface.
The path of a moving surface is, in general, a solid.

And we may then assume that the lines, surfaces, and solids, as defined before, can all be generated in this manner. From this generation of the entities it follows again that the boundaries—the first and last position of the moving element—of a line are points, and so on; and thus we come back to the considerations with which we started.

Euclid points this out in his definitions,—Def. 3, I., Def. 6, I., and Def. 2, XI. He does not, however, show the connexion which these definitions have with those mentioned before. When points and lines have been defined, a statement like Def. 3, I., "The extremities of a line are points," is a proposition which either has to be proved, and then it is a theorem, or which has to be taken for granted, in which case it is an axiom. And so with Def. 6, I., and Def. 2, XI.

§ 3. Euclid's definitions mentioned above are attempts to describe, in a few words, notions which we have obtained by inspection of and abstraction from solids. A few more notions have to be added to these, principally those of the simplest line—the straight line, and of the simplest surface—the flat surface or plane. These notions we possess, but to define them accurately is difficult. Euclid's Definition 4, I., "A straight line is that which lies evenly between its extreme points," must be meaningless to any one who has not the notion of straightness in his mind. Neither does it state a property of the straight line which can be used in any further investigation. Such a property is given in Axiom 10, I. It is really this axiom, together with Postulates 2 and 3, which characterizes the straight line.

Whilst for the straight line the verbal definition and axiom are kept apart, Euclid mixes them up in the case of the plane. Here the Definition 7, I., includes an axiom. It defines a plane as a surface which has the property that every straight line which joins any two points in it lies altogether in the surface. But if we take a straight line and a point in such a surface, and draw all straight lines which join the latter to all points in the first line, the surface will be fully determined. This construction is therefore sufficient as a definition. That every other straight line which joins any two points in this surface lies altogether in it is a further property, and to assume it gives another axiom.

Thus a number of Euclid's axioms are hidden among his first definitions. A still greater confusion exists in the present editions of Euclid between the postulates and axioms so-called, but this is due to later editors and not to Euclid himself. The latter had the last three axioms put together with the postulates (αἰτήματα), so that these were meant to include all assumptions relating to space. The remaining assumptions which relate to magnitudes in general, viz., the first eight "axioms" in modern editions, were called "common notions" (κοιναὶ ἔννοιαι). Of the latter a few may be said to be definitions. Thus the eighth might be taken as a definition of "equal," and the seventh of halves. If we wish to collect the axioms used in Euclid's *Elements*, we have therefore to take the three postulates, the last three axioms as generally given, a few axioms hidden in the definitions, and an axiom used by Euclid in the proof of Prop. 4 and on a few other occasions, viz., that figures may be moved in space without change of shape or size.

We shall not enter into the investigation how far the assumptions which would be included in such a list are sufficient, and how far they are necessary. It may be sufficient here to state that from the beginning of a geometrical science to the present century attempts without end have been made to prove the last of Euclid's axioms, that only at the beginning of the present century the futility of this attempt was shown, and that only within the last twenty years the true nature of the connexion between the axioms has become known through the researches of Riemann and Helmholz, although Grassmann had published already, in 1844, his classical but long-neglected *Ausdehnungslehre*.

§ 4. The assumptions actually made by Euclid may be stated as follows :—

1. Straight lines exist which have the property that any one of them may be produced both ways without limit, that through any two points in space such a line may be drawn, and that any two of them coincide throughout their indefinite extensions as soon as two points in the one coincide with two points in the other. (This gives the contents of Def. 4, part of Def. 35, the first two Postulates, and Axiom 10.)
2. Plane surfaces or planes exist having the property laid down in Def. 7, that every straight line joining any two points in such a surface lies altogether in it.
3. Right angles, as defined in Def. 10, are possible, and all right angles are equal ; that is to say, wherever in space we take a plane, and wherever in that plane we construct a right angle, all angles thus constructed will be equal, so that any one of them may be made to coincide with any other. (Axiom 11.)
4. The 12th Axiom of Euclid. This we shall not state now, but only introduce it when we cannot proceed any further without it.
5. Figures may be freely moved in space without change of shape or size. This is assumed by Euclid, but not stated as an axiom.
6. In any plane a circle may be described, having any point in that plane as centre, and its distance from any other point in that plane as radius. (Postulate 3.)

The definitions which have not been mentioned are all "nominal definitions," that is to say, they fix a name for a thing described. Many of them overdetermine a figure. (Compare notes to definitions in Simson's or Todhunter's edition.)

§ 5. Euclid's *Elements* are contained in thirteen books. Of these the first four and the sixth are devoted to "plane geometry," as the investigation of figures in a plane is generally called. The 5th book contains the theory of proportion which is used in Book VI. The 7th, 8th, and 9th books are purely arithmetical, whilst the 10th contains a most ingenious treatment of geometrical irrational quantities. These four books will be excluded from our survey. The remaining three books relate to figures in space, or, as it is generally called, to "solid geometry." The 7th, 8th, 9th, 10th, 13th, and part of the 11th and 12th books are now generally omitted from the school editions of the *Elements*. In the first four and in the 6th book it is to be understood that all figures are drawn in a plane.

Book I. of Euclid's "Elements."

§ 6. According to the third postulate it is possible to draw in any plane a circle which has its centre at any given point, and its radius equal to the distance of this point from any other point given in the plane. This makes it possible (Prop. 1) to construct on a given line AB an equilateral triangle, by drawing first a circle with A as centre and AB as radius, and then a circle with B as centre and BA as radius. The point where these circles intersect—that they intersect Euclid quietly assumes—is the vertex of the required triangle. Euclid does not suppose, however, that a circle may be drawn which has its radius equal to the distance between any two points unless one of the points be the centre. This implies also that we are not supposed to be able to make any straight line equal to any other straight line, or to carry a distance about in space. Euclid therefore next solves the problem: It is required along a given straight line from a point in it to set off a distance equal to the length of another straight line given anywhere in the plane. This is done in two steps. It is shown in Prop. 2 how a straight line may be drawn from a given point equal in length to another given straight line not drawn from that point. And then the problem itself is solved in Prop. 3, by drawing first through the given point some straight line of the required length, and then about the same point as centre a circle having this length as radius. This circle will cut off from the given straight line a length equal to the required one. Now-a-days, instead of going through this long process, we take a pair of compasses and set off the given length by its aid. This assumes that we may move a length about without changing it. But Euclid has not assumed it, and this proceeding would be fully justified by his desire not to take for granted more than was necessary, if he were not obliged at his very next step actually to make this assumption, though without stating it.

§ 7. We now come (in Prop. 4) to the first theorem. It is the fundamental theorem of Euclid's whole system, there being only a very few propositions (like Props. 13, 14, 15, I.), except those in the 5th book and the first half of the 11th, which do not depend upon it. It is stated very accurately, though somewhat clumsily, as follows :—

If two triangles have two sides of the one equal to two sides of the other, each to each, and have also the angles contained by those sides equal to one another, they shall also have their bases or third sides equal ; and the two triangles shall be equal ; and their other angles shall be equal, each to each, namely, those to which the equal sides are opposite.

That is to say, the triangles are "identically" equal, and one may be considered as a copy of the other. The proof is very simple. The first triangle is taken up and placed on the second, so that the parts of the triangles which are known to be equal fall upon each other. It is then easily seen that also the remaining parts of one coincide with those of the other, and that they are therefore equal. This process of applying one figure to another Euclid scarcely uses again, though many proofs would be simplified by doing so. The process introduces motion into geometry, and includes, as already stated, the axiom that figures may be moved without change of shape or size.

If the last proposition be applied to an isosceles triangle, which has two sides equal, we obtain the theorem (Prop. 5), *if two sides of a triangle are equal, then the angles opposite these sides are equal.*

Euclid's proof is somewhat complicated, and a stumbling-block to many schoolboys. The proof becomes much simpler if we consider the isosceles triangle ABC (AB = AC) twice over, once as a triangle BAC, and once as a triangle CAB; and now remember that

AB, AC in the first are equal respectively to AC, AB in the second, and the angles included by these sides are equal. Hence the triangles are equal, and the angles in the one are equal to those in the other, viz., those which are opposite equal sides, *i.e.*, angle ABC in the first equals angle ACB in the second, as they are opposite the equal sides AC, and AB in the two triangles.

There follows the converse theorem (Prop. 6). *If two angles in a triangle are equal, then the sides opposite them are equal,—i.e.*, the triangle is isosceles. The proof given consists in what is called a *reductio ad absurdum*, a kind of proof often used by Euclid, and principally in proving the converse of a previous theorem. It assumes that the theorem to be proved is wrong, and then shows that this assumption leads to an absurdity, *i.e.*, to a conclusion which is in contradiction to a proposition proved before—that therefore the assumption made cannot be true, and hence that the theorem is true. It is often stated that Euclid invented this kind of proof, but the method is most likely much older.

§ 8. It is next proved *that two triangles which have the three sides of the one equal respectively to those of the other are identically equal, hence that the angles of the one are equal respectively to those of the other, those being equal which are opposite equal sides.* This is Prop. 8, Prop. 7 containing only a first step towards its proof.

These theorems allow now of the solution of a number of problems, viz.:—

To bisect a given angle (Prop. 9).

To bisect a given finite straight line (Prop. 10).

To draw a straight line perpendicularly to a given straight line through a given point in it (Prop. 11), *and also through a given point not in it* (Prop. 12).

The solutions all depend upon properties of isosceles triangles.

§ 9. The next three theorems relate to angles only, and might have been proved before Prop. 4, or even at the very beginning. The first (Prop. 13) says, *The angles which one straight line makes with another straight line on one side of it either are two right angles or are together equal to two right angles.* This theorem would have been unnecessary if Euclid had admitted the notion of an angle such that its two limits are in the same straight line, and had besides defined the sum of two angles.

Its converse (Prop. 14) is of great use, inasmuch as it enables us in many cases to prove that two straight lines drawn from the same point are one the continuation of the other. So also is

Prop 15. *If two straight lines cut one another, the vertical or opposite angles shall be equal.*

§ 10 Euclid returns now to properties of triangles. Of great importance for the next steps (though afterwards superseded by a more complete theorem) is

Prop 16. *If one side of a triangle be produced, the exterior angle shall be greater than either of the interior opposite angles.*

Prop. 17, *Any two angles of a triangle are together less than two right angles*, is an immediate consequence of it. By the aid of these two, the following fundamental properties of triangles are easily proved :—

Prop 18 *The greater side of every triangle has the greater angle opposite to it* ;

Its converse, Prop. 19. *The greater angle of every triangle is subtended by the greater side, or has the greater side opposite to it* ;

Prop 20. *Any two sides of a triangle are together greater than the third side* ;

And also Prop 21. *If from the ends of the side of a triangle there be drawn two straight lines to a point within the triangle, these shall be less than the other two sides of the triangle, but shall contain a greater angle.*

§ 11. Having solved two problems (Props. 22, 23), he returns to two triangles which have two sides of the one equal respectively to two sides of the other. It is known (Prop. 4) that if the included angles are equal then the third sides are equal; and conversely (Prop. 8), if the third sides are equal, then the angles included by the first sides are equal. From this it follows that if the included angles are not equal, the third sides are not equal, and conversely, that if the third sides are not equal, the included angles are not equal. Euclid now completes this knowledge by proving, that "*if the included angles are not equal, then the third side in that triangle is the greater which contains the greater angle*;" and conversely, that "*if the third sides are unequal, that triangle contains the greater angle which contains the greater side.*" These are Prop. 24 and Prop. 25.

§ 12. The next theorem (Prop. 26) says that *if two triangles have one side and two angles of the one equal respectively to one side and two angles of the other, viz., in both triangles either the angles adjacent to the equal side, or one angle adjacent and one angle opposite it, then the two triangles are identically equal.*

This theorem belongs to a group with Prop. 4 and Prop. 8. Its first case might have been given immediately after Prop. 4, but the second case requires Prop. 16 for its proof.

§ 13. We come now to the investigation of parallel straight lines, *i.e.*, of straight lines which lie in the same plane, and cannot be made to meet however far they be produced either way. The investigation, which starts from Prop. 16, will become clearer if a few names be explained which are not all used by Euclid. If two straight lines be cut by a third, the latter is now generally called a "transversal" of the figure. It forms at the two points where it cuts the given lines four angles with each. Those of the angles which lie between the given lines are called interior angles, and of these, again, any two which lie on opposite sides of the transversal but one at each of the two points are called "alternate angles."

We may now state Prop. 16 thus :—*If two straight lines which meet are cut by a transversal, their alternate angles are unequal.* For the lines will form a triangle, and one of the alternate angles will be an exterior angle to the triangle, the other interior and opposite to it.

From this follows at once the theorem contained in Prop. 27. *If two straight lines which are cut by a transversal make alternate angles equal, the lines cannot meet, however far they be produced, hence they are parallel.* This proves the existence of parallel lines.

Prop. 28 states the same fact in different forms. *If a straight line, falling on two other straight lines, make the exterior angle equal to the interior and opposite angle on the same side of the line, or make the interior angles on the same side together equal to two right angles, the two straight lines shall be parallel to one another.*

Hence we know that, "if two straight lines which are cut by a transversal meet, their alternate angles are not equal"; and hence that, "if alternate angles are equal, then the lines are parallel."

The question now arises, Are the propositions converse to these true or not? That is to say, "If alternate angles are unequal, do the lines meet?" And "if the lines are parallel, are alternate angles necessarily equal?"

The answer to either of these two questions implies the answer to the other. But it has been found impossible to prove that the negation or the affirmation of either is true.

The difficulty which thus arises is overcome by Euclid assuming that the first question has to be answered in the affirmative. This gives his last axiom (12), which we quote in his own words.

AXIOM 12.—*If a straight line meet two straight lines, so as to make the two interior angles on the same side of it taken together less than two right angles, these straight lines, being continually produced, shall at length meet on that side on which are the angles which are less than two right angles.*

The answer to the second of the above questions follows from this, and gives the theorem Prop. 29. *If a straight line fall on two parallel straight lines, it makes the alternate angles equal to one another, and the exterior angle equal to the interior and opposite angle on the same side, and also the two interior angles on the same side together equal to two right angles.*

§ 14. With this a new part of elementary geometry begins. The earlier propositions are independent of this axiom, and would be true even if a wrong assumption had been made in it. They all relate to figures in a plane. But a plane is only one among an infinite number of conceivable surfaces. We may draw figures on any one of them and study their properties. We may, for instance, take a sphere instead of the plane, and obtain "spherical" in the place of "plane" geometry. If on one of these surfaces lines and figures could be drawn, answering to all the definitions of our plane figures, and if the axioms with the exception of the last all hold, then all propositions up to the 28th will be true for these figures. This is the case in spherical geometry if we substitute "shortest line" or "great circle" for "straight line," "small circle" for "circle," and if, besides, we limit all figures to a part of the sphere which is less than a hemisphere, so that two points on it cannot be opposite ends of a diameter, and therefore determine always one and only one great circle.

For spherical triangles, therefore, all the important propositions 4, 8, 26; 5 and 6; and 18, 19, and 20 will hold good.

This remark will be sufficient to show the impossibility of proving Euclid's last axiom, which would mean proving that this axiom is a consequence of the others, and hence that the theory of parallels would hold on a spherical surface, where the other axioms do hold, whilst parallels do not even exist.

It follows that the axiom in question states an inherent difference between the plane and other surfaces, and that the plane is only fully characterized when this axiom is added to the other assumptions.

§ 15. The introduction of the new axiom and of parallel lines leads to a new class of propositions.

After proving (Prop. 30) that "*two lines which are each parallel to a third are parallel to each other,*" we obtain the new properties of triangles contained in Prop. 32. Of these the second part is the most important, viz., the theorem, *The three interior angles of every triangle are together equal to two right angles.*

As easy deductions not given by Euclid but added by Simson follow the propositions about the angles in polygons, they are given in English editions as corollaries to Prop. 32.

These theorems do not hold for spherical figures. The sum of the interior angles of a spherical triangle is always greater than two right angles, and increases with the area.

§ 16. The theory of parallels as such may be said to be finished with Props. 33 and 34, which state properties of the parallelogram, *i.e.*, of a quadrilateral formed by two pairs of parallels. They are—

Prop. 33. *The straight lines which join the extremities of two equal and parallel straight lines towards the same parts are themselves equal and parallel*; and

Prop. 34. *The opposite sides and angles of a parallelogram are equal to one another, and the diameter (diagonal) bisects the parallelogram, that is, divides it into two equal parts.*

§ 17. The rest of the first book relates to areas of figures.

The theory is made to depend upon the theorems—

Prop. 35. *Parallelograms on the same base and between the same parallels are equal to one another*; and

Prop. 36. *Parallelograms on equal bases, and between the same parallels, are equal to one another.*

As each parallelogram is bisected by a diagonal, the last theorems hold also if the word parallelogram be replaced by "triangle," as is done in Props. 37 and 38.

It is to be remarked that Euclid proves these propositions only in the case when the parallelograms or triangles have their bases in the same straight line.

The theorems converse to the last form the contents of the next three propositions, viz.:—

THEOREM (Props. 40 and 41).—*Equal triangles, on the same or on equal bases, in the same straight line, and on the same side of it, are between the same parallels.*

That the two cases here stated are given by Euclid in two separate propositions proved separately is characteristic of his method.

§ 18. To compare areas of other figures, Euclid shows first, in Prop. 42, how *to draw a parallelogram which is equal in area to a given triangle, and has one of its angles equal to a given angle.* If the given angle is right, then the problem is solved *to draw a "rectangle" equal in area to a given triangle.*

Next this parallelogram is transformed into another parallelogram, *which has one of its sides equal to a given straight line*, whilst its angles remain unaltered. This may be done by aid of the theorem in

Prop. 43. *The complements of the parallelograms which are about the diameter of any parallelogram are equal to one another.*

Thus the problem (Prop. 44) is solved *to construct a parallelogram on a given line, which is equal in area to a given triangle, and which has one angle equal to a given angle* (generally a right angle).

As every polygon can be divided into a number of triangles, we can now construct a parallelogram having a given angle, say a right angle, and being equal in area to a given polygon. For each of the triangles into which the polygon has been divided, a parallelogram may be constructed, having one side equal to a given straight line, and one angle equal to a given angle. If these parallelograms be placed side by side, they may be added together to form a single parallelogram, having still one side of the given length. This is done in Prop. 45.

Herewith a means is found to compare areas of different polygons. We need only construct two rectangles equal in area to the given polygons, and having each one side of given length. By comparing the unequal sides we are enabled to judge whether the areas are equal, or which is the greater. Euclid does not state this consequence, but the problem is taken up again at the end of the second book, where it is shown how to construct a square equal in area to a given polygon.

§ 19. The first book concludes with one of the most important theorems in the whole of geometry, and one which has been celebrated since the earliest times. It is stated, but on doubtful authority, that Pythagoras discovered it, and it has been called by his name. If we call that side in a right-angled triangle which is opposite the right angle the hypotenuse, we may state it as follows:—

THEOREM OF PYTHAGORAS (Prop. 47).—*In every right-angled triangle the square on the hypotenuse is equal to the sum of the squares of the other sides.*

And conversely—

Prop. 48. *If the square described on one of the sides of a triangle be equal to the squares described on the other sides, then the angle contained by these two sides is a right angle.*

On this theorem (Prop. 47) almost all geometrical measurement depends, which cannot be directly obtained.

BOOK II.

§ 20. The propositions in the second book are very different in character from those in the first; they all relate to areas of rectangles and squares. Their true significance is best seen by stating them in an algebraic form. This is often done by expressing the lengths of lines by aid of numbers, which tell how many times a chosen unit is contained in the lines. If there is a unit to be found which is contained an exact number of times in each side of a rectangle, it is easily seen, and generally shown in the teaching of arithmetic, that the rectangle contains a number of unit squares equal to the product of the numbers which measure the sides, a unit square being the square on the unit line. If, however, no such unit can be found, this process requires that connexion between lines and numbers which is only established by aid of ratios of lines, and which is therefore at this stage altogether inadmissible. But there exists another way of connecting these propositions with algebra, based on modern notions which seem destined greatly to change and to simplify mathematics. We shall introduce here as much of it as is required for our present purpose.

At the beginning of the second book we find a definition according to which "a rectangle is said to be 'contained' by the two sides which contain one of its right angles"; in the text this phraseology is extended by speaking of rectangles contained by any two straight lines, meaning the rectangle which has two adjacent sides equal to the two straight lines.

We shall denote a finite straight line by a single small letter, $a, b, c, \ldots x$, and the area of the rectangle contained by two lines a and b by ab, and this we shall call the product of the two lines a and b. It will be understood that this definition has nothing to do with the definition of a product of numbers.

We define as follows:—

The *sum* of two straight lines a and b means a straight line c which may be divided in two parts equal respectively to a and b. This sum is denoted by $a+b$.

The *difference* of two lines a and b (in symbols, $a-b$) means a line c which when added to b gives a; that is,

$$a-b=c \text{ if } b+c=a.$$

The *product* of two lines a and b (in symbols, ab) means the area of the rectangle contained by the lines a and b. For aa, which means the square on the line a, we write a^2.

§ 21. The first ten of the fourteen propositions of the second book may then be written in the form of formulæ as follows:—

Prop. 1. $a(b+c+d+\ldots)=ab+ac+ad+\ldots$
,, 2. $ab+ac=a^2$ if $b+c=a$.
,, 3. $a(a+b)=a^2+ab$.
,, 4. $(a+b)^2=a^2+2ab+b^2$.
,, 5. $(a+b)(a-b)+b^2=a^2$.
,, 6. $(a+b)(a-b)+b^2=a^2$.
,, 7. $a^2+(a-b)^2=2a(a-b)+b^2$.
,, 8. $4(a+b)a+b^2=(2a+b)^2$.
,, 9. $(a+b)^2+(a-b)^2=2a^2+2b^2$.
,, 10. $(a+b)^2+(a-b)^2=2a^2+2b^2$.

It will be seen that 5 and 6, and also 9 and 10, are identical. In Euclid's statement they do not look the same, the figures being arranged differently.

If the letters $a, b, c, \ldots$ denoted numbers, it follows from algebra that each of these formulæ is true. But this does not prove them in our case, where the letters denote lines, and their products areas without any reference to numbers. To prove them we have to discover the laws which rule the operations introduced, viz., addition and multiplication of segments. This we shall do now; and we shall find that these laws are the same with those which hold in algebraical addition and multiplication.

§ 22. In a sum of numbers we may change the order in which the numbers are added, and we may also add the numbers together in groups, and then add these groups. But this also holds for the sum of segments and for the sum of rectangles, as a little consideration shows. That the sum of rectangles has always a meaning follows from the Props. 43–45 in the first book. These laws about addition are reducible to the two—

$$a+b=b+a \quad . \quad . \quad . \quad (1),$$
$$a+(b+c)=a \quad +c \quad . \quad . \quad (2),$$

or, when expressed for rectangles,

$$ab+ed=ed+ab \quad . \quad . \quad . \quad (3),$$
$$ab+(cd+cf)=ab+cd+cf \quad . \quad . \quad (4).$$

The brackets mean that the terms in the bracket have been added together before they are added to another term. The more general cases for more terms may be deduced from the above.

For the product of two numbers we have the law that it remains unaltered if the factors be interchanged. This also holds for our geometrical product. For if ab denotes the area of the rectangle which has a as base and b as altitude, then ba will denote the area of the rectangle which has b as base and a as altitude. But in a rectangle we may take either of the two lines which contain it as base, and then the other will be the altitude. This gives

$$ab=ba \quad . \quad . \quad . \quad . \quad (5).$$

In order further to multiply a sum by a number, we have in algebra the rule:—Multiply each term of the sum, and add the products thus obtained. That this holds for our geometrical products is shown by Euclid in his first proposition of the second book, where he proves that the area of a rectangle whose base is the sum of a number of segments is equal to the sum of rectangles which have these segments separately as bases. In symbols this gives, in the simplest case,

$$\left.\begin{aligned} a(b+c)&=ab+ac \\ \text{and} \qquad (b+c)a&=ba+ca \end{aligned}\right\} \quad . \quad . \quad . \quad (6).$$

To these laws which have been investigated by Sir William Hamilton and by Hermann Grassmann, the former has given special names. He calls the laws expressed in

(1) and (3) the commutative law for addition;
(5) „ „ multiplication;
(2) and (4) the associative laws for addition;
(6) the distributive law.

§ 23. Having proved that these six laws hold, we can at once prove every one of the above propositions in their algebraical form.

The first is proved geometrically, it being one of the fundamental laws. The next two propositions are only special cases of the first. Of the others we shall prove one, viz., the fourth:—

$$(a+b)^2=(a+b)\,(a+b)=(a+b)a+(a+b)b \qquad \text{by (6).}$$

$$\begin{aligned} \text{But} \qquad (a+b)a&=aa+ba && \text{by (6),} \\ &=aa+ab && \text{by (5);} \\ \text{and} \qquad (a+b)b&=ab+bb && \text{by (6).} \end{aligned}$$

$$\text{Therefore} \qquad \left.\begin{aligned} (a+b)^2&=aa+ab+(ab+bb) \\ &=aa+(ab+ab)+bb \\ &=aa+2ab+bb \end{aligned}\right\} \qquad \text{by (4).}$$

This gives the theorem in question.

In the same manner every one of the first ten propositions is proved.

It will be seen that the operations performed are exactly the same as if the letters denoted numbers.

Props. 5 and 6 may also be written thus—

$$(a+b)\,(a-b)=a^2-b^2.$$

Prop. 7, which is an easy consequence of Prop. 4, may be transformed. If we denote by c the line $a+b$, so that

$$c=a+b\,.\;a=c-b,$$

we get

$$\begin{aligned} c^2+(c-b)^2&=2c(c-b)+b^2 \\ &=2c^2-2bc+b^2. \end{aligned}$$

Subtracting c^2 from both sides, and writing a for c, we get

$$(a-b)^2=a^2-2ab+b^2.$$

In Euclid's *Elements* this form of the theorem does not appear, all propositions being so stated that the notion of subtraction does not enter into them.

§ 24. The remaining two theorems (Props. 12 and 13) connect the square on one side of a triangle with the sum of the squares on the other sides, in case that the angle between the latter is acute or obtuse. They are important theorems in trigonometry, where it is possible to include them in a single theorem.

§ 25. There are in the second book two problems, Props. 11 and 14.

If written in the above symbolic language, the former requires to find a line x such that $a(a-x)=x^2$. Prop. 11 contains, therefore, the solution of a quadratic equation, which we may write $x^2+ax=a^2$. The solution is required later on in the construction of a regular decagon.

More important is the problem in the last proposition (Prop. 14). It requires the construction of a square equal in area to a given rectangle, hence a solution of the equation

$$x^2=ab.$$

In Book I., 42–45, it has been shown how a rectangle may be constructed equal in area to a given figure bounded by straight lines. By aid of the new proposition we may therefore now determine a line such that the square on that line is equal in area to any given rectilinear figure, or we can *square* any such figure.

As of two squares that is the greater which has the greater side, it follows that now the comparison of two areas has been reduced to the comparison of two lines.

The problem of reducing other areas to squares is frequently met with among Greek mathematicians. We need only mention the problem of squaring the circle.

In the present day the comparison of areas is performed in a simpler way by reducing all areas to rectangles having a common base. Their altitudes give then a measure of their areas.

The construction of a rectangle having the base u, and being equal in area to a given rectangle, depends upon Prop. 43, I. This therefore gives a solution of the equation

$$ab=ux,$$

where x denotes the unknown altitude.

Book III.

§ 26. The third book of the *Elements* relates exclusively to properties of the circle. A circle and its circumference have been defined in Book I., Def. 15. We restate it here in slightly different words:—

Definition.—The circumference of a circle is a plane curve such that all points in it have the same distance from a fixed point in the plane. This point is called the "centre" of the circle.

Of the new definitions, of which eleven are given at the beginning of the third book, a few only require special mention. The first, which says that circles with equal radii are equal, is in part a theorem, but easily proved by applying the one circle to the other. Or it may be considered proved by aid of Prop. 24, equal circles not being used till after this theorem.

In the second definition is explained what is meant by a line which "touches" a circle. Such a line is now generally called a tangent to the circle. The introduction of this name allows us to state many of Euclid's propositions in a much shorter form.

For the same reason we shall call a straight line joining two points on the circumference of a circle a "chord."

Definitions 4 and 5 may be replaced with a slight generalization by the following:—

Definition.—By the distance of a point from a line is meant the length of the perpendicular drawn from the point to the line.

§ 27. From the definition of a circle it follows that every circle has a centre. Prop. 1 requires to find it when the circle is given, *i.e.*, when its circumference is drawn.

To solve this problem a chord is drawn (that is, any two points in the circumference are joined), and through the point where this is bisected a perpendicular to it is erected. Euclid then proves, first, that no point off this perpendicular can be the centre, hence that the centre must lie in this line; and, secondly, that of the points on the perpendicular one only can be the centre, viz., the one which bisects the part of the perpendicular bounded by the circle. In the second part Euclid silently assumes that the perpendicular there used does cut the circumference in two, and only in two points. The proof therefore is incomplete. The proof of the first part, however, is exact. By drawing two non-parallel chords, and the perpendiculars which bisect them, the centre will be found as the point where these perpendiculars intersect.

§ 28. In Prop. 2 it is proved that a chord of a circle lies altogether within the circle.

What we have called the first part of Euclid's solution of Prop. 1 may be stated as a theorem:—

Theorem.—*Every straight line which bisects a chord, and is at right angles to it, passes through the centre of the circle.*

The converse to this gives Prop. 3, which may be stated thus:—

If a straight line through the centre of a circle bisect a chord, then it is perpendicular to the chord, and if it be perpendicular to the chord it bisects it.

An easy consequence of this is the following theorem, which is essentially the same as Prop. 4:—

Theorem (Prop. 4).—*Two chords of a circle, of which neither passes through the centre, cannot bisect each other.*

These last three theorems are fundamental for the theory of the circle. It is to be remarked that Euclid never proves that a straight line cannot have more than two points in common with a circumference.

§ 29. The next two propositions (5 and 6) might be replaced by a single and a simpler theorem, viz.:—

Theorem.—*Two circles which have a common centre, and whose circumferences have one point in common, coincide.*

Or, more in agreement with Euclid's form:—

Theorem.—*Two different circles, whose circumferences have a point in common, cannot have the same centre.*

That Euclid treats of two cases is characteristic of Greek mathematics.

The next two propositions (7 and 8) again belong together. They may be combined thus:—

Theorem.—*If from a point in a plane of a circle, which is not the centre, straight lines be drawn to the different points of the circumference, then of all these lines one is the shortest, and one the longest, and these lie both in that straight line which joins the given point to the centre. Of all the remaining lines each is equal to one and only one other, and these equal lines lie on opposite sides of the shortest or longest, and make equal angles with them.*

Euclid distinguishes the two cases where the given point lies within or without the circle, omitting the case where it lies in the circumference.

From the last proposition it follows that if from a point more than two equal straight lines can be drawn to the circumference, this point must be the centre. This is Prop. 9.

As a consequence of this we get

Theorem.—*If the circumferences of the two circles have three points in common they coincide.*

For in this case the two circles have a common centre, because from the centre of the one three equal lines can be drawn to points on the circumference of the other. But two circles which have common centre, and whose circumferences have a point in common, coincide. (Compare above statement of Props. 5 and 6.)

This theorem may also be stated thus :—

Through three points only one circumference may be drawn; or, *Three points determine a circle.*

Euclid does not give the theorem in this form. He proves, however, *that the two circles cannot cut another in more than two points* (Prop. 10), and *that two circles cannot touch one another in more points than one* (Prop. 13).

§ 30. Propositions 11 and 12 assert that *if two circles touch, then the point of contact lies on the line joining their centres.* This gives two propositions, because the circles may touch either internally or externally.

§ 31. Propositions 14 and 15 relate to the length of chords. The first says ; *that equal chords are equidistant from the centre, and that chords which are equidistant from the centre are equal*;

Whilst Prop. 15 compares unequal chords, viz., *Of all chords the diameter is the greatest, and of other chords that is the greater which is nearer to the centre*; and conversely, *the greater chord is nearer to the centre.*

§ 32. In Prop. 16 the tangent to a circle is for the first time introduced. The proposition is meant to show that the straight line at the end point of the diameter, and at right angles to it is a tangent. The proposition itself does not state this. It runs thus :—

Prop. 16. *The straight line drawn at right angles to the diameter of a circle, from the extremity of it, falls without the circle*; *and no straight line can be drawn from the extremity, between that straight line and the circumference, so as not to cut the circle.*

Corollary.—The straight line at right angles to a diameter drawn through the end point of it touches the circle.

The statement of the proposition and its whole treatment show the difficulties which the tangents presented to Euclid.

Prop. 17 solves the problem *through a given point, either in the circumference or without it, to draw a tangent to a given circle.*

Closely connected with Prop. 16 are Props. 18 and 19, which state (Prop. 18), *that the line joining the centre of a circle to the point of contact of a tangent is perpendicular to the tangent*; and conversely (Prop. 19), *that the straight line through the point of contact of, and perpendicular to, a tangent to a circle passes through the centre of the circle.*

§ 33. The rest of the book relates to angles connected with a circle, viz., angles which have the vertex either at the centre or on the circumference, and which are called respectively angles at the centre and angles at the circumference. Between these two kinds of angles exists the important relation expressed as follows :—

Prop. 20. *The angle at the centre of a circle is double of the angle at the circumference on the same base, that is, on the same arc.*

This is of great importance for its consequences, of which the two following are the principal :—

Prop. 21. *The angles in the same segment of a circle are equal to one another*;

And Prop. 22. *The opposite angles of any quadrilateral figure inscribed in a circle are together equal to two right angles.*

Further consequences are :—

Prop. 23. *On the same straight line, and on the same side of it, there cannot be two similar segments of circles, not coinciding with one another*;

And Prop. 24. *Similar segments of circles on equal straight lines are equal to one another.*

The problem Prop. 25, *A segment of a circle being given to describe the circle of which it is a segment*, may be solved much more easily by aid of the construction described in relation to Prop. 1, III., in § 27.

§ 34. There follow four theorems connecting the angles at the centre, the arcs into which they divide the circumference, and the chords subtending these arcs. They are expressed for angles, arcs, and chords in equal circles, but they hold also for angles, arcs, and chords in the same circle.

The theorems are :—

Prop. 26. *In equal circles equal angles stand on equal arcs, whether they be at the centres or circumferences*;

Prop. 27 (converse to Prop. 26). *In equal circles the angles which stand on equal arcs are equal to one another, whether they be at the centres or the circumferences*;

Prop. 28. *In equal circles equal straight lines* (equal chords) *cut off equal arcs, the greater equal to the greater, and the less equal to the less*;

Prop. 29 (converse to Prop. 28). *In equal circles equal arcs are subtended by equal straight lines.*

§ 35. Other important consequences of Props. 20–22 are :—

Prop. 31. *In a circle the angle in a semicircle is a right angle; but the angle in a segment greater than a semicircle is less than a right angle; and the angle in a segment less than a semicircle is greater than a right angle*;

Prop. 32. *If a straight line touch a circle, and from the point of contact a straight line be drawn cutting the circle, the angles which this line makes with the line touching the circle shall be equal to the angles which are in the alternate segments of the circle.*

§ 36. Propositions 30, 33, 34, contain problems which are solved by aid of the propositions preceding them :—

Prop. 30. *To bisect a given arc, that is, to divide it into two equal parts*;

Prop. 33. *On a given straight line to describe a segment of a circle containing an angle equal to a given rectilineal angle*;

Prop. 34. *From a given circle to cut off a segment containing an angle equal to a given rectilineal angle.*

§ 37. If we draw chords through a point A within a circle, they will each be divided by A into two segments. Between these segments the law holds that the rectangle contained by them has the same area on whatever chord through A the segments are taken. The value of this rectangle changes, of course, with the position of A.

A similar theorem holds if the point A be taken without the circle. On every straight line through A, which cuts the circle in two points B and C, we have two segments AB and AC, and the rectangles contained by them are again equal to one another, and equal to the square on a tangent drawn from A to the circle.

The first of these theorems gives Prop. 35, and the second Prop. 36, with its corollary, whilst Prop. 37, the last of Book III., gives the converse to Prop. 36. The first two theorems may be combined in one :—

THEOREM.—*If through a point A in the plane of a circle a straight line be drawn cutting the circle in B and C, then the rectangle AB.AC has a constant value so long as the point A be fixed; and if from A a tangent AD can be drawn to the circle, touching at D, then the above rectangle equals the square on AD.*

Prop. 37 may be stated thus :—

THEOREM.—*If from a point A without a circle a line be drawn cutting the circle in B and C, and another line to a point D on the circle, and if $AB.AC = AD^2$, then the line AD touches the circle at D.*

It is not difficult to prove also the converse to the general proposition as above stated. It may be expressed as follows :—

If four points ABCD be taken on the circumference of a circle, and if the lines AB, CD, produced if necessary, meet at E, then

$$EA\ .\ EB = EC\ .\ ED\ ;$$

and conversely, if this relation holds then the four points lie on a circle, that is, the circle drawn through three of them passes through the fourth.

That a circle may always be drawn through three points, provided that they do not lie in a straight line, is proved only later on in Book IV.

Book IV.

§ 38. The fourth book contains only problems, all relating to the construction of triangles and polygons inscribed in and circumscribed about circles, and of circles inscribed in or circumscribed about triangles and polygons. They are nearly all given for their own sake, and not for future use in the construction of figures, as are most of those in the former books. In seven definitions at the beginning of the book it is explained what is understood by figures inscribed in or described about other figures, with special reference to the case where one figure is a circle. Instead, however, of saying that one figure is described about another, it is now generally said that the one figure is circumscribed about the other. We may then state the definitions 3 or 4 thus :—

Definition.—A polygon is said to be inscribed in a circle, and the circle is said to be circumscribed about the polygon, if the vertices of the polygon lie in the circumference of the circle.

And definitions 5 and 6 thus :—

Definition.—A polygon is said to be circumscribed about a circle, and a circle is said to be inscribed in a polygon, if the sides of the polygon are tangents to the circle.

§ 39. The first problem is merely constructive. It requires to draw in a given circle a chord equal to a given straight line, which is not greater than the diameter of the circle. The problem is not a determinate one, inasmuch as the chord may be drawn from any point in the circumference. This may be said of almost all problems in this book, especially of the next two. They are :—

Prop. 2. *In a given circle to inscribe a triangle equiangular to a given triangle*;

Prop. 3. *About a given circle to circumscribe a triangle equiangular to a given triangle.*

§ 40. Of somewhat greater interest are the next problems, where the triangles are given and the circles to be found.

Prop. 4. *To inscribe a circle in a given triangle.*

The result is that the problem has always a solution, viz., the centre of the circle is the point where the bisectors of two of the interior angles of the triangle meet. The solution shows, though Euclid does not state this, that the problem has but one solution; and also,

THEOREM.—*The three bisectors of the interior angles of any triangle* *meet in a point, and this is the centre of the circle inscribed in the triangle.*

The solutions of most of the other problems contain also theorems. Of these we shall state those which are of special interest; Euclid does not state any one of them.

§ 41. Prop. 5. *To circumscribe a circle about a given triangle.*

The one solution which always exists contains the following:—

Theorem.—*The three straight lines which bisect the sides of a triangle at right angles meet in a point, and this point is the centre of the circle circumscribed about the triangle.*

Euclid adds in a corollary the following property:—

The centre of the circle circumscribed about a triangle lies within, on a side of, or without the triangle, according as the triangle is acute-angled, right-angled, or obtuse-angled.

§ 42. Whilst it is always possible to draw a circle which is inscribed in or circumscribed about a given triangle, this is not the case with quadrilaterals or polygons of more sides. Of those for which this is possible the regular polygons are the most interesting. In each of them a circle may be inscribed. and another may be circumscribed about it.

Euclid does not use the word regular, but he describes the polygons in question as *equiangular* and *equilateral*. We shall use the name regular polygon. The regular triangle is equilateral, the regular quadrilateral is the square.

Euclid considers the regular polygons of 4, 5, 6, and 15 sides. For each of the first three he solves the problems—(1) to inscribe such a polygon in a given circle; (2) to circumscribe it about a given circle; (3) to inscribe a circle in, and (4) to circumscribe a circle about, such a polygon.

For the regular triangle the problems are not repeated, because more general problems have been solved.

Props. 6, 7, 8, and 9 solve these problems for the square.

The general problem of inscribing in a given circle a regular polygon of n sides depends upon the problem of dividing the circumference of a circle into n equal parts, or what comes to the same thing, of drawing from the centre of the circle n radii such that the angles between consecutive radii are equal, that is, to divide the space about the centre into n equal angles. Thus, if it is required to inscribe a square in a circle, we have to draw four lines from the centre, making the four angles equal. This is done by drawing two diameters at right angles to one another. The ends of these diameters are the vertices of the required square. If, on the other hand, tangents be drawn at these ends, we obtain a square circumscribed about the circle.

§ 43. To construct a *regular pentagon*, we find it convenient first to construct a *regular decagon*. This requires to divide the space about the centre into ten equal angles. Each will be $\frac{1}{10}$th of a right angle, or $\frac{1}{5}$th of two right angles. If we suppose the decagon constructed, and if we join the centre to the end of one side, we get an isoceles triangle, where the angle at the centre equals $\frac{1}{5}$th of two right angles; hence each of the angles at the base will be $\frac{2}{5}$ths of two right angles, as all three angles together equal two right angles. Thus we have to construct an isoceles triangle, having the angle at the vertex equal to half an angle at the base. This is solved in Prop. 10, by aid of the problem in Prop. 11 of the second book. If we make the sides of this triangle equal to the radius of the given circle, then the base will be the side of the regular decagon inscribed in the circle. This side being known the decagon can be constructed, and if the vertices are joined alternately, leaving out half their number, we obtain the regular pentagon.

Euclid does not proceed thus. He wants the pentagon before the decagon. This, however, does not change the real nature of his solution, nor does his solution become simpler by not mentioning the decagon.

Once the regular pentagon is inscribed, it is easy to circumscribe another by drawing tangents at the vertices of the inscribed pentagon. This is shown in Prop. 12.

Prop. 13 and 14 teach how a circle may be inscribed in or circumscribed about any given regular pentagon.

§ 44. The *regular hexagon* is more easily constructed, as shown in Prop. 15. The result is that the side of the regular hexagon inscribed in a circle is equal to the radius of the circle.

For this polygon the other three problems mentioned are not solved.

§ 45. The book closes with Prop. 16. To inscribe a regular quindecagon in a given circle. That this may be done is easily seen. If we inscribe a regular pentagon and a regular hexagon in the circle, having one vertex in common, then the arc from the common vertex to the next vertex of the pentagon is $\frac{1}{5}$th of the circumference, and to the next vertex of the hexagon is $\frac{1}{6}$th of the circumference. The difference between these arcs is, therefore, $\frac{1}{5}-\frac{1}{6}=\frac{1}{30}$th of the circumference. The latter may, therefore, be divided into thirty, and hence also in fifteen equal parts, and the regular quindecagon be described.

§ 46. We conclude with a few theorems about regular polygons which are not given by Euclid.

Theorem.—*The straight lines perpendicular to and bisecting the sides of any regular polygon meet in a point. The straight lines bisecting the angles in the regular polygon meet in the same point. This point is the centre of the circles circumscribed about and inscribed in the regular polygon.* The proof, which is easy, is left to the reader.

We can bisect any given arc (Prop. 30, III.). Hence we can divide a circumference into $2n$ equal parts as soon as it has been divided into n equal parts, or as soon as a regular polygon of n sides has been constructed. Hence—

Theorem.—*If a regular polygon of* n *sides has been constructed, then a regular polygon of* 2n *sides, of* 4n, *of* 8n *sides, &c., may also be constructed.* Euclid shows how to construct regular polygons of 3, 4, 5, and 15 sides. It follows that we can construct regular polygons of

3,	6,	12,	24...	sides
4,	8,	16,	32...	,,
5,	10,	20,	40...	,,
15,	30,	60,	120...	,,

The construction of any new regular polygon not included in one of these series will give rise to a new series. Till the beginning of this century nothing was added to the knowledge of regular polygons as given by Euclid. Then Gauss, in his celebrated *Arithmetic*, proved that every regular polgon of 2^n+1 sides may be constructed if this number 2^n+1 be prime, and that no others can be constructed by elementary methods. This shows that regular polygons of 7, 9, 13 sides cannot thus be constructed, but that a regular polygon of 17 sides is possible; for $17=2^4+1$. The next polygon is one of 257 sides. The construction becomes already rather complicated for 17 sides.

Book V.

§ 47. The fifth book of the *Elements* is not exclusively geometrical. It contains the theory of ratios and proportion of quantities in general. The treatment, as here given, is admirable, and in every respect superior to the algebraical method by which Euclid's theory is now generally replaced. It has, however, the reputation of being too difficult for schools, and is therefore very seldom read. We shall try to make the subject clear, and to show why the usual algebraical treatment of proportion is not really sound. We begin by quoting those definitions at the beginning of Book V. which are most important. These definitions have given rise to much discussion.

The only definitions which are essential for the fifth book are Defs. 1, 2, 4, 5, 6, and 7. Of the remainder 3, 8, and 9 are more than useless, and probably not Euclid's, but additions of later editors, of whom Theon of Alexandria was the most prominent. Defs. 10 and 11 belong rather to the sixth book, whilst all the others are merely nominal. The really important ones are 4, 5, 6, and 7.

§ 48. To define a magnitude is not attempted by Euclid. The first two definitions state what is meant by a "part," that is, a submultiple or measure, and by a "multiple" of a given magnitude. The meaning of Def. 4 is that two given quantities can have a ratio to one another only in case that they are comparable as to their magnitude, that is, if they are of the same kind.

Def. 3, which is probably due to Theon, professes to define a ratio, but is as meaningless as it is uncalled for, for all that is wanted is given in Defs. 5 and 7.

In Def. 5 it is explained what is meant by saying that two magnitudes have the same ratio to one another as two other magnitudes, and in Def. 7 what we have to understand by a greater or a less ratio. The 6th definition is only nominal, explaining the meaning of the word *proportional*.

Euclid represents magnitudes by lines, and often denotes them either by single letters or, like lines, by two letters. We shall use only single letters for the purpose. If a and b denote two magnitudes of the same kind, their ratio will be denoted by $a:b$; if c and d are two other magnitudes of the same kind, but possibly of a different kind from a and b, then if c and d have the same ratio to one another as a and b, this will be expressed by writing—

$$a : b :: c : d.$$

Further, if m is a (whole) number, ma shall denote the multiple of a which is obtained by taking it m times.

§ 49. The whole theory of ratios is based on Def. 5.

Def. 5. *The first of four magnitudes is said to have the same ratio to the second that the third has to the fourth when, any equimultiples whatever of the first and the third being taken, and any equimultiples whatever of the second and the fourth, if the multiple of the first be less than that of the second, the multiple of the third is also less than that of the fourth; and if the multiple of the first is equal to that of the second, the multiple of the third is also equal to that of the fourth; and if the multiple of the first is greater than that of the second, the multiple of the third is also greater than that of the fourth.*

It will be well to show at once in an example how this definition can be used, by proving the first part of the first proposition in the sixth book. *Triangles of the same altitude are to one another as their bases*, or if a and b are the bases, and α and β the areas, of two triangles which have the same altitude, then $a : b :: \alpha : \beta$.

To prove this, we have, according to Definition 5, to show—

$$\text{if } ma > nb, \text{ then } m\alpha > n\beta,$$
$$\text{if } ma = nb, \text{ then } m\alpha = n\beta,$$
$$\text{if } ma < nb, \text{ then } m\alpha < n\beta.$$

That this is true is in our case easily seen. We may suppose that the triangles have a common vertex, and their bases in the same line. We set off the base a along the line containing the bases m times; we then join the different parts of division to the vertex, and get m triangles all equal to α. The triangle on ma as base equals, therefore, $m\alpha$. If we proceed in the same manner with the base b, setting it off n times, we find that the area of the triangle on the base nb equals $n\beta$, the vertex of all triangles being the same. But if two triangles have the same altitude, then their areas are equal if the bases are equal; hence $m\alpha = n\beta$ if $ma = nb$, and if their bases are unequal, then that has the greater area which is on the greater base; in other words, $m\alpha$ is greater than, equal to, or less than $n\beta$, according as ma is greater than, equal to, or less than nb, which was to be proved.

§ 50. It will be seen that even in this example it does not become evident what a ratio really is. It is still an open question whether ratios are magnitudes which we can compare. We do not know whether the ratio of two lines is a magnitude of the same kind as the ratio of two areas. Though we might say that Def. 5 defines *equal* ratios, still we do not know whether they are equal in the sense of the axiom, that two things which are equal to a third are equal to one another. That this is the case requires a proof, and until this proof is given we shall use the :: instead of the sign =, which, however, we shall afterwards introduce.

As soon as it has been established that all ratios are like magnitudes, it becomes easy to show that, in some cases at least, they are numbers. This step was never made by Greek mathematicians. They distinguished always most carefully between continuous magnitudes and the discrete series of numbers. In modern times it has become the custom to ignore this difference.

If, in determining the ratio of two lines, a common measure can be found, which is contained m times in the first, and n times in the second, then the ratio of the two lines equals the ratio of the two numbers $m:n$. This is shown by Euclid in Prop. 5, X. But the ratio of two numbers is, as a rule, a fraction, and the Greeks did not, as we do, consider fractions as numbers. Far less had they any notion of introducing irrational numbers, which are neither whole nor fractional, as we are obliged to do if we wish to say that all ratios are numbers. The incommensurable numbers which are thus introduced as ratios of incommensurable quantities are now-a-days as familiar to us as fractions; but a proof is generally omitted that we may apply to them the rules which have been established for rational numbers only. Euclid's treatment of ratios avoids this difficulty. His definitions holds for commensurable as well as for incommensurable quantities. Even the notion of incommensurable quantities is avoided in Book V. But he proves that the more elementary rules of algebra hold for ratios. We shall state all his propositions in that algebraical form to which we are now accustomed. This may, of course, be done without changing the character of Euclid's method.

§ 51. Using the notation explained above we express the first propositions as follows:—

Prop. 1. If $a = ma'$, $b = mb'$, $c = mc'$,
then $a + b + c = m(a' + b' + c')$.

Prop. 2. If $a = mb$, and $c = md$,
$e = nb$, and $f = nd$,
then $a + e$ is the same multiple of b as $c + f$ is of d, viz.:—

$$a + e = (m + n)b, \text{ and } c + f = (m + n)d.$$

Prop. 3. If $a = mb$, $c = md$, then is na the same multiple of b that nc is of d, viz., $na = nmb$, $nc = nmd$.

Prop. 4. If $a : b :: c : d$,
then $ma : nb :: mc : nd$.

Prop. 5. If $a = mb$, and $c = md$
then $a - c = m(b - d)$.

Prop. 6. If $a = mb$, $c = md$,
then are $a - nb$ and $c - nd$ either equal to, or equimultiples of, b and d, viz., $a - nb = (m - n)b$ and $c - nd = (m - n)d$, where $m - n$ may be unity.

All these propositions relate to *equimultiples*. Now follow propositions about ratios which are compared as to their magnitude.

§ 52. Prop. 7. If $a = b$, then $a : c :: b : c$ and $c : a :: c : b$.

The proof is simply this. As $a = b$ we know that $ma = mb$:
therefore if $ma > nc$, then $mb > nc$,
if $ma = nc$, then $mb = nc$,
if $ma < nc$, then $mb < nc$,
therefore the first proportion holds by Definition 5.

Prop. 8. If $a > b$, then $a : c > b : c$,
and $c : a < c : b$.
The proof depends on Definition 7.

Prop. 9 (converse to Prop. 7). If
$a : c :: b : c$,
or if $c : a :: c : b$, then $a = b$.

Prop. 10 (converse to Prop. 8). If
$a : c > b : c$, then $a > b$
and if $c : a < c : b$, then $a < b$.

Prop. 11. If $a : b :: c : d$,
and $a : b :: e : f$,
then $c : d :: e : f$.

In words, *if two ratios are equal to a third, they are equal to one another*. After these propositions have been proved, we have a right to consider a ratio as a *magnitude*, for only now can we consider a ratio as something for which the axiom about magnitudes holds: things which are equal to a third are equal to one another.

We shall indicate this by writing in future the sign = instead of ::. The remaining propositions, which explain themselves, may then be stated as follows:—

§ 53. Prop. 12. If $a : b = c : d = e : f$,
then $a + c + e : b + d + f = a : b$.

Prop. 13. If $a : b = c : d$ and $c : d > e : f$,
then $a : b > e : f$.

Prop. 14. If $a : b = c : d$, and $a > c$, then $b > d$.

Prop. 15. Magnitudes have the same ratio to one another that their equimultiples have—

$$ma : mb = a : b.$$

Prop. 16. If a, b, c, d are magnitudes of the same kind, and if
$a : b = c : d$,
then $a : c = b : d$.

Prop. 17. If $a + b : b = c + d : d$,
then $a : b = c : d$.

Prop. 18 (converse to 17). If
$a : b = c : d$
then $a + b : b = c + d : d$.

Prop. 19. If a, b, c, d are quantities of the same kind, and if
$a : b = c : d$,
then $a - c : b - d = a : b$.

§ 54. Prop. 20. *If there be three magnitudes, and other three, which have the same ratio, taken two and two, then if the first be greater than the third, the fourth shall be greater than the sixth and if equal, equal; and if less, less.*

If we understand by

$$a : b : c : d : e : \ldots = a' : b' : c' : d' : e' : \ldots$$

that the ratio of any two consecutive magnitudes on the first side equals that of the corresponding magnitudes on the second side, we may write this theorem in symbols, thus:—

If a, b, c be quantities of one, and d, e, f magnitudes of the same or any other kind, such that
$a : b : c = d : e : f$,
and if $a > c$, then $d > f$,
but if $a = c$, then $d = f$,
and if $a < c$, then $d < f$.

Prop. 21. If $a : b = e : f$ and $b : c = d : e$,
or if $a : b : c = \frac{1}{f} : \frac{1}{e} : \frac{1}{d}$,
and if $a > c$, then $d > f$,
but if $a = c$, then $d = f$,
and if $a < c$, then $d < f$.

By aid of these two propositions the following two are proved.

§ 55. Prop. 22. *If there be any number of magnitudes, and as many others, which have the same ratio, taken two and two in order, the first shall have to the last of the first magnitudes the same ratio which the first of the others has to the last.*

We may state it more generally, thus:—

If $a : b : c : d : e : \ldots = a' : b' : c' : d' : e' : \ldots$,

then not only have two consecutive, but any two magnitudes on the first side, the same ratio as the corresponding magnitudes on the other. For instance—

$$a : c = a' : c'; \quad b : e = b' : e', \text{ \&c.}$$

Prop. 23 we state only in symbols, viz.:—

If $a : b : c : d : e : \ldots = \frac{1}{a'} : \frac{1}{b'} : \frac{1}{c'} : \frac{1}{d'} : \frac{1}{e'} \ldots$

then $a : c = c' : a'$,
$b : e = c' : b'$,
and so on.

Prop. 24 comes to this: If $a : b = c : d$ and $e : b = f : d$, then

$$a + e : b = c + f : d.$$

Some of the proportions which are considered in the above propositions have special names. These we have omitted, as being of no use, since algebra has enabled us to bring the different operations contained in the propositions under a common point of view.

§ 56. The last proposition in the fifth book is of a different character.

Prop. 25. *If four magnitudes of the same kind be proportional, the greatest and least of them together shall be greater than the other two together.* In symbols—

If a, b, c, d be magnitudes of the same kind, and if $a : b = c : d$, and if a is the greatest, hence d the least, then $a + d > b + c$.

§ 57. We return once again to the question, What is a ratio? We have seen that we may treat ratios as magnitudes, and that all ratios are magnitudes of the same kind, for we may compare any two as to their magnitude. It will presently be shown that ratios of lines may be considered as *quotients* of lines, so that a ratio appears as answer to the question, How often is one line contained in another? But the answer to this question is given by a number, at least in some cases, and in all cases if we admit incommensurable numbers. Considered from this point of view, we may say the fifth book of the *Elements* shows that some of the simpler algebraical operations hold for incommensurable numbers. In the ordinary algebraical treatment of numbers this proof is altogether omitted, or given by a process of limits which does not seem to be natural to the subject.

Book VI.

§ 58. The sixth book contains the theory of similar figures. After a few definitions explaining terms, the first proposition gives the first application of the theory of proportion.

Prop. 1. *Triangles and parallelograms of the same altitude are to one another as their bases.*

The proof has already been considered in § 49.

From this follows easily the important theorem

Prop. 2. *If a straight line be drawn parallel to one of the sides of a triangle, it shall cut the other sides, or those sides produced, proportionally; and if the sides or the sides produced be cut proportionally, the straight line which joins the points of section, shall be parallel to the remaining side of the triangle.*

§ 59. The next proposition, together with one added by Simson as Prop. A, may be expressed more conveniently if we introduce a modern phraseology, viz., if in a line AB we assume a point C between A and B, we shall say that C divides AB internally in the ratio AC : CB; but if C be taken in the line AB produced, we shall say that AB is divided externally in the ratio AC : CB.

The two propositions then come to this:

Theorem (Prop. 3).—*The bisector of an angle in a triangle divides the opposite side internally in a ratio equal to the ratio of the two sides including that angle;* and conversely, *if a line through the vertex of a triangle divide the base internally in the ratio of the two other sides, then that line bisects the angle at the vertex.*

Theorem (Simson's Prop. A).—*The line which bisects an exterior angle of a triangle divides the opposite side externally in the ratio of the other sides;* and conversely, *if a line through the vertex of a triangle divide the base externally in the ratio of the sides, then it bisects an exterior angle at the vertex of the triangle.*

If we combine both we have—

Theorem.—*The two lines which bisect the interior and exterior angles at one vertex of a triangle divide the opposite side internally and externally in the same ratio, viz.. in the ratio of the other two sides.*

§ 60. The next four propositions contain the theory of similar triangles, of which four cases are considered. They may be stated together.

Theorem.—*Two triangles are similar,*—

1. (Prop. 4). *If the triangles are equiangular*;
2. (Prop. 5). *If the sides of the one are proportional to those of the other*;
3. (Prop. 6). *If two sides in one are proportional to two sides in the other, and if the angles contained by these sides are equal*;
4. (Prop. 7). *If two sides in one are proportional to two sides in the other, if the angles opposite homologous sides are equal, and if the angles opposite the other homologous sides are both acute, both right, or both obtuse; homologous sides being in each case those which are opposite equal angles.*

An important application of these theorems is at once made to a right-angled triangle, viz.:—

Prop. 8. *In a right-angled triangle, if a perpendicular be drawn from the right angle to the base, the triangles on each side of it are similar to the whole triangle, and to one another.*

Corollary.—From this it is manifest that the perpendicular drawn from the right angle of a right-angled triangle to the base is a mean proportional between the segments of the base, and also that each of the sides is a mean proportional between the base and the segment of the base adjacent to that side.

§ 61. There follow four propositions containing problems, viz., in language slightly different from Euclid's:—

Prop. 9. *To divide a straight line into a given number of equal parts.*

Prop. 10. *To divide a straight line in a given ratio.*

Prop. 11. *To find a third proportional to two given straight lines.*

Prop. 12. *To find a fourth proportional to three given straight lines.*

Prop. 13. *To find a mean proportional between two given straight lines.*

The last three may be written as equations with one unknown quantity,—viz., if we call the given straight lines a, b, c, and the required line x, we have to find a line x so that

Prop. 11. $a : b = b : x$;
Prop. 12. $a : b = c : x$;
Prop. 13. $a : x = x : b$.

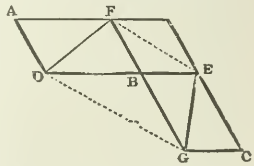
We shall see presently how these may be written without the signs of ratios.

§ 62. Euclid considers next proportions connected with parallelograms and triangles which are equal in area.

Prop. 14. *Equal parallelograms which have one angle of the one equal to one angle of the other have their sides about the equal angles reciprocally proportional; and parallelograms which have one angle of the one equal to one angle of the other, and their sides about the equal angles reciprocally proportional, are equal to one another.*

Prop. 15. *Equal triangles which have one angle of the one equal to one angle of the other, have their sides about the equal angles reciprocally proportional; and triangles which have one angle of the one equal to one angle of the other, and their sides about the equal angles reciprocally proportional, are equal to one another.*

The latter proposition is really the same as the former, for if, as in the accompanying diagram, in the figure belonging to the former the two equal parallelograms AB and BC be bisected by the lines DF and EG, and if EF be drawn, we get the figure belonging to the latter.



It is worth noticing that the lines FE and DG are parallel. We may state therefore the theorem—

Theorem.—*If two triangles are equal in area, and have one angle in the one vertically opposite to one angle in the other, then the two straight lines which join the remaining two vertices of the one to those of the other triangle are parallel.*

§ 63. A most important theorem is

Prop. 16. *If four straight lines be proportionals, the rectangle contained by the extremes is equal to the rectangle contained by the means; and if the rectangle contained by the extremes be equal to the rectangle contained by the means, the four straight lines are proportionals.*

In symbols, if a, b, c, d are the four lines, and

if $a : b = c : d$,
then $ad = bc$;
and conversely, if $ad = bc$,
then $a : b = c : d$,

where ad and bc denote (as in § 20), the areas of the rectangles contained by a and d and by b and c respectively.

This allows us to transform every proportion between four lines into an equation between two products.

It shows further that the operation of forming a product of two lines, and the operation of forming their ratio are each the inverse of the other.

If we now define a quotient $\frac{a}{b}$ of two lines as the *number* which multiplied into b gives a, so that

$$\frac{a}{b} b = a,$$

we see that from the equality of two quotients

$$\frac{a}{b} = \frac{c}{d}$$

follows, if we multiply both sides by bd,

$$\frac{a}{b} b \cdot d = \frac{c}{d} d \cdot b,$$
$$ad = cb.$$

But from this it follows according to the last theorem that

$$a : b = c : d.$$

Hence we conclude that the quotient $\frac{a}{b}$ and the ratio $a : b$ are different forms of the same magnitude, only with this important difference that the quotient $\frac{a}{b}$ would have a meaning only if a and b have a common measure, until we introduce incommensurable numbers, while the ratio $a : b$ has always a meaning, and thus gives rise to the introduction of incommensurable numbers.

Thus it is really the theory of ratios in the fifth book which enables us to extend the geometrical calculus given before in connexion with Book II. It will also be seen that if we write the ratios in Book V. as quotients, or rather as fractions, then most of the theorems state properties of quotients or of fractions.

§ 64. Prop. 17 contains only a special case of 16. After the problem, Prop. 18. *On a given straight line to describe a rectilineal figure similar and similarly situated to a given rectilineal figure,* there follows another fundamental theorem:

Prop. 19. *Similar triangles are to one another in the duplicate ratio of their homologous sides.* In other words, the areas of similar triangles are to one another as the squares on homologous sides. This is generalized in

Prop. 20. *Similar polygons may be divided into the same number of similar triangles, having the same ratio to one another that the polygons have; and the polygons are to one another in the duplicate ratio of their homologous sides.*

§ 65. Prop. 21. *Rectilineal figures which are similar to the same rectilineal figure are also similar to each other,* is an immediate consequence of the definition of similar figures. As similar figures may be said to be equal in "shape" but not in "size," we may state it also thus:

"Figures which are equal in shape to a third are equal in shape to each other."

Prop. 22. *If four straight lines be proportionals, the similar rectilineal figures similarly described on them shall also be proportionals; and if the similar rectilineal figures similarly described on four straight lines be proportionals, those straight lines shall be proportionals.*

This is essentially the same as the following:—

If $a : b = c : d,$

then $a^2 : b^2 = c^2 : d^2.$

§ 66. Now follows a proposition which has been much discussed with regard to Euclid's exact meaning in saying that a ratio is *compounded* of two other ratios, viz.:

Prop. 23. *Parallelograms which are equiangular to one another, have to one another the ratio which is compounded of the ratios of their sides.*

The proof of the proposition makes its meaning clear. In symbols the ratio $a : c$ is compounded of the two ratios $a : b$ and $b : c$, and if $a : b = a' : b'$, $b : c = b'' : c''$, then $a : c$ is compounded of $a' : b'$ and $a'' : b''$.

If we consider the ratios as numbers, we may say that the one ratio is the product of those of which it is compounded, or in symbols.

$$\frac{a}{c} = \frac{a}{b} \cdot \frac{b}{c} = \frac{a'}{b'} \cdot \frac{b''}{c''}, \text{ if } \frac{a}{b} = \frac{a'}{b'} \text{ and } \frac{b}{c} = \frac{b''}{c''}.$$

The theorem in Prop. 23 is the foundation of all mensuration of areas. From it we see at once that two rectangles have the ratio of their areas compounded of the ratios of their sides.

If A is the area of a rectangle contained by a and b, and B that of a rectangle contained by c and d, so that $A = ab$, $B = cd$, then $A : B = ab : cd$, and this is, the theorem says, compounded of the ratios $a : c$ and $b : d$. In forms of quotients,

$$\frac{a}{c} \cdot \frac{b}{d} = \frac{ab}{cd}.$$

This shows how to multiply quotients in our geometrical calculus.

Further, *Two triangles have the ratios of their areas compounded of the ratios of their bases and their altitude.* For a triangle is equal in area to half a parallelogram which has the same base and the same altitude.

To bring these theorems to the form in which they are usually given, we assume a straight line u as our unit of length (generally an inch, a foot, a mile, &c.), and determine the number α which expresses how often u is contained in a line a, so that α denotes the ratio $a : u$ whether commensurable or not, and that $a = \alpha u$. We call this number α the numerical value of a. If in the same manner β be the numerical value of a line b we have

$$a : b = \alpha : \beta ;$$

in words: *The ratio of two lines (and of two like quantities in general) is equal to that of their numerical values.*

This is easily proved by observing that $a = \alpha u$, $b = \beta u$, therefore $a : b = \alpha u : \beta u$, and this may without difficulty be shown to equal $\alpha : \beta$.

If now a, b be base and altitude of one, a', b' those of another parallelogram, α, β and α', β' their numerical values respectively, and A, A′ their areas, then

$$\frac{A}{A'} = \frac{a}{a'} \cdot \frac{b}{b'} = \frac{\alpha}{\alpha'} \cdot \frac{\beta}{\beta'} = \frac{\alpha\beta}{\alpha'\beta'}.$$

In words: *The areas of two parallelograms are to each other as the products of the numerical values of their bases and altitudes.*

If especially the second parallelogram is the unit square, *i.e.*, a square on the unit of length, then $\alpha' = \beta' = 1$, $A' = u^2$, and we have

$$\frac{A}{A'} = \alpha\beta \text{. or } A = \alpha\beta \, . \, u^2.$$

This gives the theorem: The number of unit squares contained in a parallelogram equals the product of the numerical values of base and altitude, and similarly the number of unit squares contained in a triangle equals half the product of the numerical values of base and altitude.

This is often stated by saying that the area of a parallelogram is equal to the product of the base and the altitude, meaning by this product the product of the numerical values, and not the product as defined above in § 20.

§ 68. Propositions 24 and 26 relate to parallelograms about diagonals, such as are considered in Book I., 43. They are—

Prop. 24. *Parallelograms about the diameter of any parallelogram are similar to the whole parallelogram and to one another;* and its converse (Prop. 26), *If two similar parallelograms have a common angle, and be similarly situated, they are about the same diameter.*

Between these is inserted a problem.

Prop. 25. *To describe a rectilineal figure which shall be similar to one given rectilinear figure, and equal to another given rectilineal figure.*

§ 69. Prop. 27 contains a theorem relating to the theory of maxima and minima. We may state it thus:

Prop 27. *If a parallelogram be divided into two by a straight line cutting the base, and if on half the base another parallelogram be constructed similar to one of those parts, then this third parallelogram is greater than the other part.*

Of far greater interest than this general theorem is a special case of it, where the parallelograms are changed into rectangles, and where one of the parts into which the parallelogram is divided is made a square; for then the theorem changes into one which is easily recognized to be identical with the following:—

THEOREM.—*Of all rectangles which have the same perimeter the square has the greatest area.*

This may also be stated thus:—

THEOREM.—*Of all rectangles which have the same area the square has the least perimeter.*

§ 70. The next three propositions contain problems which may be said to be solutions of quadratic equations. The first two are, like the last, involved in somewhat obscure language. We transcribe them as follows:—

Problem.—To describe on a given base a parallelogram, and to divide it either internally (Prop. 28) or externally (Prop. 29) from a point on the base into two parallelograms, of which the one has a given size (is equal in area to a given figure), whilst the other has a given shape (is similar to a given parallelogram).

If we express this again in symbols, calling the given base a, the one part x, and the altitude y, we have to determine x and y in the first case from the equations

$$(a-x)y = k^2,$$

$$\frac{x}{y} = \frac{p}{q},$$

k^2 being the given size of the first, and p and q the base and altitude of the parallelogram which determine the shape of the second of the required parallelograms.

If we substitute the value of y, we get

$$(a-x)x = \frac{pk^2}{q},$$

or,

$$ax - x^2 = b^2,$$

where a and b are known quantities, taking $b^2 = \frac{pk^2}{q}$.

The second case (Prop. 29) gives rise, in the same manner, to the quadratic

$$ax + x^2 = b^2.$$

The next problem—

Prop. 30. *To cut a given straight line in extreme and mean ratio,* leads to the equation

$$ax + x^2 = a^2.$$

This is, therefore, only a special case of the last, and is, besides, an old acquaintance, being essentially the same problem as that proposed in II. 11.

Prop. 30 may therefore be solved in two ways, either by aid of Prop. 29 or by aid of II. 11. Euclid gives both solutions.

§ 71. Prop. 31 (Theorem). *In any right-angled triangle, any rectilineal figure described on the side subtending the right angle is equal to the similar and similarly-described figures on the sides containing the right angle*,—is a pretty generalization of the theorem of Pythagoras (I. 47).

Leaving out the next proposition, which is of little interest, we come to the last in this book.

Prop. 33. *In equal circles angles, whether at the centres or the circumferences, have the same ratio which the arcs on which they stand have to one another; so also have the sectors.*

Of this, the part relating to angles at the centre is of special importance; it enables us to measure angles by arcs.

With this closes that part of the *Elements* which is devoted to the study of figures in a plane.

Book XI.

§ 72. In this book figures are considered which are not confined to a plane, viz., first relations between lines and planes in space, and afterwards properties of solids.

Of new definitions we mention those which relate to the perpendicularity and the inclination of lines and planes.

Def. 3. *A straight line is perpendicular, or at right angles, to a plane when it makes right angles with every straight line meeting it in that plane.*

The definition of perpendicular planes (Def. 4) offers no difficulty. Euclid defines the inclination of lines to planes and of planes to planes (Defs. 5 and 6) by aid of plane angles, included by straight lines, with which we have been made familiar in the first books.

The other important definitions are those of parallel planes, which never meet (Def. 8), and of solid angles formed by three or more planes meeting in a point (Def. 9).

To these we add the definition of a line parallel to a plane as a line which does not meet the plane.

§ 73. Before we investigate the contents of Book XI., it will be well to recapitulate shortly what we know of planes and lines from the definitions and axioms of the first book. There a plane has been defined as a surface which has the property that every straight line which joins two points in it lies altogether in it. This is equivalent to saying that a straight line which has two points in a plane has all points in the plane. Hence, a straight line which does not lie in the plane cannot have more than one point in common with the plane. This is virtually the same as Euclid's Prop. 1, viz.:—

Prop. 1. *One part of a straight line cannot be in a plane and another part without it.*

It also follows, as was pointed out in § 3, in discussing the definitions of Book I., that a plane is determined already by one straight line and a point without it, viz., if all lines be drawn through the point, and cutting the line, they will form a plane.

This may be stated thus:—

A plane is determined—

1st, *By a straight line and a point which does not lie on it*;

2d, *By three points which do not lie in a straight line*; for if two of these points be joined by a straight line we have case 1;

3d, *By two intersecting straight lines*; for the point of intersection and two other points, one in each line, give case 2;

4th, *By two parallel lines* (Def. 35, I.).

The third case of this theorem is Euclid's

Prop. 2. *Two straight lines which cut one another are in one plane, and three straight lines which meet one another are in one plane.*

And the fourth is Euclid's

Prop. 7. *If two straight lines be parallel, the straight line drawn from any point in one to any point in the other is in the same plane with the parallels.* From the definition of a plane further follows:

Prop. 3. *If two planes cut one another, their common section is a straight line.*

§ 74. Whilst these propositions are virtually contained in the definition of a plane, the next gives us a new and fundamental property of space, showing at the same time that it is possible to have a straight line perpendicular to a plane, according to Def. 3. It states—

Theorem (Prop. 4).—*If a straight line is perpendicular to two straight lines in a plane which it meets, then it is perpendicular to all lines in the plane which it meets, and hence it is perpendicular to the plane.*

Def. 3 may be stated thus: If a straight line is perpendicular to a plane, then it is perpendicular to every line in the plane which it meets. The converse to this would be

Theorem.—*All straight lines which meet a given straight line in the same point, and are perpendicular to it, lie in a plane which is perpendicular to that line.*

This Euclid states thus:

Prop. 5. *If three straight lines meet all at one point, and a straight line stands at right angles to each of them at that point, the three straight lines shall be in one and the same plane.*

§ 75. There follow theorems relating to the theory of parallel lines in space, viz.:—

Theorem (Prop. 6).—*Any two lines which are perpendicular to the same plane are parallel to each other*; and conversely

Theorem (Prop. 8).—*If of two parallel straight lines one is perpendicular to a plane, the other is so also.*

Further, the important theorems

Prop. 9. *Two straight lines which are each of them parallel to the same straight line, and not in the same plane with it, are parallel to one another*; where the words, "and not in the same plane with it," may be left out, for they exclude the case of three parallels in a plane, which has been proved before; and

Theorem (Prop. 10).—*If two angles in different planes have the two limits of the one parallel to those of the other, then the angles are equal.* That their planes are parallel is shown later on in Prop. 15.

This theorem is not necessarily true, for the angles in question may be supplementary; but then the one angle will be equal to that which is adjacent and supplementary to the other, and this latter angle will also have its limits parallel to those of the first.

From this theorem it follows that if we take any two straight lines in space which do not meet, and if we draw through any point P in space two lines parallel to them, then the angle included by these lines will always be the same, whatever the position of the point P may be. This angle has in modern times been called the angle between the given lines:—

Definition.—*By the angles between two not intersecting lines we understand the angles which two intersecting lines include that are parallel respectively to the two given lines.*

§ 76. It is now possible to solve the following two problems:—

Problem.—*To draw a straight line perpendicular to a given plane from a given point which lies*

1. *Not in the plane* (Prop. 11).
2. *In the plane* (Prop. 12).

The second case is easily reduced to the first—viz., if by aid of the first we have drawn any perpendicular to the plane from some point without it, we need only draw through the given point in the plane a line parallel to it, in order to have the required perpendicular given. The solution of the first part is of interest in itself. It depends upon a construction which may be expressed as a theorem.

Theorem.—*If from a point A without a plane a perpendicular AB be drawn to the plane, and if from the foot B of this perpendicular another perpendicular BC be drawn to any straight line in the plane, then the straight line joining A to the foot C of this second perpendicular will also be perpendicular to the line in the plane.*

The theory of perpendiculars to a plane is concluded by the theorem—

Prop. 13. *Through any point in space, whether in or without a plane, only one straight line can be drawn perpendicular to the plane.*

§ 77. The next four propositions treat of parallel planes. It is shown *that planes which have a common perpendicular are parallel* (Prop. 14); *that two planes are parallel if two intersecting straight lines in the one are parallel respectively to two straight lines in the other plane* (Prop. 15); *that parallel planes are cut by any plane in parallel straight lines* (Prop. 16); and lastly, *that any two straight lines are cut proportionally by a series of parallel planes* (Prop. 17).

This theory is made more complete by adding the following theorems, which are easy deductions from the last:—*Two parallel planes have common perpendiculars* (converse to 14); and *Two planes which are parallel to a third plane are parallel to each other.*

It will be noted that Prop. 15 at once allows of the solution of the problem: "Through a given point to draw a plane parallel to a given plane." And it is also easily proved that this problem allows always of one, and only of one, solution.

§ 78. We come now to planes which are perpendicular to one another. Two theorems relate to them.

Prop. 18. *If a straight line be at right angles to a plane, every plane which passes through it shall be at right angles to that plane.*

Prop. 19. *If two planes which cut one another be each of them perpendicular to a third plane, their common section shall be perpendicular to the same plane.*

§ 79. If three planes pass through a common point, and if they bound each other, a solid angle of three faces, or a *trihedral* angle, is formed, and similarly by more planes a solid angle of more faces, or a *polyhedral* angle. These have many properties which are quite analogous to those of triangles and polygons in a plane. Euclid states some, viz.:—

Prop. 20. *If a solid angle be contained by three plane angles, any two of them are together greater than the third.*

But the next—

Prop. 21. *Every solid angle is contained by plane angles, which are together less than four right angles*—has no analogous theorem in the plane.

We may mention, however, that the theorems about triangles contained in the propositions of Book I., which do not depend upon the theory of parallels (that is all up to Prop. 27), have their corresponding theorems about trihedral angles. The latter are formed, if for "side of a triangle" we write "plane angle" or "face" of trihedral angle, and for "angle of triangle" we substitute "angle between two faces" where the planes containing the solid angle are called its *faces*. We get, for instance, from I. 4, the theorem, *If two trihedral angles have the angles of two faces in the one equal to the angles of two faces in the other, and have likewise the angles included by these faces equal, then the angles in the remaining faces are equal, and the angles between the other faces are equal each to each, viz., those which are opposite equal faces.* The solid angles themselves are not necessarily equal, for they may be only symmetrical like the right hand and the left.

The connexion indicated between triangles and trihedral angles will also be recognized in

Prop. 22. *If every two of three plane angles be greater than the third, and if the straight lines which contain them be all equal, a triangle may be made of the straight lines that join the extremities of those equal straight lines.*

And Prop. 23. solves the problem, *To construct a trihedral angle having the angles of its faces equal to three given plane angles, any two of them being greater than the third.* It is, of course, analogous to the problem of constructing a triangle having its sides of given length.

Two other theorems of this kind are added by Simson in his edition of Euclid's *Elements.*

§ 80. These are the principal properties of lines and planes in space, but before we go on to their applications it will be well to define the word *distance.* In geometry distance means always "shortest distance"; viz., the distance of a point from a straight line, or from a plane, is the length of the perpendicular from the point to the line or plane. The distance between two non-intersecting lines is the length of their common perpendicular, there being but one. The distance between two parallel lines or between two parallel planes is the length of the common perpendicular between the lines or the planes.

§ 81. *Parallelepipeds.*—The rest of the book is devoted to the study of the parallelepiped. In Prop. 24 the possibility of such a solid is proved. viz :—

Prop. 24. *If a solid be contained by six planes two and two of which are parallel, the opposite planes are similar and equal parallelograms.*

Euclid calls this solid henceforth a parallelepiped, though he never defines the word. Either face of it may be taken as *base*, and its distance from the opposite face as *altitude.*

Prop 25. *If a solid parallelepiped be cut by a plane parallel to two of its opposite planes, it divides the whole into two solids, the base of one of which shall be to the base of the other as the one solid is to the other.*

This theorem corresponds to the theorem (VI. 1) that parallelograms between the same parallels are to one another as their bases. A similar analogy is to be observed among a number of the remaining propositions.

§ 82. After solving a few problems we come to

Prop. 28. *If a solid parallelepiped be cut by a plane passing through the diagonals of two of the opposite planes, it shall be cut in two equal parts.*

In the proof of this, as of several other propositions, Euclid neglects the difference between solids which are symmetrical like the right hand and the left.

Prop. 31. *Solid parallelepipeds, which are upon equal bases, and of the same altitude, are equal to one another.*

Props. 29 and 30 contain special cases of this theorem leading up to the proof of the general theorem.

As consequences of this fundamental theorem we get

Prop. 32. *Solid parallelepipeds, which have the same altitude, are to one another as their bases*; and Prop. 33, *Similar solid parallelepipeds are to one another in the triplicate ratio of their homologous sides.*

If we consider, as in § 67, the ratios of lines as numbers, we may also say—

The ratio of the volumes of similar parallelepipeds is equal to the ratio of the third powers of homologous sides.

Parallelepipeds which are not similar but equal are compared by aid of the theorem

Prop. 34. *The bases and altitudes of equal solid parallelepipeds are reciprocally proportional; and if the bases and altitudes be reciprocally proportional, the solid parallelepipeds are equal.*

§ 83. Of the following propositions the 37th and 40th are of special interest.

Prop. 37. *If four straight lines be proportionals, the similar solid parallelepipeds, similarly described from them, shall also be proportionals; and if the similar parallelepipeds similarly described from four straight lines be proportionals, the straight lines shall be proportionals.*

In symbols it says—

$$\text{If } a : b = c : d, \text{ then } a^3 . b^3 = c^3 : d^3.$$

Prop. 40 teaches how to compare the volumes of triangular prisms with those of parallelepipeds, by proving *that a triangular prism is equal in volume to a parallelepiped, which has its altitude and its base equal to the altitude and the base of the triangular prism.*

§ 84. From these propositions follow all results relating to the mensuration of volumes. We shall state these as we did in the case of areas. The starting point is the "rectangular" parallelepiped, which has every edge perpendicular to the planes it meets, and which takes the place of the rectangle in the plane. If this has all its edges equal we obtain the "cube."

If we take a certain line u as unit length, then the square on u is the unit of area, and the cube on u the unit of volume, that is to say, if we wish to measure a volume we have to determine how many unit cubes it contains.

A rectangular parallelepiped has, as a rule, the three edges unequal, which meet at a point. Every other edge is equal to one of them. If a, b, c be the three edges meeting at a point, then we may take the rectangle contained by two of them, say by b and c, as base and the third as altitude. Let V be its volume, V′ that of another rectangular parallelepiped which has the edges a', b, c, hence the same base as the first. It follows then easily, from Prop. 25 or 32, that $V : V' = a : a'$; or in words,

Rectangular parallelepipeds on equal bases are proportional to their altitudes.

If we have two rectangular parallelepipeds, of which the first has the volume V and the edges a, b, c, and the second, the volume V′ and the edges a', b', c', we may compare them by aid of two new ones which have respectively the edges a', b, c, and a', b', c, and the volumes V_1 and V_2. We then have

$$V : V_1 = a : a' ; \; V_1 : V_2 = b : b' \;\; V_r : V' = c \cdot c'.$$

Compounding these, we have

$$V : V' = (a : a')\,(b : b')\,(c : c'),$$

or

$$\frac{V}{V'} = \frac{a}{a'} \cdot \frac{b}{b'} \cdot \frac{c}{c'} .$$

Hence, as a special case, making V′ equal to the unit cube U on u we get

$$\frac{V}{U} = \frac{a}{u} \;\; \frac{b}{u} \cdot \frac{c}{u} = \alpha . \beta . \gamma,$$

where α, β, γ are the numerical values of a, b, c; that is, *The number of unit cubes in a rectangular parallelepiped* is equal to the product of the numerical values of its three edges. This is generally expressed by saying the volume of a rectangular parallelepiped is measured by the product of its sides, or by the product of its base into its altitude, which in this case is the same.

Prop. 31 allows us to extend this to any parallelepipeds, and Props. 28 or 40, to triangular prisms.

THEOREM.—*The volume of any parallelepiped, or of any triangular prism, is measured by the product of base and altitude.*

The consideration that any polygonal prism may be divided into a number of triangular prisms, which have the same altitude and the sum of their bases equal to the base of the polygonal prism, shows further that the same holds for any prism whatever.

BOOK XII.

§ 85. In the last part of Book XI. we have learnt how to compare the volumes of parallelepipeds and of prisms. In order to determine the volume of any solid bounded by plane faces we must determine the volume of pyramids, for every such solid may be decomposed into a number of pyramids.

As every pyramid may again be decomposed into triangular pyramids, it becomes only necessary to determine their volume. This is done by the

Theorem.—Every triangular pyramid is equal in volume to one third of a triangular prism having the same base and the same altitude as the pyramid.

This is an immediate consequence of Euclid's

Prop. 7. *Every prism having a triangular base may be divided into three pyramids that have triangular bases, and are equal to one another.*

The proof of this theorem is difficult, because the three triangular pyramids into which the prism is divided are by no means equal in shape, and cannot be made to coincide. It has first to be proved that two triangular pyramids have equal volumes, if they have equal bases and equal altitudes. This Euclid does in the following manner. He first shows (Prop. 3) that a triangular pyramid may be divided into four parts, of which two are equal triangular pyramids similar to the whole pyramid, whilst the other two are equal triangular prisms, and further, that these two prisms together are greater than the two pyramids, hence more than half the given pyramid. He next shows (Prop. 4) that if two triangular pyramids are given, having equal bases and equal altitudes, and if each be divided as above, then the two triangular prisms in the one are equal to those in the other, and each of the remaining pyramids in the one has its base and altitude equal to the base and altitude of the remaining pyramids in the other. Hence to these pyramids the same process is again applicable. We are thus enabled to cut out of the two given pyramids equal parts, each greater than half the original pyramid. Of the remainder we can again cut out equal parts greater than half these remainders, and so on as far as we like. This process may be continued till the last remainder is smaller than any assignable quantity, however small. It follows, so we should conclude at present, that the two volumes must be equal, for they cannot differ by any assignable quantity.

To Greek mathematicians this conclusion offers far greater difficulties. They prove elaborately, by a *reductio ad absurdum*, that the volumes cannot be unequal. This proof must be read in the *Elements*. A further discussion of this method of exhaustion, as it is called, would belong to a treatise on the history of geometry. We refer readers to Hankel, *Geschichte der Mathematik* (p. 115 *sq*). We must, however, state that we have in the above not proved Euclid's Prop. 5, but only a special case of it. Euclid does not suppose that the bases of the two pyramids to be compared are equal, and hence he proves that the volumes are as the bases. The reasoning of the proof becomes clearer in the special case, from which the general one may be easily deduced.

§ 86. Prop. 6 extends the result to pyramids with polygonal bases. From these results follow again the rules at present given for the mensuration of solids, viz., a pyramid is the third part of a triangular prism having the same base and the same altitude. But a triangular prism is equal in volume to a parallelepiped which has the same base and altitude. Hence if B is the base and h the altitude, we have

$$\text{Volume of prism} = Bh,$$
$$\text{Volume of pyramid} = \tfrac{1}{3}\,Bh,$$

statements which have to be taken in the sense that B means the number of square units in the base, h the number of units of length in the altitude, or that B and h denote the numerical values of base and altitude.

§ 87. A method similar to that used in proving Prop. 5 leads to the following results relating to solids bounded by simple curved surfaces:—

Prop. 10. *Every cone is the third part of a cylinder which has the same base, and is of an equal altitude with it.*

Prop. 11. *Cones and cylinders of the same altitude are to one another as their bases.*

Prop. 12. *Similar cones and cylinders have to one another the triplicate ratio of that which the diameters of their bases have.*

Prop. 13. *If a cylinder be cut by a plane parallel to its opposite planes or bases, it divides the cylinder into two cylinders, one of which is to the other as the axis of the first to the axis of the other*; which may also be stated thus:—

Cylinders on the same base are proportional to their altitudes.

Prop. 14. *Cones and cylinders upon equal bases are to one another as their altitudes.*

Prop. 15. *The bases and altitudes of equal cones and cylinders are reciprocally proportional, and if the bases and altitudes be reciprocally proportional, the cones and cylinders are equal to one another.*

These theorems again lead to formulæ in mensuration, if we compare a cylinder with a prism having its base and altitude equal to the base and altitude of the cylinder. This may be done by the method of exhaustion. We get, then, the result that their bases are equal, and have, if B denotes the numerical value of the base, and h that of the altitude,

$$\text{Volume of cylinder} = Bh.$$
$$\text{Volume of cone} = \tfrac{1}{3}\,Bh.$$

§ 88. The remaining propositions relate to circles and spheres. Of the sphere only one property is proved, viz.:—

Prop. 18. *Spheres have to one another the triplicate ratio of that which their diameters have.* The mensuration of the sphere, like that of the circle, the cylinder, and the cone, had not been settled in the time of Euclid. It was done by Archimedes.

Book XIII.

§ 89. The 13th and last book of Euclid's *Elements* is devoted to the regular solids. It is shown that there are five of them, viz.:—

1. The regular *tetrahedron*, with 4 triangular faces and 4 vertices;
2. The *cube*, with 8 vertices and 6 square faces;
3. The *octohedron*, with 6 vertices and 8 triangular faces;
4. The *dodecahedron*, with 12 pentagonal faces, 3 at each of the 20 vertices;
5. The *icosahedron*, with 20 triangular faces, 5 at each of the 12 vertices.

It is shown how to inscribe these solids in a given sphere, and how to determine the lengths of their edges.

These results are—if r denotes the radius of the circumscribed sphere, and a the side of the regular solid—

For tetrahedron	$a^2 = \frac{8}{3}r^2$,
„ octahedron	$a^2 = 2r^2$,
„ hexahedron or cube	$a^2 = \frac{4}{3}r^2$,
„ icosahedron	$a^2 = 2\left(1 - \frac{\sqrt{5}}{5}\right)r^2$,
„ dodecahedron	$a^2 = 2\left(1 - \frac{\sqrt{5}}{3}\right)r^2$.

§ 90. The 13th book, and therefore the *Elements*, conclude with the scholium, "that no other regular solid exists besides the five ones enumerated."

The proof is very simple. Each face is a regular polygon, hence the angles of the faces at any vertex must be angles in equal regular polygons, must be together less than four right angles (XI. 21), and must be three or more in number. Each angle in a regular triangle equals two-thirds of one right angle. Hence it is possible to form a solid angle with three, four, or five regular triangles or faces. These give the solid angles of the tetrahedron, the octohedron, and the icosahedron. The angle in a square (the regular quadrilateral) equals one right angle. Hence three will form a solid angle, that of the cube, and four will not. The angle in the regular pentagon equals $\frac{6}{5}$ of a right angle. Hence three of them equal $\frac{18}{5}$ (*i.e.*, less than 4) right angles, and form the solid angle of the dodecahedron. Three regular polygons of six or more sides cannot form a solid angle. Therefore no other regular solids are possible.

Section II.—Higher or Projective Geometry.

It is difficult, at the outset, to characterize Projective Geometry as compared with Euclidian. But a few examples will at least indicate the difference between the two.

In Euclid's *Elements* almost all propositions refer to the *magnitude* of lines, angles, areas, or volumes, and therefore to measurement. The statement that an angle is right, or that two straight lines are parallel, refers to measurement. On the other hand, the fact that a straight line does or does not cut a circle is independent of measurement, it being dependent only upon the mutual "position" of the line and the circle. This difference becomes clearer if we project any figure from one plane to another. By this the length of lines, the magnitude of angles and areas, is altered, so that the projection, or shadow, of a square on a plane will not be a square; it will, however, be some quadrilateral. Again, the projection of a circle will not be a circle, but some other curve more or less resembling a circle. But one property may be stated at once,—no straight line can cut the projection of a circle in more than two points, because no straight line can cut a circle in more than two points. There are, then, some properties of figures which do not alter by projection, whilst others do. To the latter belong nearly all properties relating to measurement, at least in the form in which they are generally given. The others are said to be projective properties, and their investigation forms the subject of Projective Geometry.

Different as are the kinds of properties investigated in the old and the new sciences, the methods followed differ in a still greater degree. In Euclid each proposition stands by itself; its connexion with others is never indicated; the leading ideas contained in its proof are not stated; general principles do not exist. In the modern methods, on the other hand, the greatest importance is attached to the leading thoughts which pervade the whole; and general principles, which bring whole groups of theorems under one aspect, are given rather than separate propositions. The whole tendency is towards generalization. A straight line is considered as given in its entirety, extending both ways to infinity, while Euclid is very careful never to admit anything but finite quantities. The treatment of the infinite is in fact another fundamental difference between the two methods. Euclid avoids it. In modern geometry it is systematically introduced, for only thus is generality obtained.

Of the different modern methods of geometry, we shall treat principally of the methods of projection and correspondence which have proved to be the most powerful. These have become independent of Euclidian Geometry, especially through the *Geometrie der Lage* of V. Staudt, and the *Ausdehnungslehre* of Grassmann.

For the sake of brevity we shall presuppose a knowledge of Euclid's *Elements*, although we shall use only a few of his propositions.

§ 1. We consider space as filled with points, lines, and planes, and these we call the elements out of which our figures are to be formed, calling any combination of these elements a "figure."

By a line we mean a straight line in its entirety, extending both ways to infinity; and by a plane, a plane surface, extending in all directions to infinity. We suppose

That through any two points in space one and only one line may be drawn (Eucl. I., Def. 4, Ax. 10, Post. 2);

That through any three points which are not in a line, one and only one plane may be placed (compare p. 386, § 73, above);

That the intersection of two planes is a line (Eucl. XI. 13);

That a line which has two points in common with a plane lies in the plane (Eucl. I., Def. 7), hence that the intersection of a line and a plane is a single point; and

That three planes which do not meet in a line have one single point in common.

These results may be stated differently in the following form:—

I. A plane is determined—	A point is determined—
1. By three points which do not lie in a line;	1. By three planes which do not pass through a line;
2. By two intersecting lines;	2. By two intersecting lines;
3. By a line and a point which does not lie in it.	3. By a line and a plane which does not pass through it.
II. A line is determined—	
1. By two points;	2. By two planes.

The reader will observe that not only are planes determined by points, but also points by planes; that therefore we have a right to consider the planes as elements, like points; and also that in any one of the above statements we may interchange the words point and plane, and we obtain again a correct statement, provided that these statements themselves are true. As they stand, we ought, in several cases, to add "if they are not parallel," or some such words, parallel lines and planes being evidently left altogether out of consideration. To correct this we have to reconsider the theory of parallels.

§ 2. Let us take in a plane a line p (fig. 1), a point S not in this line, and a line q drawn through S. Then this line q will meet the line p in a point A. If we turn the line q about S towards q', its point of intersection with p will move along p towards B, passing, on continued turning, to a greater and greater distance, until it is moved out of our reach. If we turn q still farther, its continuation will meet p, but now at the other side of A. The point of intersection has disappeared to the right and reappeared to the left. There is one intermediate position where q is parallel to p—that is where it does not cut p. In every other position it cuts p in some finite point. If, on the other hand, we move the point A to an infinite distance in p, then the line q which passes through A will be a line which does not cut p at any finite point. Thus we are led to say: *Every* line through S which joins it to any point at an infinite distance in p is parallel to p. But by Euclid's 12th axiom there is but one line parallel to p through S. The difficulty in which we are thus involved is due to the fact that we try to reason about infinity as if we, with our finite capabilities, could comprehend the infinite. To overcome this difficulty, we may say that all points at infinity in a line *appear* to us as one, and may be replaced by a single "ideal" point, just as all points in a fixed star—which is not at an infinite, only at a great distance—cannot be distinguished by us and to beings on the earth count as one. We may therefore now give the following definitions and axiom:—

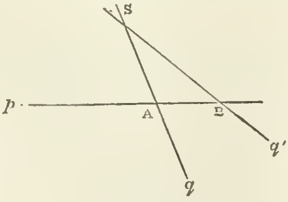


Fig. 1.

Definition.—Lines which meet at infinity are called parallel.

Axiom.—All points at an infinite distance in a line may be considered as one single point.

Definition.—This ideal point is called the point at infinity in the line.

The axiom is equivalent to Euclid's Axiom 12, for it follows from either that through any point only one line may be drawn parallel to a given line.

This point at infinity in a line is reached whether we move a point in the one or in the opposite direction of a line to infinity. A line thus appears closed by this point, and we speak as if we could move a point along the line from one position A to another B in two ways, either through the point at infinity or through finite points only.

It must never be forgotten that this point at infinity is ideal, that the results based on this assumption are true for that finite region of space which is within our reach, and that beyond this region they may or may not be true,—we do not know.

The advantage of this view of parallels will become apparent at every step as we go on.

§ 3. Having thus arrived at the notion of replacing all points at infinity in a line by one ideal point, there is no difficulty in replacing all points at infinity in a plane by one ideal line.

To make this clear, let us suppose that a line p, which cuts two fixed lines a and b in the points A and B, moves parallel to itself to a greater and greater distance. It will at last cut both a and b at their points at infinity, so that a line which joins the two points at infinity in two intersecting lines lies altogether at infinity. Every other line in the plane will meet it therefore at infinity, and thus it contains all points at infinity in the plane.

All points at infinity in a plane lie in a line, which is called the line at infinity in the plane.

It follows that parallel planes must be considered as planes having a common line at infinity, for any other plane cuts them in parallel lines (Eucl. XI. 16), which have a point at infinity in common.

If we next take two intersecting planes, then the point at infinity in their line of intersection lies in both planes, so that their lines at infinity meet. Hence every line at infinity meets every other line at infinity, and they are therefore all in one plane.

All points at infinity in space may be considered as lying in one ideal plane, which is called the plane at infinity.

§ 4. We have now the following definitions:—

Parallel lines are lines which meet at infinity;

Parallel planes are planes which meet at infinity;

A line is parallel to a plane if it meets it at infinity.

Theorems like this—Lines (or planes) which are parallel to a third are parallel to each other—follow at once.

This view of parallels leads therefore to no contradiction of Euclid's *Elements*.

As immediate consequences we get the propositions:—

Every line meets a plane in one point, or it lies in it;

Every plane meets every other plane in a line;

Any two lines in the same plane meet.

§ 5. We have called points, lines, and planes the elements of geometrical figures. We also say that an element of one kind *contains* one of the other if it lies in it or passes through it.

All the elements of one kind which are contained in one or two elements of a different kind form aggregates which have to be enumerated. They are the following:—

I. Of one dimension.
1. The *row*, or range, *of points* formed by all points in a line, which is called its base.
2. The *flat pencil* formed by all the lines through a point in a plane. Its base is the point in the plane.
3. The *axial pencil* formed by all planes through a line which is called its base or axis.

II. Of two dimensions.
1. The field of points and lines—that is, a plane with all its points and all its lines.
2. The pencil of lines and planes—that is, a point in space with all lines and all planes through it.

III. Of three dimensions.
The space of points—that is, all points in space.
The space of planes—that is, all planes in space.

IV. Of four dimensions.
The space of lines, or all lines in space.

§ 6. The word dimension in the above needs explanation.

If in a plane we take a row p and a pencil with centre Q, then through every point in p one line in the pencil will pass, and every ray in Q will cut p in one point, so that we are entitled to say a row contains as many points as a flat pencil lines, and, we may add, as an axial pencil planes, because an axial pencil is cut by a plane in a flat pencil.

The number of elements in the row, in the flat pencil, and in the axial pencil is, of course, infinite and indefinite too, but the same in all. For a moment we shall treat it as being a definite number which we denote by α. Then a plane contains α^2 points and as many lines. To see this, take a flat pencil in a plane. It contains α lines, and each line contains α points, whilst each point in the plane lies on one of these lines. Similarly, in a plane each line cuts a fixed line in a point. But this line is cut at each point by α lines and contains α points; hence there are α^2 lines in a plane.

A pencil in space contains as many lines as a plane contains points and as many planes as a plane contains lines, for any plane cuts the pencil in a field of points and lines. Hence a pencil contains α^2 lines and α^2 planes. *The field and the pencil are of two dimensions.*

To count the number of points in space we observe that each point lies on some line in a pencil. But the pencil contains α^2 lines, and each line α points; hence space contains α^3 points. Each plane cuts any fixed plane in a line. But a plane contains α^2 lines, and through each pass α planes; therefore space contains α^3 planes.

Hence space contains as many planes as points, but it contains an infinite number of times more lines than points or planes. To count them, notice that every line cuts a fixed plane in one point. But α^2 lines pass through each point, and there are α^2 points in the plane. Hence there are α^4 lines in space. *The space of points and planes is of three dimensions, but the space of lines is of four dimensions.*

A field of points or lines contains an infinite number of rows and flat pencils; a pencil contains an infinite number of flat pencils and of axial pencils; space contains a triple infinite number of pencils and of fields, α^4 rows and axial pencils, and α^5 flat pencils—or, in other words, each point is a centre of α^2 flat pencils.

§ 7. The above enumeration allows a classification of figures.

Figures in a row consist of groups of points only, and figures in the flat or axial pencil consist of groups of lines or planes. In the plane we may draw polygons; and in the pencil or in the point, solid angles, and so on.

We may also distinguish the different measurements. We have—

In the row, length of segment;
In the flat pencil, angles;
In the axial pencil, dihedral angles between two planes;
In the plane, areas;
In the pencil, solid angles;
In the space of points or planes, volumes.

Segments of a Line.

§ 8. Any two points A and B in space determine on the line through them a finite part, which may be considered as being described by a point moving from A to B. This we shall denote by AB, and distinguish it from BA, which is supposed as being described by a point moving from B to A, hence in a direction or in a "sense" opposite to AB. Such a finite line, which has a definite sense, we shall call a "segment," so that AB and BA denote different segments, which are said to be equal in length but of opposite sense. The one sense is often called positive and the other negative.

In introducing the word "sense" for direction in a line, we have the word direction reserved for direction of the line itself, so that different lines have different directions, unless they be parallel, whilst in each line we have a positive and negative sense.

We may also say, with Professor Clifford, that AB denotes the "step" of going from A to B.

§ 9. If we now have three points A, B, C in a line (fig. 2), the step AB will bring us from A to B, and the step BC from B to C. Hence both steps are equivalent to the one step AC. This is expressed by saying that AC is the "sum" of AB and BC: in symbols—

$$AB + BC = AC,$$

where account is to be taken of the sense.

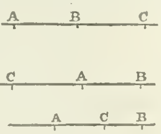

Fig. 2.

This equation is true whatever be the position of the three points on the line. As a special case we have

$$AB + BA = 0 \quad \ldots\ldots\ldots \quad (1),$$

and similarly

$$AB + BC + CA = 0 \quad \ldots\ldots\ldots \quad (2),$$

which again is true for any three points in a line.

We further write

$$AB = -BA,$$

where — denotes negative sense.

We can then, just as in algebra, change subtraction of segments into addition by changing the sense, so that AB − CB is the same as AB + (−CB) or AB + BC. A figure will at once show the truth of this. The sense is, in fact, in every respect equivalent to the "sign" of a number in algebra.

§ 10. Of the many formulæ which exist between points in a line we shall have to use only one more, which connects the segments between any four points A, B, C, D in a line. We have—

$$BC = BD + DC,$$
$$CA = CD + DA,$$
$$AB = AD + DB;$$

or multiplying these by AD, BD, CD respectively, we get—

$$BC \cdot AD = BD \cdot AD + DC \cdot AD = BD \cdot AD - CD \cdot AD$$
$$CA \cdot BD = CD \cdot BD + DA \cdot BD = CD \cdot BD - AD \cdot BD$$
$$AB \cdot CD = AD \cdot CD + DB \cdot CD = AD \cdot CD - BD \cdot CD.$$

It will be seen that the sum of the right hand sides vanishes, hence that

$$BC \cdot AD + CA \cdot BD + AB \cdot CD = 0 \quad \ldots \quad (3)$$

for any four points on a line.

§ 11. If C is any point in the line AB, then we say that C divides the segment AB in the ratio $\frac{AC}{CB}$, account being taken of the sense of the two segments AC and CB. If C lies between A and C the ratio is positive, as AC and CB have the same sense. But if C lies without the segment AB, *i.e.*, if C divides AB externally, then the ratio is negative. To see how the value of this ratio changes with C, we will move C along the whole line (fig. 3), whilst A and B remain fixed.

Fig. 3.

If C lies at the point A, then AC = 0, hence the ratio AC : CB vanishes. As C moves towards B, AC increases and CB decreases, so that our ratio increases. At the middle point M of AB it assumes the value +1, and then increases till it reaches an infinitely large value, when C arrives at B. On passing beyond B the ratio becomes negative. If C is at P we have AC = AP = AB + BP, hence

$$\frac{AC}{CB} = \frac{AB}{PB} + \frac{BP}{PB} = -\frac{AB}{BP} - 1.$$

In the last expression the ratio AB : BP is positive, has its greatest value ∞ when C coincides with B, and vanishes when BC becomes infinite. Hence, as C moves from B to the right to the point at infinity, the ratio AC : CB varies from −∞ to −1.

If on the other hand C is to the left of A, say at Q, we have $AC = AQ = AB + BQ = AB - QB$, hence $\frac{AC}{CB} = \frac{AB}{QB} - 1$

Here AB < QB, hence the ratio AB : QB is positive and always less than one, so that the whole is negative and < 1. If C is at the point at infinity it is −1, and then increases as C moves to the right, till for C at A we get the ratio = 0. Hence—

"As C moves along the line from an infinite distance to the left to an infinite distance at the right, the ratio always increases; it starts with the value −1, reaches 0 at A, +1 at M, ∞ at B, changes now sign to −∞, and increases till at an infinite distance it reaches again the value −1. *It assumes therefore all possible values from −∞ to +∞, and each value only once, so that not only does every position of* C *determine a definite value of the ratio* AC : CB, *but also, conversely, to every positive or negative value of this ratio belongs one single point in the line* AB.

Projection and Cross-Ratios.

§ 12. If we join a point A to a point S, then the point where the line SA cuts a fixed plane π is called the projection of A on the plane π from S as centre of projection. If we have two planes π and π' and a point S, we may project every point A in π to the other plane. If A′ is the projection of A, then A is also the projection of A′, so that the relations are reciprocal. To every figure in π we get as its projection a corresponding figure in π'.

It will be our business to find such properties of figures as remain true for the projection, and which are called projective properties. For this purpose it will be sufficient to consider at first only constructions in one plane.

Let us suppose we have given in a plane two lines p and p' and a centre S (fig. 4); we may then project the points in p from S to p'. Let A′, B′... be the projections of A, B..., the point at infinity in p which we shall denote by J will be projected into a finite point I′ in p', viz., into the point where the parallel to p through S cuts p'. Similarly one point J in p will be projected into the point I′ at infinity in p'. This point J is of course the point where

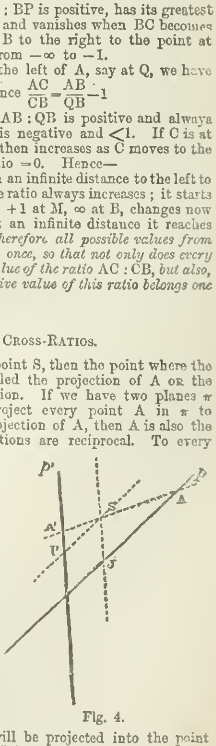

Fig. 4.

the parallel to p' through S cuts p. We thus see that every point in p is projected into a single point in p'.

A glance at fig. 5 shows that a segment AB will be projected into a segment A′B′ which is not equal to it, at least not as a rule; and also that the ratio AC : CB is not equal to the ratio A′C′ : C′B′ formed by the projections. These ratios will become equal only if p and p' are parallel, for in this case the triangle SAB is similar to the triangle SA′B′. Between three points in a line and their projections there exists therefore in general no relation. But between four points a relation does exist.

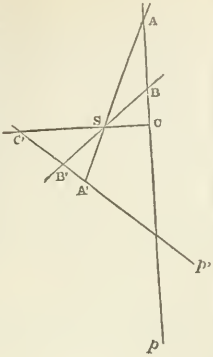

Fig. 5.

§ 13. Let A, B, C, D be four points in p, A′, B′, C′, D′ their projections in p', then the ratio of the two ratios AC : CB and AD : DB into which C and D divide the segment AB is equal to the corresponding expression between A′, B′, C′, D′. In symbols we have—

$$\frac{AC}{CB}:\frac{AD}{DB}=\frac{A'C'}{C'B'}:\frac{A'D'}{D'B'}.$$

This is easily proved by aid of similar triangles.

Through the points A and B on p draw parallels to p', which cut the projecting rays in C_2, D_2, B_2 and A_1, C_1, D_1, as indicated in fig. 6. The two triangles ACC_2 and BCC_1 will be similar, as will also be the triangles ADD_2 and BDD_1.

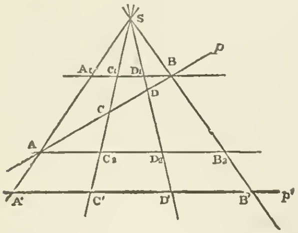

Fig. 6.

We have therefore—

$$\frac{AC}{CB}=\frac{AC_2}{C_1B},\quad \frac{AD}{DB}=\frac{AD_2}{D_1B},$$

where account is taken of the sense.

Hence—

$$\frac{AC}{CB}:\frac{AD}{DB}=\frac{AC_2}{C_1B}:\frac{AD_2}{D_1B}=\frac{AC_2}{AD_2}:\frac{C_1B}{D_1B};$$

but

$$\frac{AC_2}{AD_2}=\frac{A'C'}{A'D'}\text{ and }\frac{C_1B}{D_1B}=\frac{C'B'}{D'B'};$$

so that the above expression becomes

$$\frac{A'C'}{A'D'}:\frac{C'B'}{D'B'},$$

which is equal to $\frac{A'C'}{C'B'}:\frac{A'D'}{D'B'}$ as required.

This result is of fundamental importance.

The expression formed has been called by Chasles the anharmonic ratio of the four points A, B, C, D. Instead of this Professor Clifford has proposed the shorter and more expressive name of "cross-ratio." We shall adopt the latter. We have then the

FUNDAMENTAL THEOREM.—*The cross-ratio of four points in a line is equal to the cross-ratio of their projections on any other line which lies in the same plane with it.*

§ 14. Before we draw conclusions from this result, we must investigate the meaning of a cross-ratio somewhat more fully.

If four points A, B, C, D are given, and we wish to form their cross-ratio, we have first to divide them into two groups of two, the points in each group being taken in a definite order. Thus, let A, B be the first, C, D the second pair, A and C being the first points in each pair. The cross-ratio is then the ratio AC : CB divided by AD : DB. This will be denoted by (ABCD), so that

$$(ABCD)=\frac{AC}{CB}:\frac{AD}{DB}.$$

This is easily remembered. In order to write it out, make first the two lines for the fractions, and put above and below these the letters A and B in their places, thus, $\frac{A}{B}:\frac{A}{B}$; and then fill up, crosswise, the first by C and the other by D.

§ 15. If we take the points in a different order, the value of the cross-ratio will change. We can do this in twenty-four different ways by forming all permutations of the letters. But of these twenty-four cross-ratios groups of four are equal, so that there are really only six different ones.

We have the following rules:—

I. If in a cross-ratio the two groups be interchanged, its value remains unaltered.

$$(ABCD)=(CDAB).$$

II. If in a cross-ratio the two points belonging one of the two groups be interchanged, the cross-ratio changes into its reciprocal.

$$(ABCD)=\frac{1}{(ABDC)}.$$

III. If in a cross-ratio the two middle letters be interchanged, the cross-ratio κ changes into its complement $1-\kappa$.

$$(ABCD)=1-(ACBD).$$

The first two are easily proved by writing out their values. The third is proved by aid of the formula (3), § 10,

$$BC\,.\,AD+CA\,.\,BD+AB\,.\,CD=0.$$

If we divide this by CB . AD we get

$$-1+\frac{CA\,.\,BD}{CB\,.\,AD}+\frac{AB\,.\,CD}{CB\,.\,AD}=0,$$

or,

$$\frac{AC}{CB}:\frac{AD}{DB}+\frac{AB}{BC}:\frac{AD}{DC}=1;$$

that is,

$$(ABCD)+(ACBD)=1,$$

which was to be proved.

IV. From II. it follows at once that if we interchange the elements in each pair, the cross-ratio remains unaltered; and thus we see that

$$\begin{aligned}(ABCD)&=(CDAB)&&\text{by I.}\\&=(BADC)=(DCBA)&&\text{by II.}\end{aligned}$$

§ 16. By aid of these rules we get the following results:—

$$(ABCD)=(BADC)=(CDAB)=(DCBA)=\kappa.$$

$$(ABDC)=(BACD)=(CDBA)=(DCAB)=\frac{1}{\kappa}.$$

$$(ACBD)=(BDAC)=(CADB)=(DBCA)=1-\kappa.$$

$$(ACDB)=(BDCA)=(CABD)=(DBAC)=\frac{1}{1-\kappa}.$$

$$(ADBC)=(BCAD)=(CBDA)=(DACB)=\frac{\kappa-1}{\kappa}.$$

$$(ADCB)=(BCDA)=(CBAD)=(DABC)=\frac{\kappa}{\kappa-1}.$$

In the theorem that the cross-ratio of four points equals that of the projections, the points have, of course, to be taken in the same order.

§ 17. If one of the points of which a cross-ratio is formed is the point at infinity in the line, the cross-ratio changes into a simple ratio. It is convenient to let the point at infinity occupy the last place in the symbolic expression for the cross-ratio. Thus if I is a point at infinity, we have

$$(ABCI)=-\frac{AC}{CB},$$

because

$$AI:IB=-1.$$

Every common ratio of three points in a line may thus be expressed as a cross-ratio, by adding the point at infinity to the group of points.

§ 18. If the points have special positions, the cross-ratios κ may have such a value that, of the six different ones, two and two become equal. If the first two shall be equal, we get $\kappa=\frac{1}{\kappa}$, or $\kappa^2=1$, $\kappa=\pm1$.

If we take $\kappa=+1$, we have $(ABCD)=1$, or $\frac{AC}{CB}=\frac{AD}{DB}$; that is, the points C and D coincide, provided that A and B are different. This is too special a case to be of much interest.

If, however, we take $\kappa=-1$, so that $(ABCD)=-1$, we have $\frac{AC}{CB}=-\frac{AD}{DB}$. *Hence* C *and* D *divide* AB *internally and externally in the same ratio.*

The four points are in this case said to be *harmonic points*, and C *and* D *are said to be harmonic conjugates with regard to* A *and* B.

But we have also (CDAB) = −1, so that A and B are harmonic conjugates with regard to C and D.

The principal property of harmonic points, upon which almost all applications depend, is this, that their cross-ratio remains unaltered if we interchange the two points belonging to one pair, viz. :

$$(ABCD) = (ABDC) = (BACD).$$

For four harmonic points the six cross-ratios which are generally different become two and two equal :

$$\kappa = -1, \; 1 - \kappa = 2, \; \frac{\kappa}{\kappa - 1} = \tfrac{1}{2}.$$

$$\frac{1}{\kappa} = -1, \; \frac{1}{1-\kappa} = \tfrac{1}{2}, \; \frac{\kappa - 1}{\kappa} = 2.$$

Hence if we get four points whose cross-ratio is 2 or ½, then they are harmonic, but not arranged so that conjugates are paired. If this is the case the cross-ratio = −1.

§ 19. If we equate any two of the above six values of the cross-ratios, we get either $\kappa = 1$, 0, ∞, or $\kappa = -1$, 2, ½, or else κ becomes a root of the equation $\kappa^2 - \kappa + 1 = 0$, that is, an imaginary cube root of −1. In this case the six values become three and three equal, so that only two different values remain. This case, though important in the theory of cubic curves, is for our purposes of no interest, whilst harmonic points are all-important.

§ 20. From the definition of harmonic points, and by aid of § 11, the following properties are easily deduced.

If C and D are harmonic conjugates with regard to A and B, then one of them lies in, the other without AB ; it is impossible to move from A to B without passing either through C or through D ; the one blocks the finite way, the other the way through infinity. This is expressed by saying A and B are "separated" by C and D.

For every position of C there will be one and only one point D which is its harmonic conjugate with regard to any point pair A, B.

If A and B are different points, and if C coincides with A or B, D does. But if A and B coincide, one of the points C or D, lying between them, coincides with them, and the other may be anywhere in the line. It follows that, "*if of four harmonic conjugates two coincide, then a third coincides with them, and the fourth may be any point in the line.*"

If C is the middle point between A and B, then D is the point at infinity for AC : CB = +1, hence AD : DB must be equal to −1. *The harmonic conjugate of the point at infinity in a line with regard to two points* A, B *is the middle point of* AB.

This important property gives a first example how metric properties are connected with projective ones.

§ 21. *Complete Quadrilateral.*—A figure formed by four lines in a plane is called a complete quadrilateral or, shorter, a four-side (fig. 7). The figure has six *vertices*, that is, points where the sides meet, and three diagonals AB, EF, GH, which join *opposite* vertices.

Similarly a figure formed by four points in a plane is called a four-point. It has six sides, which join the points, or vertices, and three diagonal points, where the sides meet.

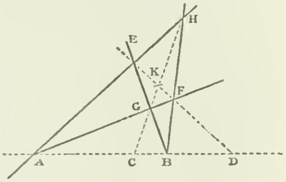

Fig. 7.

The three diagonals of a four-side cut each other harmonically.

If we project the points E, F, K, D from H to AB, we get

$$(EFKD) = (ABCD),$$

and if we project them from G, we get

$$(EFKD) = (BACD) ;$$

so that

$$(ABCD) = (BACD),$$

that is, the cross-ratio (ABCD) is equal to its reciprocal, hence = −1, as the four points are all different. This gives the important theorem :—

Theorem.—*In every four-side any diagonal is cut harmonically by the other two.*

This allows the solution of the problem :—

Problem.—*To construct the harmonic conjugate* D *to a point* C *with regard to two given points* A *and* B.

Solution.—Through A draw any two lines, and through C one cutting the former two in G and H. Join these points to B, cutting the former two lines in E and F. The point D where EF cuts AB will be the harmonic conjugate required.

This remarkable construction requires nothing but the drawing of lines, and is therefore independent of measurement. It follows, also, that *all four-sides which have two vertices at* A *and* B, *and one diagonal passing through* C *will each have the third diagonal passing through* D.

§ 22. The theory of cross-ratios may be extended from points in a row to lines in a flat pencil, and to planes in an axial pencil. We have seen (§ 13) that if the lines which join four points A, B, C, D to any point S be cut by any other line in A′, B′, C′, D′, then (ABCD) = (A′B′C′D′). In other words, four lines in a flat pencil are cut by every other line in four points whose cross-ratio is constant.

Definition.—By the cross-ratio of four rays in a flat pencil is meant the cross-ratio of the four points in which the rays are cut by any line. If a, b, c, d be the lines, then this cross-ratio is denoted by $(abcd)$.

Definition.—By the cross-ratio of four planes in an axial pencil is understood the cross-ratio of the four points in which any line cuts the planes, or, what is the same thing, the cross-ratio of the four rays in which any plane cuts the four planes.

In order that this definition may have a meaning, it has to be proved that all lines cut the pencil in points which have the same cross-ratio. This is seen at once for two intersecting lines, as their plane cuts the axial pencil in a flat pencil, which is itself cut by the two lines. The cross-ratio of the four points on one line is therefore equal to that on the other and equal to that of the four rays in the flat pencil.

If two non-intersecting lines p and q cut the four planes in A, B, C, D and A′, B′, C′, D′, draw a line r to meet both p and q, and let this line cut the planes in A″, B″, C″, D″. Then (ABCD) = (A′B′C′D′), for each is equal to (A″B″C″D″).

§ 23. We may now also extend the notion of harmonic elements, viz. :—

Definition.—Four rays in a flat pencil and four planes in an axial pencil are said to be harmonic if their cross-ratio equals −1, that is, if they are cut by a line in four harmonic points.

Harmonic pencils are constructed by aid of the theorem in § 21, which may now be stated thus :—

In a four-side two sides are harmonic conjugates with regard to the diagonal through their intersection and the line from this point to the point where the other diagonals meet. Or thus : *In a four-point the lines joining one diagonal point to the other two are harmonic conjugates with regard to the sides passing through the first.*

If we understand by a "median line" of a triangle a line which joins a vertex to the middle point of the opposite side, and by a "median line" of a parallelogram a line joining middle points of opposite sides, we get as special cases of the last theorem :—

The diagonals and median lines of a parallelogram form an harmonic pencil ; and

At a vertex of any triangle, the two sides, the median line, and the line parallel to the base form an harmonic pencil.

Taking the parallelogram a rectangle, or the triangle isosceles, we get :—

Theorem.—*Any two lines and the bisections of their angles form an harmoic pencil.* Or :—

In an harmonic pencil, if two conjugate rays are perpendicular, then the other two are equally inclined to them ; and, conversely, *if one ray bisects the angle between conjugate rays, it is perpendicular to its conjugate.*

This connects perpendicularity and bisection of angles with projective properties.

§ 24. We add a few theorems and problems which are easily proved or solved by aid of harmonics.

An harmonic pencil is cut by a line parallel to one of its rays in three equidistant points.

Through a given point to draw a line such that the segment determined on it by a given angle is bisected at that point.

Having given two parallel lines, to bisect on either any given segment without using a pair of compasses.

Having given in a line a segment and its middle point, to draw through any given point in the plane a line parallel to the given line.

To draw a line which joins a given point to the intersection of two given lines which meet off the drawing paper (by aid of § 21).

Correspondence.

§ 25. Two rows, p and p', which are one the projection of the other (as in fig. 5), stand in a definite relation to each other characterized by the following properties.

1. *To each point in either corresponds one point in the other* ; that is, those points are said to correspond which are projections of one another.

2. *The cross-ratio of any four points in one equals that of the corresponding points in the other.*

3. *The lines joining corresponding points all pass through the same point.*

If we suppose corresponding points marked, and the rows brought into any other position, then the lines joining corresponding points will no longer meet in a common point, and hence the third of the above properties will not hold any longer ; but we have still a correspondence between the points in the two rows possessing the first two properties. Such a correspondence has been called a *one-one correspondence*, whilst the two rows between which such correspondence has been established are said to be *projective* or *homologous*. Two rows which are each the projection of the other are therefore *projective*. We shall presently see, also, that any two projective rows may always be placed in such a position that one appears as the projection of the other. If they are in such a position the rows are said to be in *perspective position*, or simply to be *perspective*.

§ 26. The notion of a one-one correspondence between rows may be extended to flat and axial pencils, viz., a flat pencil will be said to be projective to a flat pencil if to each ray in the first corresponds one ray in the second, and if the cross-ratio of four rays in one equals that of the corresponding rays in the second.

Similarly an axial pencil may be projective to an axial pencil. But a flat pencil may also be projective to an axial pencil, or either pencil may be projective to a row. The definition is the same in each case: there is a one-one correspondence between the elements, and four elements have the same cross-ratio as the corresponding ones.

§ 27. There is also in each case a special position which is called *perspective*, viz.:—

1. Two projective rows are perspective if they lie in the same plane, and if the one row is a projection of the other.

2. Two projective flat pencils are perspective—(α) if they lie in the same plane, and have a row as a common section; (β) if they lie in the same pencil (in space), and are both sections of the same axial pencil; (γ) if they are in space and have a row as common section, or are both sections of the same axial pencil, one of the conditions involving the other.

3. Two projective axial pencils, if their axes meet, and if they have a flat pencil as a common section.

4. A row and a projective flat pencil, if the row is a section of the pencil, each point lying in its corresponding line.

5. A row and a projective axial pencil, if the row is a section of the pencil, each point lying in its corresponding line.

6. A flat and a projective axial pencil, if the former is a section of the other, each ray lying in its corresponding plane.

That in each case the correspondence established by the position indicated is such as has been called projective follows at once from the definition. It is not so evident that the perspective position may always be obtained. We shall show in § 30 this for the first three cases. First, however, we shall give a few theorems which relate to the general correspondence, not to the perspective position.

§ 28. Theorem.—*Two rows or pencils, flat or axial, which are projective to a third are projective to each other*, as follows at once from the definitions.

§ 29. Fundamental Theorem.—*If two rows, or two pencils, either flat or axial, or a row and a pencil, shall be projective, we may assume to any three elements in the one the three corresponding elements in the other, and then the correspondence is uniquely determined.*

Proof.—If in two projective rows we assume that the points A, B, C in the first correspond to the given points A′, B′, C′ in the second, then to any fourth point D in the first will correspond a point D′ in the second, so that

$$(ABCD) = (A'B'C'D').$$

But there is only one point, D′, which makes the cross-ratio (A′B′C′D′) equal to the given number (ABCD).

The same reasoning holds in the other cases.

§ 30. *Theorem.*—If two rows are perspective, then the lines joining corresponding points all meet in a point, the centre of projection; and the point in which the two bases of the rows intersect as a point in the first row coincides with its corresponding point in the second.

This follows from the definition. The converse also holds, viz.:—

Theorem.—*If two projective rows have such a position that one point in the one coincides with its corresponding point in the other, then they are perspective, that is, the lines joining corresponding points all pass through a common point, and form a flat pencil.*

Proof.—Let A, B, C, D . . . be points in the one, and A′, B′, C′, D′ . . . the corresponding points in the other row, and let A be made to coincide with its corresponding point A′. Let S be the point where the lines BB′ and CC′ meet, and let us join S to the point D in the first row. This line will cut the second row in a point D″, so that A, B, C, D are projected from S into the points A, B′, C′, D″. The cross-ratio (ABCD) is therefore equal to (AB′C′D″), and by hypothesis it is equal to (A′B′C′D′). Hence (A′B′C′D″) = (A′B′C′D′), that is, D″ is the same point as D′.

§ 31. *Theorem.*—If two projected flat pencils in the same plane are perspective, then the intersections of corresponding lines form a row, and the line joining the two centres as a line in the first pencil corresponds to the same line as a line in the second. And conversely,

Theorem.—*If two projective pencils in the same plane, but with different centres, have one line in the one coincident with its corresponding line in the other, then the two pencils are perspective, that is, the intersection of corresponding lines lie in a line.*

The proof is the same as in § 30.

§ 32. *Theorem.*—If two projective flat pencils in the same point (pencil in space), but not in the same plane, are perspective, then the planes joining corresponding rays all pass through a line (they form an axial pencil), and the line common to the two pencils (in which their planes intersect) corresponds to itself. And conversely,

Theorem.—If two flat pencils which have a common centre, but do not lie in a common plane, are placed so that one ray in the one coincides with its corresponding ray in the other, then they are perspective, that is, the planes joining corresponding lines all pass through a line.

§ 33. *Theorem.*—If two projective axial pencils are perspective, then the intersection of corresponding planes lie in a plane, and the plane common to the two pencils (in which the two axes lie) corresponds to itself. And conversely,

Theorem.—If two projective axial pencils are placed in such a position that a plane in the one coincides with its corresponding plane, then the two pencils are perspective, that is, corresponding planes meet in lines which lie in a plane.

The proof again is the same as in § 30.

§ 34. These theorems relating to perspective position become illusory if the projective rows of pencils have a common base. We then have:—

Theorem.—In two projective rows on the same line—and also in two projective and concentric flat pencils in the same plane, or in two projective axial pencils with a common axis—every element in the one coincides with its corresponding element in the other as soon as three elements in the one coincide with their corresponding elements in the other.

Proof (in case of two rows).—Between four elements A, B, C, D and their corresponding elements A′, B′, C′, D′ exists the relation (ABCD) = (A′B′C′D′). If now A′, B′, C′ coincide respectively with A, B, C, we get (ABCD) = (ABCD′); hence D and D′ coincide.

The last theorem may also be stated thus:—

Theorem.—In two projective rows or pencils, which have a common base but are not identical, not more than two elements in the one can coincide with their corresponding elements in the other.

Thus two projective rows on the same line cannot have more than two pairs of coincident points unless every point coincides with its corresponding point.

It is easy to construct two projective rows on the same line, which have two pairs of corresponding points coincident. Let the points A, B, C as points belonging to the one row correspond to A, B, and C′ as points in the second. Then A and B coincide with their corresponding points, but C does not. It is, however, not necessary that two such rows have twice a point coincident with its corresponding point; it is possible that this happens only once or not at all. Of this we shall see plenty of examples as we go on.

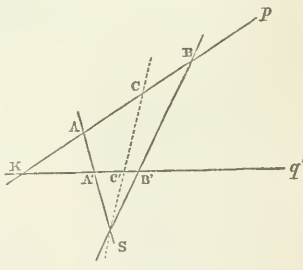

Fig. 8.

§ 35. If two projective rows or pencils are in perspective position, we know at once which element in one corresponds to any given element in the other. If p and q (fig. 8) are two projective rows, so that K corresponds to itself, and if we know that to A and B in p correspond A′ and B′ in q, then the point S, where AA′ meets BB′, is the centre of projection, and hence, in order to find the point C′ corresponding to C, we have only to join C to S; the point C′, where this line cuts q, is the point required.

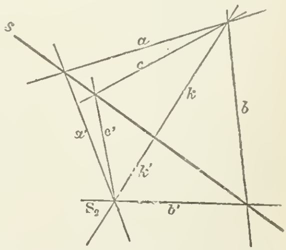

Fig. 9.

If two flat pencils, S_1 and S_2, in a plane are perspective (fig. 9), we need only to know two pairs, a, a' and b, b', of corresponding rays in order to find the axis s of projection. This being known, a ray c' in S_2, corresponding to a given ray c in S_1, is found by joining S_2 to the point where c cuts the axis s.

A similar construction holds in the other cases of perspective figures.

On this depends the solution of the following general problem.

§ 36. *Problem.*—Three pairs of corresponding elements in two projective rows or pencils being given, to determine for any element in one the corresponding element in the other.

We solve this in the two cases of two projective rows and of two projective flat pencils in a plane.

Problem I.—Let A, B, C be three points in a row s, A', B', C' the corresponding points in a projective row s', both being in a plane; it is required to find for any point D in s the corresponding point D' in s'.

Problem II.—Let a, b, c be three rays in a pencil S, a', b', c' the corresponding rays in a projective pencil S', both being in the same plane; it is required to find for any ray d in S the corresponding ray d' in S'.

The solution is made to depend on the construction of an auxiliary row or pencil which is perspective to both the given ones. This is found as follows :—

Solution of Problem I.—On the line joining two corresponding points, say AA' (fig. 10), take any two points, S and S', as centres of auxiliary pencils. Join the intersection B_1 of SB and S'B' to the intersection C_1 of SC and S'C' by the line s_1. Then a row on s_1 will be perspective to s with S as centre of projection, and to s' with S' as centre. To find now the point D' on s' corresponding to a point D on s we have only to determine the point D_1, where the line SD cuts s_1, and to draw $S'D_1$; the point where this line cuts s' will be the required point D'.

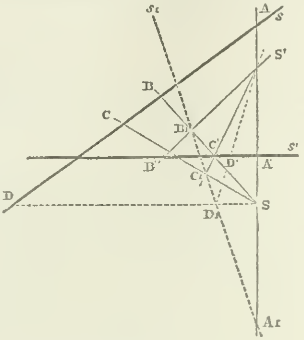

Fig. 10

Proof.—The rows s and s' are both perspective to the row s_1, hence they are projective to one another. To A, B, C, D on s correspond A_1, B_1, C_1, D_1 on s_1, and to these correspond A', B', C', D' on s'; so that D and D' are corresponding points as required.

Solution of Problem II.—Through the intersection A of two corresponding rays a and a' (fig. 11), take two lines, s and s', as bases of auxiliary rows. Let S_1 be the point where the line b_1, which joins B and B', cuts the line c_1, which joins C and C'. Then a pencil S_1 will be perspective to S with s as axis of projection. To find the ray d' in S' corresponding to a given ray d in S, cut d by s at D; project this point from S_1 to D' on s' and join D' to S'. This will be the required ray.

Proof.—That the pencil S_1 is perspective to S and also to S' follows from construction. To the lines a_1, b_1, c_1, d_1 in S_1 correspond the lines a, b, c, d in S and the lines a', b', c', d' in S', so that d and d' are corresponding rays.

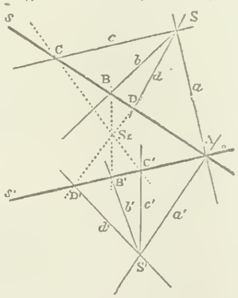

Fig. 11.

In the first solution the two centres, S, S', are *any* two points on a line joining any two corresponding points, so that the solution of the problem allows of a great many different constructions. *But whatever construction be used, the point D', corresponding to D, must be always the same,* according to the theorem in § 29. This gives rise to a number of theorems, into which, however, we shall not enter. The same remarks hold for the second problem.

§ 37. As a further application of the theorems about perspective rows and pencils we shall prove the following important theorem.

Theorem.—If ABC and A'B'C' (fig. 12) be two triangles, such that the lines AA', BB', CC' meet in a point S, then the intersections of BC and B'C', of CA and C'A', and of AB and A'B' will lie in a line.

Proof.—Let a, b, c denote the lines AA', BB', CC', which meet at S. Then these may be taken as bases of projective rows, so that A, A', S on a correspond to B, B', S on b, and to C, C', S on c. As the point S is common to all, any two of these rows will be perspective.

If S_1 be the centre of projection of rows b and c,
S_2 ,, ,, ,, c and a,
S_3 ,, ,, ,, a and b,

and if the line S_1S_2 cuts a in A_1, and b in B_1, and c in C_1, then A_1, B_1 will be corresponding points in a and b, both corresponding to C_1 in c. But a and b are perspective, therefore the line A_1B_1, that is S_1S_2, joining corresponding points must pass through the centre of projection S_3 of a and b. In other words, S_1, S_2, S_3 lie in a line. This is Desargues's celebrated theorem if we state it thus:—

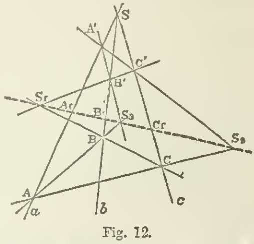

Fig. 12.

Theorem of Desargues.—If each of two triangles has one vertex on each of three concurrent lines, then the intersections of corresponding sides lie in a line, those sides being called corresponding which are opposite to vertices on the same line.

The converse theorem holds also, viz. :—

Theorem.—If the sides of one triangle meet those of another in three points which lie in a line, then the vertices lie on three lines which meet in a point.

The proof is almost the same as before.

§ 38. *Metrical relations between projective rows.*—Every row contains one point which is distinguished from all others, viz., the point at infinity. In two projective rows, to the point I at infinity in one corresponds a point I' in the other, and to the point J' at infinity in the second corresponds a point J in the first. The points I' and J are in general finite. If now A and B are any two points in the one, A', B' the corresponding points in the other row, then

$$(ABJI) = (A'B'J'I').$$

Or,

$$\frac{AJ}{JB} : \frac{AI}{IB} = \frac{A'J'}{J'B'} : \frac{A'I'}{I'B'};$$

but, by § 17,

$$\frac{AI}{IB} = \frac{A'J'}{J'B'} = -1,$$

therefore the last equation changes into

$$\frac{AJ}{JB} \cdot \frac{A'I'}{I'B'} = 1,$$

or into

$$AJ \cdot A'I' = BJ \cdot BI',$$

that is to say—

Theorem.—The product of the distances of any two corresponding points in two projective rows from the points which correspond to the points at infinity in the other is constant, viz., $AJ \cdot A'I' = k$. Steiner has called this number k the *Power of the correspondence.*

§ 39. *Similar Rows.*—If the points at infinity in two projective rows correspond so that I' and J are at infinity, this result loses its meaning. But if A, B, C be any three points in one, A', B', C' the corresponding ones on the other row, we have

$$(ABCI) = (A'B'C'I'),$$

which reduces to

$$\frac{AC}{CB} = \frac{A'C'}{C'B'}; \text{ or } \frac{AC}{A'C'} = \frac{BC}{B'C'},$$

that is, corresponding segments are proportional. Conversely, if corresponding segments are proportional, then to the point at infinity in one corresponds the point at infinity in the other. If we call such rows *similar*, we may state the result thus—

Theorem.—Two projective rows are similar if to the point at infinity in one corresponds the point at infinity in the other, and conversely, if two rows are similar then they are projective, and the points at infinity are corresponding points.

From this the well-known propositions follow :—

Two lines are cut proportionally (in similar rows) by a series of parallels. The rows are perspective, with centre of projection at infinity.

If two similar rows are placed parallel, then the lines joining homologous points pass through a common point.

§ 40. *Theorem.*—If two flat pencils be projective, then there exists in either one single pair of lines at right angles to one another, such that the corresponding lines in the other pencil are again at right angles.

To prove this, we place the pencils in perspective position (fig. 13) by making one ray coincident with its corresponding ray. Corresponding rays meet then on a line p. And now we draw the circle which has its centre O on p, and which passes through the centres S and S′ of the two pencils. This circle cuts p in two points H and K. The two pairs of rays, h, k and h', k', joining these points to S and S′ will be pairs of corresponding rays at right angles. The construction gives in general but one circle, but if the line p is the perpendicular bisector of SS′, there exists an infinite number, and *to every right angle in the one pencil corresponds a right angle in the other.*

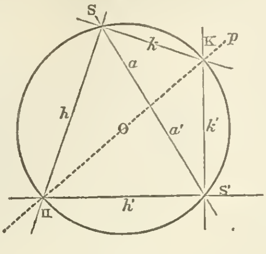

Fig. 13.

Principle of Duality.

§ 41. It has been stated in § 1 that not only points, but also planes and lines, are taken as elements out of which figures are built up. We shall now see that the construction of one figure which possesses certain properties gives rise in many cases to the construction of another figure, by replacing, according to definite rules, elements of one kind by those of another. The new figure thus obtained will then possess properties which may be stated as soon as those of the original figure are known.

We obtain thus a principle, known as the *principle of duality* or of *reciprocity*, which enables us to construct to any figure not containing any measurement in its construction a *reciprocal* figure, as it is called, and to deduce from any theorem a *reciprocal* theorem, for which no further proof is needed.

It is convenient to print reciprocal propositions on opposite sides of a page broken into two columns, and this plan will occasionally be adopted.

We begin by repeating in this form a few of our former statements:—

Two points determine a line.	Two planes determine a line.
Three points which are not in a line determine a plane.	Three planes which do not pass through a line determine a point.
A line and a point without it determine a plane.	A line and a plane not through it determine a point.
Two lines in a plane determine a point.	Two lines through a point determine a plane.

These propositions show that it will be possible, when any figure is given, to construct a second figure by taking planes instead of points, and points instead of planes, but lines where we had lines.

For instance, if in the first figure we take a plane and three points in it, we have to take in the second figure a point and three planes through it. The three points in the first, together with the three lines joining them two and two, form a triangle; the three planes in the second and their three lines of intersection form a trihedral angle. A triangle and a trihedral angle are therefore reciprocal figures.

Similarly, to any figure in a plane consisting of points and lines will correspond a figure consisting of planes and lines passing through a point S, and hence belonging to the pencil which has S as centre.

The figure reciprocal to four points in space which do not lie in a plane will consist of four planes which do not meet in a point. In this case each figure forms a tetrahedron.

§ 42. As other examples we have the following:—

To a row	is reciprocal	an axial pencil,
„ a flat pencil	„	a flat pencil,
„ a field of points and lines	„	a pencil of planes and lines,
„ the space of points	„	the space of planes.

For the row consists of a line and all the points in it, reciprocal to it therefore will be a line with all planes through it, that is, an axial pencil; and so for the other cases.

This correspondence of reciprocity breaks down, however, if we take figures which contain measurement in their construction. For instance, there is no figure reciprocal to two planes at *right angles*, because there is no segment in a row which has a magnitude as definite as a right angle.

We add a few examples of reciprocal propositions which are easily proved.

Theorem.—If A, B, C, D are any four points in space, and if the lines AB and CD meet, then all four points lie in a plane, hence also AC and BD, as well as AD and BC, meet.	*Theorem.*—If α, β, γ, δ are four planes in space, and if the lines $\alpha\beta$ and $\gamma\delta$ meet, then all four planes lie in a point (pencil), hence also $\alpha\beta$ and $\gamma\delta$, as well as $\alpha\delta$ and $\beta\gamma$, meet.

Theorem.—*If of any number of lines every one meets every other, whilst all do not*

lie in a point, then all lie in a plane.	*lie in a plane, then all lie in a point (pencil).*

§ 43. Reciprocal figures as explained lie both in space of three dimensions. If the one is confined to a plane (is formed of elements which lie in a plane), then the reciprocal figure is confined to a pencil (is formed of elements which pass through a point).

But there is also a more special principle of duality, according to which figures are reciprocal which lie both in a plane or both in a pencil. In the plane we take points and lines as reciprocal elements, for they have this fundamental property in common, that two elements of one kind determine one of the other. In the pencil, on the other hand, lines and planes have to be taken as reciprocal, and here it holds again that two lines or planes determine one plane or line.

Thus, to one plane figure we can construct one reciprocal figure in the plane, and to each one reciprocal figure in a pencil. We mention a few of these. At first we explain a few names:—

A figure consisting of n points in a plane will be called an n-point.	A figure consisting of n lines in a plane will be called an n-side.
A figure consisting of n planes in a pencil will be called an n-flat.	A figure consisting of n lines in a pencil will be called an n-edge.

It will be understood that an n-side is different from a polygon of n sides. The latter has sides of finite length and n vertices, the former has sides all of infinite extension, and every point where two of the sides meet will be a vertex. A similar difference exists between a solid angle and an n-edge or an n-flat. We notice particularly—

A four-point has six sides, of which two and two are opposite, and three diagonal points, which are intersections of opposite sides.	A four-side has six vertices, of which two and two are opposite, and three diagonals, which join opposite vertices.
A four-flat has six edges, of which two and two are opposite, and three diagonal planes, which pass through opposite edges.	A four-edge has six faces, of which two and two are opposite, and three diagonal edges, which are intersections of opposite faces.

A four-side is usually called a complete quadrilateral. The above notation, however, seems better adapted for the statement of reciprocal propositions.

§ 44.

If a point moves in a plane it describes a plane curve.	If a line moves in a plane it envelopes a plane curve (fig. 14).
If a plane moves in a pencil it envelopes a cone.	If a line moves in a pencil it describes a cone.

A curve thus appears as generated either by points, and then we call it a "locus," or by lines, and then we call it an "envelope." In the same manner a cone, which means here a surface, appears either as the locus of lines passing through a fixed point, the "vertex" of the cone, or as the envelope of planes passing through the same point.

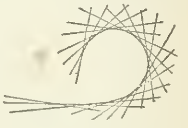

Fig. 14.

To a surface as locus of points corresponds, in the same manner, a surface as envelope of planes; and to a curve in space as locus of points corresponds a developable surface as envelope of planes. Of the latter we shall not say any more at present.

It will be seen from the above that we may, by aid of the principle of duality, construct for every figure a reciprocal figure, and that to any property of the one a reciprocal property of the other will exist, as long as we consider only properties which depend upon nothing but the positions and intersections of the different elements and not upon measurement.

For such propositions it will therefore be unnecessary to prove more than one of two reciprocal theorems.

Curves and Cones of Second Order or Second Class.

§ 45. If we have two projective pencils in a plane, corresponding rays will meet, and their point of intersection will constitute some locus which we have to investigate. Reciprocally, if two projective rows in a plane are given, then the lines which join corresponding points will envelope some curve. We prove first:—

Theorem.—If two projective flat pencils lie in a plane, but are neither perspective nor concentric, then the locus of intersections of corresponding rays is a curve of the *second order*, that is, no line contains more than two points of the locus.	*Theorem.*—If two projective rows lie in a plane, but are neither perspective nor on a common base, then the envelope of lines joining corresponding points is a curve of the *second class*, that is through no point pass more than two of the enveloping lines.
Proof.—We draw any line t. This cuts each of the pencils in a row, so that we have on t two rows, and these are projective because the pencils are projective. If corresponding rays of the two pencils meet on the line t, their intersection will be a point in the one row which coincides with its corresponding point in the other. But two projective rows on the same base cannot have more than two points of one coincident with their corresponding points in the other (§ 34).	*Proof.*—We take any point T and join it to all points in each row. This gives two concentric pencils, which are projective because the rows are projective. If a line joining corresponding points in the two rows passes through T, it will be a line in the one pencil which coincides with its corresponding line in the other. But two projective concentric flat pencils in the same plane cannot have more than two lines of one coincident with their corresponding line in the other (§ 34).

It will be seen that the proofs are reciprocal, so that the one may be copied from the other by simply interchanging the words point and line, locus and envelope, row and pencil, and so on. We shall therefore in future prove seldom more than one of two reciprocal theorems, and often state one theorem only, the reader being recommended to go through the reciprocal proof by himself, and to supply the reciprocal theorems when not given.

§ 46. We state the theorems in the pencil reciprocal to the last, without proving them :—

Theorem.—If two projective flat pencils are concentric, but are neither perspective nor co-planar, then the envelope of the planes joining corresponding rays is a cone of the second class; that is, no line through the common centre contains more than two of the enveloping planes.

Theorem.—If two projective axial pencils lie in the same pencil (their axes meet in a point), but are neither perspective nor co-axial, then the locus of lines joining corresponding planes is a cone of the second order; that is, no plane in the pencil contains more than two of these lines.

§ 47. Of theorems about cones of second order and cones of second class we shall state only very few. We point out, however, the following connexion between the curves and cones under consideration :—

The lines which join any point in space to the points on a curve of the second order form a cone of the second order.

Every plane section of a cone of the second order is a curve of the second order.

The planes which join any point in space to the lines enveloping a curve of the second class envelope themselves a cone of the second class.

Every plane section of a cone of the second class is a curve of the second class.

By its aid, or by the principle of duality, it will be easy to obtain theorems about them from the theorems about the curves.

We prove the first. A curve of the second order is generated by two projective pencils. These pencils, when joined to the point in space, give rise to two projective axial pencils, which generate the cone in question as locus of the lines where corresponding planes meet.

§ 48.

Theorem.—The curve of second order which is generated by two projective flat pencils passes through the centres of the two pencils.

Theorem.—The envelope of second class which is generated by two projective rows contains the bases of these rows as enveloping lines or tangents.

Proof.—If S and S′ are the two pencils, then to the ray SS′ or p' in the pencil S′ corresponds in the pencil S a ray p, which is different from p', for the pencils are not perspective. But p and p' meet at S, so that S is a point on the curve, and similarly S′.

Proof.—If s and s' are the two rows, then to the point ss' or P′ as a point in s' corresponds in s a point P, which is not coincident with P′, for the rows are not perspective. But P and P′ are joined by s, so that s is one of the enveloping lines, and similarly s'.

It follows that every line in one of the two pencils cuts the curve in two points, viz., once at the centre S of the pencil, and once where it cuts its corresponding ray in the other pencil. These two points, however, coincide, if the line is cut by its corresponding line at S itself. The line p in S, which corresponds to the line SS′ in S′, is therefore the only line through S which has but one point in common with the curve, or which cuts the curve in two *coincident* points. Such a line is called a tangent to the curve, touching the latter at the point S, which is called the point of contact.

In the same manner we get in the reciprocal investigation the result that through every point in one of the rows, say in s, two tangents may be drawn to the curve, the one being s, the other the line joining the point to its corresponding point in s'. There is, however, one point P in s for which these two lines coincide. Such a point in one of the tangents is called the "point of contact" of the tangent. We thus get—

Theorem.—To the line joining the centres of the projective pencils as a line in one pencil corresponds in the other the tangent at its centre.

Theorem.—To the point of intersection of the bases of two projective rows as a point in one row corresponds in the other the *point of contact* of its base.

§ 49. Two projective pencils are determined if three pairs of corresponding lines are given. Hence if a_1, b_1, c_1 are three lines in a pencil S_1, and a_2, b_2, c_2 the corresponding lines in a projective pencil S_2, the correspondence and therefore the curve of the second order generated by the points of intersection of corresponding rays is determined. Of this curve we know the two centres S_1 and S_2, and the three points a_1a_2, b_1b_2, c_1c_2, hence five points in all. This and the reciprocal considerations enable us to solve the following two problems :—

Problem.—To construct a curve of the second order, of which five points S_1, S_2, A, B, C are given.

Problem.—To construct a curve of the second class, of which five tangents u_1, u_2, a, b, c are given.

In order to solve the left-hand problem, we take two of the given points, say S_1 and S_2, as centres of pencils. These we make projective by taking the rays a_1, b_1, c_1, which join S_1 to A, B, C respectively, as corresponding to the rays a_2, b_2, c_2, which join S_2 to A, B, C respectively, so that three rays meet their corresponding rays at the given points A, B, C. This determines the correspondence of the pencils which will generate a curve of the second order passing through A, B, C and through the centres S_1 and S_2, hence through the five given points. To find more points on the curve we have to construct for any ray in S_1 the corresponding ray in S_2. This has been done in § 36. But we repeat the construction in order to deduce further properties from it. We also solve the right-hand problem. Here we select two, viz., u_1, u_2 of the five given lines, u_1, u_2, a, b, c, as bases of two rows, and the points A_1, B_1, C_1 where a, b, c cut u_1 as corresponding to the points A_2, B_2, C_2 where a, b, c cut u_2.

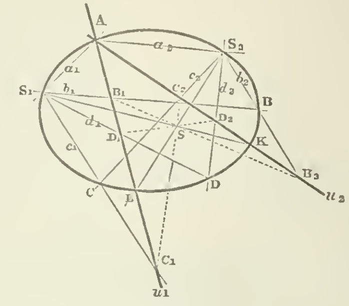

Fig. 15.

We get then the following solutions of the two problems :—

Solution.—Through the point A draw any two lines, u_1 and u_2 (fig. 15), the first u_1 to cut the pencil S_1 in a row AB_1C_1, the other u_2 to cut the pencil S_2 in a row AB_2C_2. These two rows will be perspective, as the point A corresponds to itself, and the centre of projection will be the point S, where the lines B_1B_2 and C_1C_2 meet. To find now for any ray d_1 in S_1 its corresponding ray d_2 in S_2, we determine the point D_1 where d_1 cuts u_1, project this point from S to D_2 on u_2 and join S_2 to D_2. This will be the required ray d_2 which cuts d_1 at some point D on the curve.

Solution.—In the line a take any two points S_1 and S_2 as centres of pencils (fig. 16), the first S_1 $(A_1B_1C_1)$ to project the row u_1, the other S_2 $(A_2B_2C_2)$ to project the row u_2. These two pencils will be perspective, the line S_1A_1 being the same as the corresponding line S_2A_2, and the axis of projection will be the line u, which joins the intersection B of S_1B_1 and S_2B_2 to the intersection C of S_1C_1 and S_2C_2. To find now for any point D_1 in u_1 the corresponding point D_2 in u_2, we draw S_1D_1 and project the point D where this line cuts u from S_2 to u_2. This will give the required point D_2, and the line d joining D_1 to D_2 will be a new tangent to the curve.

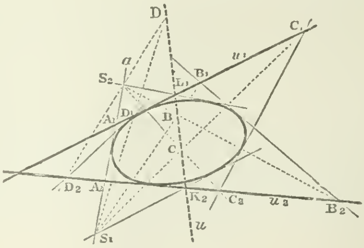

Fig. 16.

§ 50. These constructions prove, when rightly interpreted, very important properties of the curves in question.

If in fig. 15 we draw in the pencil S_1 the ray κ_1 which passes through the auxiliary centre S, it will be found that the corresponding ray k_2 cuts it on u_2. Hence—

Theorem.—In the above construction the bases of the auxiliary rows u_1 and u_2 cut the curve where they cut the rays S_2S and S_1S respectively.

Theorem.—In the above construction (fig. 16) the tangents to the curve from the centres of the auxiliary pencils S_1 and S_2 are the lines which pass through u_2u and u_1u respectively.

As A is any given point on the curve, and u_1 any line through it, we have solved the problems :—

Problem.—To find the second point in which any line through a known point on the curve cuts the curve.

Problem.—To find the second tangent which can be drawn from any point in a given tangent to the curve.

If we determine in S_1 (fig. 15) the ray corresponding to the ray S_2S_1 in S_2, we get the tangent at S_1. Similarly we can determine the point of contact of the tangents u_1 or u_2 in fig. 16.

§ 51. If five points are given, of which not three are in a line, then we can, as has just been shown, always draw a curve of the second order through them, we select two of the points as centres of projective pencils, and then one such curve is determined. It will be presently shown that we get always the same curve if two other points are taken as centres of pencils, that therefore five points deter-

mine one curve of the second order, and reciprocally, that five tangents determine one curve of the second class. Six points taken at random will therefore not lie on a curve of the second order. In order that this may be the case a certain condition has to be satisfied, and this condition is easily obtained from the construction in § 49, fig. 15. If we consider the conic determined by the five points A, S_1, S_2, K, L, then the point D will be on the curve if, and only if, the points on D_1, S, D_2 be in a line.

This may be stated differently if we take AKS_1DS_2L (figs. 15 and 17) as a hexagon inscribed in the conic, then AK and DS_2 will be opposite sides, so will be KS_1 and S_2L, as well as S_1D and LA. The first two meet in D_2, the others in S and D_1 respectively. We may therefore state the required condition, together with the reciprocal one, as follows:—

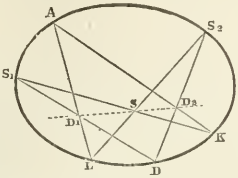

Fig. 17.

Pascal's Theorem.—If a hexagon be inscribed in a curve of the second order, then the intersections of opposite sides are three points in a line.

Brianchon's Theorem.—If a hexagon be circumscribed about a curve of the second class, then the lines joining opposite vertices are three lines meeting in a point.

These celebrated theorems, which are known by the names of their discoverers, are perhaps the most fruitful in the whole theory of conics. Before we go over to their applications we have to show that we obtain the same curve if we take, instead of S_1, S_2, any two other points on the curve as centres of projective pencils.

§ 52. We know that the curve depends only upon the correspondence between the pencils S_1 and S_2, and not upon the special construction used for finding new points on the curve. The point A (fig. 15 or fig. 17), through which the two auxiliary rows u_1, u_2 were drawn, may therefore be changed to any other point on the curve. Let us now suppose the curve drawn, and keep the points S_1, S_2, K, L, and D, and hence also the point S fixed, whilst we move A along the curve. Then the line AL will describe a pencil about L as centre, and the point D_1 a row on S_1D perspective to the pencil L. At the same time AK describes a pencil about K and D_2 a row perspective to it on S_2D. But by Pascal's Theorem D_1 and D_2 will always lie in a line with S, so that the rows described by D_1 and D_2 are perspective. It follows that the pencils K and L will themselves be projective, corresponding rays meeting on the curve. This proves that we get the same curve whatever pair of the five given points we take as centres of projective pencils. Hence—

Theorem.—Only one curve of the second order can be drawn which passes through five given points.

Theorem.—Only one curve of the second-class can be drawn which touches five given lines.

We have seen that if on a curve of the second order two points coincide at A, the line joining them becomes the tangent at A. If, therefore, a point on the curve and its tangent are given, this will be equivalent to having given two points on the curve. Similarly, if on the curve of second class a tangent and its point of contact are given, this will be equivalent to two given tangents.

We may therefore extend the last theorem:—

Theorem.—Only one curve of the second order can be drawn, of which four points and the tangent at one of them, or three points and the tangents at two of them, are given.

Theorem.—Only one curve of the second class can be drawn, of which four tangents and the point of contact at one of them, or three tangents and the points of contact at two of them, are given.

§ 53. At the same time it has been proved:—

Theorem.—If all points on a curve of the second order be joined to any two of them, then the two pencils thus formed are projective, those rays being corresponding which meet on the curve. Hence—

Theorem.—All tangents to a curve of second class are cut by any two of them in projective rows, those being corresponding points which lie on the same tangent. Hence—

The cross-ratio of four rays joining a point S on a curve of second order to four fixed points A, B, C, D in the curve is independent of the position of S, and is called the cross-ratio of the four points A, B, C, D.

The cross-ratio of the four points in which any tangent u is cut by four fixed tangents a, b, c, d is independent of the position of u, and is called the cross-ratio of the four tangents a, b, c, d.

If this cross-ratio is $= -1$, the four points are said to be four harmonic points.

If this cross-ratio equals -1, the four tangents are said to be four harmonic tangents.

We have seen that a curve of second order, as generated by projective pencils, has at the centre of each pencil one tangent; and further, that any point on the curve may be taken as centre of such pencil. Hence—

Theorem.—A curve of second order has at every point one tangent.

Theorem.—A curve of second class has on every tangent a point of contact.

§ 54. We return to Pascal's and Brianchon's theorems and their applications, and shall, as before, state the results both for curves of the second order and curves of the second class, but prove them only for the former.

Pascal's theorem may be used when five points are given to find more points on the curve, viz., it enables us to find the point where any line through one of the given points cuts the curve again. It is convenient, in making use of Pascal's theorem, to number the points, to indicate the order in which they are to be taken in forming a hexagon, which, by the way, may be done in 60 different ways. It will be seen that 1 2 and (leaving out 3) 4 5 are opposite sides, so are 2 3 and (leaving out 4) 5 6, and also 3 4 and (leaving out 5) 6 1.

If the points 1 2 3 4 5 are given, and we want a 6th point on a line drawn through 1, we know all the sides of the hexagon with the exception of 5 6, and this is found by Pascal's theorem.

If this line should happen to pass through 1, then 6 and 1 coincide, or the line 6 1 is the tangent at 1. And always if two consecutive vertices of the hexagon approach nearer and nearer, then the side joining them will ultimately become a tangent.

We may therefore consider a pentagon inscribed in a curve of second order and the tangent at one of its vertices as a hexagon, and thus get the theorem:—

Theorem.—Every pentagon inscribed in a curve of second order has the property that the intersections of two pairs of non-consecutive sides lie in a line with the point where the fifth side cuts the tangent at the opposite vertex.

Theorem.—Every pentagon circumscribed about a curve of the second class has the property that the lines which join two pairs of non-consecutive vertices meet on that line which joins the fifth vertex to the point of contact of the opposite side.

This enables us also to solve the following problems.

Problem.—Given five points on a curve of second order to construct the tangent at any one of them.

Problem.—Given five tangents to a curve of second class to construct the point of contact of any one of them.

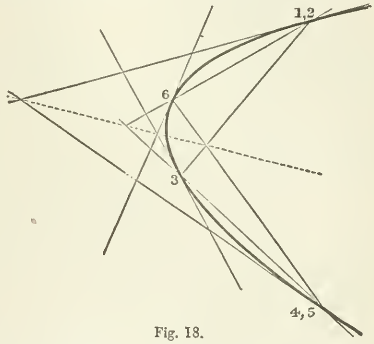

Fig. 18.

If twice two adjacent vertices coincide, the hexagon becomes a quadrilateral, with tangents at two vertices. These we take to be opposite, and get the following theorems:—

Theorem.—If a quadrilateral be inscribed in a curve of second order, the intersections of opposite sides, and also the intersections of the tangents at opposite vertices, lie in a line (fig. 18).

Theorem.—If a quadrilateral be circumscribed about a curve of second class, the lines joining opposite vertices, and also the lines joining points of contact of opposite sides, meet in a point

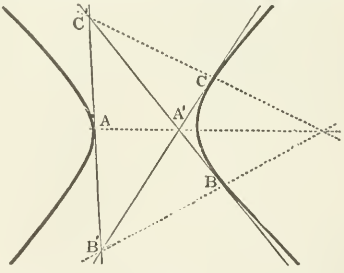

Fig. 19.

If we consider the hexagon made up of a triangle and the tangents at its vertices, we get—

Theorem.—If a triangle is inscribed in a curve of second order, the points in which the sides are cut by the tangents at the opposite vertices lie in a line.

Theorem.—If a triangle be circumscribed about a curve of second class, the lines which join the vertices to the points of contact of the opposite sides meet in a point (fig. 19).

§ 55. Of these theorems, those about the quadrilateral give rise to a number of others. Four points A, B, C, D may in three different ways be formed into a quadrilateral, for we may take them in the order ABCD, or ACBD, or ACDB, so that either of the points B, C, D may be taken as the vertex opposite to A. Accordingly we may apply the theorem in three different ways.

Let A, B, C, D be four points on a curve of second order (fig. 20), and let us take them as forming a quadrilateral by taking the

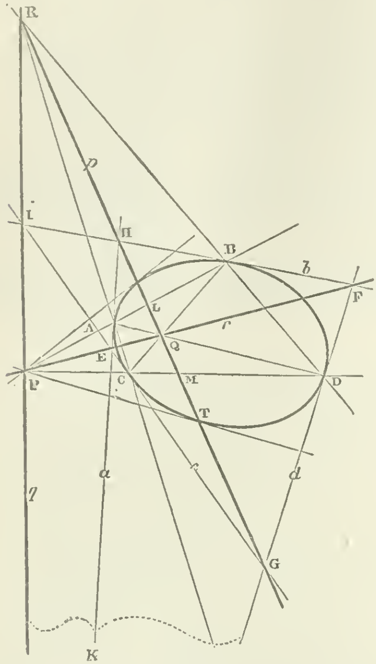

Fig. 20.

points in the order ABCD, so that A, C and also B, D are pairs of opposite vertices. Then P, Q will be the points where opposite sides meet, and E, F the intersections of tangents at opposite vertices. The four points P, Q, E, F lie therefore in a line. The quadrilateral ACBD gives us in the same way the four points Q, R, G, H in a line, and the quadrilateral ABDC a line containing the four points R, P, I, K. These three lines form a triangle PQR.

The relation between the points and lines in this figure may be expressed more clearly if we consider ABCD as a four-point inscribed in a conic, and the tangent at these points as a four-side circumscribed about it,—viz., it will be seen that P, Q, R are the diagonal points of the four-point ABCD, whilst the sides of the triangle PQR are the diagonals of the circumscribing four-side. Hence the theorem—

Theorem.—*Any four-point on a curve of the second order and the four-side formed by the tangents at these points stand in this relation that the diagonal points of the four-point lie in the diagonals of the four-side.* And conversely,

If a four-point and a circumscribed four-side stand in the above relation, then a curve of the second order may be described which passes through the four points and touches there the four sides of these figures.

That the last part of the theorem is true follows from the fact that the four points A, B, C, D and the line a, as tangent at A, determine a curve of the second order, and the tangents to this curve at the other points B, C, D are given by the construction which leads to fig. 20.

The theorem reciprocal to the last is—

Theorem.—*Any four-side circumscribed about a curve of second class and the four-point formed by the points of contact stand in this relation that the diagonals of the four-side pass through the diagonal points of the four-point.* And conversely,

If a four-side and an inscribed four-point stand in the above relation, then a curve of the second class may be described which touches the sides of the four-side at the points of the four-points.

§ 56. The four-point and the four-side in the two reciprocal theorems are alike. Hence if we have a four-point ABCD and a four-side $abcd$ related in the manner described, then not only may a curve of the second order be drawn, but also a curve of the second class, which both touch the lines a, b, c, d at the points A, B, C, D.

The curve of second order is already more than determined by the points A, B, C and the tangents a, b, c at A, B, and C. The point D may therefore be *any* point on this curve, and d any tangent to the curve. On the other hand the curve of the second class is more than determined by the three tangents a, b, c and their points of contact A, B, C, so that d is any tangent to this curve. It follows that every tangent to the curve of second order is a tangent of a curve of the second class having the same point of contact. In other words, the curve of second order is a curve of second class, and *vice versa*. Hence the important theorems:—

Theorem.—*Every curve of second order is a curve of second class.*

Theorem.—*Every curve of second class is a curve of second order.*

The curves of second order and of second class having thus been proved to be identical shall henceforth be called by the common name of *Conics*.

For these curves hold, therefore, all properties which have been proved for curves of second order or of second class. We may therefore now state Pascal's and Brianchon's theorem thus—

Pascal's Theorem.—If a hexagon be inscribed in a conic, then the intersections of opposite sides lie in a line.

Brianchon's Theorem.—If a hexagon be circumscribed about a conic, then the diagonals forming opposite centres meet in a point.

§ 57. If we suppose in fig. 20 that the point D together with the tangent d moves along the curve, whilst A, B, C and their tangents a, b, c remain fixed, then the ray DA will describe a pencil about A, the point Q a projective row on the fixed line BC, the point F the row b, and the ray EF a pencil about E. But EF passes always through Q. Hence the pencil described by AD is projective to the pencil described by EF, and therefore to the row described by F on b. At the same time the line BD describes a pencil about B projective to that described by AD (§ 53). Therefore the pencil BD and the row F on b are projective. Hence—

Theorem.—*If on a conic a point A be taken and the tangent* a *at this point then the cross-ratio of the four rays which join A to any four points on the curve is equal to the cross-ratio of the points in which the tangents at these points cut the tangent at A.*

§ 58. There are theorems about cones of second order and second class in a pencil which are reciprocal to the above, according to § 43. We mention only a few of the more important ones.

Theorem.—The locus of intersections of corresponding planes in two projective axial pencils whose axes meet is a cone of the second order.

Theorem.—The envelope of planes which join corresponding lines in two projective flat pencils, not in the same plane, is a cone of the second class.

Theorem.—Cones of second order and cones of second class are identical.

Theorem.—Every plane cuts a cone of the second order in a conic.

Theorem.—*A cone of second order is uniquely determined by five of its edges or by five of its tangent planes, or by four edges and the tangent plane at one of them, &c., &c.*

Theorem (Pascal's).—If a solid angle of six faces be inscribed in a cone of the second order, then the intersections of opposite faces are three lines in a plane.

Theorem (Brianchon's).—If a solid angle of six edges be circumscribed about a cone of the second order, then the planes through opposite edges meet in a line.

Each of the other theorems about conics may be stated for cones of the second order.

§ 59. We have not yet considered the shape of the conics. We know that any line in the plane of the conic, and hence that the line at infinity, either has no point in common with the curve, or one (counting for two coincident points), or two distinct points. If the line at infinity has no point on the curve the latter is altogether finite, and is called an *Ellipse* (fig. 20). If the line at infinity has only one point in common with the conic, the latter extends to infinity, and has the line at infinity a tangent. It is called a *Parabola* (fig. 21). If, lastly, the line at infinity cuts the curve in two points, it consists of two separate parts which each extend in two branches to the points at infinity where they meet. The curve is in this case called an *Hyperbola* (see fig. 19, 24, or 25). The tangents at the two points at infinity are finite because the line at infinity is not a tangent. They are called *Asymptotes*. The branches of the hyperbola approach these lines indefinitely as a point on the curves moves to infinity.

§ 60. That the circle belongs to the curves of the second order is seen at once if we state in a slightly different form the theorem that in a circle all angles at the circumference standing upon the same arc are equal. If two points S_1, S_2 on a circle be joined to any other two points A and B on the circle, then the angle included by the rays S_1A and S_1B is equal to that between the rays S_2A and S_2B, so that as A moves along the circumference the rays S_1A and S_2A describe equal and therefore projective pencils. The circle can thus be generated by two projective pencils, and is a curve of the second order.

If we join a point in space to all points on a circle, we get a (circular) cone of the second order (§ 43). Every plane section of this cone is a conic. This conic will be an ellipse, a parabola, or an hyperbola, according as the line at infinity in the plane has no, one, or two points in common with the conic in which the plane at infinity cuts the cone. It follows that our curves of second order may be obtained as sections of a circular cone, and that they are identical with the "Conic Sections" of the Greek mathematicians.

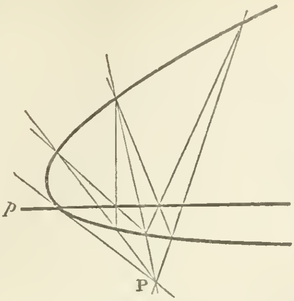

Fig. 21.

§ 61. Any two tangents to a parabola are cut by all others in projective rows; but the line at infinity being one of the tangents, the points at infinity on the rows are corresponding points, and the rows therefore similar. Hence—

THEOREM.—*The tangents to a parabola cut each other proportionally.*

Pole and Polar.

§ 62. We return once again to the remarkable figure (fig. 20) which we obtained in § 55.

If a four-side be circumscribed about and a four-point inscribed in a conic, so that the vertices of the second are the points of contact of the sides of the first, then the triangle formed by the diagonals of the first is the same as that formed by the diagonal points of the other.

Such a triangle will be called a *polar triangle* of the conic, so that PQR in fig. 20 is a polar triangle. It has the property that on the side p opposite P meet the tangents at A and B, and also those at C and D. From the harmonic properties of four-points and four-sides it follows further that the points L, M, where it cuts the lines AB and CD, are harmonic conjugates with regard to AB and CD respectively.

If the point P is given, and we draw a line through it, cutting the conic in A and B, then the point Q harmonic conjugate to P with regard to AB, and the point H where the tangents at A and B meet, are determined. But they lie both on p, and therefore this line is determined. If we now draw a second line through P, cutting the conic in C and D, then the point M harmonic conjugate to P with regard to CD, and the point G where the tangents at C and D meet, must also lie on p. As the first line through P already determines p, the second may be any line through P. Now every two lines through P determine a four-point ABCD on the conic, and therefore a polar-triangle which has one vertex at P and its opposite side at p. This result, together with its reciprocal, give the theorem :—

THEOREM.—*All polar-triangles which have one vertex in common have also the opposite side in common.*

All polar-triangles which have one side in common have also the opposite vertex in common.

§ 63. To any point P in the plane of but not on a conic corresponds thus one line p as the side opposite to P in all polar triangles which have one vertex at P, and reciprocally to every line p corresponds one point P as the vertex opposite to p in all triangles which have p as one side.

We call the line p the *polar* of P, and the point P the *pole* of the line p with regard to the conic.

If a point lies on the conic, we call the tangent at that point its polar; and reciprocally we call the point of contact the pole of tangent.

§ 64. From these definitions and former results follow—

Theorem.—The polar of any point P not on the conic is a line p, which has the following properties :—

1. On every line through P which cuts the conic, it contains the harmonic conjugate of P with regard to those points on the conic.

2. If tangents can be drawn from P, their points of contact lie on p.

3. Tangents drawn at the points where any line through P cuts the conic, meet on it; and conversely,

4. If from any point on it tangents be drawn, their points of contact will lie in a line with P.

5. Any four-point on the conic which has one diagonal point at P has the other two lying on p.

Theorem.—The pole of any line p not a tangent to the conic is a point P, which has the following properties :—

1. Of all lines through a point on p from which two tangents may be drawn to the conic, it contains the line which is harmonic conjugate to p, with regard to the two tangents.

2. If p cuts the conic, the tangents at the intersections meet at P.

3. The point of contact of tangents drawn from any point on p to the conic lie in a line with P; and conversely,

4. Tangents drawn at points where any line through P cuts the conic meet on p.

5. Any four-side circumscribed about a conic which has one diagonal on p has the other two meeting at P.

The truth of 2 follows from 1. If T be a point where p cuts the conic, then one of the points where PT cuts the conic, and which are harmonic conjugates with regard to PT, coincides with T; hence the other does—that is, PT touches the curve at T.

That 4 is true follows thus: If we draw from a point H on the polar one tangent a to the conic, join its point of contact A to the pole P, determine the second point of intersection B of this line with the conic, and draw the tangent at B, it will pass through H, and will therefore be the second tangent which may be drawn from H to the curve.

§ 65. The second property of the polar or pole gives rise to the theorem—

Theorem.—From a point in the plane of a conic, two, one, or no tangents may be drawn to the conic, according as its polar has two, one, or no points in common with the curve.

Theorem.—A line in the plane of a conic has two, one, or no points in common with the conic, according as two, one, or no tangents can be drawn from its pole to the conic.

Of any point in the plane of a conic we say that it was *without*, *on*, or *within* the curve according as two, one, or no tangents to the curve pass through it. The points on the conic separates those within the conic from those without. That this is true for a circle is known from elementary geometry. That it also holds for other conics follows from the fact that every conic may be considered as the projection of a circle, which will be proved later on.

The fifth property of pole and polar stated in § 64 shows how to find the polar of any point and the pole of any line by aid of the straight-edge only. Practically it is often convenient to draw three secants through the pole, and to determine only one of the diagonal points for two of the four-points formed by pairs of these lines and the conic (fig. 21).

These constructions also solve the problem :—

Problem.—From a point without a conic, to draw the two tangents to the conic by aid of the straight-edge only.

For we need only draw the polar of the point in order to find the points of contact.

§ 66. The property of a polar-triangle may now be stated thus—

Theorem.—In a polar-triangle each side is the polar of the opposite vertex, and each vertex is the pole of the opposite side.

If P is one vertex of a polar-triangle, then the other vertices, Q and R, lie on the polar p of P. One of these vertices we may chose arbitrarily. For if from any point Q on the polar a secant be drawn cutting the conic in A and D (fig. 22), and if the lines joining these points to P cut the conic again in B and C, then the line BC will pass through Q. Hence P and Q are two of the vertices on the polar-triangle which is determined by the four-point ABCD. The third vertex R lies also on the line p. It follows, therefore, also—

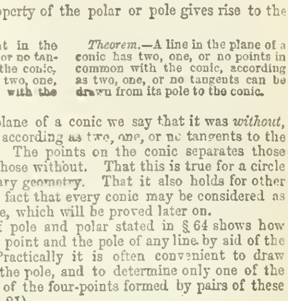

Fig. 22.

THEOREM.—*If* Q *is a point on the polar of* P, *then* P *is a point on the polar of* Q; and reciprocally,

If q *is a line through the pole of* p, *then* p *is a line through the pole of* q.

This is a very important theorem. It may also be stated thus—

THEOREM.—*If a point moves along a line describing a row, its polar turns about the pole of the line describing a pencil.*

This pencil is projective to the row, so that the cross-ratio of four poles in a row equals the cross-ratio of its four polars, which pass through the pole of the row.

To prove the last part, let us suppose that P, A, and B in fig. 22 remain fixed, whilst Q moves along the polar p of P. This will make CD turn about P and move R along p, whilst QD and RD describe projective pencils about A and B. Hence Q and R describe projective rows, and hence PR, which is the polar of Q, describes a pencil projective to either.

§ 67. Two points, of which one, and therefore each, lies on the polar of the other, are said to be *conjugate with regard to the conic*; and two lines, of which one, and therefore each, passes through the pole of the other, are said to be *conjugate with regard to the conic*. Hence all points conjugate to a point P lie on the polar of P; all lines conjugate to a line p pass through the pole of p.

If the line joining two conjugate poles cuts the conic, then the poles are harmonic conjugates with regard to the points of intersection; hence one lies within the other without the conic, and all points conjugate to a point within a conic lie without it.

Of a polar-triangle any two vertices are conjugate poles, any two sides conjugate lines. If, therefore, one side cuts a conic, then one of the two vertices which lie on this side is within and the other without the conic. The vertex opposite this side lies also without, for it is the pole of a line which cuts the curve. In this case therefore one vertex lies within, the other two without. If, on the other hand, we begin with a side which does not cut the conic, then its pole lies within and the other vertices without. Hence—

Theorem.—Every polar triangle has one and only one vertex within the conic.

We add, without a proof, the theorem—

Theorem.—The four points in which a conic is cut by two conjugate polars are four harmonic points in the conic.

§ 68. If two conics intersect in four points (they cannot have more points in common, § 52), there exists one and only one four-point which is inscribed in both, and therefore one polar triangle common to both.

Theorem.—Two conics which intersect in four points have always one and only one common polar-triangle; and reciprocally,

Two conics which have four common tangents have always one and only one common polar-triangle.

The proof that these polar triangles are identical in case of a conic which have four points and also four tangents in common is left to the reader.

Diameters and Axes of Conics.

§ 69. *Diameters.*—The theorems about the harmonic properties of poles and polars contain, as special cases, a number of important metrical properties of conics. These are obtained if either the pole or the polar is moved to infinity,—it being remembered that the harmonic conjugate to a point at infinity, with regard to two points A, B, is the middle point of the segment AB. The most important properties are stated in the following theorems:—

The middle points of parallel chords of a conic lie in a line—viz., on the polar to the point at infinity on the parallel chords.

This line is called a *diameter*.

The polar of every point at infinity is a diameter.

The tangents at the end points of a diameter are parallel, and are parallel to the chords bisected by the diameter.

All diameters pass through a common point, the pole of the line at infinity.

All diameters of a parabola are parallel, the pole to the line at infinity being the point where the curve touches the line at infinity.

In case of the ellipse and hyperbola, the pole to the line at infinity is a finite point called the *centre* of the curve.

A centre of a conic bisects every chord through it.

The centre of an ellipse is within the curve, for the line at infinity does not cut the ellipse.

The centre of an hyperbola is without the curve, because the line at infinity cuts the curve. Hence also

From the centre of an hyperbola two tangents can be drawn to the curve which have their point of contact at infinity. These are called *Asymptotes* (§ 59).

To construct a diameter of a conic, draw two parallel chords and join their middle points.

To find the centre of a conic, draw two diameters; their intersection will be the centre.

§ 70. *Conjugate Diameters.*—A polar-triangle with one vertex at the centre will have the opposite side at infinity. The other two sides pass through the centre, and are called *conjugate diameters*, each being the polar of the point at infinity on the other.

Of two conjugate diameters each bisects the chords parallel to the other, and if one cuts the curve, the tangents at its ends are parallel to the other diameter.

Further—

Every parallelogram inscribed in a conic has its sides parallel to two conjugate diameters; and

Every parallelogram circumscribed about a conic has as diagonals two conjugate diameters.

This will be seen by considering the parallelogram in the first case as an inscribed four-point, in the other as a circumscribed four-side, and determining in each case the corresponding polar-triangle. The first may also be enunciated thus—

The lines which join any point on an ellipse or an hyperbola to the ends of a diameter are parallel to two conjugate diameters.

§ 71. The Circle.—*If every diameter is perpendicular to its conjugate the conic is a circle.*

For the line which joins the ends of a diameter to any point on the curve include a right angle.

A conic which has more than one pair of conjugate diameters at right angles to each other is a circle.

Let AA′ and BB′ (fig. 23) be one pair of conjugate diameters at right angles to each other, CC′ and DD′ a second pair. If we draw through the end point A of one diameter a chord AP parallel to DD′, and join P to A′, then PA and PA′ are, according to § 70, parallel to two conjugate diameters. But PA is parallel to DD′, hence PA′ is parallel to CC′, and therefore PA and PA′ are perpendicular. If we further draw the tangents to the conic at A and A′, these will be perpendicular to AA′, they being parallel to the conjugate diameter BB′. We know thus five points on the conic, viz., the points A and A′ with their tangents, and the point P. Through these a circle may be drawn having AA′ as diameter; and as through five points one conic only can be drawn, this circle must coincide with the given conic.

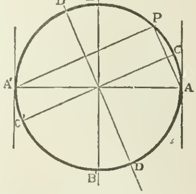

Fig. 23.

§ 72. *Axes.*—Conjugate diameters perpendicular to each other are called *axes*, and the points where they cut the curve *vertices* of the conic.

In a circle every diameter is an axis, every point on it is a vertex; and any two lines at right angles to each other may be taken as a pair of axes of any circle which has its centre at their intersection.

If we describe on a diameter AB of an ellipse or hyperbola a circle concentric to the conic, it will cut the latter in A and B (fig. 24). Each of the semicircles in which it is divided by AB will be partly within, partly without the curve, and must cut the latter therefore again in a point. The circle and the conic have thus four points A, B, C, D, and therefore one polar-triangle, in common (§ 68). Of this the centre is one vertex, for the line at infinity is the polar to this point, both with regard to the circle and the other conic. The other two sides are conjugate diameters of both, hence perpendicular to each other. This gives—

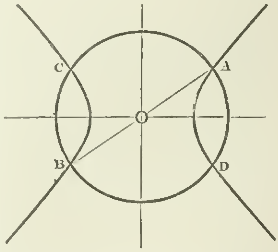

Fig. 24.

Theorem.—An ellipse as well as an hyperbola has one pair of axes.

This reasoning shows at the same time *how to construct the axis of an ellipse or of an hyperbola.*

A parabola has one axis, if we define an axis as a diameter perpendicular to the chords which it bisects. It is easily constructed. The line which bisects any two parallel chords is a diameter. Chords perpendicular to it will be bisected by a parallel diameter, and this is the axis.

§ 73. The first part of the right hand theorem in § 64 may be stated thus: any two conjugate lines through a point P without a conic are harmonic conjugates with regard to the two tangents that may be drawn from P to the conic.

If we take instead of P the centre C of an hyperbola, then the conjugate lines become conjugate diameters, and the tangents asymptotes. Hence—

Theorem.—Any two conjugate diameters of an hyperbola are harmonic conjugates with regard to the asymptotes.

As the axes are conjugate diameters at right angles to one another, it follows (§ 23)—

Theorem.—The axes of an hyperbola bisect the angles between the asymptotes.

Let O be the centre of the hyperbola (fig. 25), t any secant which cuts the hyperbola in C,D and the asymptotes in E,F, then the line OH which bisects the chord CD is a diameter conjugate to the diameter OK which is parallel to the secant t, so that OK and OM are harmonic with regard to the asymptotes. The point M therefore bisects EF. But by construction M bisects CD. It follows that DF = EC, and ED = CF; or

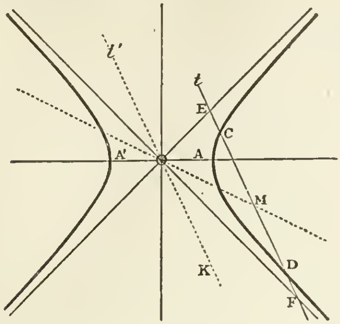

Fig. 25.

THEOREM.—*On any secant of an hyperbola the segments between the curve and the asymptotes are equal.*

If the chord is changed into a tangent, this gives

The segment between the asymptotes on any tangent to an hyperbola is bisected by the point of contact.

The first part allows a simple solution of the problem to find any number of points on an hyperbola, of which the asymptotes and one point are given. This is equivalent to three points and the tangents at two of them. This construction requires measurement.

§ 74. For the parabola, too, follow some metrical properties. A diameter PM (fig. 26) bisects every chord conjugate to it, and the pole P of such a chord BC lies on the diameter. But a diameter cuts the parabola once at infinity. Hence—

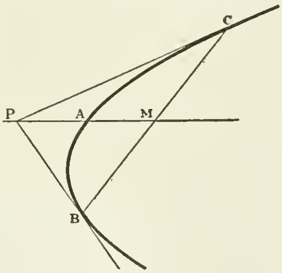

Fig 26.

Theorem.—The segment PM which joins the middle point M of a chord of a parabola to the pole P of the chord is bisected by the parabola at A.

§ 75. Two asymptotes and any two tangents to an hyperbola may be considered as a quadrilateral circumscribed about the hyperbola. But in such a quadrilateral the intersections of the

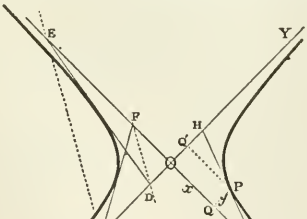

Fig. 27.

diagonals and the points of contact of opposite sides lie in a line (§ 54). If therefore DEFG (fig. 27) is such a quadrilateral, then the diagonals DF and GE will meet on the line which joins the points of contact of the asymptotes, that is, on the line at infinity; hence they are parallel. From this the following theorem is a simple deduction:—

Theorem.—All triangles formed by a tangent and the asymptotes of an hyperbola are equal in area.

If we draw at a point P (fig. 27) on an hyperbola a tangent, the part HK between the asymptotes is bisected at P. The parallelogram PQOQ' formed by the asymptotes and lines parallel to them through P will be half the triangle OHK, and will therefore be constant. If we now take the asymptotes OX and OY as oblique axes of coordinates, the lines OQ and QP will be the coordinates of P, and will satisfy the equation $xy = \text{const.} = a^2$.

Theorem.—For the asymptotes as axes of coordinates the equation of the hyperbola is

$$xy = \text{const.}$$

It is not difficult to get the equations to the ellipse and hyperbola referred to their axes as axes of coordinates. We are satisfied to have shown in one case that the curves of the second order as generated by projective pencils are the same as those which are in coordinate geometry defined by equations of the second degree.

INVOLUTION.

§ 76. If we have two projective rows, ABC on u and A'B'C' on u', and place their bases on the same line, then each point in this line counts twice, once as a point in the row u and once as a point in the row u'. In fig. 28 we denote the points as points in the one row by letters above the line A, B, C . . ., and as points in the second row by A', B', C' . . . . below the line. Let now A and B' be the same point, then to A will correspond a point A' in the second, and to B' a point B in the first row. In general these points A' and B will be different. It may, however, happen that they coincide. Then the correspondence is a peculiar one, as the following theorem shows:—

Fig. 28.

THEOREM.—*If two projective rows lie on the same base, and if it happens that to one point in the base the same point corresponds, whether we consider the point as belonging to the first or to the second row, then the same will happen for every point in the base—that is to say, to every point in the line corresponds the same point in the first as in the second row.*

Proof. In order to determine the correspondence, we may assume three pairs of corresponding points in two projective rows. Let then A', B', C', in fig. 29, correspond to A, B, C, so that A and B', and also B and A', denote the same point. Let us further denote the point C' when considered as a point in the first row by D; then it is to be proved that the point D', which corresponds to D, is the same point as C. We know that the cross-ratio of four points is equal to that of the corresponding row. Hence

Fig. 29.

$$(ABCD) = (A'B'C'D')$$

but replacing the dashed letters by those undashed ones which denote the same points, the second cross-ratio equals (BADD'), which, according to § 15, iv., equals (ABD'D); so that the equation becomes

$$(ABCD) = (ABD'D).$$

This requires that C and D' coincide.

§ 77. Two projective rows on the same base, which have the above property, that to every point, whether it be considered as a point in the one or in the other row, corresponds the same point, are said to be in *involution*, or to form an *involution* of points on the line.

We mention, but without proving it, that any two projective rows may be placed so as to form an involution.

An involution may be said to consist of a row of pairs of points, to every point A corresponding a point A', and to A' again the point A. These points are said to be conjugate.

From the definition, according to which an involution may be considered as made up of two projective rows, follow at once the following important properties:—

(1.) The cross-ratio of four points equals that of the four conjugate points.

(2.) If we call a point which coincides with its conjugate point a "focus" of the involution, we may say: An involution has either two foci, or one, or none, and is called respectively a hyperbolic, parabolic, or elliptic involution (§ 34).

(3.) In a hyperbolic involution any two conjugate points are harmonic conjugates with regard to the two foci.

For if A, A' be two conjugate points, F_1, F_2 the two foci, then to the points F_1, F_2, A, A' in the one row correspond the points F_1, F_2, A', A in the other, each focus corresponding to itself. Hence $(F_1F_2AA') = (F_1F_2A'A)$—that is, we may interchange the two points AA' without altering the value of the cross-ratio, which is the characteristic property of harmonic conjugates (§ 18).

(4.) The point conjugate to the point at infinity is called the "centre" of the involution. Every involution has a centre, unless the point at infinity be a focus, in which case we may say that the centre is at infinity.

In a hyperbolic involution the centre is the middle point between the foci.

(5.) The product of the distances of two conjugate points A, A′ from the centre O is constant:—

$$OA . OA' = c.$$

Proof.—Let A, A′, and B, B′ be two pairs of conjugate points, O the centre, I the point at infinity, then

$$(ABOI) = (A'B'IO),$$

or

$$OA . OA' = OB . OB'.$$

In order to determine the distances of the foci from the centre, we write F for A and A′ and get

$$\overline{OF}^2 = c;\ OF = \pm\sqrt{c}.$$

Hence if c is positive OF is real, and has two values, equal and opposite. The involution is hyperbolic.

If $c = 0$, $OF = 0$, and the two foci both coincide with the centre.

If c is negative, $\sqrt{c}$ becomes imaginary, and there are no foci. Hence we may write—

In a hyperbolic involution, $OA . OA' = k^2$,
In a parabolic involution, $OA . OA' = 0$,
In an elliptic involution, $OA . OA' = -k^2$.

From these expressions it follows that conjugate points A, A′ in a hyperbolic involution lie on the same side of the centre, and in an elliptic involution on opposite sides of the centre, and that in a parabolic involution one coincides with the centre.

In the first case, for instance, OA . OA′ is positive; hence OA and OA′ have the same sign.

It also follows that two segments, AA′ and BB′, between pairs of conjugate points have the following positions:—in a hyperbolic involution they lie either one altogether within or altogether without each other; in a parabolic involution they have one point in common; and in an elliptic involution they overlap, each being partly within and partly without the other.

Proof.—We have $OA . OA' = OB . OB' = k^2$ in case of a hyperbolic involution. Let A and B be the points in each pair which are nearer to the centre O. If now A, A′ and B, B′ lie on the same side of O, and if B is nearer to O than A, so that $OB < OA$, then $OB' > OA'$; hence B′ lies further away from O than A′, or the segment AA′ lies within BB′. And so on for the other cases.

(6.) An involution is determined—

(α) By two pairs of conjugate points. Hence also
(β) By one pair of conjugate points and the centre;
(γ) By the two foci;
(δ) By one focus and one pair of conjugate points;
(ε) By one focus and the centre.

(7.) The condition that A, B, C and A′, B′, C′ may form an involution may be written in one of the forms—

$$(ABCC') = (A'B'C'C),$$

or

$$(ABCA') = (A'B'C'A),$$

or

$$(ABC'A') = (A'B'CA),$$

for each expresses that in the two projective rows in which A, B, C and A′, B′, C′ are conjugate points two conjugate elements may be interchanged.

(8.) Any three pairs, A, A′, B, B′, C, C′, of conjugate points are connected by the relation—

$$\frac{BA'}{A'C} \cdot \frac{CB'}{B'A} \cdot \frac{AC'}{C'B} = -1.$$

Proof.—We have by (7) $(ABC'A') = (A'B'CA)$, which, when worked out, gives the above relation.

The latter is easily remembered by aid of the following rule of writing the first side. First write

$$\frac{B\ \ \ C\ \ \ A}{\ \ C\ \ \ A\ \ \ B},$$

and then fill up the gaps in numerator and denominator by A′, B′, C′ respectively.

§ 78. Theorem.—*The sides of any four-point are cut by any line in six points in involution, opposite sides being cut in conjugate points.*

Let $A_1B_1C_1D_1$ (fig. 30) be the four-point. If its sides be cut by the line p in the points A, A′, B, B′, C, C′, if further, C_1D_1 cuts the line A_1B_1 in C_2, and if we project the row $A.B.C_2C$ to p once from D_1 and once from C_1, we get

$$(A'B'C'C) = (BAC'C).$$

Interchanging in the last cross-ratio the letters in each pair we get

$$(A'B'C'C) = (ABCC').$$

Hence by § 77 (7) the points are in involution.

The theorem may also be stated thus:—

Theorem.—The three points in which any line cuts the sides of a triangle and the projections, from any point in the plane, of the vertices of the triangle on to the same line are six points in involution.

Or again—

The projections from any point on to any line of the six vertices

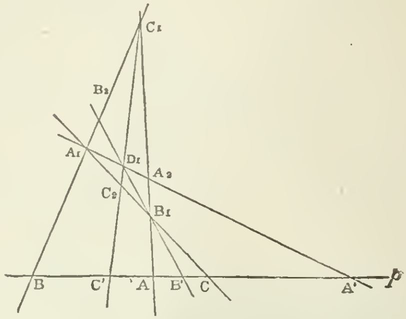

Fig 30.

of a four-side are six points in involution, the projections of opposite vertices being conjugate points.

This property gives a simple means to construct, by aid of the straight edge only, in an involution of which two pairs of conjugate points are given, to any point its conjugate.

§ 79. The theory of involution may at once be extended from the row to the flat and the axial pencil—viz., we say that there is an involution in a flat or in an axial pencil if any line cuts the pencil in an involution of points. An involution in a pencil consists of pairs of conjugate rays or planes; it has two, one, or no *focal rays* or *planes*, but nothing corresponding to a centre.

An involution in a flat pencil contains always one, and in general only one, pair of conjugate rays which are perpendicular to one another. For in two projective flat pencils exist always two corresponding right angles (§ 40).

Each involution in an axial pencil contains in the same manner one pair of conjugate planes at right angles to one another.

As a rule, there exists but one pair of conjugate lines or planes at right angles to each other. But it is possible that there are more, and then there is an infinite number of such pairs. An involution in a flat pencil, in which every ray is perpendicular to its conjugate ray, is said to be *circular*. That such involution is possible is easily seen thus:—if in two concentric flat pencils each ray on one is made to correspond to that ray on the other which is perpendicular to it, then the two pencils are projective, for if we turn the one pencil through a right angle each ray in one coincides with its corresponding ray in the other. But these two projective pencils are in involution.

A circular involution has no focal rays, because no ray in a pencil coincides with the ray perpendicular to it.

§ 80. Theorem.—*Every elliptical involution in a row may be considered as a section of a circular involution.*

Proof.—In an elliptical involution any two segments AA′ and BB′ lie partly within partly without each other (fig. 31). Hence two circles described on AA′ and BB′ as diameters will intersect in two points E and E′. The line EE′ cuts the base of the involution at a point O, which, from a well known proposition (Eucl. III. 35), has the property that OA.OA′ = OB.OB′, for each is equal to OE . OE′. The point O is therefore the centre of the involution. If we wish to construct to any

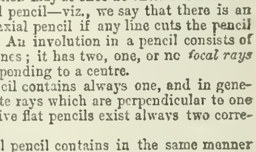

Fig. 31.

point C the conjugate point C′, we may draw the circle through CEE′. This will cut the base in the required point C′ for OC.OC′ = OA.OA′. But EC and EC′ are at right angles. Hence the involution which is obtained by joining E or E′ to the points in the given involution is circular. This may also be expressed thus:—

Every elliptical involution has the property that there are two definite points in the plane, from which any two conjugate points are seen under a right angle.

At the same time the following problem has been solved :—

Problem.—To determine the centre and also the point corresponding to any given point in an elliptical involution of which two pairs of conjugate points are given.

§ 81. By the aid of § 53, the points on a conic may be made to correspond to those on a line, so that the row of points on the conic is projective to a row of points on a line. We may also have two projective rows on the same conic, and these will be in involution as soon as one point on the conic has the same point corresponding to it all the same to whatever row it belongs. An involution of points on a conic will have the property (as follows from its definition, and from § 53) that the lines which join conjugate points of the involution to any point on the conic are conjugate lines of an involution in a pencil, and that a fixed tangent is cut by the tangents at conjugate points on the conic in points which are again conjugate points of an involution on the fixed tangent. For such involution on a conic the following theorem holds :—

THEOREM.—*The lines which join corresponding points in an involution on a conic all pass through a fixed point*; and reciprocally, *the points of intersection of conjugate lines in an involution among tangents to a conic lie on a line.*

We prove the first part only. The involution is determined by two pairs of conjugate points, say by A, A′ and B, B′ (fig. 32). Let AA′ and BB′ meet in P. If we join the points in involution to any point on the conic, and the conjugate points to another point on the conic,

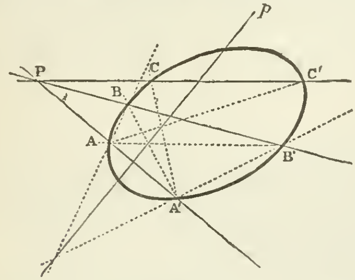

Fig. 32.

we obtain two projective pencils. We take A and A′ as centres of these pencils, so that the pencils A(A′BB′) and A′(AB′B) are projective, and in perspective position, because AA′ corresponds to A′A. Hence corresponding rays meet in a line, of which two points are found by joining AB′ to A′B and AB to A′B′. It follows that the *axis* of perspective is the polar of the point P, where AA′ and BB′ meet. If we now wish to construct to any other point C on the conic the corresponding point C′, we join C to A′ and the point where this line cuts p to A. The latter line cuts the conic again in C′. But we know from the theory of pole and polar that the line CC′ passes through P.

INVOLUTION DETERMINED BY A CONIC ON A LINE.—FOCI.

§ 82. The polars, with regard to a conic, of points in a row p form a pencil P projective to the row (§ 66). This pencil cuts the base of the row p in a projective row.

If A is a point in the given row, A′ the point where the polar of A cuts p, then A and A′ will be corresponding points. If we take A′ a point in the first row, then the polar of A′ will pass through A, so that A corresponds to A′—in other words, the rows are in involution. The conjugate points in this involution are conjugate points with regard to the conic. Conjugate points coincide only if the polar of a point A passes through A—that is, if A lies on the conic. Hence—

THEOREM.—*A conic determines on every line in its plane an involution, in which those points are conjugate which are also conjugate with regard to the conic.*

If the line cuts the conic the involution is hyperbolic, the points of intersection being the foci.

If the line touches the conic the involution is parabolic, the two foci coinciding at the point of contact.

If the line does not cut the conic the involution is elliptic, having no foci.

If, on the other hand, we take a point P in the plain of a conic, we get to each line a through P one conjugate line which joins P to the pole of a. These pairs of conjugate lines through P form an involution in the pencil at P. The focal rays of this involution are the tangents drawn from P to the conic. This gives the theorem reciprocal to the last, viz. :—

THEOREM.—*A conic determines in every pencil in its plane an involution, corresponding lines being conjugate lines with regard to the conic.*

If the point is without the conic the involution is hyperbolic, the tangents from the points being the focal rays.

If the point lies on the conic the involution is parabolic, the tangent at the point counting for coincident focal rays.

If the point is within the conic the involution is elliptic, having no focal rays.

It will further be seen that the involution determined by a conic on any line p is a section of the involution, which is determined by the conic at the pole P of p.

§ 83. *Definition.*—The centre of a pencil in which the conic determines a circular involution is called a "focus" of the conic.

In other words—

A focus is such a point that every line through it is perpendicular to its conjugate line.

The polar to a focus is called a *directrix* of the conic.

From the definition it follows that :—

Every focus lies on an axis, for the line joining a focus to the centre of the conic is a diameter to which the conjugate lines are perpendicular ; and

Every line joining two foci is an axis, for the perpendiculars to this line through the foci are conjugate to it. These conjugate lines pass through the pole of the line, the pole lies therefore at infinity, and the line is a diameter, hence by the last property an axis.

It follows that all *foci lie on one axis*, for no line joining a point in one axis to a point in the other can be an axis.

As the conic determines in the pencil which has its centre at a focus a circular involution, no tangents can be drawn from the focus to the conic. Hence *each focus lies within a conic*; and *a directrix does not cut the conic.*

Further properties are found by the following considerations :—

§ 84. Through a point P one line p can be drawn, which is with regard to a given conic conjugate to a given line q, viz., that line which joins the point P to the pole of the line q. If the line q is made to describe a pencil about a point Q, then the line p will describe a pencil about P. These two pencils will be projective, for the line p passes through the pole of q, and whilst q describes the pencil Q, its pole describes a projective row, and this row is perspective to the pencil P.

We now take the point P on an axis of the conic, draw any line p through it, and from the pole of p draw a perpendicular q to p. Let q cut the axis in Q. Then, in the pencils of conjugate lines, which have their centres at P and Q, the lines p and q are conjugate lines at right angles to one another. Besides, to the axis as a ray in either pencil will correspond in the other the perpendicular to the axis (§ 72). The conic generated by the intersection of corresponding lines in the two pencils is therefore the circle on PQ as diameter, *so that every line in P is perpendicular to its corresponding line in Q.*

To every point P on an axis of a conic corresponds thus a point Q, such that conjugate lines through P and Q are perpendicular.

We shall show that these *point-pairs P, Q form an involution.* To do this let us move P along the axis, and with it the line p, keeping the latter parallel to itself. Then P describes a row, p a perspective pencil (of parallels), and the pole of p a projective row. At the same time the line q describes a pencil of parallels perpendicular to p, and perspective to the row formed by the pole of p. The point Q, therefore, where q cuts the axis, describes a row projective to the row of points P. The two points P and Q describe thus two projective rows on the axis ; and not only does P as a point in the first row correspond to Q, but also Q as a point in the first corresponds to P. The two rows therefore form an involution. *The centre of this involution, it is easily seen, is the centre of the conic.*

A focus of this involution has the property that any two conjugate lines through it are perpendicular ; hence, it is a focus to the conic.

Such involution exists on each axis. But only one of these can have foci, because all foci lie on the same axis. The involution on one of the axis is elliptic, and appears (§ 80) therefore as the section of two circular involutions in two pencils whose centres lie in the other axis. These centres are foci, hence the one axis contains two foci, the other axis none ; *or every central conic has two foci which lie on one axis equidistant from the centre.*

The axis which contains the foci is called the *principal axis* ; in case of an hyperbola it is the axis which cuts the curve, because the foci lie within the conic.

In case of the parabola there is but one axis. The involution on this axis has its centre at infinity. One focus is therefore at infinity, the one focus only is finite. *A parabola has only one focus.*

§ 85. If through any point P (fig. 33) on a conic the tangent PT and the normal PN (*i.e.*, the perpendicular to the tangent through the point of contact) be drawn, these will be conjugate lines with regard to the conic, and at right angles to each other.

They will therefore cut the principal axis in two points, which are conjugate in the involution considered in § 84; hence they are harmonic conjugates with regard to the foci. If therefore the two foci F_1 and F_2 be joined to P, these lines will be harmonic with

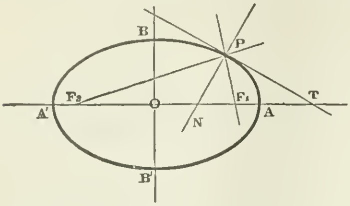

Fig. 33.

regard to the tangent and normal. As the latter are perpendicular, they will bisect the angles between the other pair. Hence—

The line joining any point on a conic to the two foci are equally inclined to the tangent and normal at that point.

In case of the parabola this becomes—

The line joining any point on a parabola to the focus and the diameter through the point, are equally inclined to the tangent and normal at that point.

From the definition of a focus it follows that—

The segment of a tangent between the directrix and the point of contact is seen from the focus belonging to the directrix under a right angle, because the lines joining the focus to the ends of this segment are conjugate with regard to the conic, and therefore perpendicular.

With equal ease the following theorem is proved :—

The two lines which join the points of contact of two tangents each to one focus, but not both to the same, are seen from the intersection of the tangents under equal angles.

§ 86. Other focal properties of a conic are obtained by the following considerations :—

Let F (fig. 34) be a focus to a conic, f the corresponding directrix, A and B the points of contact of two tangents meeting at T, and P the point where the line AB cuts the directrix. Then TF will be the polar of P (because polars of F and T meet at P). Hence TF

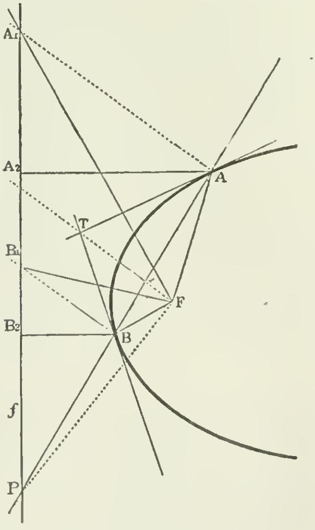

Fig. 34.

and PF are conjugate lines through a focus, and therefore perpendicular. They are further harmonic conjugates with regard to FA and FB (§§ 64 and 13), so that they bisect the angles formed by these lines. This by the way proves—

The segments between the point of intersection of two tangents to a conic and their points of contact are seen from a focus under equal angles.

If we next draw through A and B lines parallel to TF, then the points A_1, B_1 where these cut the directrix will be harmonic conjugates with regard to P and the point where FT cuts the directrix. The lines FT and FP bisect therefore also the angles between FA_1 and FB_1. From this it follows easily that the triangles FAA_1 and FBB_1 are equiangular, and therefore similar, so that

$$FA : AA_1 = FB : BB_1.$$

The triangles AA_1A_2 and BB_1B_2 formed by drawing perpendiculars from A and B to the directrix are also similar, so that $AA_1 : AA_2 = BB_1 : BB_2$.

This, combined with the above proportion, gives

$$FA : AA_2 = FB : BB_2.$$

Hence the theorem :—

The ratio of the distances of any point on a conic from a focus and the corresponding directrix is constant.

To determine this ratio we consider its value for a vertex on the principal axis. In an ellipse the focus lies between the two vertices on this axis, hence the focus is nearer to a vertex than to the corresponding directrix. Similarly in an hyperbola a vertex is nearer to the directrix than to the focus. In a parabola the vertex lies halfway between directrix and focus.

It follows in an ellipse the ratio between the distance of a point from the focus to that from the directrix is less than unity, in the parabola it equals unity, and in the hyperbola it is greater then unity.

It is here the same which focus we take, because the two foci lie symmetrical to the axis of the conic. If now P is any point on the conic having the distances r_1 and r_2 from the foci and the distances d_1 and d_2 from the corresponding directrices, then

$$\frac{r_1}{d_1} = \frac{r_2}{d_2} = e,$$

where e is constant. Hence also $\dfrac{r_1 \pm r_2}{d_1 \pm d_2} = e.$

In the ellipse, which lies between the directrices, $d_1 + d_2$ is constant, therefore also $r_1 + r_2$. In the hyperbola on the other hand $d_1 - d_2$ is constant, equal to the distance between the directrices, therefore in this case $r_1 - r_2$ is constant.

If we call the distances of a point on a conic from the focus its focal distances we have the theorem :—

In an ellipse the sum of the focal distances is constant; and in an hyperbola the difference of the focal distances is constant.

This constant sum or difference equals in both cases the length of the principal axis.

Pencil of Conics.

§ 87. Through four points A, B, C, D in a plane, of which no three lie in a line, an infinite number of conics may be drawn, viz., through these four points and any fifth one single conic. *This system of conics is called a pencil of conics.* Similarly all conics touching four fixed lines form a system such that any fifth tangent determines one and only one conic. We have here the theorems :—

Theorem.—The pairs of points in which any line is cut by a system of conics through four fixed points are in involution.	*Theorem.*—The pairs of tangents which can be drawn from a point to a system of conics touching four fixed lines are in involution.

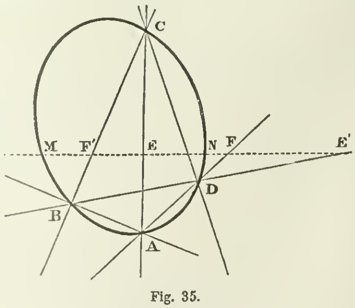

Fig. 35.

We prove the first theorem only. Let ABCD (fig. 35) be the four-point, then any line t will cut two opposite sides AC, BD in the points E, E′, the pair AD, BC in points F, F′, and any conic of the system in M, N, and we have

$$A(CDMN) = B(CDMN).$$

If we cut these pencils by t we get

$$(EFMN) = (F'E'MN)$$

or

$$(EFMN) = (E'F'NM).$$

But this is, according to § 77 (7), the condition that M, N are corresponding points in the involution determined by the point pairs E, E', F, F' in which the line t cuts pairs of opposite sides of the four-point ABCD. This involution is independent of the particular conic chosen.

§ 88. There follow several important consequences:—

THEOREM.—*Through four points two, one, or no conic may be drawn which touch any given line, according as the involution determined by the given four-point on the line has real, coincident, or imaginary foci.*

THEOREM.—*Two, one, or no conics may be drawn which touch four given lines and pass through a given point, according as the involution determined by the given four-side at the point has real, coincident, or imaginary focal rays.*

For the conic through four points which touches a given line has its point of contact at a focus of the involution determined by the four-point on the line.

As a special case we get, by taking the line at infinity:—

THEOREM.—*Through four points of which none is at infinity either two or no parabolas may be drawn.*

The problem of drawing a conic through four points and touching a given line is solved by determining the points of contact on the line, that is, by determining the foci of the involution in which the line cuts the sides of the four-point. The corresponding remark holds for the problem of drawing the conics which touch four lines and pass through a given point.

Ruled Quadric Surfaces.

§ 89. Formerly we have considered projective rows which lie in the same plane. In that case, lines joining corresponding points envelope a conic. We shall now consider projective rows whose bases do not meet. In this case, corresponding points will be joined by lines which do not lie in a plane, but on some surface, which like every surface generated by lines is called a *ruled* surface. This surface clearly contains the bases of the two rows.

If the points in either row be joined to the base of the other, we obtain two axial pencils which are also projective, those planes being corresponding which pass through corresponding points in the given rows. If A, A' be two corresponding points, α, α' the planes in the axial pencils passing through them, then AA' will be the line of intersection of the corresponding planes α, α', and also the line joining corresponding points in the rows.

If we cut the whole figure by a plane this will cut the axial pencils in two projective flat pencils, and the curve of the second order generated by these will be the curve in which the plane cuts the surface. Hence

THEOREM.—*The locus of lines joining corresponding points in two projective rows which do not lie in the same plane is a surface which contains the bases of the rows, and which can also be generated by the lines of intersection of corresponding planes in two projective axial pencils. This surface is cut by every plane in a curve of the second order, hence either in a conic or in a line-pair. No line which does not lie altogether on the surface can have more than two points in common with the surface, which is therefore said to be of the second order, or is called a ruled quadric surface.*

That no line which does not lie on the surface can cut the surface in more than two points is seen at once if a plane be drawn through the line, for this will cut the surface in a conic. It follows also that

A line which contains more than two points of the surface lies altogether on the surface.

§ 90. Through any point in space one line can always be drawn cutting two given lines which do not themselves meet.

If therefore three lines in space be given of which no two meet, then through every point in either one line may be drawn cutting the other two.

THEOREM.—*If a line moves so that it always cuts three given lines of which no two meet, then it generates a ruled quadric surface.*

Proof.—Let a, b, c be the given lines, and p, q, r .... lines cutting them in the points A, A', A''. . . ; B, B', B''. . . ; C, C', C''. . . respectively; then the planes through a containing p, q, r, and the planes through b containing the same lines, may be taken as corresponding planes in two axial pencils which are projective, because both pencils cut the line c in the same row C, C', C''. . . ; the surface can therefore be generated by projective axial pencils.

Of the lines p, q, r . . . no two can meet, for otherwise the lines a, b, c which cut them would also lie in their plane. There is a single infinite number of them, for one passes through each point of a. These lines are said to form a *set* of lines on the surface.

If now three of the lines p, q, r be taken, then every line d cutting them will have three points in common with the surface, and will therefore lie altogether on it. This gives rise to a second set of lines on the surface. From what has been said the theorem follows:—

THEOREM.—*A ruled quadric surface contains two sets of straight lines. Every line of one set cuts every line of the other, but no two lines of the same set meet.*

Any two lines of the same set may be taken as bases of two projective rows, or of two projective pencils which generate the surface. They are cut by the lines of the other set in two projective rows.

The plane at infinity like every other plane cuts the surface either in a conic proper or in a line-pair. In the first case the surface is called an *Hyperboloid of one sheet*, in the second an *Hyperbolic Paraboloid.*

The latter may be generated by a line cutting three lines of which one lies at infinity that is, cutting two lines and remaining parallel to a given plane.

Quadric Surfaces.

§ 91. The conics, the cones of the second order, and the ruled quadric surfaces complete the figures which can be generated by projective rows or flat and axial pencils, that is, by those aggregates of elements which are of one dimension (§§ 5, 6). We shall now consider the simpler figures which are generated by aggregates of two dimensions. The space at our disposal will not, however, allow us to do more than indicate a few of the results.

§ 92. We establish a correspondence between the lines and planes in pencils in space, or reciprocally between the points and lines in two or more planes, but consider principally pencils.

In two pencils we may either make planes correspond to planes and lines to lines, or else planes to lines and lines to planes. If hereby the condition be satisfied that to a flat, or axial, pencil corresponds in the first case a projective flat, or axial, pencil, and in the second a projective axial, or flat, pencil, the pencils are said to be *projective* in the first case and *reciprocal* in the second.

For instance, two pencils which join two points S_1 and S_2 to the different points and lines in a given plane π are projective (and in perspective position), if those lines and planes be taken as corresponding which meet the plane π in the same point or in the same line. In this case every plane through both centres S_1 and S_2 of the two pencils will correspond to itself. If these pencils are brought into any other position they will be projective (but not perspective).

The correspondence between two projective pencils is uniquely determined, if to four rays (or planes) in the one the corresponding rays (or planes) in the other are given, provided that no three rays of either set lie in a plane.

Proof.—Let a, b, c, d be four rays in the one, a', b', c', d' the corresponding rays in the other pencil. We shall show that we can find for every ray e in the first a single corresponding ray e' in the second. To the axial pencil a (b, c, d . . .) formed by the planes which join a to b, c, d . . . , respectively corresponds the axial pencil a' (b', c', d . . .), and this correspondence is determined. Hence, the plane $a'e'$ which corresponds to the plane ae is determined. Similarly the plane $b'c'$ may be found and both together determine the ray e'.

Similarly the correspondence between two reciprocal pencils is determined if for four rays in the one the corresponding planes in the other are given.

§ 93. We may now combine—

1. Two reciprocal pencils.
   Each ray cuts its corresponding plane in a point, the locus of these points is a quadric surface.
2. Two projective pencils.
   Each plane cuts its corresponding plane in a line, but a ray as a rule does not cut its corresponding ray. The locus of points where a ray cuts its corresponding ray is a twisted cubic. The lines where a plane cuts its corresponding plane are secants
3. Three projective pencils.
   The locus of intersection of corresponding planes is a cubic surface.

Of these we consider only the first two cases.

§ 94. If two pencils are reciprocal, then to a plane in either corresponds a line in the other, to a flat pencil an axial pencil, and so on. Every line cuts its corresponding plane in a point. If S_1 and S_2 be the centres of the two pencils, and P be a point where a line a_1 in the first cuts its corresponding plane α_2, *then the line b_2 in the pencil S_2 which passes through* P *will meet its corresponding plane β_1 in* P. For b_2 is a line in the plane α_2. The corresponding plane β_1 must therefore pass through the line a_1, hence through P.

The points in which the lines in S_1 cut the planes corresponding to them in S_2 are therefore the same as the points in which the lines in S_2 cut the planes corresponding to them in S_1.

The locus of these points is a surface which is cut by a plane in a conic or in a line-pair and by a line in not more than two points unless it lies altogether on the surface. The surface itself is therefore called a quadric surface, or a surface of the second order.

To prove this we consider any line p in space.

The flat pencil in S_1 which lies in the plane drawn through p and the corresponding axial pencil in S_2 determine on p two projective rows, and these points in these which coincide with their corresponding points lie on the surface. But there exist only two, or one, or no such points, unless every point coincides with its corresponding point. In the latter case the line lies altogether on the surface.

This proves also that a plane cuts the surface in a curve of the second order, as no line can have more than two points in common with it. To show that this is a curve of the same kind as those considered before, we have to show that it can be generated by projective flat pencils. We prove first that this is true for any plane through the centre of one of the pencils, and afterwards that every point on the surface may be taken as the centre of such pencil. Let then α_1 be a plane through S_1. To the flat pencil in S_1 which it contains corresponds in S_2 a projective axial pencil with axis a_2, and this cuts α_1 in a second flat pencil. These two flat pencils in α_1 are projective, and, in general, neither concentric nor perspective. They generate therefore a conic. But if the line a_2 passes through S_1 the pencils will have S_1 as common centre, and may therefore have two, or one, or no lines united with their corresponding lines. The section of the surface by the plane α_1 will be accordingly a line-pair or a single line, or else the plane α_1 will have only the point S_1 in common with the surface.

Every line l_1 through S_1 cuts the surface in two points, viz., first in S_1 and then at the point where it cuts its corresponding plane. If now the corresponding plane passes through S_1, as in the case just considered, then the two points where l_1 cuts the surface coincide at S_1, and the line is called a *tangent* to the surface with S_1 as *point of contact*. Hence if l_1 be a tangent, it lies in that plane τ_1 which corresponds to the line S_2S_1 as a line in the pencil S_2. The section of this plane has just been considered. It follows that—

All tangents to quadric surface at the centre of one of the reciprocal pencils lie in a plane which is called the tangent plane to the surface at that point as point of contact.

To the line joining the centres of the two pencils as a line in one corresponds in the other the tangent plane at its centre.

The tangent plane to a quadric surface either cuts the surface in two lines, or it has only a single line, or else only a single point in common with the surface.

In the first case the point of contact is said to be hyperbolic, in the second parabolic, in the third elliptic.

§ 95. It remains to be proved that every point S on the surface may be taken as centre of one of the pencils which generate the surface. Let S be any point on the surface Φ' generated by the reciprocal pencils S_1 and S_2. We have to establish a reciprocal correspondence between the pencils S and S_1, so that the surface generated by them is identical with Φ. To do this we draw two planes α_1 and β_1 through S_1, cutting the surface Φ in two conics which we also denote by α_1 and β_1. These conics meet at S_1, and at some other point T where the line of intersection of α_1 and β_1 cuts the surface.

In the pencil S we draw some plane σ which passes through T, but not through S_1 or S_2. It will cut the two conics first at T, and therefore each at some other point which we call A and B respectively. These we join to S by lines a and b, and now establish the required correspondence between the pencils S_1 and S as follows:—To S_1T shall correspond the plane σ, to the plane α_1 the line a, and to β_1 the line b, hence to the flat pencil in α_1 the axial pencil a. These pencils are made projective by aid of the conic in α_1.

In the same manner the flat pencil in β_1 is made projective to the axial pencil b by aid of the conic in β_1, corresponding elements being those which meet on the conic. This determines the correspondence, for we know for more than four rays in S_1 the corresponding planes in S. The two pencils S and S_1 thus made reciprocal generate a quadric surface Φ', which passes through the point S and through the two conics α_1 and β_1.

The two surfaces Φ and Φ' have therefore the points S and S_1 and the conics α_1 and β_1 in common. To show that they are identical, we draw a plane through S and S_2, cutting each of the conics α_1 and β_1 in two points, which will always be possible. This plane cuts Φ and Φ' in two conics which have the point S and the points where it cuts α_1 and β_1 in common, that is five points in all. The conics therefore coincide.

This proves that all those points P on Φ' lie on Φ which have the property that the plane SS_2P cuts the conics α_1, β_1 in two points each. If the plane SS_2P has not this property, then we draw a plane SS_1P. This cuts each surface in a conic, and these conics have in common the points S, S_1, one point on each of the conics α_1, β_1, and one point on one of the conics through S and S_2 which lie on both surfaces, hence five points. They are therefore coincident, and our theorem is proved.

§ 96. The following propositions follow:—

A quadric surface has at every point a tangent plane.

Every plane section of a quadric surface is a conic or a line-pair.

Every line which has three points in common with a quadric surface lies on the surface.

Every conic which has five points in common with a quadric surface lies on the surface.

Through two conics which lie in different planes, but have two points in common, and through one external point always one quadric surface may be drawn.

§ 97. *Every plane which cuts a quadric surface in a line-pair is a tangent plane.* For every line in this plane through the centre of the line-pair (the point of intersection of the two lines) cuts the surface in two coincident points and is therefore a tangent to the surface, *the centre of the line-pair being the point of contact.*

If a quadric surface contains a line, then every plane through this line cuts the surface in a line-pair (*or in two coincident lines*). For this plane cannot cut the surface in a conic. Hence

If a quadric surface contains one line p *then it contains an infinite number of lines, and through every point* Q *on the surface, one line* q *can be drawn which cuts* p. For the plane through the point Q and the line p cuts the surface in a line-pair which must pass through Q and of which p is one line.

No two such lines q *on the surface can meet.* For as both meet p their plane would contain p and therefore cut the surface in a triangle.

Every line which cuts three lines q *will be on the surface*; for it has three points in common with it.

Hence the quadric surfaces which contain lines are the same as the ruled quadric surfaces considered in §§ 89-93, but with one important exception. In the last investigation we have left out of consideration the possibility of a plane having only one line (two coincident lines) in common with a quadric surface.

§ 98. To investigate this case we suppose first that there is one point A on the surface through which two different lines a, b can be drawn, which lie altogether on the surface.

If P is any other point on the surface which lies neither on a nor b, then the plane through P and a will cut the surface in a second line a' which passes through P and which cuts a. Similarly there is a line b' through P which cuts b. These two lines a' and b' *may* coincide, but then they must coincide with PA.

If this happens for one point P, it happens for every other point Q. For if two different lines could be drawn through Q, then by the same reasoning the line PQ would be altogether on the surface, hence two lines would be drawn through P against the assumption. From this follows:—

If there is one point on a quadric surface through which one, but only one, line can be drawn on the surface, then through every point one line can be drawn, and all these lines meet in a point. The surface is a cone of the second order.

If through one point on a quadric surface, two, and only two, lines can be drawn on the surface, then through every point two lines may be drawn, and the surface is a ruled quadric surface.

If through one point on a quadric surface no line on the surface can be drawn, then the surface contains no lines.

Using the definitions at the end of § 95, we may also say:—

On a quadric surface the points are all hyperbolic, or all parabolic, or all elliptic.

As an example of a quadric surface with elliptical points, we mention the sphere which may be generated by two reciprocal pencils, where to each line in one corresponds the plane perpendicular to it in the other.

§ 99. *Poles and Polar Planes.*—The theory of poles and polars with regard to a conic is easily extended to quadric surfaces.

Let P be a point in space not on the surface, which we suppose not to be a cone. On every line through P which cuts the surface in two points we determine the harmonic conjugate Q of P with regard to the points of intersection. Through one of these lines we draw two planes α and β. The locus of the points Q in α is a line a, the polar of P with regard to the conic in which α cuts the surface. Similarly the locus of points Q in β is a line b. This cuts a, because the line of intersection of α and β contains but one point Q. The locus of all points Q therefore is a plane. *This plane is called the polar plane of the point* P, *with regard to the quadric surface. If* P *lies on the surface we take the tangent plane of* P *as its polar.*

The following propositions hold:—

1. *Every point has a polar plane*, which is constructed by drawing the polars of the point with regard to the conics in which two planes through the point cut the surface.

2. *If* Q *is a point in the polar of* P, *then* P *is a point in the polar of* Q, because this is true with regard to the conic in which a plane through PQ cuts the surface.

3. *Every plane is the polar plane of one point, which is called the Pole of the plane.*

The pole to a plane is found by constructing the polar planes of three points in the plane. Their intersection will be the pole.

4. *The points in which the polar plane of* P *cuts the surface are points of contact of tangents drawn from* P *to the surface*, as is easily seen. Hence:—

5. *The tangents drawn from a point* P *to a quadric surface form a cone of the second order*, for the polar plane of P cuts it in a conic.

6. *If the pole describes a line* a, *its polar plane will turn about another line* a′, as follows from 2. *These lines* a *and* a′ *are said to be conjugate with regard to the surface.*

§ 100. The pole of the line at infinity is called the *centre* of the surface. If it lies at the infinity, the plane at infinity is a tangent plane, and the surface is called a *paraboloid.*

The polar plane to any point at infinity passes through the centre, and is called a diametrical plane.

A line through the centre is called a diameter. It is bisected at the centre. The line conjugate to it lies at infinity.

If a point moves along a diameter its polar plane turns about the conjugate line at infinity; that is, *it moves parallel to itself, its centre moving on the first line.*

The middle points of parallel chords lie in a plane, viz., in the polar plane of the point at infinity through which the chords are drawn.

The centres of parallel sections lie in a diameter which is a line conjugate to the line at infinity in which the planes meet.

Twisted Cubics.

§ 101. If two pencils with centres S_1 and S_2 are made projective, then to a ray in one corresponds a ray in the other, to a plane a plane, to a flat or axial pencil a projective flat or axial pencil, and so on.

There is a double infinite number of lines in a pencil. We shall see that a single infinite number of lines in one pencil meets its corresponding ray, and that the points of intersection form a curve in space.

Of the double infinite number of planes in the pencils each will meet its corresponding plane. This gives a system of a double infinite number of lines in space. We know (§ 5) that there is a quadruple infinite number of lines in space. From among these we may select those which satisfy one or more given conditions. The systems of lines thus obtained was first systematically investigated and classified by Plücker, in his *Geometrie des Raumes.* He uses the following names:—

A *treble infinite* number of lines, that is, all lines which satisfy one condition, are said to form a *complex of lines*; *e.g.*, all lines cutting a given line, or all lines touching a surface.

A *double infinite* number of lines, that is, all lines which satisfy two conditions, or which are common to two complexes, are said to form a *congruence of lines*; *e.g.*, all lines in a plane, or all lines cutting two curves, or all lines cutting a given curve twice.

A *single infinite* number of lines, that is, all lines which satisfy three conditions, or which belong to three complexes, form a *ruled surface*; *e.g.*, one set of lines on a ruled quadric surface, or developable surfaces which are formed by the tangents to a curve.

It follows that all lines in which corresponding planes in two projective pencils meet form a congruence. We shall see this congruence consists of all lines which cut a twisted cubic twice, or of all *secants* to a twisted cubic.

§ 102. Let l_1 be the line S_1S_2 as a line in the pencil S_1. To it corresponds a line l_2 in S_2. *At each of the centres two corresponding lines meet.* The two axial pencils with l_1 and l_2 as axes are projective, and, as their axes meet at S_2, the intersections of corresponding planes form a cone of the second order (§ 58), with S_2 as centre. If π_1 and π_2 be corresponding planes, then their intersection will be a line p_2 which passes through S_2. Corresponding to it in S_1 will be a line p_1 which lies in the plane π_1, and which therefore meets p_2 at some point P. Conversely, if p_2 be any line in S_2 which meets its corresponding line p_1 at a point P, then to the plane l_2p_2 will correspond the plane l_1p_1, that is, the plane S_1S_2P. These planes intersect in p_2, so that p_2 is a line on the quadric cone generated by the axial pencils l_1 and l_2. Hence:—

All lines in one pencil which meet their corresponding lines in the other form a cone of the second order which has it centre at the centre of the first pencil, and passes through the centre of the second.

From this follows that the points in which corresponding rays meet lie on two cones of the second order which have the ray joining their centres in common, and form therefore, together with the line S_1S_2 or l_1, the intersection of these cones. Any plane cuts each of the cones in a conic. These two conics have necessarily that point in common in which it cuts the line l_1, and therefore besides either one or three other points. It follows that the curve is of the *third order* as a plane may cut it in three, but not in more than three, points. Hence:—

The locus of points in which corresponding lines on two projective pencils meet is a curve of the third order or a "twisted cubic" k, *which passes through the centres of the pencils, and which appears as the intersection of two cones of the second order, which have one line in common.*

A line belonging to the congruence determined by the pencils is a secant of the cubic; it has two, or one, or no points in common with this cubic, and is called accordingly a secant proper, a tangent, or a secant improper of the cubic. A secant improper may be considered, to use the language of coordinate geometry, as a secant with imaginary points of intersection.

§ 103. If a_1 and a_2 be any two corresponding lines in the two pencils, then corresponding planes in the axial pencils having a_1 and a_2 as axes generate a ruled quadric surface. If P be any point on the cubic k, and if p_1, p_2 be the corresponding rays in S_1 and S_2 which meet at P, then to the plane a_1p_1 in S_1 corresponds $a_2\,p_2$ in S_2. These therefore meet in a line through P. This may be stated thus:—

Those secants of the cubic which cut a ray a_1, *drawn through the centre* S_1 *of one pencil, form a ruled quadric surface which passes through both centres, and which contains the twisted cubic* k. *Of such surfaces an infinite number exists. Every ray through* S_1 *or* S_2 *which is not a secant determines one of them.*

If, however, the rays a_1 and a_2 are secants meeting at A, then the ruled quadric surface becomes a cone of the second order, having A as centre. Or *all lines of the congruence which pass through a point on the twisted cubic* k *form a cone of the second order.* In other words, the projection of a twisted cubic from any point in the curve on to any plane is a conic.

If a_1 is not a secant, but made to pass through any point Q in space, the ruled quadric surface determined by a_1 will pass through Q. *There will therefore be one line of the congruence passing through* Q, *and only one.* For if two such lines pass through Q, then the lines S_1Q and S_2Q will be corresponding lines; hence Q will be a point on the cubic k, and an infinite number of secants will pass through it. Hence:—

Through every point in space not on the twisted cubic one and only one secant to the cubic can be drawn.

§ 104. The fact that all the secants through a point on the cubic form a quadric cone shows that the centres of the projective pencils generating the cubic are not distinguished from any other points on the cubic. If we take any two points S, S′ on the cubic, and draw the secants through each of them, we obtain two quadric cones, which have the line SS′ in common, and which intersect besides along the cubic. If we make these two pencils having S and S′ as centres projective by taking four rays on the one cone as corresponding to the four rays on the other which meet the first on the cubic, the correspondence is determined. These two pencils will generate a cubic, and the two cones of secants having S and S′ as centres will be identical with the above cones, for each has five rays in common with one of the first, viz., the line SS′ and the four lines determined for the correspondence; therefore these two cones intersect in the original cubic. This gives the theorem:—

On a twisted cubic any two points may be taken as centres of projective pencils which generate the cubic, corresponding planes being those which meet on the same secant.

Of the two projective pencils at S and S′ we may keep the first fixed, and move the centre of the other along the curve. The pencils will hereby remain projective, and a plane α in S will be cut by its corresponding plane α' always in the same secant a. Whilst S′ moves along the curve the plane α' will turn about a, describing an axial pencil.

In this article we have given a purely geometrical theory of conics, cones of the second order, quadric surfaces, &c. In doing so we have followed, to a great extent, Reye's *Geometrie der Lage*, and to this excellent work those readers are referred who wish for a more exhaustive treatment of the subject.

It will have been observed that scarcely any use has been made of algebra, and it would have been even possible to avoid this little, as is done by Reye. There are, however, other systems of geometry which start more or less from theorems known to the Greeks, and using more or less algebra.

We cannot do more here than enumerate a few of the more prominent works on the subject, which, however, are almost all Continental. These are the following:—

Monge, *Géométrie Descriptive*: Carnot, *Géométrie de Position* (1803), containing a theory of transversals; Poncelet's great work, *Traité des Propriétés Projectives des Figures* (1822); Möbius, *Barycentrischer Calcul* (1826); Steiner, *Abhängigkeit Geometrischer Gestalten* (1832), containing the first full discussion of the projective relations between rows, pencils, &c.; Von Staudt, *Geometrie der Lage* (1847) and *Beiträge zur Geometrie der Lage* (1856-60), in which a system of geometry is built up from the beginning without any reference to number, so that ultimately a number itself gets a geometrical definition, and in which imaginary elements are systematically introduced into pure geometry; Chasles, *Aperçu Historique* (1837), in which the author gives a brilliant account of the progress of modern geometrical methods, pointing out the advantages of the different purely geometrical methods as compared with the analytical ones, but without taking as much account of the German as of the French authors; Id., *Rapport sur les Progrès de la Géométrie* (1870), a continuation of the *Aperçu*; Id., *Traité de Géométrie Supérieure* (1852); Cremona, *Introduzione ad una Teoria Geometrica della Curve Plane* (1862) and its continuation *Preliminari di una Teoria Geometrica delle Superficie*, which at present are most easily procurable in their German translations by Curtze. As more elementary books, we mention Steiner, *Vorlesungen über Synthetische Geometrie*, edited by Geiser and Schröder (1867); Cremona, *Éléments de Géométrie Projective* (1875), translated from the Italian by Dewulf; Townsend, *Modern Geometry of the Point, Line, and Circle* (1863), which contains a variety of modern methods, but, unfortunately is confined to circles, without entering into conics. A great many of the propositions are, however, easily extended to conics. (O. H.)

PART II.—ANALYTICAL GEOMETRY.

This will be here treated as a method. The science is Geometry; and it would be possible, analytically, or by the method of coordinates, to develop the truths of geometry in a systematic course. But it is proposed not in any way to attempt this, but simply to explain the method, giving such examples, interesting (it may be) in themselves, as are suitable for showing how the method is employed in the demonstration and solution of theorems or problems.

Geometry is one-, two-, or three-dimensional, or, what is the same thing, it is lineal, plane, or solid, according as the space dealt with is the line, the plane, or ordinary (three-dimensional) space. No more general view of the subject need here be taken:—but in a certain sense one-dimensional geometry does not exist, inasmuch as the geometrical constructions for points in a line can only be performed by travelling out of the line into other parts of a plane which contains it, and conformably to the usual practice Analytical Geometry will be treated under the two divisions, Plane and Solid.

It is proposed to consider Cartesian coordinates almost exclusively; for the proper development of the science homogeneous coordinates (three and four in plane and solid geometry respectively) are required; and it is moreover necessary to have the correlative line- and plane-coordinates; and in solid geometry to have the *six* coordinates of the line. The most comprehensive English works are those of Dr Salmon, *The Conics* (5th edition, 1869), *Higher Plane Curves* (2d edition, 1873), and *Geometry of Three Dimensions* (3d edition, 1874); we have also on plane geometry Clebsch's *Vorlesungen über Geometrie*, posthumous, edited by Dr F. Lindemann, Leipsic, 1875, not yet complete.

I. Plane Analytical Geometry (§§ 1–25).

1. It is assumed that the points, lines, and figures considered exist in one and the same plane, which plane, therefore, need not be in any way referred to. The position of a point is determined by means of its (Cartesian) coordinates; *i.e.*, as explained under the article Curve, we take the two lines $x'Ox$ and $y'Oy$, called the axes of x and y respectively, intersecting in a point O called the origin, and determine the position of any other point P by means of its coordinates $x = \text{OM}$ (or NP), and $y = \text{MP}$ (or ON).

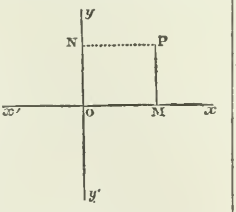

Fig. 1.

The two axes are usually (as in fig. 1) at right angles to each other, and the lines PM, PN are then at right angles to the axes of x and y respectively. Assuming a scale at pleasure, the coordinates x, y of a point have numerical values.

It is necessary to attend to the signs: x has opposite signs according as the point is on one side or the other of the axis of y, and similarly y has opposite signs according as the point is on the one side or the other of the axis of x. Using the letters N, E, S, W as in a map, and considering the plane as divided into four quadrants by the axes, the signs are usually taken to be—

x	y	for quadt.
+	+	N E
+	−	S E
−	+	N W
−	−	S W

A point is said to have the coordinates (a, b), and is referred to as the point (a, b), when its coordinates are $x = a$, $y = b$; the coordinates x, y of a variable point, or of a point which is for the time being regarded as variable, are said to be current coordinates.

2. It is sometimes convenient to use oblique coordinates; the only difference is that the axes are not at right angles to each other; the lines PM, PN are drawn parallel to the axes of y and x respectively, and the figure OMPN is thus a parallelogram. But in all that follows the Cartesian coordinates are taken to be rectangular; polar coordinates and other systems will be briefly referred to in the sequel.

3. If the coordinates (x, y) of a point are not given, but only a relation between them $f(x, y) = 0$, then we have a curve. For, if we consider x as a real quantity varying continuously from $-\infty$ to $+\infty$, then, for any given value of x, y has a value or values. If these are all imaginary, there is not any real point; but if one or more of them be real, we have a real point or points, which (as the assumed value of x varies continuously) varies or vary continuously therewith; and the locus of all these real points is a curve. The equation completely defines the curve; to trace the curve directly from the equation, nothing else being known, we obtain as above a series of points sufficiently near to each other, and draw the curve through them. For instance, let this be done in a simple case. Suppose $y = 2x - 1$; it is quite easy to obtain and lay down a series of points as near to each other as we please, and the application of a ruler would show that these were in a line; that the curve is a line depends upon something more than the equation itself, viz., the theorem that every equation of the form $y = ax + b$ represents a line; supposing this known, it will be at once understood how the process of tracing the curve may be abbreviated; we have $x = 0, y = -1$, and $x = \frac{1}{2}, y = 0$; the curve is thus the line passing through these two points. But in the foregoing example the notion of a line is taken to be a known one, and such notion of a line does in fact precede the consideration of any equation of a curve whatever, since the notion of the coordinates themselves rests upon that of a line. In other cases it may very well be that the equation is the definition of the curve; the points laid down, although (as finite in number) they do not actually determine the curve, determine it to any degree of accuracy; and the equation thus enables us to construct the curve.

A curve may be determined in another way; viz., the coordinates x, y may be given each of them as a function of the same variable parameter θ; $x, y = f(\theta), \phi(\theta)$ respectively. Here, giving to θ any number of values in succession, these equations determine the values of x, y, that is, the positions of a series of points on the curve. The ordinary form $y = \phi(x)$, where y is given explicitly as a function of x, is a particular case of each of the other two forms: we have $f(x, y), = y - \phi(x), = 0$; and $x = \theta$, $y = \phi(\theta)$.

4. As remarked under Curve, it is a useful exercise to trace a considerable number of curves, first taking equations which are purely numerical, and then equations which contain literal constants (representing numbers); the equations most easily dealt with are those wherein one coordinate is given as an explicit function of the other, say $y = \phi(x)$ as above. A few examples are here given, with such explanations as seem proper.

(1.) $y=2x-1$, as before; it is at once seen that this is a line; and taking it to be so, any two points, for instance, $(0, -1)$ and $(\frac{1}{2}, 0)$, determine the line.

(2.) $y=x^2$. The equation shows that x may be positive or negative, but that y is always positive, and has the same values for equal positive and negative values of x: the curve passes through the origin, and through the points $(\pm 1, 1)$. It is already known that the curve lies wholly above the axis of x. To find its form in the neighbourhood of the origin, give x a small value, $x=\pm 0{\cdot}1$ or $\pm 0{\cdot}01$, then y is very much smaller, $=0{\cdot}01$ and $0{\cdot}0001$ in the two cases respectively; this shows that the curve touches the axis of x at the origin. Moreover, x may be as large as we please, but when it is large, y is much larger; for instance, $x=10$, $y=100$. The curve is a parabola (fig. 2).

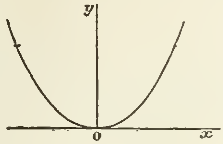

Fig. 2.

(3.) $y=x^3$. Here x being positive y is positive, but x being negative y is also negative: the curve passes through the origin, and also through the points $(1, 1)$ and $(-1, -1)$. Moreover, when x is small, $=0{\cdot}1$ for example, then not only is $y, =0{\cdot}001$, very much smaller than x, but it is also very much smaller than y was for the last-mentioned curve $y=x^2$, that is, in the neighbourhood of the origin the present curve approaches more closely the axis of x. The axis of x is a tangent at the origin, but it is a tangent of a peculiar kind (a stationary or inflexional tangent), cutting the curve at the origin, which is an inflexion. The curve is the cubical parabola (fig. 3).

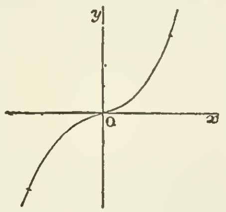

Fig. 3.

(4.) $y^2=x-1.x-3.x-4$. Here $y=0$ for $x=1, =3, =4$. Whenever $x-1.x-3.x-4$ is positive, y has two equal and opposite values; but when $x-1.x-3.x-4$, is negative, then y is imaginary. In particular, for x less than 1, or between 3 and 4, y is imaginary, but for x between 1 and 3, or greater than 4, y has two values. It is clear that for x somewhere between 1 and 3, y will attain a maximum, the values of x and y may be found approximately by trial. The curve will consist of an oval and infinite branch, and it is easy to see that, as shown in fig. 4, the curve where it cuts the axis of x cuts it at right angles. It may be further remarked that, as x increases from 4, the value of y will increase more and more rapidly; for instance, $x=5$, $y^2=8$, $x=10$, $y^2=378$, &c., and it is easy to see that this implies that the curve has on the infinite branch two inflexions as shown.

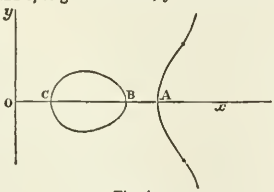

Fig. 4.

(5.) $y^2=x-c.x-b.x-a$, where $a > b > c$ (that is, a nearer to $+\infty$, c to $-\infty$). The curve has the same general form as in the last figure, the oval extending between the limits $x=c$, $x=b$, the infinite branch commencing at the point $x=a$.

(6.) $y^2=(x-c)^2(x-a)$. Suppose that in the last-mentioned curve, $y^2=x-c.x-b.x-a$, b gradually diminishes, and becomes ultimately $=c$. The infinite branch (see fig. 5) changes its form, but not in a very marked manner, and it retains the two inflexions. The oval lies always between the values $x=c$, $x=b$, and therefore its length continually diminishes; it is easy to see that its breadth will also continually diminish; ultimately it shrinks up into a mere point. The curve has thus a conjugate or isolated point, or acnode. For a direct verification observe that $x=c$, $y=0$, so that $(c, 0)$ is a point of the curve, but if x is either less than c, or between c and a, y^2 is negative, and y is imaginary.

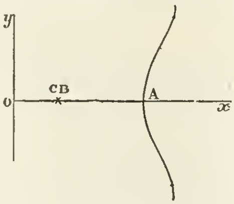

Fig. 5.

(7.) $y^2=(x-c)(x-a)^2$. If in the same curve b gradually increases and becomes ultimately $=a$, the oval and the infinite branch change each of them its form, the oval extending always between the values $x=c$, $x=b$, and thus continually approaching the infinite branch, which begins at $x=a$. The consideration of a few numerical examples, *with careful drawing*, would show that the oval and the infinite branch as they approach sharpen out each towards the other (the two inflexions on the infinite branch coming always nearer to the point $(a, 0)$),—so that finally, when b becomes $=a$, the curve has the form shown in fig. 6, there being now a double point or node (crunode) at A, and the inflexions on the infinite branch having disappeared.

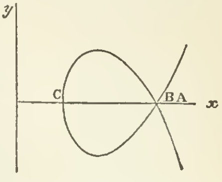

Fig. 6.

In the last four examples the curve is one of the cubical curves called the divergent parabolas: 4 is a mere numerical example of 5, and 6, 7, 8 are in Newton's language the parabola *cum ovali*, *punctata*, and *nodata* respectively. When a, b, c are all equal, or the form is $y^2=(x-c)^3$, we have a cuspidal form, Newton's parabola *cuspidata*, otherwise the semicubical parabola.

(8.) As an example of a curve given by an implicit equation, suppose the equation is

$$x^3+y^3-3xy=0;$$

this is a nodal cubic curve, the node at the origin, and the axes touching the two branches respectively (fig. 7). An easy mode of tracing it is to express x, y each of them in terms of a variable θ, $x=\dfrac{3\theta}{1+\theta^3}$, $y=\dfrac{3\theta^2}{1+\theta^3}$; but it is instructive to trace the curve directly from its equation.

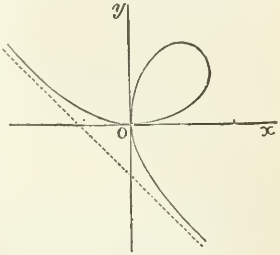

Fig. 7.

5. It may be remarked that the purely algebraical process, which is in fact that employed in finding a differential coefficient $\dfrac{dy}{dx}$, if applied directly to the equation of the curve, determines the point consecutive to any given point of the curve, that is, the direction of the curve at such given point, or, what is the same thing, the direction of the tangent at that point. In fact, if α, β are the coordinates of any point on a curve $f(x, y)=0$, then writing in the equation of the curve $x=\alpha+h$, $y=\beta+k$, and in the resulting equation $f(\alpha+h, \beta+k)=0$ (developed in powers of h and k), omitting the term $f(\alpha, \beta)$, which vanishes, and the terms containing the second and higher powers of h, k, we have a linear equation $\mathrm{A}h+\mathrm{B}k=0$, which determines the ratio of the increments h, k. Of course, in the analytical development of the theory, we translate this into the notation of the differential calculus; but the question presents itself, and is thus seen to be solvable, as soon as it is attempted to trace a curve from its equation.

Geometry is Descriptive, or Metrical.

6. A geometrical proposition is either *descriptive* or *metrical*; in the former case it is altogether independent of the idea of magnitude (length, inclination, &c.); in the latter case it has reference to this idea. It is to be noticed that, although the method of coordinates seems to be by its inception essentially metrical, and we can hardly, except by metrical considerations, connect an equation with the curve which it represents (for instance, even assuming it to be known that an equation $\mathrm{A}x+\mathrm{B}y+\mathrm{C}=0$ represents a line, yet if it be asked what line, the only form of answer is, that it is the line cutting

the axes at *distances* from the origin $-C\div A$, $-C\div B$ respectively), yet in dealing by this method with descriptive propositions, we are, in fact, eminently free from all metrical considerations.

7. It is worth while to illustrate this by the instance of the well-known theorem of the radical centre of three circles. The theorem is that, given any three circles A, B, C (fig. 8), the common chords $\alpha\alpha'$, $\beta\beta'$, $\gamma\gamma'$ of the three pairs of circles meet in a point.

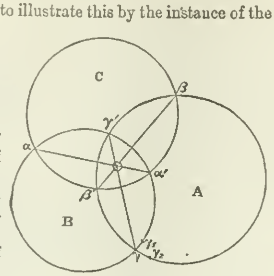

Fig. 8.

The geometrical proof is metrical throughout:—

Take O the point of intersection of $\alpha\alpha'$, $\beta\beta'$, and joining this with γ', suppose that γ'O does not pass through γ, but that it meets the circles A, B in two distinct points γ_1, γ_2 respectively. We have then the known metrical property of intersecting chords of a circle; viz., in circle C where $\alpha\alpha'$, $\beta\beta'$ are chords meeting at a point O,

$$O\alpha . O\alpha' = O\beta . O\beta\,,$$

where, as well as in what immediate follows Oα, &c., denote, of course, *lengths* or *distances.*

Similarly in circle A

$$O\beta . O\beta' = O\gamma_1 . O\gamma',$$

and in circle B,

$$O\alpha . O\alpha' = O\gamma_2 . O\gamma'.$$

Consequently $O\gamma_1 . O\gamma' = O\gamma_2 . O\gamma'$, that is, $O\gamma_1 = O\gamma_2$, or the points γ_1 and γ_2 coincide; that is, they each coincide with γ.

We contrast this with the analytical method:—

Here it only requires to be known that an equation $Ax+By+C=0$ represents a line, and an equation $x^2+y^2+Ax+By+C=0$ represents a circle. A, B, C have, in the two cases respectively, metrical significations; but these we are not concerned with. Using S to denote the function $x^2+y^2+Ax+By+C$, the equation of a circle is $S=0$, where S stands for its value; more briefly, we say the equation is $S, =x^2+y^2+Ax+By+C, =0$. Let the equation of any other circle be $S', =x^2+y^2+A'x+B'y+C'=0$; the equation $S-S'=0$ is a linear equation ($S-S'$ is in fact $=(A-A')\,x+(B-B')\,y+C-C'$), and it thus represents a line; this equation is satisfied by the coordinates of each of the points of intersection of the two circles (for at each of these points $S=0$ and $S'=0$, therefore also $S-S'=0$); hence the equation $S-S'=0$ is that of the line joining the two points of intersection of the two circles, or say it is the equation of the common chord of the two circles. Considering then a third circle $S'', =x^2+y^2+A''x+B''y+C''=0$, the equations of the common chords are $S-S'=0$, $S-S''=0$, $S'-S''=0$ (each of these a linear equation); at the intersection of the first and second of these lines $S=S'$ and $S=S''$, therefore also $S'=S''$, or the equation of the third line is satisfied by the coordinates of the point in question; that is, the three chords intersect in a point O, the coordinates of which are determined by the equations $S=S'=S''$.

It further appears that if the two circles $S=0$, $S=0'$ do not intersect in any real points, they must be regarded as intersecting in two imaginary points, such that the line joining them is the real line represented by the equation $S-S'=0$; or that two circles, whether their intersections be real or imaginary, have always a real common chord (or radical axis), and that for *any* three circles the common chords intersect in a point (of course real) which is the radical centre. And by this very theorem, given two circles with imaginary intersections, we can, by drawing circles which meet each of them in real points, construct the radical axis of the first-mentioned two circles.

8. The principle employed in showing that the equation of the common chord of two circles is $S-S'=0$ is one of very extensive application, and some more illustrations of it may be given.

Suppose $S=0$, $S'=0$ are lines (that is, let S, S' now denote linear functions $Ax+By+C$, $A'x+B'y+C'$), then $S-kS'=0$ (k an arbitrary constant) is the equation of *any* line passing through the point of intersection of the two given lines. Such a line may be made to pass through any given point, say the point (x_0, y_0); *i.e.*, if S_0, S'_0 are what S, S' respectively become on writing for (x, y) the values (x_0, y_0), then the value of k is $k=S_0\div S'_0$. The equation in fact is $SS'_0-S_0S'=0$; and starting from this equation we at once verify it *a posteriori*; the equation is a linear equation satisfied by the values of (x, y) which make $S=0$, $S'=0$; and satisfied also by the values (x_0, y_0); and it is thus the equation of the line in question.

If, as before, $S=0$, $S'=0$ represent circles, then (k being arbitrary) $S-k\,S'=0$ is the equation of any circle passing through the two points of intersection of the two circles; and to make this pass through a given point (x_0, y_0) we have again $k=S_0\div S'_0$. In the particular case $k=1$, the circle becomes the common chord (more accurately, it becomes the common chord together with the line infinity, but this is a question which is not here gone into).

If S denote the general quadric function,

$$S=ax^2+2hxy+by^2+2fy+2gx+c, =(a, b, c, f, g, h)(x, y, 1)^2,$$

then the equation $S=0$ represents a conic; assuming this, then, if $S'=0$ represents another conic, the equation $S-kS'=0$ represents *any* conic through the four points of intersection of the two conics.

Returning to the equation $Ax+By+C=0$ of a line, if this pass through two given points (x_1, y_1), (x_2, y_2), then we must have $Ax_1+By_1+C=0$, $Ax_2+By_2+C=0$, equations which determine the ratios A : B : C, and it thus appears that the equation of the line through the two given points is

$$x(y_1-y_2)-y(x_1-x_2)+x_1y_2-x_2y_1=0\,;$$

or what is the same thing—

$$\begin{vmatrix} x, & y, & 1 \\ x_1, & y_1, & 1 \\ x_2, & y_2, & 1 \end{vmatrix} =0\,;$$

9. The object still being to illustrate the mode of working with coordinates, we consider the theorem of the polar of a point in regard to a circle. Given a circle and a point O (fig. 9), we draw through O any two lines meeting the circle in the points A, A' and B, B' respectively, and then taking Q as the intersection of the lines AB' and A'B, the theorem is that the locus of the point Q is a right line depending only upon O and the circle, but independent of the particular lines OAA' and OBB'.

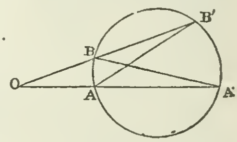

Fig. 9.

Taking O as the origin, and for the axes any two lines through O at right angles to each other, the equation of the circle will be

$$x^2+y^2+2Ax+2By+C=0\,;$$

and if the equation of the line OAA' is taken to be $y=mx$, then the points A, A' are found as the intersections of the straight line with the circle; or to determine x we have

$$x^2(1+m^2)+2x(A+Bm)+C=0\,.$$

If (x_1, y_1) are the coordinates of A, and (x_2, y_2) of A', then the roots of this equation are x_1, x_2, whence easily

$$\frac{1}{x_1}+\frac{1}{x_2}=-2\,\frac{A+Bm}{C}\,.$$

And similarly, if the equation of the line OBB' is taken to be $y=m'x$, and the coordinates of B, B' to be (x_3, y_3) and (x_4, y_4) respectively, then

$$\frac{1}{x_3}+\frac{1}{x_4}=-2\,\frac{A+Bm'}{C'}\,.$$

We have then

$$x(y_1-y_4)-y(x_1-x_4)+x_1y_4-x_4y_1=0\,,$$
$$x(y_2-y_3)-y(x_2-x_3)+x_2y_3-x_3y_4=0\,,$$

as the equations of the lines AB' and A'B respectively; for the first of these equations, being satisfied if we write therein (x_1, y_1) or (x_4, y_4) for (x, y), is the equation of the line AB', and similarly the second equation is that of the line A'B. Reducing by means of the relations $y_1-mx_1=0$, $y_2-mx_2=0$, $y_3-m'x_3=0$, $y_4-m'x_4=0$, the two equations become

$$x(mx_1-m'x_4)-y(x_1-x_4)+(m'-m)x_1x_4=0,$$
$$x(mx_2-m'x_3)-y(x_2-x_3)+(m'-m)x_2x_3=0,$$

and if we divide the first of these equations by m_1m_4, and the second by m_2m_3, and then add, we obtain

$$x\left\{m\left(\frac{1}{x_3}+\frac{1}{x_4}\right)-m'\left(\frac{1}{x_1}+\frac{1}{x_2}\right)\right\}-y\left\{\frac{1}{x_3}+\frac{1}{x_4}-\left(\frac{1}{x_1}+\frac{1}{x_2}\right)\right\}$$
$$+2m'-2m=0,$$

or, what is the same thing,

$$\left(\frac{1}{x_1}+\frac{1}{x_2}\right)(y-m'x)-\left(\frac{1}{x_3}+\frac{1}{x_4}\right)(y-mx)+2m'-2m=0,$$

which by what precedes is the equation of a line through the point Q. Substituting herein for $\frac{1}{x_1}+\frac{1}{x_2}$, $\frac{1}{x_3}+\frac{1}{x_4}$ their foregoing values, the equation becomes

$$-(A+Bm)(y-m'x)+(A+Bm')(y-mx)+m'-m=0\ ;$$

that is,

$$(m-m')(Ax+By+C)=0\ ;$$

or finally it is $Ax+By+C=0$, showing that the point Q lies in a line the position of which is independent of the particular lines OAA′, OBB′ used in the construction. It is proper to notice that there is no correspondence to each other of the points A, A′ and B, B′; the grouping might as well have been A, A′ and B′, B; and it thence appears that the line $Ax+By+C=0$ just obtained is in fact the line joining the point Q with the point R which is the intersection of AB and A′B′.

10. The equation $Ax+By+C=0$ of a line contains in appearance 3, but really only 2 constants (for one of the constants can be divided out), and a line depends accordingly upon 2 parameters, or can be made to satisfy 2 conditions. Similarly, the equation $(a, b, c, f, g, h\between x, y, 1)^2=0$ of a conic contains really 5 constants, and the equation $(*)(x, y, 1)^3=0$ of a cubic contains really 9 constants. It thus appears that a cubic can be made to pass through 9 given points, and that the cubic so passing through 9 given points is completely determined. There is, however, a remarkable exception. Considering two given cubic curves $S=0$, $S'=0$, these intersect in 9 points, and through these 9 points we have the whole series of cubics $S-kS'=0$, where k is an arbitrary constant: k may be determined so that the cubic shall pass through a given tenth point ($k=S_0\div S'_0$, if the coordinates are (x_0, y_0), and S_0, S'_0 denote the corresponding values of S, S′). The resulting curve $SS'_0-S'S_0=0$ may be regarded as the cubic determined by the conditions of passing through 8 of the 9 points and through the given point (x_0, y_0); and from the equation it thence appears that the curve passes through the remaining one of the 9 points. In other words, we thus have the theorem, any cubic curve which passes through 8 of the 9 intersections of two given cubic curves passes through the 9th intersection.

The applications of this theorem are very numerous; for instance, we derive from it Pascal's theorem of the inscribed hexagon. Consider a hexagon inscribed in a conic. The three alternate sides constitute a cubic, and the other three alternate sides another cubic. The cubics intersect in 9 points, being the 6 vertices of the hexagon, and the 3 Pascalian points, or intersections of the pairs of opposite sides of the hexagon. Drawing a line through two of the Pascalian points, the conic and this line constitute a cubic passing through 8 of the 9 points of intersection, and it therefore passes through the remaining point of intersection—that is, the third Pascalian point; and since obviously this does not lie on the conic, it must lie on the line—that is, we have the theorem that the three Pascalian points (or points of intersection of the pairs of opposite sides) lie on a line.

Metrical Theory.

11. The foundation of the metrical theory consists in the simple theorem that if a finite line PQ (fig. 10) be projected upon any other line OO′ by lines perpendicular to OO′, then the length of the projection P′Q′ is equal to the length of PQ into the cosine of its inclination to P′Q′; or, what is the same thing, that the perpendicular distance P′Q′ of any two parallel lines is equal to the inclined distance PQ into the cosine of the inclination. It at once follows that the algebraical sum of the projections of the sides of a closed polygon upon any line is $=0$; or, reversing the signs of certain sides, and considering the polygon as consisting of two broken lines, each extending from the same initial to the same terminal point, the sum of the projections of the lines of the first set upon any line is equal to the sum of the projections of the lines of the second set. Observe that if any line be perpendicular to the line on which the projection is made, then its projection is $=0$.

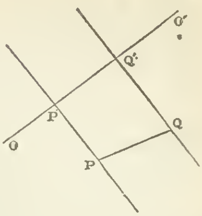

Fig. 10.

Thus, if we have a right-angled triangle PQR (fig. 11), where QR, RP, QP are $=\xi, \eta, \rho$ respectively, and whereof the base angle is $=\alpha$, then projecting successively on the three sides, we have

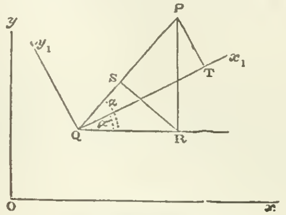

Fig. 11.

$$\xi=\rho\cos\alpha,\ \eta=\rho\sin\alpha,\ \rho=\xi\cos\alpha+\eta\sin\alpha\ ;$$

and we thence obtain

$$\rho^2=\xi^2+\eta^2\ ;\ \cos^2\alpha+\sin^2\alpha=1.$$

And again, by projecting on a line Qx_1, inclined at the angle α' to QR, we have

$$\rho\cos(\alpha-\alpha')=\xi\cos\alpha'+\eta\sin\alpha'\ ;$$

and by substituting for ξ, η their foregoing values,

$$\cos(\alpha-\alpha')=\cos\alpha\cos\alpha'+\sin\alpha\sin\alpha'.$$

It is to be remarked that, assuming only the theory of similar triangles, we have herein a *proof* of Euclid, Book I., Prop 47; in fact, the same as is given Book VI., Prop. 31; and also a *proof* of the trigonometrical formula for $\cos(\alpha-\alpha')$. The formulæ for $\cos(\alpha+\alpha')$ and $\sin(\alpha\pm\alpha')$ could be obtained in the same manner.

Draw PT at right angles to Qx_1, and suppose QT, TP $=\xi_1, \eta_1$ respectively, so that we have now the quadrilateral QRPTQ, or, what is the same thing, the two broken lines QRP and QTP, each extending from Q to P. Projecting on the four sides successively, we have

$$\begin{aligned}\xi &= \ \ \xi_1\cos\alpha'-\eta_1\sin\alpha',\\ \eta &= \ \ \xi_1\sin\alpha'+\eta_1\cos\alpha',\\ \xi_1 &= \ \ \xi\cos\alpha'+\eta\sin\alpha',\\ \eta_1 &= -\xi\sin\alpha'+\eta\cos\alpha',\end{aligned}$$

where the third equation is that previously written

$$\rho\cos(\alpha-\alpha')=\xi\cos\alpha+\eta\sin\alpha.$$

Equations of Right Line and Circle.—Transformation of Coordinates.

12. The required formulæ are really contained in the foregoing results. For, in fig. 11, supposing that the axis of x is parallel to QR, and taking a, b for the coordinates of Q, and (x, y) for those of P, then we have $\xi, \eta=x-a,\ y-b$ respectively; and therefore

$$x-a=\rho\cos\alpha,\quad y-b=\rho\sin\alpha,$$
$$\rho^2\ \ =(x-a)^2+(y-b)^2.$$

Writing the first two of these in the form

$$\frac{x-a}{\cos\alpha}=\frac{y-b}{\sin\alpha}(=\rho),$$

we may regard Q as a fixed point, but P as a point moving in the direction Q to P, so that α remains constant, and then, omitting the equation $(=\rho)$, we have a relation between the coordinates x, y of the point P thus moving in a right line,—that is, we have the equation of the line through the given point (a, b) at a given inclination α to the axis of x. And, moreover, if, using this equation ($=\rho$), we write $x=a+\rho\cos\alpha$, $y=b+\rho\sin\alpha$, then we have expressions for the coordinates x, y of a point of this line, in terms of the variable parameter ρ.

Again, take the point T to be fixed, but consider the point P as moving in the line TP at right angles to QT. If instead of ξ_1 we take p for the distance QT, then the equation $\xi_1=\xi\cos\alpha'+\eta\sin\alpha'$ will be

$$(x-a)\cos\alpha'+(y-b)\sin\alpha'=p;$$

that is, this will be the equation of a line such that its perpendicular distance from the point (a, b) is $=p$, and that the inclination of this distance to the axis of x is $=\alpha'$.

From either form it appears that the equation of a line is, in fact, a linear equation of the form $Ax+By+C=0$. It is important to notice that, starting from this equation, we can determine conversely the α but not the (a, b) of the form of equation which contains these quantities; and in like manner the α' but not the (a, b) or p of the other form of equation. The reason is obvious. In each case (a, b) denote the coordinates of a point, fixed indeed, but which is in the first form any point of the line, and in the second form any point whatever. Thus, in the second form the point from which the perpendicular is let fall may be the origin. Here $(a, b)=(0, 0)$, and the equation is $x\cos\alpha'+y\sin\alpha'-p=0$. Comparing this with $Ax+By+C=0$, we have the values of $\cos\alpha'$, $\sin\alpha'$, and p.

13. The equation

$$\rho^2=(x-a)^2+(y-b)^2$$

is an expression for the squared distance of the two points (a, b) and (x, y). Taking as before the point Q, coordinates (a, b), as a fixed point, and writing c in the place of ρ, the equation

$$(x-a)^2+(y-b)^2=c^2$$

expresses that the point (x, y) is always at a given distance c from the given point (a, b); viz., this is the equation of a circle, having (a, b) for the coordinates of its centre, and c for its radius.

The equation is of the form

$$x^2+y^2+2Ax+2By+C=0,$$

and here, the number of constants being the same, we can identify the two equations; we find $a=-A$, $b=-B$, $c^2=A^2+B^2-C$, or the last equation is that of a circle having $-A$, $-B$ for the coordinates of its centre, and $\sqrt{A^2+B^2-C}$ for its radius.

14. Drawing (fig. 11) Qy_1 at right angles at Qx_1, and taking Qx_1, Qy_1 as a new set of rectangular axes, if instead of ξ_1, η_1 we write x_1, y_1, we have x_1, y_1 as the new coordinates of the point P; and writing also α in place of α' (α now denoting the inclination of the axes Qx_1 and Ox), we have the formulæ for transformation between two sets of rectangular axes. These are :

$$x-a=x_1\cos\alpha-y_1\sin\alpha,$$
$$y-b=x_1\sin\alpha+y_1\cos\alpha,$$

and

$$x_1=(x-a)\cos\alpha+(y-b)\sin\alpha,$$
$$y_1=-(x-a)\sin\alpha+(y-b)\cos\alpha,$$

each set being obviously at once deducible from the other one. In these formulæ (a, b) are the xy-coordinates of the new origin Q_1, and α is the inclination of Qx_1 to Ox. It is to be noticed that Qx_1, Qy_1 are so placed that, by moving O to Q, and then turning the axes Ox_1, Oy_1 round Q (through an angle α measured in the sense Ox to Oy), the original axes Ox, Oy will come to coincide with Qx_1, Qy_1 respectively. This could not have been done if Qy_1 had been drawn (at right angles always to Qx_1) in the reverse direction, we should then have had in the formulæ $-y_1$ instead of y_1. The new formulæ which would be thus obtained are of an essentially distinct form: the analytical test is that in the formulæ as written down we can, by giving to α a proper value (in fact $\alpha=0$), make the $(x-a)$ and $(y-b)$ equal to x_1 and y_1 respectively; in the other system we could only make them equal to $x_1, -y_1$, or $-x_1, y_1$ respectively. But for the very reason that the second system can be so easily derived from the first, it is proper to attend exclusively to the first system,—that is, always to take the new axes so that the two sets admit of being brought into coincidence.

In the foregoing system of two pairs of equations, the first pair give the original coordinates x, y in terms of the new coordinates x_1, y_1; the second pair the new coordinates x_1, y_1 in terms of the original coordinates x, y. The formulæ involve (a, b), the original coordinates of the new origin; it would be easy instead of these to introduce (a_1, b_1), the new coordinates of the origin. Writing $(a, b)=(0, 0)$, we have, of course, the formulæ for transformation between two sets of rectangular axes *having the same origin*, and it is as well to write the formulæ in this more simple form; the subsequent transformation to a new origin, but with axes parallel to the original axes, can then be effected without any difficulty.

15. All questions in regard to the line may be solved by means of one or other of the foregoing forms—

$$Ax+By+C=0,$$
$$y=Ax+B,$$
$$\frac{x-a}{\cos\alpha}=\frac{y-b}{\sin\alpha},$$
$$(x-a)\cos\alpha'+(y-b)\sin\alpha'-p=0;$$

or it may be by a comparison of these different forms: thus, using the first form, it has been already shown that the equation of the line through two given points (x_1, y_1), (x_2, y_2) is

$$x(y_1-y_2)-y(x_1-x_2)+x_1y_2-x_2y_1=0,$$

or, as this may be written,

$$y-y_1=\frac{y_2-y_1}{x_2-x_1}(x-x_1).$$

A particular case is the equation

$$\frac{x}{a}+\frac{y}{b}=1,$$

representing the line through the points $(a, 0)$ and $(0, b)$, or, what is the same thing, the line meeting the axes of x and y at the distances from the origin a and b respectively. It may be noticed that, in the form $Ax+By+C=0$, $-\frac{A}{B}$ denotes the tangent of the inclination to the axis of x, or we may say that $B\div\sqrt{A^2+B^2}$ and $-A\div\sqrt{A^2+B^2}$ denote respectively the cosine and the sine of the inclination to the axis of x. A better form is this: $A\div\sqrt{A^2+B^2}$ and $B\div\sqrt{A^2+B^2}$ denote respectively the cosine and the sine of inclination to the axis of x of the perpendicular upon the line. So of course, in regard to the form $y=Ax+B$, A is here the tangent of the inclination to the axis of x; $1\div\sqrt{A^2+1}$ and $A\div\sqrt{A^2+1}$ are the cosine and sine of this inclination, &c. It thus appears that the condition in order that the lines $Ax+By+C=0$ and $A'x+B'y-C'=0$ may meet at right angles is $AA'+BB'=0$; so when the equations are $y=Ax+B$, $y=A'x+B'$, the condition is $AA'+1=0$, or say the value of A' is $=-1\div A$.

The perpendicular distance of the point (a, b) from the line $Ax+By+C=0$ is $(Aa+Bb+C)\div\sqrt{A^2+B^2}$. In all the formulæ involving $\sqrt{A^2+B^2}$ or $\sqrt{A^2+1}$, the radical should be written with the sign $\pm$, which is essentially indeterminate: the like indeterminateness of sign presents itself in the expression for the distance of two points $\rho=\pm\sqrt{(x-a)^2+(y-b)^2}$; if, as before, the points are Q, P, and the indefinite line through these is $z'QPz$, then it is the same thing whether we measure off from Q along this line, considered as drawn from z' towards z, a positive distance k, or along the line considered as drawn reversely from z towards z', the equal negative distance $-k$, and the expression for the distance ρ is thus properly of the form $\pm k$. It is interesting to compare expressions which do not involve a radical: thus, in seeking for the expression for the perpendicular distance of the point (a, b) from a given line, let the equation of the given line be taken in the form, $x \cos \alpha + y \sin \alpha - p = 0$ (p being the perpendicular distance from the origin, α its inclination to the axis of x): the equation of the line may also be written $(x-a) \cos \alpha + (y-b) \sin \alpha - p_1 = 0$, and we have thence $p_1 = p - a \cos \alpha - b \sin \alpha$, the required expression for the distance p_1: it is here assumed that p_1 is drawn from (a, b) in the same sense as p is drawn from the origin, and the indeterminateness of sign is thus removed.

16. As an instance of the mode of using the formulæ, take the problem of finding the locus of a point such that its distance from a given point is in a given ratio to its distance from a given line.

We take (a, b) as the coordinates of the given point, and it is convenient to take (x, y) as the coordinates of the variable point, the locus of which is required: it thus becomes necessary to use other letters, say (X, Y), for current coordinates in the equation of the given line. Suppose this is a line such that its perpendicular distance from the origin is $=p$, and that the inclination of p to the axis of x is $=\alpha$; the equation is $X \cos \alpha + Y \sin \alpha - p = 0$. In the result obtained in § 15, writing (x, y) in place of (a, b); it appears that the perpendicular distance of this line from the point (x, y) is

$$= p - x \cos \alpha - y \sin \alpha;$$

hence the equation of the locus is

$$\sqrt{(x-a)^2 + (y-b)^2} = e\,(p - x \cos \alpha - y \sin \alpha),$$

or say

$$(x-a)^2 + (y-b)^2 - e^2\,(x \cos \alpha + y \sin \alpha - p)^2 = 0,$$

an equation of the second order.

The Conics (Parabola, Ellipse, Hyperbola).

17. The conics or, as they were called, conic sections were originally defined as the sections of a right circular cone; but Apollonius substituted a definition, which is in fact that of the last example: the curve is the locus of a point such that its distance from a given point (called the focus) is in a given ratio to its distance from a given line (called the directrix); taking the ratio as $e : 1$, then e is called the eccentricity.

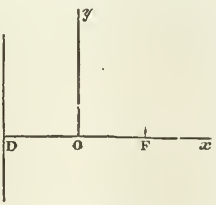

Fig. 12.

Take FD for the perpendicular from the focus F upon the directrix, and the given ratio being that of $e : 1$ ($e >, =,$ or < 1, but positive), and let the distance FD be divided at O in the given ratio, say we have $OD = m$, $OF = em$, where m is positive;—then the origin may be taken at O, the axis Ox being in the direction OF (that is from O to F), and the axis Oy at right angles to it. The distance of the point (x, y) from F is $= \sqrt{(x-em)^2 + y^2}$, its distance from the directrix is $= x + m$; the equation therefore is

$$(x - em)^2 + y^2 = e^2\,(x+m)^2\,,$$

or, what is the same thing, it is

$$(1 - e^2)x^2 - 2me\,(1+e)x + y^2 = 0.$$

If $e^2 = 1$, or, since e is taken to be positive, if $e = 1$, this is

$$y^2 - 4mx = 0,$$

which is the parabola.

If e^2 not $= 1$, then the equation may be written

$$(1-e^2)\left(x - \frac{me}{1-e}\right)^2 + y^2 = \frac{m^2e^2(1+e)}{1-e}$$

Supposing e positive and < 1, then, writing $m = \frac{a(1-e)}{e}$, the equation becomes

$$(1-e^2)(x-a)^2 + y^2 = a^2(1-e^2),$$

that is,

$$\frac{(x-a)^2}{a^2} + \frac{y^2}{a^2(1-e^2)} = 1;$$

or, changing the origin and writing $b^2 = a^2(1-e^2)$, this is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1,$$

which is the ellipse.

And similarly if e be positive and > 1, then writing $m = \frac{a(e-1)}{e}$, the equation becomes

$$(1-e^2)(x+a)^2 + y^2 = a^2(1-e^2)$$

that is,

$$\frac{(x+a)^2}{a^2} + \frac{y^2}{a^2(1-e^2)} = 1,$$

or changing the origin and writing $b^2 = a^2(e^2-1)$, this is

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1.$$

which is the hyperbola.

18. The general equation $ax^2 + 2hxy + by^2 + 2fy + 2gx + c = 0$, or as it is written $(a, b, c, f, g, h)(x, y, 1)^2 = 0$, may be such that the quadric function breaks up into factors, $= (\alpha x + \beta y + \gamma)(\alpha' x + \beta' y + \gamma')$; and in this case the equation represents a pair of lines, or (it may be) two coincident lines. When it does not so break up, the function can be put in the form $\lambda\{(x-a')^2 + (y-b')^2 - e^2(x \cos\alpha + y \sin\alpha - p)^2\}$, or, equating the two expressions there will be six equations for the determination of λ, a', b', e, p, α; and by what precedes, if a', b', e, p, α are real, the curve is either a parabola, ellipse, or hyperbola. The original coefficients (a, b, c, f, g, h) may be such as not to give any system of real values for a' b', e, p, α; but when this is so the equation $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ does not represent a real curve[1]; the imaginary curve which it represents is, however, regarded as a conic. Disregarding the special cases of the pair of lines and the twice repeated line, it thus appears that the only real curves represented by the general equation $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ are the parabola, the ellipse, and the hyperbola. The circle is considered as a particular case of the ellipse.

The same result is obtained by transforming the equation $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ to new axes. If in the first place the origin be unaltered, then the directions of the new (rectangular) axes Ox_1, Oy_1 can be found so that h_1 (the coefficient of the term x_1y_1) shall be $=0$; when this is done, then either one of the coefficients of x_1^2, y_1^2 is $=0$, and the curve is then a parabola, or neither of these coefficients is $= 0$, and the curve is then an ellipse or hyperbola, according as the two coefficients are of the same sign or of opposite signs.

19. The curves can be at once traced from their equations:—

$y^2 = 4mx$, for the parabola (fig. 13),

$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, for the ellipse (fig. 14),

$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$, for the hyperbola (fig. 15);

and it will be noticed how the form of the last equation puts in evidence the two asymptotes $\frac{x}{a} = \pm\frac{y}{b}$ of the hyperbola. Referred to the asymptotes (as a set of

[1] It is proper to remark that, when $(a, b, c, f, g, \lambda)(x, y, 1)^2 = 0$ *does* represent a real curve, there are in fact four systems of values of a', b', e, p, α, two real, the other two imaginary; we have thus two real equations and two imaginary equations, each of them of the form $(x-a')^2 + (y-b')^2 = e^2\,(\cos\alpha + y \cos\beta - p)^2$, representing each of them one and the same real curve. This is consistent with the assertion of the text that the real curve is in every case represented by a real equation of this form.

oblique axes) the equation of the hyperbola takes the form $xy=c$; and in particular, if in this equation the

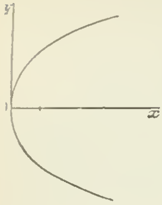

Fig. 13.

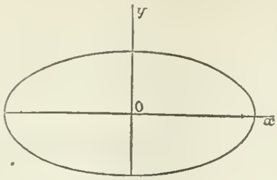

Fig. 14.

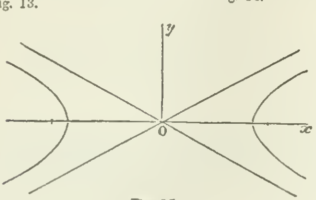

Fig. 15.

axes are at right angles, then the equation represents the rectangular hyperbola referred to its asymptotes as axes.

Tangent, Normal, Circle and Radius of Curvature, &c.

20. There is great convenience in using the language and notation of the infinitesimal analysis; thus we consider on a curve a point with coordinates (x, y), and a consecutive point the coordinates of which are $(x+dx,\ y+dy)$, or again a second consecutive point with coordinates $(x+dx+\frac{1}{2}d^2x,\ y+dy+\frac{1}{2}d^2y)$, &c.; and in the final results the ratios of the infinitesimals must be replaced by differential coefficients in the proper manner; thus, if x, y are considered as given functions of a parameter θ, then dx, dy have in fact the values $\frac{dx}{d\theta}d\theta$, $\frac{dy}{d\theta}d\theta$, and (only the ratio being really material) they may in the result be replaced by $\frac{dx}{d\theta}$, $\frac{dy}{d\theta}$. This includes the case where the equation of the curve is given in the form $y=\phi(x)$; θ is here $=x$, and the increments dx, dy are in the result to be replaced by 1, $\frac{dy}{dx}$. So also with the infinitesimals of the higher orders d^2x, &c.

21. The tangent at the point (x, y) is the line through this point and the consecutive point $(x+dx, y+dy)$; hence, taking ξ, η as current coordinates, the equation is

$$\frac{\xi-x}{dx}=\frac{\eta-y}{dy},$$

an equation which is satisfied on writing therein $\xi, \eta=(x, y)$ or $=(x+dx,\ y+dy)$. The equation may be written

$$\eta-y=\frac{dy}{dx}(\xi-x),$$

$\frac{dy}{dx}$ being now the differential coefficient of y in regard to x; and this form is applicable whether y is given directly as a function of x, or in whatever way y is in effect given as a function of x: if as before x, y are given each of them as a function of θ, then the value of $\frac{dy}{dx}$ is $=\frac{dy}{d\theta}\div\frac{dx}{d\theta}$, which is the result obtained from the original form on writing therein $\frac{dx}{d\theta}$, $\frac{dy}{d\theta}$, for dx, dy respectively.

So again, when the curve is given by an equation $u=0$ between the coordinates (x, y), then $\frac{dy}{dx}$ is obtained from the equation $\frac{du}{dx}+\frac{du}{dy}\frac{dy}{dx}=0$. But here it is more elegant, using the original form, to eliminate dx, dy by the formula $\frac{du}{dx}dx+\frac{du}{dy}dy$; we thus obtain the equation of the tangent in the form

$$\frac{du}{dx}(\xi-x)+\frac{du}{dy}(\eta-y)=0.$$

For example, in the case of the ellipse $\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$, the equation is $\frac{x}{a^2}(\xi-x)+\frac{y}{b^2}(\eta-y)=0$; or reducing by means of the equation of the curve the equation of the tangent is

$$\frac{\xi x}{a^2}+\frac{\eta y}{b^2}=1.$$

The normal is a line through the point at right angles to the tangent; the equation therefore is

$$(\xi-x)dx+(\eta-y)dy=0,$$

where dx, dy are to be replaced by their proportional values as before.

22. The circle of curvature is the circle through the point and two consecutive points of the curve. Taking the equation to be

$$(\xi-\alpha)^2+(\eta-\beta)^2=\gamma^2,$$

the values of α, β are given by

$$x-\alpha=\frac{dy(dx^2+dy^2)}{dxd^2y-dyd^2x},\ y-\beta=\frac{-dx(dx^2+dy^2)}{dxd^2y-dyd^2x},$$

and we then have

$$\gamma^2,=(x-\alpha)^2+(y-\beta)^2,=\frac{(dx^2+dy^2)^3}{(dx\,d^2y-dy\,d^2x)^2}.$$

In the case where y is given directly as a function of x, then, writing for shortness $p=\frac{dy}{dx}$, $q=\frac{d^2y}{dx^2}$, this is $\gamma^2=\frac{(1+p^2)^3}{q^2}$, or, as the equation is usually written, $\gamma=\frac{(1+p^2)^{\frac{3}{2}}}{-q}$, the radius of curvature, considered to be positive or negative according as the curve is concave or convex to the axis of x.

It may be added that the centre of curvature is the intersection of the normal by the consecutive normal.

The locus of the centre of curvature is the evolute. If from the expressions of α, β regarded as functions of x we eliminate x, we have thus an equation between (α, β), which is the equation of the evolute.

Polar Coordinates.

23. The position of a point may be determined by means of its distance from a fixed point and the inclination of this distance to a fixed line through the fixed point. Say we have r the distance from the origin, and θ the inclination of r to the axis of x; r and θ are then the polar coordinates of the point, r the radius vector, and θ the inclination. These are immediately connected with the Cartesian coordinates x, y by the formulæ $x=r\cos\theta$, $y=r\sin\theta$; and the transition from either set of coordinates to the other can thus be made without difficulty. But the use of polar coordinates is very convenient, as well in reference to certain classes of questions relating to curves of any kind—for instance, in the dynamics of central forces—as in relation to curves having in regard to the origin the symmetry of the regular polygon (curves such as that represented by the equation $r=\cos m\theta$), and also in regard to the class of curves called spirals, where

thé radius vector r is given as an algebraical or exponential function of the inclination θ.

Trilinear Coordinates.

24. Consider a fixed triangle ABC, and (regarding the sides as indefinite lines) suppose for a moment that p, q, r denote the distances of a point P from the sides BC, CA, AB respectively,—these distances being measured either perpendicularly to the several sides, or each of them in a given direction. To fix the ideas each distance may be considered as positive for a point inside the triangle, and the sign is thus fixed for any point whatever. There is then an identical relation between p, q, r: if a, b, c are the lengths of the sides, and the distances are measured perpendicularly thereto, the relation is $ap+bq+cr=$ twice the area of triangle. But taking x, y, z proportional to p, q, r, or if we please proportional to given multiples of p, q, r, then only the ratios of x, y, z are determined; their absolute values remain arbitrary. But the ratios of p, q, r, and consequently also the ratios of x, y, z determine, and that uniquely, the point; and it being understood that only the ratios are attended to, we say that (x, y, z) are the coordinates of the point. The equation of a line has thus the form $ax+by+cz=0$, and generally that of a curve of the nth order is a homogeneous equation of this order between the coordinates, $(*\between x, y, z)^n=0$. The advantage over Cartesian coordinates is in the greater symmetry of the analytical forms, and in the more convenient treatment of the line infinity and of points at infinity. The method includes that of Cartesian coordinates, the homogeneous equation in x, y, z is in fact an equation in $\frac{x}{z}, \frac{y}{z}$, which two quantities may be regarded as denoting Cartesian coordinates; or, what is the same thing, we may in the equation write $z=1$. It may be added that if the trilinear coordinates (x, y, z) are regarded as the Cartesian coordinates of a point of space, then the equation is that of a cone having the origin for its vertex; and conversely that such equation of a cone may be regarded as the equation in trilinear coordinates of a plane curve.

General Point-Coordinates.—Line-Coordinates.

25. All the coordinates considered thus far are point-coordinates. More generally, any two quantities (or the ratios of three quantities) serving to determine the position of a point in the plane may be regarded as the coordinates of the point; or, if instead of a single point they determine a system of two or more points, then as the coordinates of the system of points. But, as noticed under CURVE, there are also line-coordinates serving to determine the position of a line; the ordinary case is when the line is determined by means of the ratios of three quantities ξ, η, ζ (correlative to the trilinear coordinates x, y, z). A linear equation $a\xi+b\eta+c\zeta=0$ represents then the system of lines such that the coordinates of each of them satisfy this relation, in fact, all the lines which pass through a given point; and it is thus regarded as the line-equation of this point; and generally a homogeneous equation $(*\between \xi,\eta,\zeta)^n=0$ represents the curve which is the envelope of all the lines the coordinates of which satisfy this equation, and it is thus regarded as the line-equation of this curve.

II. SOLID ANALYTICAL GEOMETRY (§§26–40).

26. We are here concerned with points in space,—the position of a point being determined by its three coordinates x, y, z. We consider three coordinate planes, at right angles to each other, dividing the whole of space into eight portions called octants, the coordinates of a point being the perpendicular distances of the point from the three planes respectively, each distance being considered as positive or negative according as it lies on the one or the other side of the plane. Thus the coordinates in the eight octants have respectively the signs

x	y	z
+	+	+
+	−	+
−	+	+
−	−	+
+	+	−
+	−	−
−	+	−
−	−	−

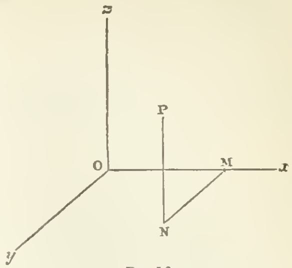

Fig. 16.

The positive parts of the axes are usually drawn as in fig. 16, which represents a point P, the coordinates of which have the positive values OM, MN, NP.

27. It may be remarked, as regards the delineation of such solid figures, that if we have in space three lines at right angles to each other, say Oa, Ob, Oc, of equal lengths, then it is possible to project these by parallel lines upon a plane in such wise that the projections Oa', Ob', Oc' shall be at given inclinations to each other, and that these lengths shall be to each other in given ratios: in particular the two lines Oa', Oc' may be at right angles to each other, and their lengths equal, the direction of Ob', and its proportion to the two equal lengths Oa', Oc' being arbitrary. It thus appears that we may as in the figure draw Ox, Oz at right angles to each other, and Oy in an arbitrary direction; and moreover represent the coordinates x, z on equal scales, and the remaining coordinate y on an arbitrary scale (which may be that of the other two coordinates x, z, but is in practice usually smaller). The advantage, of course, is that a figure in *one* of the coordinate planes xz is represented in its proper form without distortion; but it may be in some cases preferable to employ the isometrical projection, wherein the three axes are represented by lines inclined to each other at angles of 120°, and the scales for the coordinates are equal (fig. 17).

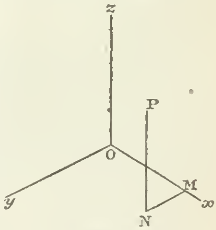

Fig. 17.

For the delineation of a surface of a tolerably simple form, it is frequently sufficient to draw (according to the foregoing projection) the sections by the coordinate planes; and in particular when the surface is symmetrical in regard to the coordinate planes, it is sufficient to draw the quarter-sections belonging to a single octant of the surface; thus fig. 18 is a convenient representation of an octant of the wave surface. Or a surface may be delineated by means of a series of parallel sections, or (taking these to be the sections by a series of horizontal planes) say by a series of contour lines. Of course, other sections may be drawn or indicated, if necessary. For the delineation of a curve, a convenient method is to represent, as above, a series of the points P thereof, each point P being accompanied by the ordinates PN, which serves to refer the point to the plane of xy; this is in effect a representation of each point P of the curve, by means of two points P, N such that the line PN has a fixed direction. Both as regards curves and surfaces, the employment of stereographic representations is very interesting.

28. In plane geometry, reckoning the line as a curve of the first order, we have only the point and the curve. In solid geometry, reckoning a line as a curve of the first order, and the plane as a surface of the first order, we

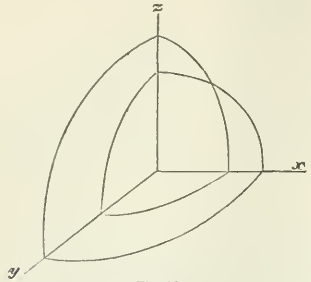

Fig. 18.

have the point, the curve, and the surface; but the increase of complexity is far greater that would hence at first sight appear. In plane geometry a curve is considered in connexion with lines (its tangents); but in solid geometry the curve is considered in connexion with lines and planes (its tangents and osculating planes), and the surface also in connexion with lines and planes (its tangent lines and tangent planes); there are surfaces arising out of the line—cones, skew surfaces, developables, doubly and triply infinite systems of lines, and whole classes of theories which have nothing analogous to them in plane geometry: it is thus a very small part indeed of the subject which can be even referred to in the present article.

In the case of a surface we have between the coordinates (x, y, z) a single, or say a onefold relation, which can be represented by a single relation $f(x, y, z)=0$; or we may consider the coordinates expressed each of them as a given function of two variable parameters p, q; the form $z=f(x, y)$ is a particular case of each of these modes of representation; in other words, we have in the first mode $f(x, y, z)=z-f(x,y)$, and in the second mode $x=p, y=q$ for the expression of two of the coordinates in terms of the parameters.

In the case of a curve we have between the coordinates (x, y, z) a twofold relation: two equations $f(x, y, z)=0$, $\phi(x, y, z)=0$ give such a relation; *i.e.*, the curve is here considered as the intersection of two surfaces (but the curve is not always the complete intersection of two surfaces, and there are hence difficulties); or, again, the coordinates may be given each of them as a function of a single variable parameter. The form $y=\phi x$, $z=\psi x$, where two of the coordinates are given in terms of the third, is a particular case of each of these modes of representation.

29. The remarks under plane geometry as to descriptive and metrical propositions, and as to the non-metrical character of the method of coordinates when used for the proof of a descriptive proposition, apply also to solid geometry; and they might be illustrated in like manner by the instance of the theorem of the radical centre of four spheres. The proof is obtained from the consideration that S and S′ being each of them a function of the form $x^2+y^2+z^2+ax+by+cz+d$, the difference $S-S'$ is a mere linear function of the coordinates, and consequently that $S-S'=0$ is the equation of the plane containing the circle of intersection of the two spheres $S=0$ and $S'=0$.

Metrical Theory.

30. The foundation in solid geometry of the metrical theory is in fact the before-mentioned theorem that if a finite right line PQ be projected upon any other line OO′ by lines perpendicular to OO′, then the length of the projection P′Q′ is equal to the length of PQ into the cosine of its inclination to P′Q′—or (in the form in which it is now convenient to state the theorem) the perpendicular distance P′Q′ of two parallel planes is equal to the inclined distance PQ into the cosine of the inclination. Hence also the algebraical sum of the projections of the sides of a closed polygon upon any line is $=0$; or, reversing the signs of certain sides and considering the polygon as made up of two broken lines each extending from the same initial to the same terminal point, the sum of the projections of the one set of lines upon any line is equal to the sum of the projections of the other set of lines upon the same line. When any of the lines are at right angles to the given line (or, what is the same thing, in a plane at right angles to the given line) the projections of these lines severally vanish.

31. Consider the skew quadrilateral QMNP, the sides QM, MN, NP being respectively parallel to the three rectangular axes Ox, Oy, Oz; let the lengths of these sides be ξ, η, ζ, and that of the side QP be $=\rho$; and let the cosines of the inclinations (or say the cosine-inclinations) of ρ to the three axes be α, β, γ; then projecting successively on the three sides and on QP we have

$$\xi,\ \eta,\ \zeta=\rho\alpha,\ \rho\beta,\ \rho\gamma,$$

and

$$\rho=\alpha\xi+\beta\eta+\gamma\zeta,$$

whence $\rho^2=\xi^2+\eta^2+\zeta^2$, which is the relation between a distance ρ and its projections ξ, η, ζ upon three rectangular axes. And from the same equations we obtain $\alpha^2+\beta^2+\gamma^2=1$, which is a relation connecting the cosine-inclinations of a line to three rectangular axes.

Suppose we have through Q any other line QT, and let the cosine-inclinations of this to the axes be α', β', γ', and δ be its cosine-inclination to QP; also let p be the length of the projection of QP upon QT; then projecting on QT we have

$$p=\alpha'\xi+\beta'\eta+\gamma'\zeta,\ =\rho\delta.$$

And in the last equation substituting for ξ, η, ζ their values $\rho\alpha, \rho\beta, \rho\gamma$ we find

$$\delta=\alpha\alpha'+\beta\beta'+\gamma\gamma',$$

which is an expression for the mutual cosine-inclination of two lines, the cosine-inclinations of which to tha axes are α, β, γ and α', β', γ' respectively. We have of course $\alpha^2+\beta^2+\gamma^2=1$, and $\alpha'^2+\beta'^2+\gamma'^2=1$; and hence also

$$1-\delta^2=\alpha^2+\beta^2+\gamma^2)(\alpha'^2+\beta'^2+\gamma'^2)-(\alpha\alpha'+\beta\beta'+\gamma\gamma')^2,$$
$$=(\beta\gamma'-\beta'\gamma)^2+(\gamma\alpha'-\gamma'\alpha)^2+(\alpha\beta'-\alpha'\beta)^2;$$

so that the sine of the inclination can only be expressed as a square root. These formulæ are the foundation of spherical trigonometry.

The Line, Plane, and Sphere.

32. The foregoing formulæ give at once the equations of these loci.

For first, taking Q to be a fixed point, coordinates (a, b, c) and the cosine-inclinations (α, β, γ) to be constant, then P will be a point in the line through Q in the direction thus determined; or, taking (x, y, z) for its coordinates, these will be the current coordinates of a point in the line. The values of ξ, η, ζ then are $x-a$, $y-b$, $z-c$, and we thus have

$$\frac{x-a}{\alpha}=\frac{y-b}{\beta}=\frac{z-c}{\gamma}(=\rho),$$

which (omitting the last equation, $=\rho$) are the equations of the line through the point (a, b, c), the cosine-inclinations to the axes being α, β, γ, and these quantities being connected by the relation $\alpha^2+\beta^2+\gamma^2=1$. This equation may be omitted, and then α, β, γ, instead of being equal, will only be proportional to the cosine-inclinations.

Using the last equation, and writing

$$x,\ y,\ z=a+\alpha\rho,\ b+\beta\rho,\ c+\gamma\rho,$$

these are expressions for the current coordinates in terms of a parameter ρ, which is in fact the distance from the fixed point (a, b, c).

It is easy to see that, if the coordinates (x, y, z) are connected by any two linear equations, these equations can always be brought into the foregoing form, and hence that the two linear equations represent a line.

Secondly, taking for greater simplicity the point Q to be coincident with the origin, and α', β', γ', p to be constant, then p is the perpendicular distance of a plane from the origin, and α', β', γ' are the cosine-inclinations of this distance to the axes ($\alpha'^2+\beta'^2+\gamma'^2=1$). P is any point in this plane, and taking its coordinates to be (x, y, z) then (ξ, η, ζ) are $=(x, y, z)$, and the foregoing equation $p=\alpha'\xi+\beta'\eta+\gamma'\zeta$ becomes

$$\alpha' x+\beta' y+\gamma' z=p\,,$$

which is the equation of the plane in question.

If, more generally, Q is not coincident with the origin, then, taking its coordinates to be (a, b, c), and writing p_1 instead of p, the equation is

$$\alpha'(x-a)+\beta'(y-b)+\gamma'(z-c)=p_1\,;$$

and we thence have $p_1=p-(a\alpha'+b\beta'+c\gamma')$, which is an expression for the perpendicular distance of the point (a, b, c) from the plane in question.

It is obvious that any linear equation $Ax+By+Cz+D=0$ between the coordinates can always be brought into the foregoing form, and hence that such equation represents a plane.

Thirdly, supposing Q to be a fixed point, coordinates (a, b, c) and the distance QP, $=\rho$, to be constant, say this is $=d$, then, as before, the values of ξ, η, ζ are $x-a$, $y-b$, $z-c$, and the equation $\xi^2+\eta^2+\zeta^2=\rho^2$ becomes

$$(x-a)^2+(y-b)^2+(z-c)^2=d^2,$$

which is the equation of the sphere, coordinates of the centre $=(a, b, c)$ and radius $=d$.

A quadric equation wherein the terms of the second order are $x^2+y^2+z^2$, viz., an equation

$$x^2+y^2+z^2+Ax+By+Cz+D=0,$$

can always, it is clear, be brought into the foregoing form; and it thus appears that this is the equation of a sphere, coordinates of the centre $-\frac{1}{2}A$, $-\frac{1}{2}B$, $-\frac{1}{2}C$, and squared radius $=\frac{1}{4}(A^2+B^2+C^2)-D$.

Cylinders, Cones, Ruled Surfaces.

33. A singly infinite system of lines or system of lines depending upon one variable parameter forms a surface; and the equation of the surface is obtained by eliminating the parameter between the two equations of the line.

If the lines all pass through a given point, then the surface is a cone; and, in particular, if the lines are all parallel to a given line, then the surface is a cylinder.

Beginning with this last case, suppose the lines are parallel to the line $x=mz$, $y=nz$, the equations of a line of the system are $x=mz+a$, $y=nz+b$,—where a, b are supposed to be functions of the variable parameter, or, what is the same thing, there is between them a relation $f(a, b)=0$: we have $a=x-mz$, $b=y-nz$, and the result of the elimination of the parameter therefore is $f(x-mz, y-nz)=0$, which is thus the general equation of the cylinder the generating lines whereof are parallel to the line $x=mz$, $y=nz$. The equation of the section by the plane $z=0$ is $f(x, y)=0$, and conversely if the cylinder be determined by means of its curve of intersection with the plane $z=0$, then, taking the equation of this curve to be $f(x, y)=0$, the equation of the cylinder is $f(x-mz, y-nz)=0$. Thus, if the curve of intersection be the circle $(x-\alpha)^2+(y-\beta)^2=\gamma^2$, we have $(x-mz-\alpha)^2+(y-nz-\beta)^2=\gamma^2$ as the equation of an oblique cylinder on this base, and thus also $(x-\alpha)^2+(y-\beta)^2=\gamma^2$ as the equation of the right cylinder.

If the lines all pass through a given point (a, b, c), then the equations of a line are $x-a=\alpha(z-c)$, $y-b=\beta(z-c)$, where α, β are functions of the variable parameter, or, what is the same thing, there exists between them an equation $f(\alpha, \beta)=0$; the elimination of the parameter gives, therefore, $f\left(\dfrac{x-a}{z-c}, \dfrac{y-b}{z-c}\right)=0$; and this equation, or, what is the same thing, any homogeneous equation $f(x-a, y-b, z-c)=0$, or, taking f to be a rational and integral function of the order n, say $(*)(x-a, y-b, z-c)^n=0$, is the general equation of the cone having the point (a, b, c) for its vertex. Taking the vertex to be at the origin, the equation is $(*)(x, y, z)^n=0$; and, in particular, $(*)(x, y, z)^2=0$ is the equation of a cone of the second order, or quadricone, having the origin for its vertex.

34. In the general case of a singly infinite system of lines, the locus is a ruled surface (or *regulus*). If the system be such that a line does not intersect the consecutive line, then the surface is a skew surface, or scroll; but if it be such that each line intersects the consecutive line, then it is a developable, or torse.

Suppose, for instance, that the equations of a line (depending on the variable parameter θ) are $\dfrac{x}{a}+\dfrac{y}{c}=\theta\left(1+\dfrac{y}{b}\right)$, $\dfrac{x}{a}-\dfrac{z}{c}=\dfrac{1}{\theta}\left(1-\dfrac{y}{b}\right)$, then, eliminating θ, we have $\dfrac{x^2}{a^2}-\dfrac{z^2}{c^2}=1-\dfrac{y^2}{b^2}$, or say $\dfrac{x^2}{a^2}+\dfrac{y^2}{b^2}-\dfrac{z^2}{c^2}=1$, the equation of a quadric surface, afterwards called the hyperboloid of one sheet; this surface is consequently a scroll. It is to be remarked that we have upon the surface a second singly infinite series of lines; the equations of a line of this second system (depending on the variable parameter ϕ) are

$$\frac{x}{a}+\frac{z}{c}=\phi\left(1-\frac{y}{b}\right),\ \frac{x}{a}-\frac{z}{c}=\frac{1}{\phi}\left(1+\frac{y}{b}\right).$$

It is easily shown that any line of the one system intersects every line of the other system.

Considering any curve (of double curvature) whatever, the tangent lines of the curve form a singly infinite system of lines, each line intersecting the consecutive line of the system,—that is, they form a developable, or torse; the curve and torse are thus inseparably connected together, forming a single geometrical figure. A plane through three consecutive points of the curve (or osculating plane of the curve) contains two consecutive tangents, that is, two consecutive lines of the torse, and is thus a tangent plane of the torse along a generating line.

Transformation of Coordinates.

35. There is no difficulty in changing the origin, and it is for brevity assumed that the origin remains unaltered. We have, then, two sets of rectangular axes, Ox, Oy, Oz, and Ox_1, Oy_1, Oz_1, the mutual cosine-inclinations being shown by the diagram—

	x	y	z
x_1	α	β	γ
y_1	α'	β'	γ'
z_1	α''	β''	γ''

that is, α, β, γ are the cosine-inclinations of Ox_1 to Ox, Oy, Oz; α', β', γ' those of Oy_1, &c.

And this diagram gives also the linear expressions of the coordinates (x_1, y_1, z_1) or (x, y, z) of either set in terms of those of the other set; we thus have

$$\begin{aligned} x_1&=\alpha\,x+\beta\,y+\gamma\,z\,, & x&=\alpha x_1+\alpha' y_1+\alpha'' z_1\,,\\ y_1&=\alpha' x+\beta' y+\gamma' z\,, & y&=\beta x_1+\beta' y_1+\beta'' z_1\,,\\ z_1&=\alpha'' x+\beta'' y+\gamma'' z\,, & z&=\gamma x_1+\gamma' y_1+\gamma'' z_1\,,\end{aligned}$$

which are obtained by projection, as above explained. Each of these equations is, in fact, nothing else than the before-mentioned equation $p=\alpha'\xi+\beta'\eta+\gamma'\zeta$, adapted to the problem in hand.

But we have to consider the relations between the nine coefficients. By what precedes, or by the consideration that we must have identically $x^2+y^2+z^2=x_1{}^2+y_1{}^2+z_1{}^2$, it appears that these satisfy the relations—

$$\begin{aligned} \alpha^2+\beta^2+\gamma^2&=1\,, & \alpha^2+\alpha'^2+\alpha''^2&=1\,,\\ \alpha'^2+\beta'^2+\gamma'^2&=1\,, & \beta^2+\beta'^2+\beta''^2&=1\,,\\ \alpha''^2+\beta''^2+\gamma''^2&=1\,, & \gamma^2+\gamma'^2+\gamma''^2&=1\,,\\ \alpha'\alpha''+\beta'\beta''+\gamma'\gamma''&=0\,, & \beta\gamma+\beta'\gamma'+\beta''\gamma''&=0\,,\\ \alpha''\alpha+\beta''\beta+\gamma''\gamma&=0\,, & \gamma\alpha+\gamma'\alpha'+\gamma''\alpha''&=0\,,\\ \alpha\alpha'+\beta\beta'+\gamma\gamma'&=0\,, & \alpha\beta+\alpha'\beta'+\alpha''\beta''&=0\,,\end{aligned}$$

either set of six equations being implied in the other set.

It follows that the square of the determinant

$$\begin{vmatrix} \alpha, & \beta, & \gamma \\ \alpha', & \beta', & \gamma' \\ \alpha'', & \beta'', & \gamma'' \end{vmatrix}$$

is $=1$; and hence that the determinant itself is $=\pm 1$. The distinction of the two cases is an important one: if the determinant is $=+1$, then the axes Ox_1, Oy_1, Oz_1 are such that they can by a rotation about O be brought to coincide with Ox, Oy, Oz respectively; if it is $=-1$, then they cannot. But in the latter case, by measuring x_1, y_1, z_1 in the opposite directions we change the signs of all the coefficients and so make the determinant to be $=+1$; hence this case need alone be considered, and it is accordingly assumed that the determinant is $=+1$. This being so, it is found that we have a further set of nine equations, $\alpha=\beta'\gamma''-\beta''\gamma'$, &c.; that is, the coefficients arranged as in the diagram have the values

$\beta'\gamma'' - \beta''\gamma'$	$\gamma'\alpha'' - \gamma''\alpha'$	$\alpha'\beta' - \alpha'\beta'$
$\beta''\gamma - \beta\gamma''$	$\gamma''\alpha - \gamma\alpha''$	$\alpha''\beta - \alpha\beta''$
$\beta\gamma' - \beta'\gamma$	$\gamma\alpha' - \gamma'\alpha$	$\alpha\beta' - \alpha'\beta$

36. It is important to express the nine coefficients in terms of three independent quantities. A solution which, although unsymmetrical, is very convenient in Astronomy and Dynamics is to use for the purpose the three angles θ, ϕ, τ of fig. 19; say θ = longitude of the node; ϕ = inclination; and τ = longitude of x_1 from node.

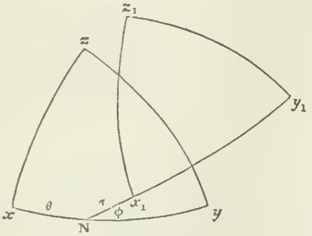

Fig. 19.

The diagram of transformation then is

	x	y	z
x_1	$\cos\tau\cos\theta - \sin\tau\sin\theta\cos\phi$	$\cos\tau\sin\theta + \sin\tau\cos\theta\cos\phi$	$\sin\tau\sin\phi$
y_1	$-\sin\tau\cos\theta - \cos\tau\sin\theta\cos\phi$	$-\sin\tau\sin\theta + \cos\tau\cos\theta\cos\phi$	$\cos\tau\sin\phi$
z_1	$\sin\theta\sin\phi$	$-\cos\theta\sin\phi$	$\cos\phi$

But a more elegant solution (due to Rodrigues) is that contained in the diagram

	x	y	z
x_1	$1+\lambda^2-\mu^2-\nu^2$	$2(\lambda\mu-\nu)$	$2(\lambda\nu+\mu)$
y_1	$2(\lambda\mu+\nu)$	$1-\lambda^2+\mu^2-\nu^2$	$2(\mu\nu-\lambda)$
z_1	$2(\nu\lambda-\mu)$	$2(\mu\nu+\lambda)$	$1-\lambda^2-\mu^2+\nu^2$

$$\div(1+\lambda^2-\mu^2+\nu^2)$$

The nine coefficients of transformation are the nine functions of the diagram, each divided by $1+\lambda^2+\mu^2+\nu^2$; the expressions contain as they should do the three arbitrary quantities λ, μ, ν; and the identity $x_1^2+y_1^2+z_1^2=x^2+y^2+z^2$ can be at once verified. It may be added that the transformation can be expressed in the quaternion form

$$ix_1+jy_1+kz_1=(1+\Lambda)(ix+jy+kz)(1+\Lambda)^{-1}$$

where Λ denotes the vector $i\lambda+j\mu+k\nu$.

Quadric Surfaces (Paraboloids, Ellipsoid, Hyperboloids).

37. It appears by a discussion of the general equation of the second order $(a, \ldots \between x, y, z, 1)^2=0$ that the proper quadric surfaces[1] represented by such an equation are the following five surfaces (a and b positive):—

(1.) $z = \frac{x^2}{2a}+\frac{y^2}{2b}$, elliptic paraboloid.

(2.) $z = \frac{x^2}{2a}-\frac{y^2}{2b}$, hyperbolic paraboloid.

(3.) $\frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2} = 1$, ellipsoid.

(4.) $\frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2} = 1$, hyperboloid of one sheet.

(5.) $\frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2} = -1$, hyperboloid of two sheets.

It is at once seen that these are distinct surfaces; and the equations also show very readily the general form and mode of generation of the several surfaces.

In the elliptic paraboloid (fig. 20), the sections by the planes of zx and zy are the parabolas

$$z=\frac{x^2}{2a},\ z=\frac{y^2}{2b},$$

having the common axis Oz; and the section by any plane $z=\gamma$ parallel to that of xy is the ellipse

$$\gamma=\frac{x^2}{2a}+\frac{y^2}{2b};$$

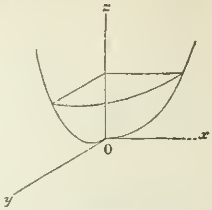

Fig. 20.

so that the surface is generated by a variable ellipse moving parallel to itself along the parabolas as directrices.

In the hyperbolic paraboloid (fig. 21) the sections by the planes of zx, zy are the parabolas $z=\frac{x^2}{2a}$, $z=-\frac{x^2}{2b}$, having the opposite axes Oz, Oz', and the section by a plane $z=\gamma$ parallel to that of xy is the hyperbola $\gamma=\frac{x^2}{2a}-\frac{y^2}{2b}$, which has its transverse axis parallel to Ox or Oy according as γ is positive or negative. The surface is thus generated by a variable hyperbola moving parallel to itself along the parabolas as directrices. The form is best seen from fig. 22, which represents the sections by planes parallel to the plane of xy, or say the contour lines; the continuous lines are the sections above the plane of xy, and the dotted lines the sections below this plane. The form is, in fact, that of a saddle.

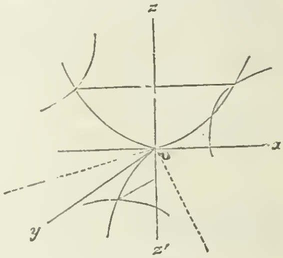

Fig. 21.

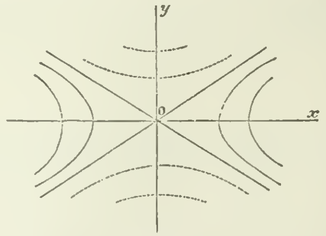

Fig. 22.

In the ellipsoid (fig. 23) the sections by the planes of zx, zy, and xy are each of them an ellipse, and the section by any parallel plane is also an ellipse. The surface may be considered as generated by an ellipse moving parallel to itself along two ellipses as directrices.

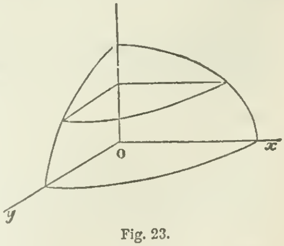

Fig. 23.

In the hyperboloid of one sheet (fig. 24), the sections by the planes of zx, zy are the hyperbolas

$$\frac{x^2}{a}-\frac{z^2}{c^2}=1,\ \frac{y^2}{b^2}-\frac{z^2}{c^2}=1,$$

having a common conjugate axis zOz'; the section by the plane of

[1] The improper quadric surfaces represented by the general equation of the second order are (1) the pair of planes or plane-pair, including as a special case the twice repeated plane, and (2) the cone, including as a special case the cylinder. There is but one form of cone; but the cylinder may be parabolic, elliptic, or hyperbolic.

xy, and that by any parallel plane is an ellipse; and the surface may be considered as generated by a variable ellipse moving parallel to itself along the two hyperbolas as directrices.

In the hyperboloid of two sheets (fig. 25), the sections by the planes of zx and zy are the hyperbolas

$$\frac{z^2}{c^2}-\frac{x^2}{a^2}=1\,,\ \frac{z^2}{c^2}-\frac{y^2}{b^2}=1\,,$$

having the common transverse axis zOz'; the section by any plane $z=\pm\gamma$ parallel to that of xy, γ being in absolute magnitude $>c$, is the ellipse

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}=\frac{y^2}{c^2}-1$$

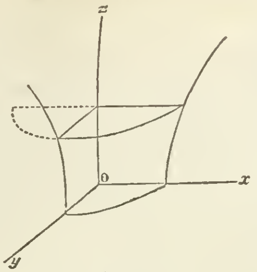

Fig. 24.

and the surface, consisting of two distinct portions or sheets, may be considered as generated by a variable ellipse moving parallel to itself along the hyperbolas as directrices.

The hyperbolic paraboloid is such (and it is easy from the figure to understand how this may be the case) that there exist upon it two singly infinite series of right lines. The same is the case with the hyperboloid of one sheet (ruled or skew hyperboloid, as with reference to this property it is termed). If we imagine two equal and parallel circular disks, their points connected by strings of equal length, so that these are the generating lines of a right circular cylinder, then by turning one of the disks about its centre through the same angle in one or the other direction, the strings will in each case generate one and the same hyperboloid, and will in regard to it be the two systems of lines on the surface, or say the two systems of generating lines; and the general configuration is the same when instead of circles we have ellipses. It has been already shown analytically that the equation $\frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2}=1$ is satisfied by each of two pairs of linear relations between the coordinates.

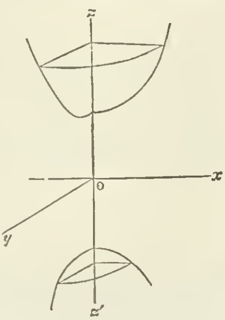

Fig. 25.

Curves; Tangent, Osculating Plane, Curvature, &c.

38. It will be convenient to consider the coordinates (x, y, z) of the point on the curve as given in terms of a parameter θ, so that dx, dy, dz, d^2x, &c., will be proportional to $\frac{dx}{d\theta}, \frac{dy}{d\theta}, \frac{dz}{d\theta}, \frac{d^2x}{d\theta^2}$, &c. But only a part of the analytical formulæ will be given. ξ, η, ζ are used as current coordinates.

The tangent is the line through the point (x, y, z) and the consecutive point $(x+dx, y+dy, z+dz)$; its equations therefore are

$$\frac{\xi-x}{dx}=\frac{\eta-y}{dy}=\frac{\zeta-z}{dz}\,.$$

The osculating plane is the plane through the point and two consecutive points, and contains therefore the tangent; its equation is

$$\begin{vmatrix} \xi-x, & \eta-y, & \zeta-z \\ dx\ , & dy\ , & dz \\ d^2x\,, & d^2y\ , & d^2z \end{vmatrix}=0$$

or, what is the same thing,

$$(\xi-x)(dy\,d^2z-dz\,d^2y)+(\eta-y)(dz\,d^2x-dx\,d^2z)+(\zeta-z)(dx\,d^2y-dy\,d^2x)=0.$$

The normal plane is the plane through the point at right angles to the tangent. It meets the osculating plane in a line called the principal normal; and drawing through the point a line at right angles to the osculating plane, this is called the binormal. We have thus at the point a set of three rectangular axes—the tangent, the principal normal, and the binormal.

We have through the point and three consecutive points a sphere of spherical curvature,—the centre and radius thereof being the centre, and radius, of spherical curvature. The sphere is met by the osculating plane in the circle of absolute curvature,—the centre and radius thereof being the centre, and radius, of absolute curvature. The centre of absolute curvature is also the intersection of the principal normal by the normal plane at the consecutive point.

Surfaces; Tangent Lines and Plane, Curvature, &c.

39. It will be convenient to consider the surface as given by an equation $f(x, y, z)=0$ between the coordinates; taking (x, y, z) for the coordinates of a given point, and $(x+dx,\ y+dy,\ z+dz)$ for those of a consecutive point, the increments dx, dy, dz satisfy the condition

$$\frac{df}{dx}dx+\frac{df}{dy}dy+\frac{df}{dz}dz=0\,,$$

but the ratio of two of the increments, suppose $dx:dy$, may be regarded as arbitrary. Only a part of the analytical formulæ will be given. ξ, η, ζ are used as current coordinates.

We have through the point a singly infinite series of right lines, each meeting the surface in a consecutive point, or say having each of them two-point intersection with the surface. These lines lie all of them in a plane which is the tangent plane; its equation is

$$\frac{df}{dx}(\xi-x)+\frac{df}{dy}(\eta-y)+\frac{df}{dz}(\zeta-z)=0,$$

as is at once verified by observing that this equation is satisfied (irrespectively of the value of $dx:dy$) on writing therein $\xi, \eta, \zeta=x+dx,\ y+dy,\ z+dz$.

The line through the point at right angles to the tangent plane is called the normal; its equations are

$$\frac{\xi-x}{\frac{df}{dx}}=\frac{\eta-y}{\frac{df}{dy}}=\frac{\zeta-z}{\frac{df}{dz}}\,.$$

In the series of tangent lines there are in general two (real or imaginary) lines, each of which meets the surface in a second consecutive point, or say it has three-point intersection with the surface; these are called the chief-tangents (Haupt-tangenten). The tangent-plane cuts the surface in a curve, having at the point of contact a node (double point), the tangents to the two branches being the chief-tangents.

In the case of a quadric surface the curve of intersection, *qua* curve of the second order, can only have a node by breaking up into a pair of lines; that is, every tangent-plane meets the surface in a pair of lines, or we have on the surface two singly infinite systems of lines; these are real for the hyperbolic paraboloid and the hyperboloid of one sheet, imaginary in other cases.

At each point of a surface the chief-tangents determine two directions; and passing along one of them to a consecutive point, and thence (without abrupt change of direction) along the new chief-tangent to a consecutive point, and so on, we have on the surface a chief-tangent curve; and there are, it is clear, two singly infinite series of such curves. In the case of a quadric surface, the curves are the right lines on the surface.

40. If at the point we draw in the tangent-plane two lines bisecting the angles between the chief-tangents, these lines (which are at right angles to each other) are called the principal tangents.[1] We have thus at each point of

[1] The point on the surface may be such that the directions of the principal tangents become arbitrary; the point is then an umbilicus. It is in the text assumed that the point on the surface is not an umbilicus.

the surface a set of rectangular axes, the normal and the two principal tangents.

Proceeding from the point along a principal tangent to a consecutive point on the surface, and thence (without abrupt change of direction) along the new principal tangent to a consecutive point, and so on, we have on the surface a curve of curvature; there are, it is clear, two singly infinite series of such curves, cutting each other at right angles at each point of the surface.

Passing from the given point in an arbitrary direction to a consecutive point on the surface, the normal at the given point is not intersected by the normal at the consecutive point; but passing to the consecutive point along a curve of curvature (or, what is the same thing, along a principal tangent) the normal at the given point is intersected by the normal at the consecutive point; we have thus on the normal two centres of curvature, and the distances of these from the point on the surface are the two principal radii of curvature of the surface at that point; these are also the radii of curvature of the sections of the surface by planes through the normal and the two principal tangents respectively; or say they are the radii of curvature of the normal sections through the two principal tangents respectively. Take at the point the axis of z in the direction of the normal, and those of x and y in the directions of the principal tangents respectively, then, if if the radii of curvature be a, b (the signs being such that the coordinates of the two centres of curvature are $z=a$ and $z=b$ respectively), the surface has in the neighbourhood of the point the form of the paraboloid

$$z=\frac{x^2}{2a}+\frac{y^2}{2b}$$

and the chief-tangents are determined by the equation $0=\frac{x^2}{2a}+\frac{y^2}{2b}$. The two centres of curvature may be on the same side of the point or on opposite sides; in the former case a and b have the same sign, the paraboloid is elliptic, and the chief-tangents are imaginary; in the latter case a and b have opposite signs, the paraboloid is hyperbolic, and the chief-tangents are real.

The normal sections of the surface and the paraboloid by the same plane have the same radius of curvature; and it thence readily follows that the radius of curvature of a normal section of the surface by a plane inclined at an angle θ to that of zx is given by the equation

$$\frac{1}{\rho}=\frac{\cos^2\theta}{a}+\frac{\sin^2\theta}{b}.$$

The section in question is that by a plane through the normal and a line in the tangent plane inclined at an angle θ to the principal tangent along the axis of x. To complete the theory, consider the section by a plane having the same trace upon the tangent plane, but inclined to the normal at an angle ϕ; then it is shown without difficulty (Meunier's theorem) that the radius of curvature of this inclined section of the surface is $=\rho\cos\phi$. (A. CA.)

GEORGE I., king of Great Britain and Ireland (*George Louis*, 1660-1727), born in 1660, was heir through his father Ernest Augustus to the hereditary lay bishopric of Osnabrück, and to the duchy of Calenburg, which formed one portion of the Hanoverian possessions of the house of Brunswick, whilst he secured the reversion of the other portion, the duchy of Celle or Zell, by his marriage (1682) with the heiress, his cousin Sophia Dorothea. The marriage was not a happy one. The morals of German courts in the end of the 17th century took their tone from the splendid profligacy of Versailles. It became the fashion for a prince to amuse himself with a mistress or more frequently with many mistresses simultaneously, and he was often content that the mistresses whom he favoured should be neither beautiful nor witty. George Louis followed the usual course. Count Königsmark—a handsome adventurer—seized the opportunity of paying court to the deserted wife. Conjugal infidelity was held at Hanover to be a privilege of the male sex. Count Königsmark was assassinated. Sophia Dorothea was divorced in 1694, and remained in seclusion till her death in 1726. When her descendant in the fourth generation attempted in England to call his wife to account for sins of which he was himself notoriously guilty, free-spoken public opinion reprobated the offence in no measured terms. In the Germany of the 17th century all free-spoken public opinion had been crushed out by the misery of the Thirty Years' War, and it was understood that princes were to arrange their domestic life according to their own pleasure.

The prince's father did much to raise the dignity of his family. By sending help to the emperor when he was struggling against the French and the Turks, he obtained the grant of a ninth electorate in 1692. His marriage with Sophia, the youngest daughter of Elizabeth the daughter of James I. of England, was not one which at first seemed likely to confer any prospect of advancement to his family. But though there were many persons whose birth gave them better claims than she had to the English crown, she found herself, upon the death of the duke of Gloucester, the next Protestant heir after Anne. The Act of Settlement in 1701 secured the inheritance to herself and her descendants. Being old and unambitious she rather permitted herself to be burthened with the honour than thrust herself forward to meet it. Her son George took a deeper interest in the matter. In his youth he had fought with determined courage in the wars of William III. Succeeding to the electorate on his father's death in 1698, he had sent a welcome reinforcement of Hanoverians to fight under Marlborough at Blenheim. With prudent persistence he attached himself closely to the Whigs and to Marlborough, refusing Tory offers of an independent command, and receiving in return for his fidelity a guarantee by the Dutch of his succession to England in the Barrier treaty of 1709. In 1714 when Anne was growing old, and Bolingbroke and the more reckless Tories were coquetting with the son of James II., the Whigs invited George's eldest son, who was duke of Cambridge, to visit England in order to be on the spot in case of need. Neither the elector nor his mother approved of a step which was likely to alienate the queen, and which was specially distasteful to himself, as he was on very bad terms with his son. Yet they did not set themselves against the strong wish of the party to which they looked for support, and it is possible that troubles would have arisen from any attempt to carry out the plan, if the deaths, first of the electress (May 28) and then of the queen (August 1, 1714), had not laid open George's way to the succession without further effort of his own.

In some respects the position of the new king was not unlike that of William III. a quarter of a century before. Both sovereigns were foreigners, with little knowledge of English politics and little interest in English legislation. Both sovereigns arrived at a time when party spirit had been running high, and when the task before the ruler was to still the waves of contention. In spite of the difference between an intellectually great man and an intellectually small one, in spite too of the difference between the king who began by choosing his ministers from both parties, and the king who persisted in choosing his ministers from only one, the work of pacification was accomplished by George even more thoroughly than by William.

George I. was fortunate in arriving in England when a great military struggle had come to an end. He had therefore no reason to call upon the nation to make great sacrifices. All that he wanted was to secure for himself and his family a high position which he hardly knew how to occupy, to fill the pockets of his German attendants and his German mistresses, to get away as often as possible from the uncongenial islanders whose language he was unable to speak, and to use the strength of England to obtain petty advantages for his German principality. In order to do this he attached himself entirely to the Whig party, though he refused to place himself at the disposal of its leaders. He gave his confidence, not to Somers and Wharton and Marlborough, but to Stanhope and Townshend, the statesmen of the second rank. At first he seemed to be playing a dangerous game. The Tories, whom he rejected, were numerically superior to their adversaries, and were strong in the support of the country gentlemen and the country clergy. The strength of the Whigs lay in the towns and in the higher aristocracy. Below both parties lay the mass of the nation, which cared nothing for politics except in special seasons of excitement, and which asked only to be let alone. In 1715 a Jacobite insurrection in the north, supported by the appearance of the Pretender, the son of James II., in Scotland, was suppressed, and its suppression not only gave to the Government a character of stability, but displayed its adversaries in an unfavourable light as the disturbers of the peace.

Even this advantage, however, would have been thrown away, if the Whigs in power had continued to be animated by violent party spirit. What really happened was that the Tory leaders were excluded from office, but that the principles and prejudices of the Tories were admitted to their full weight in the policy of the Government. The natural result followed. The leaders to whom no regard was paid continued in opposition. The rank and file who would personally have gained nothing by a party victory were conciliated into quiescence.

This mingling of two policies was conspicuous both in the foreign and the domestic actions of the reign. In the days of Queen Anne, the Whig party had advocated the continuance of war with a view to the complete humiliation of the king of France, whom they feared as the protector of the Pretender, and in whose family connexion with the king of Spain they saw a danger for England. The Tory party on the other hand had been the authors of the peace of Utrecht, and held that France was sufficiently depressed. A fortunate concurrence of circumstances enabled George's ministers, by an alliance with the regent of France, the duke of Orleans, to pursue at the same time the Whig policy of separating France from Spain and from the cause of the Pretender, and the Tory policy of the maintenance of a good understanding with their neighbour across the Channel. The same eclecticism was discernible in the proceedings of the home Government. The Whigs were conciliated by the repeal of the Schism Act and the Occasional Conformity Act, whilst the Tories were conciliated by the maintenance of the Test Act in all its vigour. The satisfaction of the masses was increased by the general well-being of the nation.

Very little of all that was thus accomplished was directly owing to George I. The policy of the reign is the policy of his ministers. Stanhope and Townshend from 1714 to 1717 were mainly occupied with the defence of the Hanoverian settlement. After the dismissal of the latter in 1717, Stanhope in conjunction with Sunderland took up a more decided Whig policy. The Occasional Conformity Act and the Schism Act were repealed in 1719. But the wish of the liberal Whigs to modify if not to repeal the Test Act remained unsatisfied. In the following year the bursting of the South Sea bubble, and the subsequent deaths of Stanhope in 1721 and of Sunderland in 1722, cleared the way for the accession to power of Sir Robert Walpole, to whom and not to the king was due the conciliatory policy which quieted Tory opposition by abstaining from pushing Whig principles to their legitimate consequences.

Nevertheless something of the honour due to Walpole must be reckoned to the king's credit. It is evident that at his accession his decisions were by no means unimportant. The royal authority was still able within certain limits to make its own terms. This support was so necessary to the Whigs that they made no resistance when he threw aside their leaders on his arrival in England. When by his personal intervention he dismissed Townshend and appointed Sunderland, he had no such social and parliamentary combination to fear as that which almost mastered his great-grandson in his struggle for power. If such a combination arose before the end of his reign it was owing more to his omitting to fulfil the duties of his station than from the necessity of the case. As he could talk no English, and his ministers could talk no German, he absented himself from the meetings of the cabinet, and his frequent absences from England and his want of interest in English politics strengthened the cabinet in its tendency to assert an independent position. Walpole at last by his skill in the management of parliament rose as a subject into the almost royal position denoted by the name of prime minister. In connexion with Walpole the force of wealth and station established the Whig aristocracy in a point of vantage from which it was afterwards difficult to dislodge them. Yet, though George had allowed the power which had been exercised by William and Anne to slip through his hands, it was understood to the last that if he chose to exert himself he might cease to be a mere cipher in the conduct of affairs. As late as in 1727 Bolingbroke gained over one of the king's mistresses, the duchess of Kendal; and though her support of the fallen Jacobite took no effect, Walpole was not without fear that her reiterated entreaties would lead to his dismissal. The king's death in a carriage on his way to Hanover, in the night between 10th and 11th June in the same year, put an end to these apprehensions.

His only children were his successor George II., and Sophia Dorothea (1687-1757), who married in 1706 Frederick William, crown prince (afterwards king) of Prussia. She was the mother of Frederick the Great. (S. R. G.)

GEORGE II. (*George Augustus*, 1683-1760), the only son of George I., was born in 1683. In 1705 he married Wilhelmina Caroline of Anspach. In 1706 he was created earl of Cambridge. In 1708 he fought bravely at Oudenarde. At his father's accession to the English throne he was thirty-one years of age. He was already on bad terms with his father. The position of an heir-apparent is in no case an easy one to fill with dignity, and the ill treatment of the prince's mother by his father was not likely to strengthen in him a reverence for paternal authority. It was most unwillingly that, on his first journey to Hanover in 1716, George I. appointed the prince of Wales guardian of the realm during his absence. In 1717 the existing ill feeling ripened into an open breach. At the baptism of one of his children, the prince selected one godfather whilst the king persisted in selecting another. The young man spoke angrily, was ordered into arrest, and was subsequently commanded to leave St James's, and to be excluded from all court ceremonies. The prince took up his residence at Leicester House, and did everything in his power to support the opposition against his father's ministers.

When therefore George I. died in 1727, it was generally supposed that Walpole would be at once dismissed. The first direction of the new king was that Sir Spencer Compton would draw up the speech in which he was to announce to the Privy Council his accession. Compton, not knowing how to set about his task, applied to Walpole for aid. The queen took advantage of this evidence of incapacity, advocated Walpole's cause with her husband, and procured his continuance in office. This curious scene was indicative of the course likely to be taken by the new sovereign. His own mind was incapable of rising above the merest details of business. He made war in the spirit of a drill-sergeant, and he economized his income with the minute regularity of a clerk. A blunder of a master of the ceremonies in marshalling the attendants on a levee put him out of temper. He took the greatest pleasure in counting his money piece by piece, and he never forgot a date. He was above all things methodical and regular. "He seems," said one who knew him well, "to think his having done a thing to-day an unanswerable reason for his doing it to-morrow."

Most men so utterly immersed in details would be very impracticable to deal with. They would obstinately refuse to listen to a wisdom and prudence which meant nothing in their ears, and which brought home to them a sense of their own inferiority. It was the happy peculiarity of George II. that he was exempt from this failing. He seemed to have an instinctive understanding that such and such persons were either wiser or even stronger than himself, and when he had once discovered that, he gave way with scarcely a struggle. Thus it was that, though in his domestic relations he was as loose a liver as his father had been, he allowed himself to be guided by the wise but unobtrusive counsels of his wife until her death in 1737, and that when once he had recognized Walpole's superiority he allowed himself to be guided by the political sagacity of the great minister. It is difficult to exaggerate the importance of such a temper upon the development of the constitution. The apathy of the nation in all but the most exciting political questions, fostered by the calculated conservatism of Walpole, had thrown power into the hands of the great landowners. They maintained their authority by supporting a minister who was ready to make use of corruption, wherever corruption was likely to be useful, and who could veil over the baseness of the means which he employed by his talents in debate and in finance. To shake off a combination so strong would not have been easy. George II. submitted to it without a struggle.

So strong indeed had the Whig aristocracy grown that it began to lose its cohesion. Walpole was determined to monopolize power, and he dismissed from office all who ventured to oppose him. An Opposition formidable in talents was gradually formed. In its composite ranks were to be found Tories and discontented Whigs, discarded official hacks who were hungry for the emoluments of office, and youthful purists who fancied that if Walpole were removed, bribes and pensions would cease to be attractive to a corrupt generation. Behind them was Bolingbroke, excluded from parliament but suggesting every party move. In 1737 the opposition acquired the support of Frederick prince of Wales. The young man, weak and headstrong, rebelled against the strict discipline exacted by his father. His marriage in 1736 to Augusta of Saxony brought on an open quarrel. In 1737 just as the princess of Wales was about to give birth to her first child, she was hurried away by her husband from Hampton Court to St James's Palace at the imminent risk of her life, simply in order that the prince might show his spite to his father who had provided all necessary attendance at the former place. George ordered his son to quit St James's, and to absent himself from court. Frederick in disgrace gave the support of his name, and he had nothing else to give, to the Opposition. Later in the year 1737, on November 20, Queen Caroline died. In 1742 Walpole, weighed down by the unpopularity both of his reluctance to engage in a war with Spain and of his supposed remissness in conducting the operations of that war, was driven from office. His successors formed a composite ministry in which Walpole's old colleagues and Walpole's old opponents were alike to be found.

The years which followed settled conclusively, at least for this reign, the constitutional question of the power of appointing ministers. The war between Spain and England had broken out in 1739. In 1741 the death of the emperor Charles VI. brought on the war of the Austrian succession. The position of George II. as a Hanoverian prince drew him to the side of Maria Theresa through jealousy of the rising Prussian monarchy. Jealousy of France led England in the same direction, and in 1741 a subsidy of £300,000 was voted to Maria Theresa. The king himself went to Germany and attempted to carry on the war according to his own notions. Those notions led him to regard the safety of Hanover as of far more importance than the wishes of England. Finding that a French army was about to march upon his German states, he concluded with France a treaty of neutrality for a year without consulting a single English minister. In England the news was received with feelings of disgust. The expenditure of English money and troops was to be thrown uselessly away as soon as it appeared that Hanover was in the slightest danger. In 1742 Walpole was no longer in office. Lord Wilmington, the nominal head of the ministry, was a mere cipher. The ablest and most energetic of his colleagues, Lord Carteret, attached himself specially to the king, and sought to maintain himself in power by his special favour and by brilliant achievements in diplomacy.

In part at least by Carteret's mediation the peace of Breslau was signed, by which Maria Theresa ceded Silesia to Frederick (July 28, 1742). Thus relieved on her northern frontier, she struck out vigorously towards the west. Bavaria was overrun by her troops. In the beginning of 1743 one French army was driven across the Rhine. On June 27th another French army was defeated by George II. in person at Dettingen. Victory brought elation to Maria Theresa. Her war of defence was turned into a war of vengeance. Bavaria was to be annexed. The French frontier was to be driven back. George II. and Carteret after some hesitation placed themselves on her side. Of the public opinion of the political classes in England they took no thought. Hanoverian troops were indeed to be employed in the war, but they were to be taken into British pay. Collisions between British and Hanoverian officers were frequent. A storm arose against the preference shown to Hanoverian interests. After a brief struggle Carteret, having become Lord Granville by his mother's death, was driven from office in November 1744.

Henry Pelham, who had become prime minister in the preceding year, thus saw himself established in power. By the acceptance of this ministry, the king acknowledged that the function of choosing a ministry and directing a policy had passed from his hands. In 1745 indeed he recalled Granville, but a few days were sufficient to convince him of the futility of his attempt, and the effort to exclude Pitt at a later time proved equally fruitless.

Important as were the events of the remainder of the reign, therefore, they can hardly be grouped round the name of George II. The resistance to the invasion of the young Pretender in 1745, the peace of Aix-la-Chapelle in 1748, the great war ministry of Pitt at the close of the reign, did not receive their impulse from him. He had indeed done his best to exclude Pitt from office. He disliked him on account of his opposition in former years to the sacrifices demanded by the Hanoverian connexion. When in 1756 Pitt became secretary of state in the Devonshire administration, the King bore the yoke with difficulty. Early in the next year he complained of Pitt's long speeches as being above his comprehension, and on April 5, 1757, he dismissed him, only to take him back shortly after, when Pitt, coalescing with Newcastle, became master of the situation. Before Pitt's dismissal George II. had for once an opportunity of placing himself on the popular side, though, as was the case of his grandson during the American war, it was when the popular side happened to be in the wrong. In the true spirit of a martinet, he wished to see Admiral Byng executed. Pitt urged the wish of the House of Commons to have him pardoned. "Sir," replied the king, "you have taught me to look for the sense of my subjects in another place than in the House of Commons." When George II. died in 1760, he left behind him a settled understanding that the monarchy was one of the least of the forces by which the policy of the country was directed. To this end he had contributed much by his disregard of English opinion in 1743; but it may fairly be added that, but for his readiness to give way to irresistible adversaries, the struggle might have been far more bitter and severe than it was.

Of the connexion between Hanover and England in this reign two memorials remain more pleasant to contemplate than the records of parliamentary and ministerial intrigues. With the support of George II., amidst the derision of the English fashionable world, the Hanoverian Handel produced in England those masterpieces which have given delight to millions, whilst the foundation of the university of Göttingen by the same king opened a door through which English political ideas afterwards penetrated into Germany.

George II. had three sons,—Frederick Louis (1707–1751); George William (1717–1718); and William Augustus, duke of Cumberland (1721–1765); and five daughters, Anne (1709–1759), married to William, prince of Orange, 1734; Amelia Sophia Eleonora (1711–1786); Elizabeth Caroline (1713–1757); Mary (1723–1772), married to Frederick, landgrave of Hesse Cassel, 1740; Louisa (1724–1751), married to Frederick V., king of Denmark, 1743. (S. R. G.)

GEORGE III. (*George William Frederick*, 1738–1820), born 4th June 1738, was the son of Frederick prince of Wales and the grandson of George II., whom he succeeded in 1760. After his father's death in 1751 he had been educated in seclusion from the fashionable world under the care of his mother and of her favourite counsellor the earl of Bute. He had been taught to revere the maxims of Bolingbroke's "Patriot King," and to believe that it was his appointed task in life to break the power of the Whig houses resting upon extensive property and the influence of patronage and corruption.

That power had already been gravely shaken. The Whigs from their incompetency were obliged when the Seven Years' War broke out to leave its management in the hands of William Pitt. The nation learned to applaud the great war minister who succeeded where others had failed, and whose immaculate purity put to shame the ruck of barterers of votes for places and pensions. In some sort the work of the new king was the continuation of the work of Pitt. But his methods were very different. He did not appeal to any widely spread feeling or prejudice; nor did he disdain the use of the arts which had maintained his opponents in power. The patronage of the crown was to be really as well as nominally his own; and he calculated, not without reason, that men would feel more flattered in accepting a place from a king than from a minister. The new Toryism of which he was the founder was no recurrence to the Toryism of the days of Charles II. or even of Anne. The question of the amount of toleration to be accorded to Dissenters had been entirely laid asleep. The point at issue was whether the crown should be replaced in the position which George I. might have occupied at the beginning of his reign, selecting the ministers and influencing the deliberations of the cabinet. For this struggle George III. possessed no inconsiderable advantages. With an inflexible tenacity of purpose, he was always ready to give way when resistance was really hopeless. As the first English-born sovereign of his house, speaking from his birth the language of his subjects, he found a way to the hearts of many who never regarded his predecessors as other than foreign intruders. The contrast, too, between the pure domestic life which he led with his wife Charlotte of Mecklenburg-Strelitz, whom he married in 1761, and the habits of three generations of his house, told in his favour with the vast majority of his subjects. Even his marriage had been a sacrifice to duty. Soon after his accession he had fallen in love with Lady Sarah Lennox, and had been observed to ride morning by morning along the Kensington Road, from which the object of his affections was to be seen from the lawn of Holland House making hay, or engaged in some other ostensible employment. Before the year was over Lady Sarah appeared as one of the queen's bridesmaids, and she was herself married to Sir Charles Bunbury in 1762.

At first everything seemed easy to him. Pitt had come to be regarded by his own colleagues as a minister who would pursue war at any price, and in getting rid of Pitt in 1761 and in carrying on the negotiations which led to the peace of Paris in 1762, the king was able to gather round him many persons who would not be willing to acquiesce in any permanent change in the system of government. With the signature of the peace his real difficulties began. The Whig houses, indeed, were divided amongst themselves by personal rivalries. But they were none of them inclined to let power and the advantages of power slip from their hands without a struggle. For some years a contest of influence was carried on without dignity and without any worthy aim. The king was not strong enough to impose upon parliament a ministry of his own choice. But he gathered round himself a body of dependants known as the king's friends, who were secure of his favour, and who voted one way or the other according to his wishes. Under these circumstances no ministry could possibly be stable; and yet every ministry was strong enough to impose some conditions on the king. Lord Bute, the king's first choice, resigned from a sense of his own incompetency in 1763. George Grenville was in office till 1765; the marquis of Rockingham till 1766; Pitt, becoming earl of Chatham, till illness compelled him to retire from the conduct of affairs in 1767, when he was succeeded by the duke of Grafton. But a struggle of interests could gain no real strength for any Government, and the only chance the king had of effecting a permanent change in the balance of power lay in the possibility of his associating himself with some phase of strong national feeling, as Pitt had associated himself with the war feeling caused by the dissatisfaction spread by the weakness and ineptitude of his predecessors.

Such a chance was offered by the question of the right to tax America. The notion that England was justified in throwing on America part of the expenses caused in the late war was popular in the country, and no one adopted it more pertinaciously than George III. At the bottom the position which he assumed was as contrary to the principles of parliamentary government as the encroachments of Charles I. had been. But it was veiled in the eyes of Englishmen by the prominence given to the power of the British parliament rather than to the power of the British king. In fact the theory of parliamentary government, like most theories after their truth has long been universally acknowledged, had become a superstition. Parliaments were held to be properly vested with authority, not because they adequately represented the national will, but simply because they were parliaments. There were thousands of people in England to whom it never occurred that there was any good reason why a British parliament should be allowed to levy a duty on tea in the London docks and should not be allowed to levy a duty on tea at the wharves of Boston. Undoubtedly George III. derived great strength from his honest participation in this mistake. Contending under parliamentary forms, he did not wound the susceptibilities of members of parliament, and when at last in 1770 he appointed Lord North—a minister of his own selection—prime minister, the object of his ambition was achieved with the concurrence of a large body of politicians who had nothing in common with the servile band of the king's friends.

As long as the struggle with America was carried on with any hope of success they gained that kind of support which is always forthcoming to a Government which shares in the errors and prejudices of its subjects. The expulsion of Wilkes from the House of Commons in 1769, and the refusal of the House to accept him as a member after his re-election, raised a grave constitutional question in which the king was wholly in the wrong; and Wilkes was popular in London and Middlesex. But his case roused no national indignation, and when in 1774 those sharp measures were taken with Boston which led to the commencement of the American rebellion in 1775, the opposition to the course taken by the king made little way either in parliament or in the country. Burke might point out the folly and inexpedience of the proceedings of the Government. Chatham might point out that the true spirit of English government was to be representative, and that that spirit was being violated at home and abroad. George III., who thought that the first duty of the Americans was to obey himself, had on his side the mass of unreflecting Englishmen who thought that the first duty of all colonists was to be useful and submissive to the mother-country. The natural dislike of every country engaged in war to see itself defeated was on his side, and when the news of Burgoyne's surrender at Saratoga arrived in 1777, subscriptions of money to raise new regiments poured freely in.

In March 1778 the French ambassador in London announced that a treaty of friendship and commerce had been concluded between France and the new United States of America. Lord North was anxious to resign power into stronger hands, and begged the king to receive Chatham as his prime minister. The king would not hear of it. He would have nothing to say to "that perfidious man" unless he would humble himself to enter the ministry as North's subordinate. Chatham naturally refused to do anything of the kind, and his death in the course of the year relieved the king of the danger of being again overruled by too overbearing a minister. England was now at war with France, and in 1779 she was also at war with Spain.

George III. was still able to control the disposition of office. He could not control the course of events. His very ministers gave up the struggle as hopeless long before he would acknowledge the true state of the case. Before the end of 1779, two of the leading members of the cabinet, Lords Gower and Weymouth, resigned rather than bear the responsibility of so ruinous an enterprise as the attempt to overpower America and France together. Lord North retained office, but he acknowledged to the king that his own opinion was precisely the same as that of his late colleagues.

The year 1780 saw an agitation rising in the country for economical reform, an agitation very closely though indirectly connected with the war policy of the king. The public meetings held in the country on this subject have no unimportant place in the development of the constitution. Since the presentation of the Kentish Petition in the reign of William III. there had been from time to time upheavings of popular feeling against the doings of the legislature, which kept up the tradition that parliament existed in order to represent the nation. But these upheavings had all been so associated with ignorance and violence as to make it very difficult for men of sense to look with displeasure upon the existing emancipation of the House of Commons from popular control. The Sacheverel riots, the violent attacks upon the Excise Bill, the no less violent advocacy of the Spanish war, the declamations of the supporters of Wilkes at a more recent time, and even in this very year the Gordon riots, were not likely to make thoughtful men anxious to place real power in the hands of the classes from whom such exhibitions of folly proceeded. But the movement for economical reform was of a very different kind. It was carried on soberly in manner, and with a definite practical object. It asked for no more than the king ought to have been willing to concede. It attacked useless expenditure upon sinecures and unnecessary offices in the household, the only use of which was to spread abroad corruption amongst the upper classes. George III. could not bear to be interfered with at all, or to surrender any element of power which had served him in his long struggle with the Whigs. He held out for more than another year. The news of the capitulation of York Town reached London on November 25, 1781. On March 20, 1782, Lord North resigned.

George III. accepted the consequences of defeat. He called the marquis of Rockingham to office at the head of a ministry composed of pure Whigs and of the disciples of the late earl of Chatham, and he authorized the new ministry to open negotiations for peace. Their hands were greatly strengthened by Rodney's victory over the French fleet, and the failure of the combined French and Spanish attack upon Gibraltar; and before the end of 1782 a provisional treaty was signed with America, preliminaries of peace with France and Spain being signed early in the following year. On September 3, 1783, the definitive treaties with the three countries were simultaneously concluded. "Sir," said the king to Mr Adams the first minister of the United States of America accredited to him, "I wish you to believe, and that it may be understood in America, that I have done nothing in the late contest but what I thought myself indispensably bound to do by the duty which I owed to my people. I will be very frank with you. I was the last to consent to the separation; but the separation having been made and having become inevitable, I have always said, as I say now, that I would be the first to meet the friendship of the United States as an independent power."

Long before the signature of the treaties Rockingham died (July 1, 1782). The king chose Lord Shelburne, the head of the Chatham section of the Government, to be prime minister. Fox and the followers of Rockingham refused to serve except under the duke of Portland, a minister of their own selection, and resigned office. The old constitutional struggle of the reign was now to be fought out once more. Fox, too weak to obtain a majority alone, coalesced with Lord North, and defeated Shelburne in the House of Commons on February 17, 1783. On April 2 the coalition took office, with Portland as nominal prime minister, and Fox and North the secretaries of state as its real heads.

This attempt to impose upon him a ministry which he disliked made the king very angry. But the new cabinet had a large majority in the House of Commons, and the only chance of resisting it lay in an appeal to the country against the House of Commons. Such an appeal was not likely to be responded to unless the ministers discredited themselves with the nation. George III. therefore waited his time. Though a coalition between men bitterly opposed to one another in all political principles and drawn together by nothing but love of office was in itself discreditable, it needed some more positive cause of dissatisfaction to arouse the constituencies, which were by no means so ready to interfere in political disputes at that time as they are now. Such dissatisfaction was given by the India Bill, drawn up by Burke. As soon as it had passed through the Commons the king hastened to procure its rejection in the House of Lords by his personal intervention with the Peers. He authorized Lord Temple to declare in his name that he would count any peer who voted for the Bill as his enemy. On December 17, 1783, the Bill was thrown out. The next day ministers were dismissed. William Pitt became prime minister. After some weeks' struggle with a constantly decreasing majority in the Commons, the king dissolved parliament on March 25, 1784. The country rallied round the crown and the young minister, and Pitt was firmly established in office.

Since the publication of a letter from Mr Orde in Lord E. Fitzmaurice's *Life of Shelburne* (iii. 393) there can be no reasonable doubt that Pitt not only took advantage of the king's intervention in the Lords, but was cognizant of the intrigue before it was actually carried out. It was upon him, too, that the weight of reconciling the country to an administration formed under such circumstances lay. How he acquitted himself under the task, what were his great achievements, and what his still greater unaccomplished projects should be told in connexion with his name rather than with that of the king. The general result, so far as George III. was concerned, was that to all outward appearance he had won the great battle of his life. It was he who was to appoint the prime minister, not any clique resting on a parliamentary support. But the circumstances under which the victory was won were such as to place the constitution in a position very different from that in which it would have been if the victory had been gained earlier in the reign. Intrigue there was indeed in 1783 and 1784 as there had been twenty years before. Parliamentary support was conciliated by Pitt by the grant of royal favours as it had been in the days of Bute. The actual blow was struck by a most questionable message to individual peers. But the main result of the whole political situation was that George III. had gone a long way towards disentangling the reality of parliamentary government from its accidents. His ministry finally stood because it had appealed to the constituencies against their representatives. At the present day it has properly become a constitutional axiom that no such appeal should be made by the crown itself. But it may reasonably be doubted whether any one but the king was at that time capable of making the appeal. Lord Shelburne, the leader of the ministry expelled by the coalition, was unpopular in the country, and the younger Pitt had not had time to make his great abilities known beyond a limited circle. The real question for the constitutional historian to settle is not whether under ordinary circumstances a king is the proper person to place himself really as well as nominally at the head of the government; but whether under the special circumstances which existed in 1783 it was not better that the king should call upon the people to support him, than that government should be left in the hands of men who rested their power on close boroughs and the dispensation of patronage, without looking beyond the walls of the House of Commons for support.

Of the glories of Pitt's ministry this is not the place to write. That the king gained credit by them far beyond his own deserts is beyond a doubt. Nor can there be any reasonable doubt that his own example of domestic propriety did much to strengthen the position of his minister. It is true that that life was unsufferably dull. No gleams of literary or artistic taste lightened it up. The dependants of the court became inured to dull routine unchequered by loving sympathy. The sons of the household were driven by the sheer weariness of such an existence into the coarsest profligacy. But all this was not visible from a distance. The tide of moral and religious improvement which had set in in England since the days of Wesley brought popularity to a king who was faithful to his wife, in the same way that the tide of manufacturing industry and scientific progress brought popularity to the minister who in some measure translated into practice the principles of the *Wealth of Nations*.

Nor were there wanting subjects of importance beyond the circle of politics in which George III. showed a lively interest. The voyages of discovery which made known so large a part of the islands and coasts of the Pacific Ocean received from him a warm support. In the early days of the Royal Academy, its finances were strengthened by liberal grants from the privy purse. His favourite pursuit, however, was farming. When Arthur Young was issuing his *Annals of Agriculture*, he was supplied with information by the king, under the assumed name of Mr Ralph Robinson, relating to a farm at Petersham.

The life of the king was suddenly clouded over. Early in his reign, in 1765, he had been out of health, and it is now known—what was studiously concealed at the time—that symptoms of mental aberration were even then to be perceived. In October 1788 he was again out of health, and in the beginning of the following month his insanity was beyond a doubt. Whilst Pitt and Fox were contending in the House of Commons over the terms on which the regency should be committed to the prince of Wales, the king was a helpless victim to the ignorance of physicians and the brutalities of his servants. At last Dr Willis, who had made himself a name by prescribing gentleness instead of rigour in the treatment of the insane, was called in Under his more humane management the king rapidly recovered. Before the end of February 1789 he was able to write to Pitt thanking him for his warm support of his interests during his illness. On April 23. he went in person to St Paul's to return thanks for his recovery.

The popular enthusiasm which burst forth around St Paul's was but a foretaste of a popularity far more universal. The French Revolution frightened the great Whig landowners till they made their peace with the king. Those who thought that the true basis of government was aristocratical were now of one mind with those who thought that the true basis of government was monarchical; and these two classes were joined by a far larger multitude which had no political ideas whatever, but which had a moral horror of the guillotine. As Elizabeth had once been the symbol of resistance to Spain, George was now the symbol of resistance to France. He was not, however, more than the symbol. He allowed Pitt to levy taxes and incur debt, to launch armies to defeat, and to prosecute the English imitators of French revolutionary courses. At last, however, after the Union with Ireland was accomplished, he learned that Pitt was planning a scheme to relieve the Catholics from the disabilities under which they laboured. The plan was revealed to him by the chancellor, Lord Loughborough, a selfish and intriguing politician who had served all parties in turn, and who sought to forward his own interests by falling in with the king's prejudices. George III. at once took up the position from which he never swerved. He declared that to grant concessions to the Catholics involved a breach of his coronation oath. All thinking men of a later generation are of opinion that the objection was untenable. But no one has ever doubted that the king was absolutely convinced of the serious nature of the objection, or that he believed the measure itself to be beyond measure injurious to church and state. Nor can there be any doubt that he had the English people behind him. Both in his peace ministry and in his war ministry Pitt had taken his stand on royal favour and on popular support. Both failed him alike now, and he resigned office at once. The shock to the king's mind was so great that it brought on a fresh attack of insanity. This time, however, the recovery was rapid. On March 14, 1801, Pitt's resignation was formally accepted, and the late speaker, Mr Addington, was installed in office as prime minister.

The king was well pleased with the change. He was never capable of appreciating high merit in any one; and he was unable to perceive that the question on which Pitt had resigned was more than an improper question, with which he ought never to have meddled. "Tell him," he said, in directing his physician to inform Pitt of his restoration to health, "I am now quite well, quite recovered from my illness; but what has he not to answer for, who has been the cause of my having been ill at all?" Addington was a minister after his own mind. Thoroughly honest and respectable, with about the same share of abilities as was possessed by the king himself, he was certainly not likely to startle the world by any flights of genius. But for one circumstance Addington's ministry would have lasted long. So strong was the reaction against the Revolution that the bulk of the nation was almost as suspicious of genius as the king himself. Not only was there no outcry for legislative reforms, but the very idea of reform was unpopular. The country gentlemen were predominant in parliament, and the country gentlemen as a body looked upon Addington with respect and affection. Such a minister was therefore admirably suited to preside over affairs at home in the existing state of opinion. But those who were content with inaction at home would not be content with inaction abroad. In time of peace Addington would have been popular for a season. In time of war even his warmest admirers could not say that he was the man to direct armies in the most terrible struggle which had ever been conducted by an English Government.

For the moment this difficulty was not felt. On October 1, 1801, preliminaries of peace were signed between England and France, to be converted into the definitive peace of Amiens on March 27, 1802. The ruler of France was now Napoleon Bonaparte, and few persons in England believed that he had any real purpose of bringing his aggressive violence to an end. "Do you know what I call this peace?" said the king; "an experimental peace, for it is nothing else. But it was unavoidable."

The king was right. On May 18, 1803, the declaration of war was laid before parliament. The war was accepted by all classes as inevitable, and the French preparations for an invasion of England roused the whole nation to a glow of enthusiasm only equalled by that felt when the Armada threatened our shores. On October 26 the king reviewed the London volunteers in Hyde Park. He found himself the centre of a great national movement with which he heartily sympathized, and which heartily sympathized with him.

On February 12, 1804, the king's mind was again affected. When he recovered, he found himself in the midst of a ministerial crisis. Public feeling allowed but one opinion to prevail in the country,—that Pitt, not Addington, was the proper man to conduct the administration in time of war. Pitt was anxious to form an administration on a broad basis, including Fox and all prominent leaders of both parties. The king would not hear of the admission of Fox. His dislike of him was personal as well as political, as he knew that Fox had had a great share in drawing the prince of Wales into a life of profligacy. Pitt accepted the king's terms, and formed an administration in which he was the only man of real ability. Eminent men such as Lord Grenville refused to join a ministry from which the king had excluded a great statesman on purely personal grounds.

The whole question was reopened on Pitt's death on January 23, 1806. This time the king gave way. The ministry of All the Talents, as it was called, included Fox amongst its members. At first the king was observed to appear depressed at the necessity of surrender. But Fox's charm of manner soon gained upon him. "Mr Fox," said the king, "I little thought that you and I should ever meet again in this place; but I have no desire to look back upon old grievances, and you may rest assured I never shall remind you of them." On September 13 Fox died, and it was not long before the king and the ministry were openly in collision. The ministry proposed a measure enabling all subjects of the crown to serve in the army and navy in spite of religious disqualifications. The king objected even to so slight a modification of the laws against the Catholics and Dissenters, and the ministers consented to drop the bill. The king asked more than this. He demanded a written and positive engagement that this ministry would never, under any circumstances, propose to him "any measure of concession to the Catholics, or even connected with the question." The ministers very properly refused to bind themselves for the future. They were consequently turned out of office, and a new ministry was formed with the duke of Portland as first lord of the treasury and Mr Perceval as its real leader. The spirit of the new ministry was distinct hostility to the Catholic claims. On April 27, 1807, a dissolution of parliament was announced, and a majority in favour of the king's ministry was returned in the elections which speedily followed.

The elections of 1807, like the elections of 1784, gave the king the mastery of the situation. In other respects they were the counterpart of one another. In 1784 the country declared, though perhaps without any clear conception of what it was doing, for a wise and progressive policy. In 1807 it declared for an unwise and retrogressive policy, with a very clear understanding of what it meant. It is in his reliance upon the prejudices and ignorance of the country that the constitutional significance of the reign of George III. appears. Every strong Government derives its power from its representative character. At a time when the House of Commons was less really representative than at any other, a king was on the throne who represented the country in its good and bad qualities alike, in its hatred of revolutionary violence, its moral sturdiness, its contempt of foreigners, and its defiance of all ideas which were in any way strange. Therefore it was that his success was not permanently injurious to the working of the constitution as the success of Charles I. would have been. If he were followed by a king less English than himself, the strength of representative power would pass into other hands than those which held the sceptre.

The overthrow of the ministry of All the Talents was the last political act of constitutional importance in which George III. took part. The substitution of Perceval for Portland as the nominal head of the ministry in 1809 was not an event of any real significance, and in 1811 the reign practically came to an end. The king's reason finally broke down after the death of the Princess Amelia, his favourite child. The remaining nine years of his life were passed in insanity and blindness, and when he died on January 29, 1820, in his eighty-second year, no political results were to be anticipated.

George III. had nine sons. After his successor came Frederick, duke of York and Albany (1763–1827); William Henry, duke of Clarence, afterwards King William IV. (1765–1837); Edward Augustus, duke of Kent (1767–1825), father of Queen Victoria; Ernest Augustus, duke of Cumberland, afterwards king of Hanover (1771–1851); Augustus Frederick, duke of Sussex (1773–1843); Adolphus Frederick, duke of Cambridge (1774–1850); Octavius (1779–1783); Alfred (1780–1782). He had also six daughters—Charlotte Augusta (1766–1816), married in 1797 to Frederick, king of Würtemberg; Augusta Sophia (1768–1840); Elizabeth (1770–1840), married Frederick, landgrave of Hesse-Homburg, 1818; Mary (1776–1857), married to William Frederick, duke of Gloucester, 1816; Sophia (1777–1848); Amelia (1783–1810). (S. R. G.)

GEORGE IV. (*George Augustus Frederick*, 1762–1830), lived long enough to strip the crown of the leadership of the nation which his father had won for it. Born on August 12, 1762, he was noted in the years of his early manhood for good looks, for ease of carriage, and graciousness of manner. He soon plunged into the whirl of sensual excitement. His life was passed in the grossest profligacy. He was false as well as licentious His word was never to be trusted. Not even an occasional gleam of brightness lights up the dark picture of his career. If he now and then flung to a dependant a kindly word which cost him nothing, no serious project of well-doing ever occupied his thoughts. Politics had no attraction for him except so far as changes of Government might minister to his ease, or bring him money to be squandered in some new scheme of folly.

Such a character was probably beyond the reach of any education. But it is certain that the education which he received in the strict and formal domestic circle of his parents was only fitted to repel him from the path of virtue. His father became to him the type of uninteresting formality. He gladly sought the society of his father's Whig opponents, and was initiated by Fox and Sheridan in the vices of the fashionable world. In 1783 he naturally supported the coalition ministry which his father detested, and the coalition ministry in return proposed to raise his income from £50,000 to £100,000. The king saved the ministry from committing one more blunder in its career by refusing to sanction the proposition. In 1786 the prince's friends urged Pitt to increase the allowance, but Pitt refused to do anything of the kind. All the world knew that the money would be frittered away at the gambling table or in some other equally disreputable way. Applying to the king and getting a distinct refusal, the prince sold his horses and carriages, shut up his house, and dismissed his servants. As it was well known that these were not the expenses which had brought him to distress, he was only laughed at for his pains. A lower depth was soon reached. The prince fell in love with Mrs Fitzherbert who had been twice a widow at twenty-five. She was ready to marry him, but she would yield to him on no other terms. She was a Roman Catholic, and a marriage by the heir of the crown with a Roman Catholic forfeited his succession by the Act of Settlement. Nor, by the Royal Marriage Act, could he legally contract marriage even with a Protestant without his father's consent, unless at the end of a year after formal notice had been given, and then only if parliament had not expressed its disapprobation. Believing truly that he could contract no legal marriage with Mrs Fitzherbert, he was quite ready to go through the form of marriage. Mrs Fitzherbert, holding that the performance of the ceremony by a priest of her church was of sacramental efficacy, was indifferent to the legality of the proceeding. The marriage took place. Not long afterwards, in April 1787, Alderman Newenham moved in the House of Commons for a grant in relief of the prince. In the course of debate allusion was made to a marriage which might bring in question the succession. Fox went to the prince, and was assured by him that the marriage had never even formally taken place. Fox, deceived by his apparent openness, came down to the House and assured the Commons that the whole story was a malicious falsehood. The next day a friend of Fox's opened his eyes to the trick which had been played on him. "I see by the papers, Mr Fox," he said, "that you have denied the fact of the marriage of the prince of Wales with Mrs Fitzherbert. You have been misinformed. I was present at that marriage." The prince was not content with his original falsehood. He threw out hints to his friends that Fox had exceeded his instructions. He led Mrs Fitzherbert to believe that Fox had uttered the denial unsuggested. "Only conceive, Maria," he said to her, "what Fox did yesterday. He went down to the House and denied that you and I were man and wife." The denial however cleared away for the moment one cause of the prince's unpopularity. With the consent of the Government he received an addition of £10,000 to his income, £161,000 to pay his debts, and £20,000 for the repairs of Carlton House. The temporary insanity of the king in 1788 again brought the prince's name prominently before the public. Fox maintained and Pitt denied that the prince of Wales, as the heir-apparent, had a right to assume the regency independently of any parliamentary vote. Pitt, with the support of both Houses, proposed to confer upon him the regency with certain restrictions. The recovery of the king in February 1789 put an end to the prince's hopes. During the king's illness he had been in the habit of amusing his companions by mimicry of his unfortunate father. The disgust caused by his behaviour had doubtless some part in the enthusiasm with which the king was received when he went in state to St Paul's to return thanks for his recovery. In 1795 the prince married Caroline of Brunswick, because his father would not pay his debts on any other terms. Her behaviour was light and flippant, and he was brutal and unloving. The ill-assorted pair soon parted, and soon after the birth of their only child, the Princess Charlotte, they were formally separated. With great unwillingness the House of Commons voted fresh sums of money to pay the prince's debts. In 1811 the prince at last became regent in consequence of his father's definite insanity. No one doubted at that time that it was in his power to change the ministry at his pleasure. He had always lived in close connexion with the Whig opposition, and he now empowered Lord Grenville to form a ministry. There soon arose differences of opinion between them on the answer to be returned to the address of the Houses, and the prince regent then informed the prime minister, Mr Perceval, that he should continue the existing ministry in office. The ground alleged by him for this desertion of his friends was the fear lest his father's recovery might be rendered impossible if he should come to hear of the advent of the Opposition to power. Lord Wellesley's resignation in February 1812 made the reconstruction of the ministry inevitable. As there was no longer any hope of the king's recovery, the former objection to a Whig administration no longer existed. Instead of taking the course of inviting the Whigs to take office, he asked them to join the existing administration. The Whig leaders however refused to join, on the ground that the question of the Catholic disabilities was too important to be shelved, and that their difference of opinion with Mr Perceval was too glaring to be ignored. The prince regent was excessively angry, and continued Perceval in office till that minister's assassination on May 11, when he was succeeded by Lord Liverpool, after a negotiation in which the proposition of entering the cabinet was again made to the Whigs and rejected by them. In the military glories of the following years the prince regent had no share. When the allied sovereigns visited England in 1814, he played the part of host to perfection. So great was his unpopularity at home that hisses were heard in the streets as he accompanied his guests into the city. The disgust which his profligate and luxurious life caused amongst a people suffering from almost universal distress after the conclusion of the war rapidly increased. In 1817 the windows of the prince regent's carriage were broken as he was on his way to open parliament.

The death of George III. on January 29, 1820, gave to his son the title of king without in any way altering the position which he had now held for nine years. Indirectly, however, this change brought out a manifestation of popular feeling such as his father had never been subjected to even in the early days of his reign, when mobs were burning jack-boots and petticoats. The relations between the new king and his wife unavoidably became the subject of public discussion. In 1806 a charge against the princess of having given birth to an illegitimate child had been conclusively disproved, and the old king had consequently refused to withdraw her daughter, the Princess Charlotte, from her custody. When in the regency the prince was able to interfere, and prohibited his wife from seeing her daughter more than once a fortnight. On this, in 1813, the princess addressed to her husband a letter setting forth her complaints, and receiving no answer published it in the *Morning Chronicle*. The prince regent then referred the letter, together with all papers relating to the inquiry of 1806, to a body of twenty-three privy councillors for an opinion whether it was fit that the restrictions on the intercourse between the Princess Charlotte and her mother should continue in force. All except two answered as the regent wished them to answer. But if the official leaning was towards the husband, the leaning of the general public was towards the wife of a man whose own life had not been such as to justify him in complaining of her whom he had thrust from him without a charge of any kind. Addresses of sympathy were sent up to the princess from the city of London and other public bodies. The discord again broke out in 1814 in consequence of the exclusion of the princess from court during the visit of the allied sovereigns. In August in that year she left England, and after a little time took up her abode in Italy. The accession of George IV. brought matters to a crisis. He ordered that no prayer for his wife as queen should be admitted into the Prayer Book. She at once challenged the accusation which was implied in this omission by returning to England. On June 7 she arrived in London. Before she left the Continent she had been informed that proceedings would be taken against her for adultery if she landed in England. Two years before, in 1818, commissioners had been sent to Milan to investigate charges against her, and their report, laid before the cabinet in 1819, was made the basis of the prosecution. On the day on which she arrived in London a message was laid before both Houses recommending the criminating evidence to parliament. A secret committee in the House of Lords after considering this evidence brought in a report on which the prime minister founded a Bill of Pains and Penalties to divorce the queen and to deprive her of her royal title. The Bill passed the three readings with diminished majorities, and when on the third reading it obtained only a majority of nine, it was abandoned by the Government. The king's unpopularity, great as it had been before, was now greater than ever. Public opinion, without troubling itself to ask whether the queen was guilty or not, was roused to indignation by the spectacle of such a charge being brought by a husband who had thrust away his wife to fight the battle of life alone, without protection or support, and who, whilst surrounding her with spies to detect, perhaps to invent, her acts of infidelity, was himself living in notorious adultery. In the following year (1821) she attempted to force her way into Westminster Abbey to take her place at the coronation. On this occasion the popular support failed her; and her death not long afterwards relieved the king from further annoyance.

Immediately after the death of the queen, the king set out for Ireland. He remained there but a short time, and his effusive declaration that rank, station, honours, were nothing compared with the exalted happiness of living in the hearts of his Irish subjects gained him a momentary popularity which was beyond his attainment in a country where he was better known. His reception in Dublin encouraged him to attempt a visit to Edinburgh in the following year (August 1822). Since Charles II. had come to play the sorry part of a covenanting king in 1650 no sovereign of the country had set foot on Scottish soil. Sir Walter Scott took the leading part in organizing his reception. The enthusiasm with which he was received equalled, if it did not surpass, the enthusiasm with which he had been received in Dublin. But the qualities which enabled him to fix the fleeting sympathies of the moment were not such as would enable him to exercise the influence in the government which had been indubitably possessed by his father. He returned from Edinburgh to face the question of the appointment of a secretary of state which had been raised by the death of Lord Londonderry, better known to the world by his earlier title of Castlereagh. It was upon the question of the appointment of ministers that the battle between the Whigs and the king had been fought in the reign of George III. George IV. had neither the firmness nor the moral weight to hold the reins which his father had grasped. He disliked Canning for having taken his wife's side very much as his father had disliked Fox for taking his own. But Lord Liverpool insisted on Canning's admission to office, and the king gave way. Tacitly and without a struggle the constitutional victory of the last reign was surrendered. But it was not surrendered to the same foe as that from which it had been won. The coalition ministry in 1784 rested on the great landowners and the proprietors of rotten boroughs. Lord Liverpool's ministry had hitherto not been very enlightened, and it supported itself to a great extent upon a narrow constituency. But it did appeal to public opinion in a way that the coalition did not, and what it wanted itself in popular support would be supplied by its successors. What one king had gained from a clique another gave up to the nation. Once more, on Lord Liverpool's death in 1827, the same question was tried with the same result. The king not only disliked Canning personally, but he was opposed to Canning's policy. Yet after some hesitation he accepted Canning as prime minister; and when, after Canning's death and the short ministry of Lord Goderich, the king in 1828 authorized the duke of Wellington to form a ministry, he was content to lay down the principle that the members of it were not expected to be unanimous on the Catholic question. When in 1829 the Wellington ministry unexpectedly proposed to introduce a Bill to remove the disabilities of the Catholics, he feebly strove against the proposal and quickly withdrew his opposition. The worn-out debauchee had neither the merit of acquiescing in the change nor the courage to resist it.

George IV. died on June 26, 1830. He had rendered to the constitution of his country the service of tacitly abandoning a position which had been perhaps necessarily achieved by his father, but which it was not desirable that the sovereigns of England should permanently occupy.

His only child by his wife Queen Caroline was the Princess Charlotte Augusta, married in 1816 to Leopold of Saxe-Coburg, afterwards king of the Belgians. She died in childbirth November 6, 1817. (S. R. G.)

GEORGE OF CAPPADOCIA, who from 356 to 361 was Arian archbishop of Alexandria, was born about the beginning of the 4th century. According to Ammianus (xxii. 11), he was a native of Epiphania, in Cilicia; but universal tradition makes him a Cappadocian. Gregory Nazianzen tells us that his father was a fuller, and that he himself soon became notorious as a parasite of so mean a type that he would "sell himself for a cake." By his powers of insinuation he succeeded in obtaining a lucrative contract for supplying bacon to the army, but fulfilled its terms so ill that he was soon compelled to abscond after he had with difficulty escaped death at the hands of the indignant soldiers. After many wanderings, in the course of which he seems to have lived for some time at Constantinople, and to have amassed a considerable fortune as receiver of taxes, he ultimately reached Alexandria. It is not known how or when he obtained ecclesiastical orders; but, after Athanasius had been banished in 356, George was promoted by the influence of the then prevalent Arian faction to the vacant see. His persecutions and oppressions of the orthodox ultimately raised a rebellion which compelled him to flee for his life; but his authority was restored, although with difficulty, by a military demonstration. Untaught by experience he resumed his course of selfish tyranny over Christians and heathen alike, and raised the irritation of the populace to such a pitch that, within a few days after the accession of Julian, they rose *en masse*, dragged him out of prison, where he had been placed by the magistrates for safety, paraded him with every indignity through the streets on the back of a camel, burnt his dead body, and cast the ashes into the sea (December 24, 361). With much that was sordid and brutal in his character George combined a highly cultivated literary taste, and in the course of his chequered career he had found the means of collecting a splendid library, which Julian ordered to be carefully preserved and conveyed to Antioch for his own use. The original sources for the facts of the life of George of Cappadocia are Ammianus, Gregory Nazianzen, Epiphanius, and Athanasius. In modern times his character has been drawn with graphic fidelity by Gibbon in the 23d chapter of the *Decline and Fall*.

GEORGE, SAINT, according to Metaphrastes the Byzantine hagiologist, whose narrative is substantially repeated in the Roman *Acta Sanctorum* and in the Spanish breviary, was born in Cappadocia of noble Christian parents, from whom he received a careful religious training. Having embraced the profession of a soldier, he rapidly rose under Diocletian to high military rank. When that emperor had begun to manifest a pronounced hostility towards Christianity George sought a personal interview with him, in which he made deliberate profession of his faith, and, earnestly remonstrating against the persecution which had begun, resigned his commission. He was immediately laid under arrest, and after various tortures, finally put to death at Nicomedia (or, according to other accounts, at Lydda) April 23, 303. His festival is observed on that anniversary by the entire Roman Church as a semi-duplex, and by the Spanish Catholics as a duplex of the first class with an octave. The day is also celebrated as a principal feast in the Greek Church, where the saint is distinguished by the titles *μεγαλόμαρτυρ* and *τροπαιοφόρος*.

In the canon of Pope Gelasius (494) George is mentioned among the martyrs whom the Roman Church venerates, but whose gesta it does not read.[1] The language implies that even at that date much had been written concerning him, but little that the Catholic Church could accept as trustworthy. Numerous traits from the biography of the heretical archbishop had already crept, it would seem, into the acta of the orthodox soldier; and it was feared that any vigorous attempt to eliminate these would leave but a small residue of fact. Modern investigation has proved that apprehension to have been well-founded, for even on the Catholic side in the controversy regarding the existence and character of St George, the chief contention is simply the improbability that within the space of 150 years a turbulent and unscrupulous Arian ecclesiastic should have come to be reputed a holy martyr for the Catholic faith. The caution displayed with regard to St George in the 5th century was not long preserved; Gregory of Tours, for example, asserts that his relics actually existed in the French village of Le Maine, where many miracles were wrought by means of them; and the venerable Bede, while still explaining that the gesta of St George are reckoned apocryphal, commits himself to the statement that the martyr was beheaded under Dacian, king of Persia, whose wife Alexandra, however, adhered to the Catholic faith. The dragon was a still later introduction into the legend, which, as given by Jacobus de Voragine and later writers, ceases to represent the hero as in any sense a sufferer. In its current popular form the story of his successful conflict is probably a mere modification of the old Aryan mythus, to which many interpreters are now disposed to attach a solar interpretation.

The popularity of the name of St George in England dates from the time of Richard Cœur de Lion, who, it was said, had successfully invoked his aid during the first crusade; but it was not till the time of Edward III. that he was made patron of the kingdom, although at the council of Oxford in 1222 it had already been ordered that his feast should be kept as a national festival. The republics of Genoa and Venice were also under his protection; and his name is much revered in all the Oriental churches.

See Heylin, *The History of that most famous Saynt and Souldier of Christ Jesus, St George of Cappadocia* (1631); and Milner, *An Historical and Critical Inquiry into the Existence and Character of St George, Patron of England* (1795). For some account of the numerous artistic representations, whether of his martyrdom or of his triumph, see Jamieson's *Sacred and Legendary Art*, vol. ii.

GEORGE, known as PISIDES or PISIDA, a Byzantine writer of the 7th century, was, as his surname implies, a native of Pisidia; but of his personal history nothing is known except that he had been ordained a deacon, and that he held either simultaneously or successively the offices of "Chartophylax," "Scenophylax," and "Referendarius" in the "Great Church" (that of St Sophia) at Constantinople. He is also believed to have accompanied the first expedition (622) of the emperor Heraclius against the Persians; at all events his earliest work, consisting of 1098 iambic trimeter verses under the title Ἐις *τὴν κατὰ Περσῶν ἐκστρατείαν Ἡρακλείου τοῦ βασιλέως ἀκροάσεις τρεῖς*, is devoted to such a description of that campaign as could hardly have come from any other than an eye-witness. This composition was followed by the *Ἀβαρικά* or *Πόλεμος Ἀβαρικός* in 541 verses, containing the details of a futile attack on Constantinople made by the Avari in 626, while the emperor was absent and the Persian army in occupation of Chalcedon; and by the *Ἡρακλιάς*, a general survey of the exploits both at home and abroad of Heraclius down to the final overthrow of Chosroes in 627, which is believed to have been written before the end of 628. In addition to these three works, which have been edited by Bekker in the *Corpus scriptorum histor. Byzant.* (1836), we have from the pen of

[1] The full text of this canon is given by Heylin, p. i. c. 9.

George of Pisidia the Ἑξαήμερον ἤτοι Κοσμουργία, a poem upon the creation of the world, containing in its present form 1910 trimeter iambic verses; a treatise on the vanity of life, Ἐις τὸν μάταιον βίον, in 262 verses; a controversial composition against Severus of Antioch, Κατὰ Σευήρου, in 731 verses; two short poems upon the resurrection of Christ and upon the temple of the Virgin at Blachernæ respectively, and a prose encomium upon Anastasius the martyr, (Ἐγκώμιον εἰς τὸν ἅγιον Αναστάσιον μάρτυρα). George of Pisidia is known to have written several other works, which, however, are no longer extant; and there is no sufficient reason for assigning to him the compilation of the *Chronicon Paschale*, or the astronomical poem entitled *Empedoclis Sphæra.* The *Hexaemeron* and *De Vanitate Vitæ* were first printed along with a Latin version at Paris in 1584 or 1585 by Federicus Morellus. They are also to be found in the *Max. Bibliotheca Vett. Patrum*, xii. p. 322 (1677); and in the 46th vol. of Migne's *Patrologia Græca.* The only complete edition of all the extant works is that of Quercus in Foggini's *Corp. Hist. Byzant. Nova Appendix* (Rome, 1777). As a versifier George is correct and even elegant; as a chronicler of contemporary events he is exceedingly useful; but the modern verdict on his merits as a poet has not confirmed that of those later Byzantine writers whose enthusiastic admiration led them to compare him with and even prefer him to Euripides. Recent criticism is unanimous in characterizing his composition as artificial and almost uniformly dull.

GEORGE OF TREBIZOND (1396–1486), one of the distinguished writers in the great controversy between Aristotelianism and Platonism in the 15th century, was born at Chandace in the island of Crete. He received his cognomen apparently from the fact that his ancestors had come from Trebizond. At what period he came to Italy is not absolutely certain; according to some accounts he arrived as early as 1430, and settled as teacher of philosophy and rhetoric at Venice; according to others he did not come over to Italy till the period of the council of Florence (1438–9). His reputation as a teacher and as translator of Aristotle was very great, and he was selected as secretary by Pope Nicholas V., an ardent Aristotelian. The needless bitterness of his attacks upon Plato (in the *Comparatio Aristotelis et Platonis*), which drew forth a powerful response from BESSARION (*q.v.*), and the manifestly hurried and inaccurate character of his translations both of Plato and of Aristotle, combined to ruin his fame as a scholar, and to endanger his position as a teacher of philosophy. The indignation against him on account of his first-named work was so great that he would probably have been compelled to leave Italy, had not Alphonso V. given him protection at the court of Naples. He died at Rome in 1486. Many of his translations of Aristotelian treatises are to be found in the older editions of Aristotle. A notice of his other writings is given in Fabricius, *Biblioth. Græca.*

GEORGETOWN, the port of entry for the District of Columbia in the United States of North America, is situated on the left bank of the Potomac at the head of navigation, about 2½ miles W.N.W. of the capitol of Washington City, with which it communicates by four iron bridges thrown across Rock Creek. Founded by the colonial Government of Maryland in 1751, Georgetown was a city with a distinct administration from 1789 to 1871; but in the latter year it was merged in the District of Columbia, and in 1878 it was incorporated with the city of Washington, so that now it has properly no distinct existence. It is beautifully situated along a range of hills, whose loftier eminences, locally called the Heights, afford delightful positions for villas and country seats, with extensive prospects over the river and Washington. The most noteworthy institution is Georgetown College, the oldest Roman Catholic college in the United States, which occupies two handsome brick buildings in the midst of extensive grounds at the west end. It was founded as an academy in 1789, was chartered as a college in 1799, and in 1815 received the right of conferring degrees. Its medical department, originated in 1851, and the legal department, dating from 1870, are both in Washington. The university has a library of upwards of 30,000 volumes, an extensive apparatus for physical science, and a museum of natural history. In 1873 the teaching staff numbered 35. Among the other institutions in the town may be mentioned the Convent of the Visitation, with a female academy attached; the Peabody library; the Linthicum institute (founded in 1872 by a retired merchant, who left $50,000 for the education of poor white boys); the aged women's house, maintained by voluntary subscription; and the industrial home for juvenile vagrants. The aqueduct which conveys a branch of the Chesapeake and Ohio canal over the Potomac is 1446 feet long, and its granite piers, nine in number, rise 36 feet above the ordinary surface of the water, and rest on the solid rock 17 feet below the bottom of the river. A great decline has taken place in the commercial activity of Georgetown. Its foreign trade is very slight, being represented in the year ending June 30, 1878, by no more than 6113 dollars of imports and 10,056 dollars of exports; but its share in the coasting trade is still considerable, 187 steamers and 45 sailing vessels, affording a total tonnage of 96,339 tons, having entered in the year already mentioned; its position at the terminus of the Chesapeake and Ohio canal secures for it a fair share in the shipping of the coal from the Alleghany fields; and its fisheries render it a great market for shad and herrings. Among the industrial establishments the first place is held by the flour-mills, six in number; but there are also corn-mills, timberyards, tanneries, foundries, breweries, a paper-mill, and a vinegar factory. The principal cemetery for Washington occupies a beautiful situation on Georgetown Heights. In 1830 the population of Georgetown was 8441; in 1840 it was only 7312; by 1860 it had reached 8733; and in 1870 it was 11,384.

GEORGETOWN, known as Stabroek during the Dutch period, now the capital of British Guiana, is situated in the county of Demerara on the east bank of the Demerara river, about a mile from its mouth, in 6° 49′ 30″ N. lat. and 58° 11′ 30″ W. long. It is one of the prettiest towns of that part of the world, and presents an unusually attractive appearance to the approaching voyager. The streets are wide and straight, intersecting each other at right angles, and recalling, by the canals that run along the centre, the memory of the Dutch; and the houses are so richly embosomed by cabbage-palms, cocoa-nut trees, and other trees and shrubs, that they look rather like a collection of villas than a town. The street along the river side, where the shops and stores are mainly situated, forms, however, an exception; there everything is plain, bare, and business-like. Private dwelling-houses are usually built of wood and raised 3 or 4 feet above the soil on wooden piles or brick pillars; they are painted in various simple colours, for the most part in white; in front they have open verandahs. Among the public edifices the first place is due to a building in the centre of the town which was erected between 1829 and 1834 at a cost of £60,000, to accommodate the legislative council, the courts of justice, the custom house, the treasury, and other administrative offices; it is of considerable extent and architectural beauty, with shady porticoes and marble-paved galleries supported on cast-iron columns. Besides a cathedral, which cost £15,000, there are churches belonging to the Wesleyans, the Baptists, the London Missionary Society, and other ecclesiastical organizations, several liberally maintained hospitals, an icehouse, and two market-places, of which the one opened in 1844 cost £11,400, and the other opened in 1852 cost £2450. The prison, a large building, or rather collection of buildings, surrounded by a strong wooden wall, can accommodate upwards of 200 prisoners. A fort, the Frederick William, situated below the town, only contains a small battery, but in the vicinity there are extensive and well-organized barracks. One of the principal disadvantages due to the position of Georgetown is the lack of drinking water; but this is so far remedied by the construction of both private and public tanks for the storage of the rain, by the introduction of water from the Lamaha creek, by a canal, and further by the boring of Artesian wells. The first attempts to apply the Artesian principle was made in 1831 by Major Staple, and his example has been widely imitated not only in the town itself but also in the surrounding country. Though the water thus obtained is strongly impregnated with iron, carbonic acid gas, salt, and magnesia, it is readily drunk by horses and cattle, and after it has been scummed and filtered it can be used for cooking. As it rises to the surface the water has a temperature of 84° Fahr., 5° higher than the water in the river. Ice is almost a necessity of life in the town, and it forms a regular import from Boston, along with fresh meat and other northern produce. The population of Georgetown in 1851 was 25,508; in 1861 it was 29,174; and by 1871 it had reached 36,562. (See Appun, *Unter den Tropen*, Jena, vol. ii).

GEORGIA, a kingdom in central Transcaucasia, remarkable for the long list of its sovereigns, the monarchy having extended over a period of upwards of 2000 years, the kings reigning at times independently, or under the rule of Persia, Turkey, or the Eastern empire. The earliest name of the country was Karthli; the ancients knew it as Iberia, bounded on the one side by Colchis and on the other by Albania; and it has for centuries been called Georgia.

Georgia proper, which includes Karthli and Kakhetia, is bounded on the N. by Ossety and Daghestan, on the E. by Shekynn, on the S. by Shamshadyl and the khanates of Erivan and Kars, and on the W. by Gouria and Imeritia; but the kingdom at times included Gouria, Mingrelia, Abkhasia, Imeritia, and Daghestan, and extended from the great mountain range to the Araxes. It now forms the government of Tiflis, divided into the districts of Doushett, Telav, Sygnah, Gori, and Akhalzikh, having an area of nearly 25,000 square miles, and in 1873 a population of 635,313, made up chiefly of Georgians and Armenians,—there being also Persians, Tatars, and a few Jews and Europeans. The chief city is the ancient capital of Tiflis, the seat of government, under a governor-general, for the whole of Transcaucasia, and the principal centre of commerce. See CAUCASUS and TIFLIS.

Vegetable Products.—The valleys and declivities are fertile, producing maize, millet, barley, oats, rice, beans, lentils, and corn (which is best in the plains near Gori), also cotton, flax, and hemp, now exported exclusively to Russia. The vineyards cover 75,400 acres, the average produce of wine being at the rate of 230 gallons per acre; the valley of the Alazan yields the best qualities. It is consumed in the country and adjoining districts, the only wine exported being that produced from vine-canes brought from the Crimea. Grapes are gathered in September, and the wine is fit for use one month after it has been put into a *bourdyouk*, "skin," or *kvevry*, a huge earthen jar in which it may be preserved for years. New vines are planted every six, eight, or ten years, according to the nature of the soil, and are cut after the fruit is gathered, and again in March and April when the soil is turned up. The *Lecanium vitis* and *Oidium* have attacked the plants from time to time, though not in severe form, but the *Phylloxera vastatrix* has been hitherto quite unknown. In the vineyards are often seen the apple, pear, and quince trees; other fruits include the pomegranate, peach, apricot, plum, almond, mulberry, pistachio, fig, cherry, walnut, hazel-nut, medlar, melon and water melon, raspberry, &c. In summer the banks of streams are covered with beautiful wild flowers,—the primrose in double form, the crocus of varied colours, and snowdrops appearing early in March in the greatest profusion.

Animals.—The domestic animals are the camel, ox, mule, ass, and buffalo as beasts of burden, with the goat, and an immense number of pigs, pork being favourite food. The horse—small, hardy, and enduring—is ridden more frequently unshod, except in the hills; no pains are taken to improve the breed. The wild animals of greatest importance are the bear, ibex, wolf, hyæna, fox, wild boar, wild goat, and antelope; while the pheasant, woodcock, quail, and "partridge of the Caucasus" are the principal winged game. The fish taken in the Kour and other rivers are the sturgeon, silurus, carp, perch, trout, gudgeon, and a fish resembling the salmon, called *oragoula* by the Georgians. The great sturgeon, *belouga* or hausen, is taken at the estuary of the Kour in the Caspian.

Communication.—A railroad connects Tiflis with Poti on the Black Sea, the line over the Souram pass, 3037 feet above the sea, being laid at gradients of 1 in 22, over a distance of about 8 miles. Lines of rail are projected for connecting Vladykavkaz in the north, and Djoulpha at the Persian frontier, with the capital. Post-roads are excellent, and saddle-horses and comfortable vehicles for post-horses are to be obtained at the principal towns. Locomotion is very inexpensive.

History.—The material at the disposal of the historian of Georgia is scanty. An anonymous work of the 12th century gives the history from the earliest times to the year 1124; another, also anonymous, is a continuation to the division of the kingdom in 1445; and a third is the compilation by the Czarevitch Wakhoucht, being the complete annals from the earliest times to the year 1745. These, and a few pamphlets indifferently edited, if we except the memoirs of his family by Stephen Orbeliani, archbishop of Siouny in the 13th century, comprise all that is left to us during an interval of upwards of 2000 years.

The earliest Armenian chroniclers have included facts on Georgia, which it is believed were founded on traditions they received from the Georgians. According to these authorities, the Georgian, Armenian, Kakhetian, Lesghian, Mingrelian, and other races in Transcaucasia are the descendants of Thargamos, who was the great-grandson of Japhet, the son of Noah, though we read in Gen. x. 3 that Togarmah was the son of Gomer, who was the son of Japhet. Those different populations were afterwards included under the general name of Thargomosiany. The second son of Thargamos, named Karthlos, having settled in that part where is now the rivulet Karthli, became the patriarch and king of the people in the land around, called Karthli after himself. His son Mtzkhethos founded the city of Mtzkhetha, which became the capital; and a son of Mtzkhethos, named Ouphlis, was the author of the rock-cut town near Gori. At that period the title assumed by the ruler was *mamasaklysy*, "lord or head of the house," the worship being that of the sun, moon, and five planets. The first to revive the title of king was Pharnawaz, 302-237 B.C., who rid the country of the tyrant Ason, a governor appointed by Alexander the Great. Pharnawaz originated the orthography of the Georgian language, and is said to have invented the military alphabet. In 140 B.C. Mirvan became king. His son and successor was dethroned by his own subjects, and the crown offered to Ardaces I., whose son, Arshag, ascended the throne 71 B.C., the dynasty of Arsaces thus commencing its rule. The deeds of Sulla, Lucullus, Pompey, and Mithradates next serve to illustrate the courage and warlike qualities of the people of Iberia. In 265 the Sassanian dynasty commenced in the person of Miriam, son of Shapour I., who was married to a daughter of the late king Asphagor. Miriam and all his subjects were converted to Christianity by Nouna or Nina, a poor captive, who had escaped the persecution of Tiridates, king of Armenia. She prevailed upon the people of Karthli to desist from offering human victims, and to overturn their pagan altars; and the king erected a sanctuary, which was afterwards replaced by a noble edifice, 364–379, on the spot where now stands the cathedral at M'zhett. Miriam applied to Constantine for priests to instruct his people, and many were sent, among them being Eustace of Antioch. In 469 King Vakhtang, surnamed *Gourgasal*, "wolf-lion," founded a city which he called Tbylysys-Kalaky, now Tiflis, on account of the warm springs there. Vakhtang established a patriarchate at Mtzkhetha, and constructed the fortress of Souram. He conquered Mingrelia, and brought the Ossets and Abkhasians under subjection. He also took possession of a large part of Armenia, and having formed an alliance with Chosroes, king of Persia, even advanced into India. The seat of government was transferred from Mtzkhetha to Tbylysys-Kalaky, when Datchy came to the throne in 499. At this epoch the Georgian and Armenian Churches had separated; and a century later, the Georgian and Russian Churches united. On the death of Stephanos, who had ruled under the protection of the Eastern empire, a Bagratide named Gouram was nominated couropolate by the emperor. Soon after the appearance of Mahomet in the 7th century, the Arabs, having conquered the Persians, entered Armenia and Georgia, and for nearly a century compelled all, under pain of death, to embrace Mahometanism. In 787 the Sassanian dynasty came to an end. Ashod I., *Medz*, "the Great," a Bagratide, succeeded, receiving from the caliph Haroun al Raschid the title of grand prince, and that of couropolate from the emperor; but it was not until about 841 that the sovereign (Bagrat I.) was recognized by the caliph as ruler, the country during the interval having been continually ravaged by the Arabs. Their last expedition, in the reign of Bagrat I., included the occupation of Tiflis. The reign of Bagrat III. marks an epoch, for that monarch, who was king of Abkhasia, succeeded to the crown of Georgia by right of inheritance, his sovereignty extending from the Black Sea to the Caspian. He encouraged the arts and sciences, and was the founder of the noble cathedral at Koutaïs, the first building in the style of architecture thenceforth denominated Georgian. During the reign of Bagrat IV. the Seljuks commenced in 1048 a succession of invasions, until they were effectually repulsed by Liparit Orboulk at the head of a comparatively small force of Georgians, Armenians, and Greeks. Liparit himself was taken prisoner, and Bagrat carried off his wife in his absence; but, regaining his liberty, Liparit took up arms against his sovereign, and drove him out of his capital into Abkhasia. Bagrat appealing to the emperor, it was arranged that he should return to his kingdom of Georgia and Abkhasia, Liparit being suffered, as his dutiful subject, to retain the province of Meskhy.

In 1064 the Seljuks under Arp-Aslan again overran Georgia, destroying Tiflis and slaughtering the inhabitants. In 1072 George II. ascended the throne, and in his reign Tiflis was again devastated by the Seljuks, the king himself being forced to fly. With his valiant son and successor, David III., the fortunes of Georgia changed, for the enemy was driven out of the plains of Kakhetia, and the land from Tiflis to Ani was freed of his presence in 1123 by Ivan Orbeliani, whose signal services were rewarded by elevation to the rank of constable. The next monarchs were Demetrius I. and David IV., the latter, at his death, entrusting his son Demna or Demetrius to the guardianship of Ivan Orbeliani, and the regency to his brother George, who with the assistance of Ivan, greatly extended the Georgian territory, rescuing from the Seljuks a large portion of Armenia. When in 1177 Demna had attained his majority, the nobles desirous of supporting the young prince's claims called upon Ivan, whose popularity had meanwhile been increasing, to place him on the throne. George fortified himself at Tiflis and awaited events; his rule, however, was too firmly established to be easily shaken, and, many of Ivan's partisans espousing his cause, he at length set out to besiege Lorhy, which Ivan and his charge had made their headquarters. Numerous desertions reduced the ranks of the besieged, until young Demna fled at last to the encampment of his uncle, and entreated him to spare his life. His prayer was granted, but he was deprived of his eyes, and otherwise mutilated. The prince having surrendered, Ivan declared his readiness to submit on condition that he should be honourably treated. George assented, showed his prisoner all honour until he had got the whole of his relatives into his power, when he ordered that all should be massacred, Ivan himself being blinded and brutally treated. Three only of his kinsmen were saved—a brother named Liparit, and his two sons who had gone to Persia to solicit the aid of the atabek Ildegouz. From them are descended the Orbeliani of the present day. At the time of their extermination, the possessions of the Orboulk comprised more than the half of Georgia. It is related that the ancestors of this powerful family, princes of the family of Djenkapour of the royal race of Djenesdan, first came to Karthli from that part of Asia which lies between China and the Ural; the fortress of Orpeth was given to them for a residence. In return for the friendly reception accorded to them, they united with the Karthlosides in throwing off the Persian yoke, a service which obtained for the chief Orboulk the rank of *sbasalar* or generalissimo. During the reign of Pharnawaz, the Orboulk took precedence next to the sovereign, and matrimonial alliances were formed with the royal house. The first of the family individualized in the annals was the warrior Liparit (875 900). George III. died in 1184, and was succeeded by his only child Thamar, whose kingdom extended from the Caspian to the Black Sea, and from beyond the Caucasus to Armenia, for Trebizond, Erzeroum, Tovin, Kars, and Ani fell to her arms. Her missionaries travelled far and wide, and numerous churches were constructed, and thus it was that her many virtues and brilliant rule secured to her the title of *Mep'he*, "king." This great queen was succeeded in 1212-13 by her son George IV., surname *Lasha*, "He who enlightens the world," who, assisted by the powerful noble, Ivan Mkhargrdzelidze, of the family that had replaced the Orbeliani in the royal favour, vanquished the Persians in many battles, conquering Gandja, and permanently occupying Kars. In 1220 and 1222 the Mongols again visited Georgia. The king left an infant son who afterwards reigned as David IV., but his own sister, Roussoudan, seized the crown in 1223, and passed a life not free from reproach. To revenge himself upon the queen, who refused his suit, Jalal-uddin twice occupied her capital, and her kingdom was again overrun by the Mongols, who committed fearful ravages. Next follow the exploits of Timur, who invaded Georgia in 1386, and, having seized upon the capital, carried away the king, Bagrat V., who feigned conversion to Islamism that he might gain the confidence of the conqueror. By this means he succeeded in obtaining from Timur a force of 12,000 men, for the purpose of prevailing upon his people to embrace Mahometanism. Bagrat had preconcerted his plans, and in due course every Tatar in his suite was slaughtered by his own warriors. In an ungovernable passion Timur re-entered Georgia (1393–94), and laid waste the entire country, levelling towns and villages, without sparing a single life. Satiated of bloodshed, he withdrew to the plains of Karabagh, and George VII., son and successor to Bagrat, returned upon the death of his father (1401) from the mountains where he had remained concealed, and occupied the capital. Timur made war upon him as well, compelling his submission, and in 1403 finally quitted the country. George was succeeded by Constantine II., whose successor, Alexander I., son of George VII., restored the kingdom to prosperity; but towards the close of his days he conceived the unhappy idea of dividing his kingdom among his three sons, an act that was followed by internecine wars, rebellions, massacres, and foreign invasions. From about this period commence the relations of Russia with Georgia and its neighbouring principalities, for in 1492, during the war fomented between Turkey and Persia, Alexander, king of Kakhetia, sought the protection of the czar John III. Again, in 1587, Boris Godounoff was appealed to for succour; and when, in 1618, Shah Abbas invaded Georgia, Teimouraz I. applied for assistance to Michael Feódorovitch (the first of the Romanoffs), as did also, in 1621, George III. king of Imeritia, and Mamia Gouriel the ruler of Gouria. In 1638 Levan, sovereign of Mingrelia, took the oath of allegiance to Alexis Michaelovitch, and in 1650 Alexander of Imeritia acknowledged the sovereignty of Russia. That empire, however, could not render material assistance to those petty sovereigns in distress, and little was done until fresh excesses committed by the Turks and Persians afforded Peter the Great the excuse for sending an expedition, in 1716, under Bekevitch a Circassian chieftain, to survey the Caspian shore and erect defences. Bekevitch was overpowered by the Tatars, and slaughtered with the whole of his force. Peter then occupied the western shore of the Caspian, taking the king of Georgia under his protection. This was Vakhtang VI., the author of a code that was in vogue until 1841, when Russian laws were in great measure introduced. But he was unable to resist Nadir Shah, and abdicating in 1724, retired to Astrakhan, where he died. Peter being at peace with Turkey, and having concluded the treaty of Nystadt with Sweden, left Moscow, May 24, 1722, and embarked at Astrakhan with troops destined for Georgia and the Persian provinces. Derbent, Bakou, Ghylan, and Mazanderan fell into his power, and he constructed a fort on the river Soulak, which he named St. Croix. All these places were ceded by treaty, in 1732, after Nadir Shah had delivered Karthli and Kakhetia from Turkish oppression. A few years later, in 1735, Turkey renounced all claim to those countries in favour of Persia. When war broke out with Turkey in 1768, General Todleben was sent to the assistance of Solomon I., king of Imeritia, and the Turks were expelled that kingdom. Then followed the treaty of Kainardschi in 1744, by which Georgia, Imeritia, and Mingrelia were placed under the protection of Russia. In 1795 Aga Mahomet Shah laid Tiflis in ruins, a disaster that was succeeded by dissensions in the royal family; and Heraclius II., who in 1783 had declared himself the vassal of Russia, now appealed to that country for protection. The next sovereign, George XIII., renewed this appeal, which would have been granted but for the sudden death of the emperor Paul. Alexander I. hesitated for a time, until George finally renounced his crown in 1799 in favour of Russia, drawing down upon him the hatred and curses of his country. His younger brother, Alexander, made an effort to secure the crown, but the chiefs saw the hopelessness of attempting to throw off the Russian yoke, and, being but poorly supported, the prince was beaten on the banks of the Lora. George died the following year, being the last of the Bagratides to occupy the throne of Georgia, which his ancestors had held for the space of 1029 years. It may be stated that the Bagrationa claim descent from David, by his adulterous intercourse with the wife of Uriah! Georgia was now virtually annexed to the empire, and on

September 12, 1801, Alexander I. issued a proclamation announcing the fact to the people of that country. In 1810 the prince of Imeritia revolted against Russia; but this movement was quickly suppressed, and the principality annexed. Mamia V., the ruler of Gouria, recognized the suzerainty of Russia in the same year, his principality being eventually annexed in 1829.

J. Buchan Telfer, R.N., *The Crimea and Transcaucasia*, 1877. (J. B. TE.)

Ethnology.—Of the three main groups into which the Caucasian races are now usually divided, the Georgian is in every respect the most important and interesting. It has accordingly largely occupied the attention of Orientalists almost incessantly from the days of Klaproth to the present time. Yet such are the difficulties connected with the origin and mutual relations of the Caucasian peoples that its affinities are still far from being clearly established. Anton Schiefner and P. V. Uslar, however, who must be accepted as undoubtedly the greatest authorities on the subject, have at least arrived at some negative conclusions valuable as starting points for further research. In their valuable papers, published in the *Memoirs* of the St Petersburg Imperial Academy of Sciences and elsewhere, they have finally disposed of the views of Bopp and Brosset, who attempted on linguistic grounds to connect the Georgians with the Aryan family. They also clearly show that Max Müller's "Turanian" theory is untenable, and they go a long way towards proving that the Georgian, with all the other Caucasian languages except the Ossetian, forms a distinct linguistic family absolutely independent of all others. This had already been suspected by Klaproth, and as the same conclusion has been arrived at by Fr. Müller and Zagarelli, it is not likely to be set aside by further investigation.

Uslar's "Caucasian Family" comprises the following three great divisions:—

1. Western Group. Typical races: Tcherkessians and Abkhasians.
2. Eastern Group. Typical races: Tchetchenzes and Lesghians.
3. Southern Group. Typical race: Georgians.

Here the term "family" must be taken in a far more elastic sense than when applied, for instance, to the Aryan, Semitic, or Eastern Polynesian divisions of mankind. Indeed, Uslar would perhaps be the first to admit that the fundamental unity of the three groups has not yet been established, and that they present at least as wide divergencies as are found to exist between the Semitic and Hamitic linguistic families, whose primitive relationship has not yet been definitely determined. Thus, while the Abkhasian of group 1 is still at the agglutinating, the Lesghian of group 2 has fairly reached the inflecting state, and the Georgian seems still to waver between the two. In consequence of these different stages of development, Uslar hesitates finally to fix the position of Georgian in the family, regarding it as possibly a connecting link between groups 1 and 2, but possibly also radically distinct from both.

Including all its numerous ramifications, the Georgian or southern group occupies the greater part of Transcaucasia, reaching from about the neighbourhood of Batoum on the Euxine eastwards to the Caspian, and merging southwards with the Armenians of Aryan stock. It comprises altogether nine subdivisions, as in the subjoined table:—

1. The GEORGIANS PROPER, who are the *Iberians* of the ancients and the *Grusya* of the Russians, but who call themselves *Karthalinians*, and who in mediæval times were masters of the Rion and Upper Kur as far as its junction with the Alazan.
2. The IMERITIANS, west of the Suram mountains as far as river Tzchenis-Tzchali.
3. The GURIANS, between the Rion and Lazistan.
4. The LAZES of Lazistan on the Euxine.
5. The SWANITHIANS, SHVANS, or SWANIANS, on the Upper Ingur and Tzchenis-Tzchali rivers.
6. The MINGRELIANS, between rivers Tzchenis-Tzchali, Rion, Ingur, and the Black Sea.
7. The TUSHES or MOSOKS, ... }
8. The PSHAVS or PH'TCHAVY,..... } about the headstreams of the Alazan and Jora rivers.
9. The KHEVSURS, ... }

All these formed jointly the ancient kingdom of Iberia, whose *mep'hé* or "king" resided at Mtzkhet till 469 A.D., when the seat of government was removed to the neighbouring Tphilissi or Tphilis-kalaki, *i.e.*, "warm town," so called from its thermal springs. This place has ever since continued to be the capital of the kingdom, and now bears the abbreviated name of Tiflis. The representative branch of the race have always been the Karthalinians, a name which the native Christian chroniclers profess to trace back to Khartlos, second son of Thargamos, son of Japhet, son of Noah. From Thargamos all their tribes are by their writers called, collectively, Thargamossiani, and from Khartlos their country receives the name of Karthveli or Karthli. But no weight can be attached to these genealogies and etymologies, which would doubtless never have been heard of but for the national desire to connect the race with the Mosaic account of the dispersion. It is now pretty well established that the Georgians are the descendants of the aborigines of the Pambaki highlands, and that they found their way to their present homes from the south-east some four or five thousand years ago, possibly under pressure from the great waves of Aryan migration flowing from the Eranian table-land westwards to Asia Minor and Europe. The terms Georgian and Grusya are simply corruptions of the Persian *Gurj*, as in Gurjistan = Gurjland = Georgia. The Georgians proper are limited on the east by the Alazan, on the north by the Caucasus, on the west by the Meskhian hills, separating them from the Imeritians, and on the south by the Kur river and the Karadagh and the Pambaki mountains. Southwards, however, no hard and fast ethnical line can be drawn, for even immediately south of Tiflis, Georgians, Armenians, and Tatars are found intermingled confusedly together.

The Georgian race, which represents the oldest elements of civilization in the Caucasus, is distinguished by some excellent mental qualities, and is especially noted for personal courage and a passionate love of music. The people, however, are described as fierce and cruel, and addicted to the vice of intemperance, though Von Thielmann speaks of them as "rather hard drinkers than drunkards." Physically they are a fine athletic race of pure Caucasian type; hence during the Moslem ascendency Georgia supplied, next to Circassia, the largest number of female slaves for the Turkish harems and of recruits for the Osmanli armies, more especially for the select corps of the famous Mameluks.

The social organization rested on a highly aristocratic basis, and the lowest classes were separated by several grades of vassalage from the highest. But since their incorporation with the Russian empire, these relations have become greatly modified, and a more sharply defined middle class of merchants, traders, and artisans has been developed. The power of life and death, formerly claimed and freely exercised by the nobles over their serfs, has also been expressly abolished. They are altogether at present in a fairly well-to-do condition, and it cannot be denied that under the Russian administration they have become industrious, and have made considerable moral and material progress.

Missionaries sent by Constantine the Great introduced Christianity about the beginning of the 4th century. Their efforts were greatly aided by the exemplary life of a female slave named Nina, who came into Georgia during the reign of King Miriam (265–318), and who occupies a prominent place in the ecclesiastical records of the country. Since that time the people have, under severe pressure from surrounding Mahometan communities, remained faithful to the principles of Christianity, and are still amongst the most devoted adherents of the orthodox Greek Church. Indeed it was their attachment to the national religion that caused them to call in the aid of the Christian Muscovites against the proselytizing attempts of the Shiite Persians—a step which ultimately brought about their political extinction.

As already stated, the Karthli language is not only fundamentally distinct from the Aryan linguistic family, but cannot be shown to possess any clearly ascertained affinities with either of the two northern Caucasian groups. It resembles them chiefly in its phonetic system, so that according to Rosen (*Sprache der Lazen*) all the languages of central and western Caucasus might be adequately rendered by the Georgian alphabet. Though certainly not so harsh as the Avar, Serghian, and other Daghestan languages, it is very far from being euphonious, and the frequent recurrence of such sounds as *ts*, *ds*, *thz*, *kh*, *khh*, *gh* (Arab. غ), *q* (Arab. ق), for all of which there are distinct characters, renders its articulation rather more energetic and rugged than is agreeable to ears accustomed to the softer tones of the Irenian and western Aryan tongues. It presents great facilities for composition, the laws of which are very regular. Its peculiar morphology, standing midway between agglutination and true inflexion, is well illustrated by its simple declension common to noun, adjective, and pronoun, and its more intricate verbal conjugation, with its personal endings, seven tenses, and incorporation of pronominal subject and object, all showing decided progress towards the inflecting structure of the Aryan and Semitic tongues.

Georgian is written in a native alphabet obviously based on the Armenian, and like it attributed to St Mesropius (Mesroh), who flourished in the 6th century. Of this alphabet there are two forms, differing so greatly in outline and even in the number of the letters that they might almost be regarded as two distinct alphabetic systems. The first and oldest, used exclusively in the Bible and liturgical works, is the square or monumental *Khutsuri*, *i.e.*, "sacerdotal," consisting of 38 letters, approaching the Armenian in appearance. The second is the *Mkhedrūli khēli*, *i.e.*, "soldier's hand," used in ordinary writing, and consisting of 40 letters, neatly shaped and full of curves, hence at first sight not unlike the modern Burmese form of the Pali.

Of the Karthli language there are several varieties; and, besides those comprised in the above table, mention should be made of the Kakhetian current in the historic province of Kakhetia. A distinction is sometimes drawn between the Karthalinians proper and the Kakhetians, but it rests on a purely political basis, having originated with the partition in 1424 of the ancient Iberian estates into the three new kingdoms of Karthalinia, Kakhetia, and Imeritia. On the other hand, both the Laz of Lazistan and the Swanian present such serious structural and verbal differences from the common type that they seem to stand rather in the relation of sister tongues than of dialects to the Georgian proper. All derive obviously from a common source, but have been developed independently of each other. The *Tush* or *Mosok* appears to be fundamentally a Kistian or Tchetchenz idiom affected by Georgian influences.

The Bible is said to have been translated into Georgian as early as the 5th century. The extant version, however, dates only from the 8th century, and is attributed to St Euthymius. But even so, it is far the most ancient work known to exist in the language. Next in importance is, perhaps, the curious poem entitled *The Amours of Turiel and Nestan Darejan*, or *The man clothed in the panther's skin*, attributed to Rustevel, who lived during the prosperous reign of Queen Thamar (11th century). Prince Leonidze of Akhmeti in Kakhetia showed Baron von Thielmann a rare and very old MS. of this poem, written on fine hemp paper in exquisite Mkhedruli characters, and embellished with arabesques and miniatures evidently the work of an eminent artist. Other noteworthy compositions are the national epics of the *Baramiani* and the *Rostomiani*, and the prose romances of *Visramiani* and *Darejaniani*, the former by Sarg of Thmogvi, the latter by Mosi of Khoni. Apart from these, the great bulk of Georgian literature consists of ecclesiastical writings, hymns sacred and profane, national codes, and chronicles.

See Baron Max von Thielmann's *Journey in the Caucasus, Persia, and Turkey in Asia*, translated by Dr Charles Hemeage, London 1875; Fr. Müller's *Ethnographie* and *Reise der Oestr. Fregatte Novarra*, Vienna, 1868; Anton Schiefner and General P. V. Uslar, numerous papers in the Bulletins of the Académie Impériale des Sciences de Saint Petersbourg for 1859, &c.; M. Zagarelli's *Examen de la littérature relative à la grammaire Géorgienne*, St Petersburg, 1873; Michel Smirnow's paper in *Revue d'Anthropologie*, April 15, 1878. (A. H. K.)

GEORGIA.

GEORGIA, a southern Atlantic State of the American Union, is one of the thirteen original States. It lies between the parallels 30° 20′ 39″ and 35° north latitude, and between the meridians 81° and 85° 53′ 38″ longitude west from Greenwich. Tennessee and North Carolina bound it on the north, South Carolina and the Atlantic Ocean on the east, Florida on the south and Alabama on the west. Georgia extends 320 miles from north to south, and its greatest breadth from east to west is 256 miles, embracing an area of 59,475 square miles or 38,064,000 acres. The Savannah River forms the boundary line between Georgia and South Carolina. The St. Mary's River forms a part of the boundary line between Georgia and Florida, and the Chattahoochee River nearly the southern half of the boundary between Georgia and Alabama on the west.

Topography.—Georgia presents every possible variety of surface, from the low alluvial lands and swamps along the coast, which finally spread out into the great Okefinokee Swamps, with a circumference of 180 miles, to the mountains of the Blue Ridge, in the northwestern part of the state. This variation of surface gives Georgia three distinct zones, differing in soil, productions and climate.

Low islands, separated by narrow necks from the main land, skirt her sea coast and produce cotton of a superior quality, known as sea-island cotton. This coast section with the adjacent islands is essentially tropical. About twenty miles from the shore line the first plateau rises 70 feet above the sea level, having a breadth of about 20 miles; here a second terrace 70 or 75 feet high rises, with a gradual ascending table land to the center of the state, where, in certain sections, the elevation is 575 feet above the level of the sea. Here, about 200 miles from the sea, begin the hills which, gradually increasing, reach a height of from 2,500 to 4,000 feet. This is the most extensive and fertile region of the state, embracing about 25 counties. The Blue Ridge Mountains, running through Virginia and North Carolina, cross the northern part of the State of Georgia and are finally lost in Alabama. This is the most picturesque district of Georgia. The Toccoa Falls, the cataracts of Tallulah, Esatoia Falls, Hiawassie Falls and the falls of Towalaga add much to the beauty of the region.

Harbors and Streams.—Georgia is well watered by many fine rivers which furnish avenues for trade and power for turning the wheels of industry. They find an outlet for their waters the Atlantic Ocean and the Gulf of Mexico. The Savannah, Altamaha, Ogeechee, Satilla and St. Mary's empty into the Atlantic, the Chattahoochee and Flint into the Gulf. The falls occurring at the second plateau interrupt travel, but up to these points her larger rivers are navigable. The Savannah is navigable to Augusta, 248 miles; the Chattahoochee to the falls of Columbus, 300 miles; and Flint river to Albany, over 100 miles from its mouth in the Chattahoochee River. The course of the rivers in the eastern half of the State is southeast; in the western half the general direction is south.

The Savannah is the largest river of the State; its length is about 450 miles. It is formed by the confluence of two small streams, the Tugaloo and Kiowee Rivers which rise near the North Carolina line and meet on the boundary between South Carolina and Georgia. It has three considerable affluents,—the Brier River, Broad River and Beaverdam Creek. The Savannah flows south by southeast for 450 miles, and empties its waters into the Atlantic near parallel 32° north latitude. It is navigable for large ships to Savannah, 18 miles, and for steamboats to Augusta, 230 miles farther, whence small steamboats pass around the falls at that point, through a canal constructed in 1845, and ascend 150 miles higher up the river. The canal, which is nine miles in length, furnishes power for the manufactories of Augusta. The valley of the river, from Augusta down to the sea, is rich in cotton fields, semi-tropical vegetation and magnificent live-oak forests. Rice plantations flourish on the low, alluvial soil near the sea-board. The Ogeechee is about 200 miles in length. It rises in Green county in the north, and flows nearly parallel with the Savannah, discharging its waters into Ossabaw Sound a few miles south of the Savannah. It drains the region between the Savannah and Altamaha rivers. It is navigable for large vessels to Louisville and for small ones 30 or 40 miles further; the Cannouchee is its principal affluent. The Altamaha is formed by the union of the Oconnee, which rises in Hall county, and the Ocmulgee, which rises in Gwinnett county. The two rivers flow about 250 miles in parallel courses, when the Ocmulgee turns to the east and joins the Oconnee to form the Altamaha. Their principal affluents are the Little Ocmulgee and the Appalachee. The Ocmulgee is navigable to Macon for steamers, and the Oconnee to Milledgeville, the former capital of the State. St. Mary's and the Satilla drain the southeastern corner of the State. Between them lies the great Okefinokee Swamp. They are both navigable for 30 or 40 miles. The Chattahoochee has a length of 550 miles from the Gulf, of which the first 350 are navigable. It rises in the Blue Ridge mountains, flows southwest through the gold mining region of Georgia, then nearly south until it nears the Florida line, where it joins the Flint River, which rises in Campbell county, and under the name of the Appalachicola the two flow south through Florida to the Gulf.

The falls of the Chattahoochee at Columbus are utilized for water power and make that city one of the first three of manufacturing importance in the State. The rapids and bluffs overlooking them called "Lovers' Leap" are of interest on account of their picturesque scenery as well as of the legend connected with them. Fort Gaines and West Point are two other important towns on the river. The Withlacoochee and the Allapaha, which unite in Florida to form the Suwanee, and the Ockloconee, which empties into the gulf in Florida, drain Georgia's southern counties. In the northwest, to the north of the Chattahoochee, which turns eastward on the 33° parallel of latitude, is the Tallapoosa, one of the rivers which unite to form the Alabama. The Coosa is another tributary of the Alabama, while the Hiawassee and the Chattanooga find their way into the Tennessee, thence through the Ohio and Mississippi into the Gulf of Mexico.

Georgia has about 128 miles of sea coast, extending from the mouth of St. Mary's river to the Savannah; but except where the rivers find their outlet, there are no good harbors. This sea line is faced with islands, producing the famous sea-island cotton. Between these islands and the main land are seven sounds. They are St. Andrew's, St. Simon's, Altamaha, Doboy, Sapelo, St. Catharine's and Ossabaw. Cumberland is one of the largest and most attractive islands. It is 30 miles long and covered with live-oaks, palmettos and pines. Jekyl, St. Simon's, Sapelo, St. Catharine's, Ossabaw and Cabbage are other of the more important islands. With these islands, Georgia has about 480 miles of coast line. Her principal seaport towns are Savannah, Darien, Brunswick and St. Mary's.

Geology and Mineral Products.—Georgia's varied surface furnishes examples of almost every known formation. A strip twenty miles broad along the coast is low, level, except for occasional sand-dunes, and rich in alluvial soil. Beginning here with the first terrace, and extending to a line drawn from Augusta to Georgetown, the eocene overlies the metamorphic slates and gneiss. Along the Ogeechee River. in Jefferson

county, the surface is broken by the cretaceous formation, which appears again in Crawford county, and extends to the west as far as the Chattahoochee River. In the northern part of the State, covering about half its entire territory, are the Metamorphic, Palæozoic and Eozoic formations of the Appalachian range.

The Silurian strata appear above Augusta on the Savannah river for a short distance, also along the west line of the State from the Nattey river to Dugdown Mountain. Here appear occasional outcrops of Devonian rock; while the northwestern corner of the State is covered with bituminous coal deposits, which extend in rich beds to Northeastern and Northern Alabama. On the western range of the Cohutta mountains are found iron ore deposits. Limestone and coal are found in close proximity to the iron ore deposits, furnishing every facility for the cheap and abundant production of iron. Lumpkin, Hall, Habersham and Forsyth counties produce gold, and until 1852 these mines and "placers" were profitably worked. Gold was first discovered there in October, 1828, by a negro slave. The largest deposits are along the eastern slope of the Alleghanies in a belt about twenty miles wide. A branch mint was established by the Government at an expense of $80,000, in Dahlonega, Lumpkin county, which in 1853 coined gold to the value of nearly $500,000; but, as in California, the surface deposits became exhausted, and after the war for the Union, the mint was given to the State for an agricultural college and the expensive machinery sold for old iron. South of the Blue Ridge, lying between the Coputta mountains and next to the gold bearing schists, is a vein of marble. In another place copper is found, also silver and lead, manganese, slate, baryta, and brown hæmatite, limestone, gypsum, granite, soapstone, sienite, marl, burrstone, asbestos, shales, kaolin, fluor-spar, tripoli, porcelain clay, arragonite, tourmaline, carnelian, emerald, ruby, opal, chalcedony, amethyst, agate, jasper, garnet, zircon, schorl, beryl, rose-quartz, and occasionally diamonds, are among the other minerals of the State. There are sulphur springs in the center of the State, and chalybeate springs of high reputation in the north of Forsyth county. There are also fossil remains of the mastodon, megatherium, mylodon, elephant, *ox, mollusks and turtles*.

Climate.—Along the sea coast the summers are intensely hot and malarial diseases are prevalent. Savannah and the coast region south are sometimes visited by the dreaded scourge of cholera and yellow fever. The mean temperature for July has been known to be as high as 99° Fahr. The northern, hilly and mountainous part of the State has a cool and salubrious climate for the same season of the year, and invalids are taking advantage of this healthful climate, coming to the mountain resorts from all parts of the Union. Lung and throat troubles are almost unknown among the inhabitants of northern and central Georgia. The belt of country running across the State, taking in Augusta, Atlanta and Columbus, is pronounced a very healthful region. The southern and central districts are sickly, particularly in the river valleys, and the climate is perilous in the summer to those unacclimated, though the natives enjoy fair health. The mean summer temperature at Augusta is about 79° Fahr., winter, 47°; at Atlanta, 75°; winter, 45°. At Berne the mean temperature is about 60° for the year.

Soil.—As in its climate, Georgia has a variety of soil. In the northern portion it is thin, but well fitted for grazing purposes. This country, known as the "Cherokee Country," has been under cultivation for unknown years by the Indians, but still produces in its valleys wheat, corn, Irish potatoes, and northern fruits. By fertilizing, cotton may be successfully cultivated, but this product is grown to better advantage on the river lands.

The red soil of the middle section of Georgia is "poor," but may be made productive of tobacco, cotton and cereals.

Peaches, apples, grapes and melons are plentiful. The cotton "belt" is in the southeast section of the State, and rice, sugar-cane and sweet potatoes grow abundantly.

In the southwest the soil is light and sandy. Millions of feet of yellow pine, of great value in ship and house building, are ready to be used. In the southern part of the State turpentine manufactories have been opened up in the forests. In the southeast is the live oak, much valued in ship-building, while the many swamps afford cyprus, cedar and palmetto. The coast and adjacent sea islands are composed of a sandy alluvial soil, in which is mixed decomposed coral. This soil is well fitted for the production of rice. Further inland are the Pine Barrens, capable of being cleared and cultivated, but chiefly of value for their timber, used in ship-building, and for their by-products. About one-half of the land surface of the State is still timbered, though the original forests of oak, elm, chestnut, maple, fir, beech, poplar and ash have disappeared from the older settled parts.

Products.—The staple agricultural products of Georgia are corn and cotton, though her varied climate and soil make it possible to grow almost anything that is raised in any of the other states, with the exception of a few tropical fruits raised in Florida. Since the war and the loss of slave labor, the cotton product has fallen off until in 1888 there were nearly 200,000 acres more in corn than in cotton. Georgia ranks third in the list of cotton producing States. In 1880 she exported or consumed 814,771 bales valued at more than $40,000,000. One-fourth of the product of the whole State is raised in the counties of Washington, Stewart, Sumter, Burke, Lee, Dougherty and Monroe.

In the southwestern part of the State a fine quality of wheat is raised, averaging 64 pounds to the bushel. Oats are raised to good advantage, but barley is little cultivated. Sweet potatoes grow readily in the sandy soil, and Irish potatoes are raised largely for the early northern market. Orchard and fruit crops are becoming more valuable, and peanuts or groundnuts form no small portion of the export products, while the rice plantations form the main feature of agricultural interest on the coast and islands.

In addition to her cotton production, Georgia produced in 1880 23,202,018 bushels of corn, estimated at $14,000,000; 5,548,745 bushels of oats, valued at more than $3,000,000; 3,159,771 bushels of wheat. Besides these cereals there were the timber products and 14,409 tons of hay.

The rice crop of 1880 was 25,368,687 pounds; molasses, more than 500,000 gallons; tobacco, 228,590 pounds; sweet potatoes, 4,397,778 bushels; Irish potatoes, 249,590 bushels; butter, 7,424,485 pounds; wool, 1,289,560 pounds.

In 1880 there were 17,838,562 acres in unimproved farms, an increase of about 1,000,000 acres since 1870; 8,204,720 acres were in improved farms, valued at $111,910,540. The value of farming implements and machinery was $5,317,416; value of live stock, $25,930,352; estimated value of all farm products for 1879, $67,028,929, which gives Georgia the tenth place in agriculture in the rank of States. The value of mechanical products was $36,447,448. The number of horses in the State in 1880 was 98,520; mules, 132,078; sheep, 527,589; swine, 1,471,003; milch cows, 315,073; working oxen, 50,026; other cattle, 544,812. The State valuation for 1880 was $554,000,000, a decrease of $91,895,237 since 1860. The decrease is owing to the loss of slave labor, in a large measure, but the State is steadily growing in the number of acres under cultivation, in the number of manufactories, and the productive capacity of both is increasing, while everywhere indications point to a normal and steady growth.

Trade and Commerce.—The principal exports are cotton and lumber. In 1878 the export of cotton amounted to 610,419 bales, of which 11,309 were of the famous sea-island variety; 988,339 pounds of wool were exported the same year. Her coast-wise and foreign trade employs some hundred vessels of about 20,000 tons' burden. For the year 1878, the total tonnage of the vessels cleared at the Port of Savannah was 642,843 tons; entered, 609,427; while the respective value of each was $24,014,535, and $505,596. At the port of St. Mary's, for the same year, the entries were 36,217 tons, valued at $1,421, and her exports were valued at $120,186. In the ports of Brunswick and Darien the exports were 32,579 tons, the entries 124,711 tons. These statistics do not do justice to the trade of the State, because the three ports of Savannah, Brunswick and Darien only share the commerce of Georgia with Charlestown, which receives a considerable portion of the exports from the northeastern portion of the State, while Fernandina, Appalachicola and Pensacola receive those from the southern counties and the western and southwestern districts go to Mobile. Large vessels have but four accessible harbors: Savannah, Brunswick, St. Mary's and Darien, but the sounds formed by the outlying islands are navigable to small craft. The four principal harbors have from fourteen to nineteen feet of water at mean low tide. The ports of entry for the state are Savannah, Brunswick, and St. Mary's.

Counties.—Georgia is divided into 137 counties, which had the following population in 1880: Appling, 5,258; Baker, 7,304; Baldwin, 13,721; Banks, 7,332; Bartow, 18,628; Berrien, 6,612; Bibb, 26,536; Brooks, 11,712; Bryan, 4,921; Bulloch, 8,034; Burke, 2,076; Butts, 8,307; Calhoun, 7,020; Camden, 6,126; Campbell, 9,923; Carroll, 16,881; Catoosa, 4,716; Charlton, 2,151; Chatham, 41,718; Chattahoochee, 5,664; Chattooga, 10,015; Cherokee, 14,300; Clarke, 11,549; Clay, 6,638; Clayton, 8,004; Clinch, 4,135; Cobb, 20,684; Coffee, 5,057; Colquitt, 2,524; Columbia, 10,452; Coweta, 21,072; Crawford, 8,648; Dade, 4,667; Dawson, 5,832; Decatur, 19,017; De Kalb, 14,452; Dodge, 5,347; Dooly, 12,412; Dougherty, 12,508; Douglas, 6,922; Early, 7,604; Echols, 2,552; Effingham, 5,957; Elbert, 12,929; Emanuel, 9,727; Fannin, 7,236; Fayette, 8,599; Floyd, 24,274; Forsyth, 10,552; Franklin, 11,444; Fulton, 47,588; Gilmer, 8,383; Glascock, 3,575; Glynn, 6,318; Gordon, 11,147; Greene, 17,513; Gwinnett, 19,516; Habersham, 8,668; Hall, 15,239; Hancock, 16,946; Haralson, 5,973; Harris, 15,732; Hart, 9,088; Heard, 8,762; Henry, 14,179; Houston, 22,350; Irwin, 2,696; Jackson, 16,285; Jasper, 11,841; Jefferson, 15,639; Johnston, 4,797; Jones, 11,600; Laurens, 10,040; Lee, 10,566; Liberty, 10,616; Lincoln, 6,405; Lowndes, 11,027; Lumpkin, 6,520; Macon, 11,663; Madison, 7,971; Marion, 8,595; McDuffie, 9,427; McIntosh, 6,110; Meriwether, 17,630; Miller, 3,717; Milton, 6,258; Mitchell, 9,384; Monroe, 18,787; Montgomery, 5,371; Morgan, 14,001; Murray, 8,257; Muscogee, 18,995; Newton, 13,609; Oconee, 6,346; Oglethorpe, 15,369; Paulding, 10,882; Pickens, 6,781; Pierce, 4,522; Pike, 15,825; Polk, 11,916; Pulaski, 14,022; Putnam, 14,512; Quitman, 4,386; Rabun, 4,629; Randolph, 13,306; Richmond, 33,191; Rockdale, 6,828; Schley, 5,301; Scriven, 12,745; Spalding, 12,545; Stewart, 13,981; Sumter, 18,192; Talbot, 14,102; Taliaferro, 7,004; Tattnall, 6,972; Taylor, 8,589; Telfair, 4,816; Terrell, 10,435; Thomas, 20,496; Towns, 3,260; Troup, 20,579; Twiggs, 8,910; Union, 6,429; Upson, 12,396; Walker, 11,012; Walton, 15,617; Ware, 4,135; Warren, 10,872; Washington, 21,928; Wayne, 5,954; Webster, 5,235; White, 5,335; Whitfield, 11,797; Wilcox, 3,106; Wilkes, 15,930; Wilkinson, 12,045; Worth, 5,888. Besides these there were in all the counties of the State 10,564 foreigners.

Principal Cities and Towns.—Georgia has six cities, but none of them are large. Atlanta, the capital, had in 1888, 37,409 persons; Savannah, the chief seaport city, had 30,709; Augusta, the county seat of Richmond county, on the Savannah, 21,891; Macon, county seat of Bibb county, 12,749; Columbus, county seat of Muscogee county, 10,123; Athens, 6,099; Milledgeville and Rome have between two and three thousand. The larger and more important towns are: Albany, Americus, Bainbridge, Brunswick, Cartersville, Covington, Cuthbert, Dalton, Dawson, Eatonton, Fort Valley, Griffin, La Grange, Marietta, Newnan, Thomasville, Valdosta, Washington and West Point.

Andersonville, the site of the chief prison of the Confederacy during the civil war, has acquired considerable notoriety. The University of Georgia is located at Athens, while three denominational colleges are situated at Macon. Savannah, Columbus, Americus, Atlanta and Rome are large shipping points for cotton, while St. Mary's, Darien and Brunswick saw and export large amounts of lumber.

Atlanta is in many ways the most progressive of the cities of the State. Its population increased from a little over 21,000 in 1870, to about 37,500 in 1888. It is one of the railway centers of the South, and its manufacturing interests are of large and growing importance.

It is one of the best examples of recuperation among the cities devastated by the civil war. Atlanta is an historic place, as some of the most important maneuvers of the war were conducted about it.

Railways and Canals.—In 1888 Georgia had 3,328 miles of railway, with 2,617 miles in operation, divided between 28 different lines, and valued at about $82,000,000. Twenty-six miles of the Alabama Great Southern, from Wauhatchie, Tenn., to Meridian, Miss., are in Georgia. West Point and East Point are connected by the Atlanta and West Point line, 81 miles in length. The Atlanta and Charlotte Air Line has 109 miles in Georgia. From Savannah to Bainbridge the Atlantic and Gulf Railway crosses the State, 237 miles in length. The Augusta and Savannah, from Miller to Augusta, has a length of 53 miles; the Brunswick and Albany, from Brunswick to Albany, is 172 miles long. Another line connects Brunswick with Macon, 187 miles; and the Georgia Central joins Savannah, Macon and Atlanta, 294 miles, with a branch, 17 miles, connecting Milledgeville and Gordon. The Eastern Tennessee, Virginia and Georgia, from Bristol to Chattanooga, Tenn., has a branch to Dalton, 30 miles. The Southwestern, 144 miles, runs from Macon to Eufaula, Ala., with one branch 72 miles long, from Fort Valley to Columbus, another, 23½ miles long, from Smithville to Albany; a third from Cuthbert to Fort Gaines, twenty miles; a fourth from Fort Valley to Perry, 13 miles; and a fifth from Albany to Arlington, 36 miles. The Upson Co. road runs from Barnesville to Thomaston; the Western and Atlantic has 121 miles in Georgia; the Elberton Air Line, from Toccoa City to Elberton, has 50 miles of road; the Georgia, from Augusta to Atlanta, with branches from Union Point to Athens, and from Barnet to Washington, has in all 231 miles; the Rome, from Rome to Kingston, 20 miles; the Savannah, Griffin and North Alabama, from Griffin to Carrolton, 63 miles.

The Western and Atlantic, for whose possession several great battles were fought during the civil war, connects Atlanta and the Georgia system with the Louisville and Nashville, Crescent and Tennessee lines at Chattanooga. This places Atlanta on the great highway from the north to New Orleans, Mobile and Florida. The Alabama and Chattanooga runs across the northwest corner of the State. The Cherokee connects Rockmart with Cartersville on the Western and Atlantic. The Columbus and Atlanta, projected between Columbus and Rome, is open to Hamilton, a distance of 23 miles; the North Eastern, from Athens to Lula, 39 miles; the Ocmulgee and Horse Creek, seven miles. Besides these there are several other roads less than ten miles in length. The cost of the railroads now in operation in the State exceeds $43,000,000, or one-sixth of the entire valuation of the State. There are but few canals in the State.

Manufacturing Interests.—Georgia is now among the very foremost of the Southern States of the Union in her manufacturing and railway interests, and both are increasing in number and extent. During the decade ending in 1870, Georgia had doubled the number as well as the products of her manufactories. Her navigable rivers and abundant railroads afford every facility for transportation of products, while her streams are turning water-wheels and her cotton manufactories bid fair to rival those of New England. In the development of her resources and industries a great future is in store for Georgia.

Since 1870 all the industries have received new impulses. In 1880 there were 3,593 manufactories, of which 38 were cotton factories, with 123,233 spindles and 135 looms; 14 woolen factories with 4,200 spindles and 135 looms. The number of persons employed in all her manufactories was 24,875, of whom 18,937 were males over 16 years of age; 3,619 females over 16, and 2,319 were children. The estimated capital invested in these establishments was $20,672,410; the wages paid were $5,266,152; value of material used, $24,143,939; value of products, $36,440,948. There are 1,332 grain mills.

	No.	Capital.	Materials.	Products.
		$916,510	$8,619,092	$9,793,898
Cotton Manufactures	44	6,537,657	4,039,673	6,513,490
Saw Mills	655	3,101,452	3,197,155	4,875,310
Rice Cleaning and Polishing	9	263,000	1,309,400	1,488,769
Foundry and Machine Shops	39	916,510	612,483	1,299,491
Tar and Turpentine	84	513,885	490,355	1,455,739
Iron and Steel	14	1,135,900	631,707	990,850
Carriages and Wagons	59	275,300	246,470	582,581
Brick and Tile	76	212,660	115,747	409,025

Besides these there are leather manufactories, printing interests, meat, leather, tin, copper and iron ware works, ice, rope, twine, logging, tobacco, sashes and blinds, fertilizers, agricultural tools, boilers and other machinery.

Labor is cheap in Georgia; her raw products are found at her very door, saving the cost of transportation; a never-failing supply of water furnishes power for the machinery summer and winter; while the State, to encourage investment of foreign capital, has exempted manufactories from taxation for the term of ten years. Moreover, the southern and southwestern cities furnish a ready market for all her products.

Augusta and Columbus take the lead in the manufacture of cotton and woolen goods. Athens, Macon, West Point, Decatur and Atlanta are also important centers for the production of these goods. Thomasville, Dalton, Albany, Marietta and Rome are also manufacturing points of considerable importance.

Augusta and Columbus have important advantages over any of the rest, and during the financial depression of 1877 their mills were kept constantly going, and paid profitable dividends. Nor was the same less true of many other plants in the State. The fact that in three years, from 1870 to 1873, the consumption of cotton in her cotton mills increased from 24,820 bales, to 39,122 bales, shows to some degree the growth of her manufactories.

Population.—The census of 1880, gives the population of Georgia as 1,542,180; 817,047 being whites, 725,133, or nearly one-half, blacks. The following shows the increase since 1790:

Census.	White.	Free Col'd.	Slaves.	Total.
1790	52,886	398	29,264	82,548
1800	102,261	1,019	59,406	162,686
1810	145,414	1,801	105,218	252,433
1820	189,566	1,763	149,656	340,985
1830	296,806	2,486	217,531	516,823
1840	407,693	2,755	280,944	691,392
1850	521,572	2,931	381,682	906,185
1860	591,588	3,500	462,198	1,057,286
1870	638,967	545,142	....	1,184,109
1880	817,047	725,133	....	1,542,180

The density of population in 1880 was 26.01 to the square mile. In 1880 there were only 10,564 persons of foreign birth in the state. This population is distributed among 136 counties, in which there are eight cities and 134 incorporated towns. Georgia is the twelfth State in the Union in point of population, and tenth in area. Indications point to an increase in population, and especially in her northern districts.

Education.—No organized plan of public instruction was in operation in Georgia previous to the year 1873. Since that time there has been increased interest in public schools among the members of the legislature, but, as yet, no legal provision for normal schools has been made. The liberality of the Peabody fund makes the latter possible and efficient, and the normal scholarships at Nashville, Tenn., received from the same source since 1877, offer some opportunity for professional training. For the year 1887, Georgia held 14 Peabody normal scholarships at Nashville, with 10 graduates in a class of 54. The number of scholars enrolled in 1887 was 319,724. The school age was 6 to 18; average daily attendance, 226,407; number of schools, 7,211; number of teachers, 7,700. The school revenue for the year was $453,294.

The higher branches are well provided for. As early as 1801 steps were taken to found Franklin College at Athens, and the first commencement was held there in 1804. She admits to her privileges, each year, fifty young men free of charge; also as many as may stand in need of aid who are studying for the ministry. Connected with Franklin University there is a medical department at Augusta and an agricultural department at Dahlonega, with about 250 students, whose tuition is free. The United States government has fixed an endowment of $240,000 on the State Agricultural and Mechanical Arts department, also connected with the University, which makes the total endowment fund $376,500. The university, exclusive of its departments of letters and agriculture, has five departments, 13 professors and 200 students, with a library containing over 1,400 volumes. In connection with the university there is a preparatory course and a law school. This is, perhaps, the only true university in the State, and under proper management may become of the highest order.

Mercer University, situated at Macon, has connected with it a theological department, while Oglethorpe University, at Atlanta, is only a college. Atlanta University is for colored students desiring to become ministers. Bowdon College at Bowdon, Emory College at Oxford, Masonic College at Covington, Marshall College at Griffin, have about 45 professors and 1,450 students. There are about 20 female colleges, or academies, or seminaries of high grade. These have 91 teachers and 1,476 pupils, who pay an average fee of $50 per annum. The Wesleyan Female College, at Macon, was one of the very first female colleges established in the world, having been chartered in 1836. It is under the direction of the M. E. Church South, and has about 200 students; 1,080 degrees have been conferred since 1840. The Bishop of Savannah has recently established a Catholic institution, called Pio Nono, at Macon. There are also institutions for the blind at Macon, and for the deaf and dumb at Cava Spring, near Rome, which together receive $25,000 per annum from the State. Though she has no distinctly normal schools, courses for teachers are being introduced into the high schools. In 1880 there were in Georgia no reformatories for either boys or girls, no asylums for idiots or inebriates, and but one or two hospitals for the insane. State prison labor was yet farmed out. The larger proportion of the inmates were colored.

Government, Constitution, Courts, etc.—The present constitution was adopted in March, 1868, by the convention, and ratified in April of the same year. It declares all citizens of the United States residing in its borders citizens of the State. No laws shall be made to abridge or infringe the rights of any of the citizens thereof, or to deny to any person within its jurisdiction the equal protection thereof. The governor is elected by a majority of the people. In him is vested the executive power, and his office holds through a term of four years. In case there is no election by the people, the general assembly choose the governor from the two receiving the highest number of votes. The legislative power is vested in a Senate and House of Representatives, elected by the people for the terms respectively of four and five years. These bodies convene annually, beginning the second Wednesday in January. The general assembly elect the following officers for a term of four years: Secretary of State, Comptroller-General, Treasurer and Surveyor General. The judiciary of the State is vested in a supreme court of three judges, who hold office for twelve years, one retiring every four years, entrusted with appellate jurisdiction only; in a superior court, for each judicial district, having exclusive jurisdiction in cases of divorce, in criminal cases, where penalty inflicted is death or imprisonment, in land title cases and in cases of equity. There is no lieutenant-governor, the president of the senate filling the office of governor when it becomes vacant. The supreme judges and other officers of the judiciary department of the State are appointed by the governor and confirmed by the senate. The governor of the State must be thirty years of age, fifteen years a resident of the United States and six years a resident of the State. Senators must be twenty-five years of age, and two years resident in the State. Representatives must be twenty-one years of age and one year resident in the State. Suffrage is given to all males twenty-one years of age or over, who have resided in the State six months, and in the county where their vote is cast three months, and who have paid such public assessments as may have been made. Defaulters of public money are ineligible to office, also those convicted of felony or larceny, unless pardoned. There is a homestead exemption to the value of $2,000, and an exemption on personal property to the value of $1,000, except for taxes, for labor or materials, or money borrowed for the purchase or improvement of said homestead sought to be exempt. Property owned by a woman at the time of marriage, acquired, presented or inherited, is exempt from all liabilities on account of her husband's debts. In her own name she may sue or be sued in matters relating to such property, and in other ways carry on business as if single. Legal interest is seven per cent., but there is no penalty for usury. A debtor may not discharge his liabilities by assignment. Treason, arson, rape, murder and castration are punishable by death.

Slavery, or "involuntary servitude," is prohibited by law, except where such servitude is inflicted as a punishment for crime. The law prohibits imprisonment for debt, also the infringement of that "free exercise of personal liberty" guaranteed by the United States to her citizens. Georgia is entitled to 9 representatives in congress, 2 senators, and has 11 electoral votes. Military duty may be demanded of all her male inhabitants between the ages of 18 and 40.

History.—Georgia was one of the thirteen original colonies that ratified the Declaration of Independence in 1776. Not till 1732 was the patent granted, by George II., for whom the state was named, to certain trustees for settling the colony of Georgia; so that this colony was settled much later than any of the rest. Previous to the year 1733, this territory had been claimed by both Spain and England, but in this year it was explored by Gen. James E. Oglethorpe, afterwards governor of the colony, who purchased land of the Creek Indians and laid the first foundations for the city of Savannah.

Among the "trustees" of the colony and those who were deeply interested in it were George Whitefield and the Wesleys.

the founders of Methodism and the eloquent preachers and hymnists of the period. The tribe of the Cherokees possessed the northern part of the State, together with the whole of the magnificent valley of the Tennessee; the Creeks lived in the southern portion of the State. In 1729 all the country of the Cherokees was ceded by treaty to the English. The object of the colonization of this territory was to found a refuge for debtors, destitutes, orphans and homeless youth, and to form a barrier against the aggressions of the Spanish and Indians in the Carolinas. When war was declared between England and Spain, Gen. Oglethorpe was put in command of the troops of Georgia and South Carolina, and led a futile expedition against St. Augustine.

The military service was at first given as pay for the land, which was divided out, but this proved so irksome that many deserted the colony, going to South Carolina, and the policy of the colony was altered by the offering of fifty acres to each settler. As a result of this, many Scotch and Germans settled in the colony. Ten thousand pounds was given by the English government to aid in the establishment of the colony and twenty-six thousand pounds more was given by private subscription.

In 1742 the Spanish retaliated upon the English for their expedition against St. Augustine and sent a fleet up the Altamaha river, making some captures, but were repulsed by Gen. Oglethorpe, and the fleet of 36 ships and 3,000 men sailed for Florida, after which peace was again restored. The colony grew slowly. Negro slavery which was tolerated in other sections, was prohibited here, and the people became so much discontented that in 1752 complaints were made of the restrictions and the trustees surrendered the charter.

A governor was then appointed and the colony came under the royal government, having the same privileges as to trade, land and negro slavery that were enjoyed by the other colonies. In 1755 a local legislature was appointed and the progress of the colony was rapid. The Cherokees had ravaged the remote settlements during the French and Indian wars. At this time the boundaries were the Atlantic Ocean on the east, the Pacific on the west. Altamaha river on the south and the Savannah on the north. In 1763 the south boundary was extended to the St.Mary's river, so as to take in the rich cotton and rice lands between the St. Mary's and Altamaha. Immigration increased, agriculture flourished, and in ten years from 1753 the exports had increased over £12.000.

At the time of the breaking out of the war of Independence, the population of Georgia was 70,000. Georgia was not hesitant about ratifying the movement that was being made by the other colonies to break away from the rule of the Mother Country. Georgia was more remote from the influences of the royal government, and had less cause of grievance; the colony was more prosperous and so had less to gain by a change, but feeling that the cause of all the colonists was one, she prepared at once to take an active part in the coming struggle. A delegate represented Georgia in the famous Continental Congress of 1775 and a convention of the people held in July of the same year gave full sanction to the revolutionary measures. The same year the governor, Sir James Wright, left the colony. Georgia suffered severely during the war. In 1778 a British force landed in Savannah and Augusta. The Americans, aided by the French, retook Augusta in the following year, but failed to recapture Savannah. After the capture of Charleston by the British, Georgia was not able to participate very actively in the war till Gen. Green repulsed the royal forces from the southern provinces. Georgia formed three constitutions, the first in 1777, the second in 1778, the third in 1779, which last remained in force till Georgia joined the Southern Confederacy in 1861. January 2, 1788, Georgia ratified the Constitution of the United States. The Creeks and Cherokees made repeated assaults upon the more remote colonists till 1790 and 1791, when treaties of peace were established and the western boundary of the State was fixed. In 1802 the large tract of land in Southwest Georgia was ceded by the treaty of Fort Wilkinson to the United States government by the Creeks. In 1803 the land west of the Chattahoochee River was ceded to the United States government by the State. This territory amounted to about 100,000 square miles.

The purchase of Louisiana in 1815, and the cession of Florida in 1821, was a great relief to Georgia in putting an end to the wars with the Indians, which were brought about largely by the incitations of the Spanish.

In 1838 the Indians were removed to the Indian Territory, and an end was made of the Indian troubles. It is interesting to note that among these Indians was the first red man who invented an Indian alphabet and a system of figures. Georgia grew in prosperity till at the breaking out of the civil war she was the leading State of the South.

Georgia was among the foremost States to secede. The formal ordinance was rendered January 19, 1861. Her favor was naturally thrown on the side of slavery, though there was a very determined minority against secession. The vote stood 208 to 89. The State was represented by ten members at the Confederate Congress, and the State adopted the Confederate Constitution in March of the year 1861.

Forts, arsenals and war supplies were captured, and laws were enacted to resume control of those lands which had been ceded to the United States Government. The State was active in furnishing aid to the cause, and felt the devastating result of the presence of Northern armies, though during the first part of the war the suffering was confined to those who were enduring the actual hardships of the field and camp. In 1863 the war was carried into her own borders by cavalry raids, and in 1864 Sherman devastated the fairest portion of her land in his "March to the Sea." A strip fifty miles in width was laid waste, followed by great loss of life, from Atlanta to Savannah. In April, 1865, a cavalry force under Gen. Wilson entered Georgia from Alabama, capturing West Point, Macon and Columbus, capturing Jefferson Davis, the President of the Southern Confederacy, near Irwinville.

Andersonville, Georgia, became a centre of interest by being the seat of the chief Confederate prison. In 1865, humbled in the hands of conquerors, Georgia accepted the terms of Gen. Johnston, and on October 25, 1865, a convention elected by the people assembled, which repudiated the war debt, prohibited slavery and formed a new constitution. A provisional governor was appointed by the United States president, and a new legislature ratified the Thirteenth Amendment of the United States. The Reconstruction Act of Congress, February, 1867, set aside this new constitution and State government, and made a registration of voters, enrolling in all 96,262 white and 95,973 colored citizens.

An election was held for a new constitutional convention, which consisted of 166 delegates. In March, 1868, a constitution was made, and ratified by the people in April, and on the 30th of that month an end was made of military government. Reconstruction was delayed on account of trouble that arose in regard to the test oath, and not till July 15th, 1870, was the act signed for the readmission of Georgia into the Union, and her senators and representatives given a seat in the Federal Congress. Georgia furnished about 80,000 troops to the Confederate armies. Her largest cities were in ruins, the State bankrupt, industries prostrate, the government revolutionized, at the close of the war; but the State has recovered from its prostration, and under a free people is administering the affairs and developing the resources with a firmer hand and with greater rapidity than almost any State that felt the shock of the war.

Natural Scenery.—The most picturesque scenery in the State is to be found, no doubt, in the mountains of the north. Toccoa falls, near the town by that name, on the Air Line Railway, have a descent of 185 feet, and in the same neighborhood are the rapids of Tallulah, where the water flows between perpendicular walls of rock 800 feet high.

Stone Mountain, not far from Decatur, is much visited, and the Chattahoochee, in its course through the neighborhood of Columbus is very interesting. The mineral springs scattered through the north and central part of the state are becoming favorite resorts for invalids and pleasure seekers. Savannah is one of the most interesting cities in all the South. It has preserved its uniqueness and distinctively southern aspect, notwithstanding the devastation of war. It is much visited by southern tourists, as well as the famous battle ground all the way from Atlanta to Chattanooga. The country, which for months was the tramping ground for opposing armies and the scene of bloody encounters, Kenesaw Mountain now looks down upon in a state of peace and prosperity. The state is also interesting as having been the home and hunting ground, in part, of the most extensive, powerful and intelligent tribes of Indians.

GEORGSWALDE, a town of Northern Bohemia, on the borders of Saxony, in the circle of Leitmeritz, about 35 miles E. of Dresden, with a station on the North Bohemian railway. Besides Old and New Georgswalde, it comprises Wiesenau and Phillippsdorf, the latter a place which since 1868 has attained celebrity through the miracles attributed to its image of the Virgin. Georgswalde was founded in the beginning of the 17th century, and ranks as one of the oldest industrial centres of Bohemia, sharing with the neighbouring town of Rumburg, a reputation for excellent linen. The parish church is a fine building. In 1869 the total population was 8220, of whom 5671 were in Old Georgswalde.

GERA, the chief town of the principality of Reuss-Schleiz, stands in a valley on the banks of the White Elster, 35 miles S.S.W. of Leipsic. It has been all rebuilt since a great fire in 1780, and the streets are in general wide and straight, and contain many handsome houses. The principal buildings are the churches of St Salvator's and St Trinity, the town-hall, the buildings of the imperial bank and of the Gera bank, the music hall, and the central hall. Its educational establishments include a gymnasium, a general town school (which contains a real school of the first order, a higher female school, and three citizen schools), a commercial school, a normal school, and a weaving school. The castle of Osterstein, the residence of the prince of Reuss, dates from the 9th century, but has been nearly all rebuilt within the last thirty years. Gera has long been noted for its industrial activity. Its manufactures comprise woollen, cotton, and silk goods, tapestry, artificial flowers, oil-cloth, leather, hats, tobacco, soap, beer, vinegar, chocolate, glue, porcelain and other earthenware, bricks, musical instruments, and carriages.

Gera was raised to the rank of a town in the 11th century, at which time it belonged to the counts of Groitch. In the 12th century it came into the possession of the lords of Reuss. It was stormed and sacked by the Bohemians in 1450, was two-thirds burned down by the Swedes in 1639 during the Thirty Years' War, and suffered afterwards from great conflagrations in 1686 and 1780, being in the latter year almost completely destroyed. The population in 1875 was 20,810, nearly all of whom are Protestants.

GERACE or GIERACE, a town of Italy in the province of Reggio di Calabria, about 59 miles from Reggio on the railway between that city and Monasterace, is situated on a limestone hill not far from the coast, 30 miles N.N.E. of Cape Spartivento, between the rivers Merico and Novito. It is the seat of a bishop and of a subprefect, and has a civil and criminal court dependent on that of Catanzaro. The citadel, formerly of great strength, was reduced to ruins by the earthquake of 1793; and the cathedral was at the same time so severely injured that only a portion of the crypt remained available for public worship. There is a good trade in a white wine known as *Vino Greco*; silk is manufactured; and the warm sulphur springs of the neigbourhood attract patients to the town. About 5 miles off, at Torre di Gerace, are the ruins of the Greek city of Locri Epizephyrii, from which Gerace derived materials for its buildings, and more especially fine marble columns for the cathedral. The population in 1871 was 7257. This Gerace is not to be confounded with Gerace Siculo, a town of between 3000 and 4000 inhabitants, 4 miles from Cefalu, which was the first place in Sicily erected into a marquisate.

GERANIUM is the name of a genus of polypetalous exogenous plants, which is taken by botanists as the type of the natural order *Geraniaceæ*. The name, as a scientific appellation, has a much more restricted application than when taken in its popular sense. Formerly the genus *Geranium* was almost conterminous with the order *Geraniaceæ*, which latter had then a more limited meaning than is given to it by those of our leading botanists of the present day who include in it the *Tropæolaceæ*, the *Oxalidaceæ*, and the *Balsaminaceæ*. Then as now the geranium was very popular as a garden plant, and the species included in the original genus became widely known under that name, which has more or less clung to them ever since, in spite of scientific changes which have removed the larger number of them to the genus *Pelargonium*. This result has been probably brought about in some degree by an error of the nurserymen, who seem in many cases to have acted on the conclusion that the group commonly known as *Scarlet Geraniums* were really geraniums and not pelargoniums, and have in consequence inserted them under the former name in their trade catalogues. In fact it may be said that, from a popular point of view, the pelargoniums of the botanist are better known as geraniums than are the geraniums themselves.

The species of *Geranium* bear the English name of Cranesbill, and consist mostly of herbs, of annual or perennial duration, dispersed throughout the temperate regions of the world. They number nearly a hundred, and bear a considerable family resemblance. The leaves are for the most part palmately-lobed, and the flowers are regular, consisting of five sepals, five imbricating petals, alternating with five glandules at their base, ten stamens, and a beaked ovary. Some dozen or more species are natives of the British Isles; and many of those of exotic origin form handsome border plants in our gardens of hardy perennials. Amongst these *G. ibericum*, *G. platypetalum*, *G. sanguineum*, *G. Backhousianum*, and the double-flowered varieties of *G. pratense* are conspicuous. The genus is not without its virtues, *G. maculatum* being the alum-root of North America, used there as an astringent in diarrhœa, dysentery, and such like complaints, while the native Herb Robert of English hedgesides, *G. Robertianum*, which is both astringent and aromatic, is used as a remedy in nephritic disorders.

From these regular-flowered herbs, with which they had been mixed up by the earlier botanists, L'Heritier in 1787 separated those plants which have since borne the name of *Pelargonium*, and which, though agreeing with them in certain points of structure, differ in others which are admitted to be of generic value. One obvious distinction of *Pelargonium* is that the flowers are irregular, the two petals which stand uppermost being different—larger, smaller, or differently marked—from the other three, which latter are occasionally wanting. This difference of irregularity the modern florist has done very much to annul, for the increased size given to the flowers by high breeding has usually been accompanied by the enlargement of the smaller petals, so that a very near approach to regularity has been in some cases attained. Another well-marked difference however remains in *Pelargonium*: the back or dorsal sepal is furnished with a hollow spur, which spur is adnate, *i.e.*, joined for its whole length with the flower-stalk; while in *Geranium* there is no spur. This peculiarity is best seen by cutting clean through the flower-stalk just behind the flower, when in *Pelargonium* there will be seen the hollow tube of the spur, which in the case of *Geranium* will not be found as it does not exist, but the stalk will appear as a solid mass. There are other characters which support those already pointed out, such as the absence of the glandules, and the declination of the stamens; but the features already described offer the most ready and obvious distinctions.

To recapitulate, the geraniums properly so-called are regular-flowered herbs with the flower stalks solid, while many geraniums falsely so-called in popular language are really pelargoniums, and may be distinguished by their irregular flowers and hollow flower stalks. In a great majority of cases too, the pelargoniums so commonly met with in greenhouses and summer parterres are of shrubby or sub-shrubby habit.

GERARD OF CREMONA (1114–1187), the mediæval translator of Ptolemy and Avicenna, was born at Cremona, Lombardy, in 1114. Dissatisfied with the meagre philosophies of his Italian teachers, he went to Toledo to study among the Moors, who were at that time the chief depositaries and interpreters of the wisdom of the ancients; and, having thus acquired a knowledge of the Arabic language, he appears to have devoted the remainder of his life to the business of making Latin translations from its literature. The date of his return to his native town is uncertain, but he is known to have died there in 1187. His original version of Avicenna's *Canon of Medicine* was the basis of all the very numerous subsequent Latin editions of that well-known work; and the Latin translation by which alone Ptolemy's *Almagest* until the discovery of the original μεγάλη σύνταξις was known to Europe is also ascribed to him. In addition to these, he translated various other treatises in medicine, mathematics, and astronomy, to the number, it is said, of sixty-six; but some of the works with which he has been credited (including the translation of the *Almansorius* of Er-Razi or Rhazes) are more probably due to a later Gerard also called "Cremonensis," but more precisely "de Sabloneta." See Boncompagni, *Della Vita e delle Opere di Gherardo Cremonense e di Gherardo da Sabbionetta*.

GERARD, variously surnamed TUM, TUNC, TENQUE, or THOM (*c.* 1040–1120), founder of the order of the knights hospitallers of St John or of Malta, was born at Amalfi about the year 1040. According to other accounts Martigues in Provence was his birthplace, while one authority even names the Château d'Avesnes in Hainault. Whether as a soldier or a merchant, he in the course of the latter part of the 11th century found his way to Jerusalem, where a hospice had for some time existed for the convenience of those who wished to visit the holy places. Of this institution Gerard became guardian or provost at a date not later than 1100; and here he organized that religious order of St John which received papal recognition from Pascal II. in 1113, by a bull which was renewed and confirmed by Calixtus II shortly before the death of Gerard in 1120.

GÉRARD, ÉTIENNE MAURICE, COUNT (1773-1852), a distinguished French general, was born at Damvilliers in the department of Meuse, 4th April 1773. He joined the second battalion of the Meuse in 1791, and served in the campaigns of 1792-1793 under Generals Dumouriez and Jourdan. In 1798 he accompanied Bernadotte as aide-de-camp in his embassy to Vienna. In 1799 he was named chief of a squadron, and in 1800 colonel. He distinguished himself by a brilliant charge against the Russian imperial guard at the battle of Austerlitz, and being raised to the rank of general in November 1806, played a prominent part in the battles of Halle, Jena, and Erfurt; and for his conduct in the battle of Wagram, where he greatly contributed to the victory, he was created a baron. In the Spanish campaign of 1810 and 1811 he gained special distinction at the battle of Fuentes-de-Onoro; and in the subsequent expedition to Russia he was present at the capture of Smolensk, had a principal share in the victory of Walontina-Gora, displayed such bravery and ability in the battle of the Moskova that he was made general of division, and by his coolness and energy in the disastrous retreat from Moscow saved the rearguard of the French army at the passage of the Wilna. In the campaign of 1813, in command of a division under Macdonald, he took part in the battles of Lützen, Bautzen, Goldberg, and Leipsic, where he was dangerously wounded. After the battle of Bautzen he was created by Napoleon a count of the empire. In the campaign of France of 1814, in command of the army of reserves composed chiefly of recruits, he by his skilful manœuvres powerfully assisted in securing the victories of Nogent, Nangis, and Montereau sur-Yonne. After the first restoration he was named by Louis XVIII. grand cross of the legion of honour and chevalier of St Louis. On the return of Napoleon from Elba he was entrusted with the command of the army of the Moselle, and took part in the battle of Ligny. On the morning of the battle of Waterloo, being under the orders of Grouchy, who was marching towards Wavre, he strongly urged him to proceed in the direction whence they heard cannon firing, but his advice was not followed. Gérard retired to Brussels after the fall of Napoleon, and did not return to France till 1817. He was chosen a member of the chamber of deputies in 1822, and was re-elected in 1823 and 1827. He took part in the revolution of 1830, after which he was appointed minister of war and named a marshal of France. On account of his health he resigned the office of war minister in the October following, but in 1831 he took the command of the northern army, and was successful in thirteen days in driving the army of Holland out of Belgium. In 1832 he compelled the surrender of Antwerp, and in the same year he was raised to the peerage of France. He was again chosen war minister in July 1834, and again resigned that office in the October following. In 1835 he was named grand chancellor of the legion of honour, and in 1838 commander-general of the national guards of the Seine, an office which he held till 1842. He became a senator under the empire in 1852, and died in April of the same year.

GÉRARD, FRANÇOIS, BARON (1770-1837), was born on May 4, 1770, at Rome, where his father occupied a post in the house of the French ambassador. At the age of twelve Gérard left Rome with his family for Paris, and there obtained admission into the Pension du Roi. From the Pension he passed to the studio of Pajou (sculptor), which he left at the end of two years for that of the painter Brenet, whom he quitted almost immediately to place himself under David. In 1789 Gérard competed for the Prix de Rome, which was carried off by his comrade Girodet. In the following year (1790) he again presented himself, but the death of his father prevented the completion of his work, and obliged him to accompany his mother to Rome. In 1791 he returned to Paris; but his poverty was so great that he was forced to forego his studies in favour of employment which should bring in immediate profit. David at once availed himself of his help, and one of that master's most celebrated portraits—Le Pelletier de St Fargeau—is due to the hand of "le petit Gérard." This portrait was executed early in 1793, the year in which Gérard, at the request of David, was named a member of the revolutionary tribunal, from the fatal decisions of which he, however, invariably absented himself. In 1794 he obtained the first prize in a competition, the subject of which was "The Tenth of August," and, further stimulated by the successes of his rival and friend Girodet in the Salons of 1793 and 1794, Gérard (nobly aided by Isabey the miniaturist) produced in 1795 his famous "Bélisaire." In 1796 a portrait of his generous friend (Louvre) obtained undisputed success, and the money received from Isabey for these two works enabled Gérard to execute in 1797 his "Psyché et l'Amour." At last, in 1799, his portrait of Madame Bonaparte established his position as one of the first portrait painters of the day. In 1808 as many as eight, in 1810 no less than fourteen portraits by him, were exhibited at the Salon, and these figures afford only an indication of the enormous numbers which he executed yearly; all the leading figures of the empire and of the restoration, all the most celebrated men and women of Europe, sat to Gérard. This extraordinary vogue was due partly to the charm of his manner and conversation, for his *salon* was as much frequented as his studio; Madame de Stael, Canning, Talleyrand, the duke of Wellington, have all borne witness to the attraction of his society. Rich and famous, Gérard was stung by remorse for earlier ambitions abandoned; at intervals he had indeed striven to prove his strength with Girodet and other rivals, and his "Bataille d'Austerlitz" (1810) showed a breadth of invention and style which are even more conspicuous in "L'Entrée d'Henri IV." (Versailles),—the work with which in 1817 he did homage to the Bourbons. After this date Gérard declined, watching with impotent grief the progress of the Romantic school. Loaded with honours—baron of the empire, member of the Institute, officer of the legion of honour, first painter to the king—he worked on sad and discouraged; the revolution of 1830 added to his disquiet; and in 1837 on 11th January, after three days of fever, he died. By his portraits Gérard is best remembered; the colour of his paintings has suffered, but his drawings show in uninjured delicacy the purity of his line; and those of women are specially remarkable for a virginal simplicity and frankness of expression.

M. Ch. Lenormant published in 1846 *Essai de Biographie et de Critique sur François Gerard*, a second edition of which appeared in 1847; and M. Delécluze devoted several pages to the same subject in his work *Louis David, son école et son temps.*

GÉRARD, JEAN IGNACE ISIDORE (1803-1847), a French caricaturist generally known by the pseudonym of Grandville—the professional name of his grandparents, who were actors—was born at Nancy, 13th September 1803. He received his first instruction in drawing from his father, a miniature painter, and at the age of twenty-one came to Paris, where he soon afterwards published a collection of lithographs entitled *Les tribulations de la petite propriété.* He followed this by *Les plaisirs de tout âge*, and *La sibylle des salons*; but the work which first established his fame was *Métamorphoses du jour*, published in 1828, a series of 70 scenes in which individuals with the bodies of men and faces of animals are made to play a human comedy. These drawings are remarkable for the extraordinary skill with which human characteristics are represented in animal features, but they are liable to the objection of attempting to express by the pencil what can be properly done only by the pen; while at the same time, in conquering difficulties incident to his purpose, much ingenuity and labour has been wasted which might have been employed otherwise with better results. The success of this work led to his being engaged as artistic contributor to various periodicals such as *La Silhouette*, *L'Artiste*, *La Caricature*, *Le Charivari*; and his political caricatures, which were characterized by marvellous fertility of satirical humour, soon came to enjoy a general popularity which never diminished. Besides supplying illustrations for various standard works, such as the songs of Béranger, the fables of La Fontaine, *Don Quixote*, *Gulliver's Travels*, *Robinson Crusoe*, he also continued the issue of various lithographic collections, among which may be mentioned *La vie privée et publique des animaux*, *Les cent proverbes*, *L'autre monde*, and *Les fleurs animées*. Though the designs of Gérard are occasionally unnatural and absurd, they usually display keen analysis of character and marvellous inventive ingenuity, and his humour is always tempered and refined by delicacy of sentiment and a vein of sober thoughtfulness. He died of mental disease 17th March 1847.

A short notice of Gérard, under the name of Grandville, is contained in Theophile Gautier's *Portraits Contemporains*. See also Charles Blanc, *Grandville*, Paris, 1855.

GERARD, JOHN (1545–1608), herbalist and surgeon, was born towards the end of 1545 at Nantwich in Cheshire. He was educated at Wisterson, or Willaston, 2 miles from Nantwich, and eventually, after spending some time in travelling, took up his abode in London, where he exercised his profession. For more than twenty years he also acted as superintendent of the gardens of Lord Burghley, secretary of state to Queen Elizabeth. In 1596 he published a catalogue of plants cultivated in his own garden, 1039 in number, inclusive of varieties of the same species. Their English as well as their Latin names are given in a revised edition of the catalogue issued in 1599. In 1597 appeared Gerard's well-known *Herball*, described by him in its preface as "the first fruits of these mine own labours," but more truly an adaptation of the *Stirpium historiæ pemptades* of Rembert Dodoens, published in 1583, or rather of a translation of the whole or part of the same by Dr Priest, with L'Obel's arrangement. Of the numerous illustrations of the *Herball* sixteen appear to be original, the remainder are mostly impressions from the wood blocks employed by Jacob Theodorus (Tabernæmontanus) in his *Icones Stirpium*, published at Frankfort in 1590. A second edition of the *Herball*, with considerable improvements and additions, was brought out by Thomas Johnson in 1633, and reprinted in 1636. Gerard was elected a member of the court of assistants of the barber-surgeons in 1595, by which company he was appointed an examiner in 1598, junior warden in 1605, and master in 1608. He died in February 1612, and was buried at St Andrews, Holborn.

See Johnson's preface to his edition of the *Herball*; and *A Catalogue of Plants cultivated in the Garden of John Gerard in the years* 1596–1599, *edited with Notes, References to Gerard's Herball, the Addition of modern Names, and a Life of the Author, by Benjamin Daydon Jackson, F.L.S.*, privately printed, Lond., 1876, 4to.

GÉRARD DE NERVAL (1808–1855) is the adopted name of Gérard Labrunie, a French litterateur, and that by which he is generally known. The son of an officer in the army, and born at Paris, May 21, 1808, he received his early education chiefly from his father, who taught him German, and he afterwards studied at the college of Charlemagne. He made his literary début by the publication of a volume of political odes, and in 1828 he published a translation of Goethe's *Faust*, of which Goethe himself expressed high approval, and the choruses of which were afterwards made use of by Berlioz for his legend-symphony, *The Damnation of Faust*. Several other translations from the German, contributed chiefly to the *Mercure de France*, a number of poetical pieces, and three comedies combined to acquire for him, at the age of twenty-one, a considerable literary reputation, and led to his being associated with Theophile Gautier in the preparation of the dramatic *feuilleton* for the *Presse*. On the death of Jennie Colon, an actress with whom he had contracted a *liaison*, he resigned his connexion with the *Presse*, and travelled in various parts of Europe, leading a somewhat dissipated life. He contributed an account of his travels to the *Revue des Deux Mondes* and other periodicals. After his return to Paris in 1844 he resumed for a short time the *feuilleton*. From 1841 he was subject to periodical attacks of insanity, and he committed suicide by hanging, 25th January 1855. The literary style of Gérard is simple and unaffected, and he has a peculiar faculty of giving to his imaginative creations an air of naturalness and reality. In a series of novelletes, afterwards published under the name of *Les Illuminés ou les Precurseurs du Socialisme* (1852), he gave a sort of analysis of the feelings which followed his third attack of insanity; and among his numerous other works the principal are *Élégies nationales et Satires politiques*, 1827; *Scènes de la Vie Orientale*, 2 vols., 1848–1850; *Contes et Facéties*, 1852; *La Bohême galante*, 1856; and *L'Alchimiste*, a drama in five acts, the joint composition of Gérard and Alexander Dumas. His *Œuvres complètes* were published in 1868 in 5 volumes.

GERASA, the modern GERASH or JERASH, a city of Palestine, in the Decapolis of Peræa, situated amid the mountains of Gilead, about 1757 feet above the level of the sea, at a distance of 20 miles from the Jordan and 21 miles to the north of Philadelphia. Of its origin nothing is known. Its name is never mentioned in the Old Testament, and in the New Testament the only reference to its existence is the alternative reading of Gerasenes for Gadarenes in Matthew viii. 28. From Josephus we learn that it was captured by Alexander Jannæus, burned by the Jews in revenge for the massacre at Cæsarea, and again plundered and depopulated by Annius the general of Vespasian; but in spite of these disasters it was still in the 2d and 3d centuries of the Christian era one of the wealthiest and most flourishing cities of Palestine. As late as 1121 it gave employment to the soldiers of Baldwin II., who found it defended by a castle built by a king of Damascus; but at the beginning of the following century the Arabian geographer Yakut speaks of it as deserted and overthrown. The ruins of Jerash, discovered by Seitzen about 1806 and since then frequently visited and described, still attest the splendour of the Roman city. They are distributed along both banks of the Kerwan, a brook which flows south through the Wady-ed-Dêr to join the Zerka or Jabbok; but all the principal buildings are situated on the level ground to the right of the stream. The town walls, which can still be traced and indeed are partly standing, had a circuit of not more than 2 miles, and the main street was less than half a mile in length; but remains of buildings skirt the road for fully a mile beyond the south gate, and show that the town had far outgrown the limit of its fortifications. The most striking feature of the ruins is the profusion of columns, no fewer than 230 being even now in position: the main street is a continuous colonnade, a large part of which is still entire, and it terminates to the south in a forum of similar formation. Among the public buildings still recognizable are a theatre capable of accommodating 6000 spectators, a naumachia or circus for naval combats, and several temples, of which the largest was probably the grandest structure in the city, possessing a portico of Corinthian pillars 38 feet high. The desolation of the city is probably due to earthquake; and the absence of Moslem erections or restorations would seem to show that the disaster took place before the Mahometan period.

GERBA or JERBA, German *Dscherba*, an island off the African coast in the Gulf of Gabès, belonging to the regency of Tunis. It is flat and well wooded with date palms, has an area of 425 square miles, and contains a population of 30,000. Most of the inhabitants are of Berber origin, though a certain proportion have adopted the Arabic language. About 5000 Jews live apart in villages of their own, and a number of European merchants are settled in the chief town of Haumt-es-Suk for the purposes of trade. The island has a considerable reputation for the manufacture of the woollen tissues interwoven with silk which are known as burnous stuffs; a market for the sale of sponges from the neighbouring seas is held from November till March; and a good trade is maintained in the export of dates and other fruits. Gerba is the Lothophagitis or Lotus-eaters' Island of the Greek and Roman geographers, and it may also be identified with the Brachion of Scylax. The modern name appears as early as the 3d century in Aurelius Victor, who, mentioning the births of the emperors Gallus Trebonianus and Volusianus his son, says—"Creati in insula Meninge, quæ nunc Girba dicitur." Meninge or Menins was the name of one of the two ancient towns in the island, the other being Thoar. A castle erected by the Spaniards in 1284 at Haumt-es-Suk still remains; but the pyramid built of the skulls of the Spaniards under Garcia, who perished in 1516, was removed in 1837.

See Barth, *Wanderungen durch die Küstenl. des Mittelmeres*; and Maltzan, *Reise in Tunis und Tripolis*, Leipsic, 1870.

GERBER, ERNST LUDWIG (1746–1819), author of the well-known dictionary of musicians, was born at Sondershausen 29th September 1746. His father, Henry Nicolas Gerber (1702–1775), a pupil of J. S. Bach, was an organist and composer of some distinction, and under his direction Ernst Ludwig at an early age had made great progress in his musical studies. In 1765 he went to Leipsic with the view of studying law, but the claims of music, which had gained additional strength from his acquaintanceship with J. A. Hiller, soon came to occupy almost his sole attention. On his return to Sondershausen he was appointed music teacher to the children of the prince, and in 1775 he succeeded his father as court organist. Latterly he devoted much of his time to the study of the literature and history of music, and with this view he made himself master of several of the modern languages. His *Historisch-biographisches Lexicon der Tonkünstler* appeared in 1790 and 1792 in two volumes; and the first volume of what was virtually an improved and corrected edition of this work was published in 1810 under the title *Neues historisch-biographisches Lexikon der Tonkünstler*, followed by other three volumes in 1812, 1813, and 1814. Gerber also contributed a number of papers to musical periodicals, and published several minor musical compositions. He died at Sondershausen 30th June 1819.

GERBERON, GABRIEL (1628–1711), a Jansenist monk, one of the most diligent students and prolific writers of his century, was born August 12, 1628, at St Calais, in the department of Sarthe. At the age of twenty he took the vows of the Benedictine order at St Melaine, Rennes, and after having taught rhetoric and philosophy in the monasteries of Bourgueil (Touraine) and St Denis, he became sub-prior at Compiègne, whence he was afterwards removed to St Germain-des-Pres. In the year 1669 he fully and finally committed himself in the Jansenist controversy by the publication of his first work, which was an apology for the abbé Rupert of Tuits. In 1672 he was ordered to Argenteuil and in 1675 to Corbie; but having by this time aroused the most bitter hostility of the entire Jesuit order, he found it necessary to save himself by flight into the Low Countries, where he seems to have lived in various towns during the next twenty-eight years, and where he published a great number of works, including the *Histoire Générale du Jansenisme* (1700), by which he is now best known. Arrested on the 30th of May 1703 at Brussels, at the instance of the archbishop of Malines, he was sent into France and condemned to imprisonment, from which he was not released till 1710, and even then only after he had consented to abjure the five Jansenist propositions. The first use he made of his freedom was to write a work (which, however, his friends prudently prevented him from publishing) *Le vaine triomphe des Jesuites*, containing a virtual withdrawal of the compulsory recantation. He died at the abbey of St Denis on the 29th of March 1711. A full list of his works is given in the *Biographie Générale*.

GERBERT. See SILVESTER II.

GERBERT, MARTIN (1720–1793), a Catholic prelate and writer on church music, was a descendant of the Gerberts of Hornau, and was born at Horb on the Neckar, Würtemberg, 12th August 1720. He received his education at the Jewish school of Freiburg in the Breisgau, at Klingenau in Switzerland, and at the monastery of St Blaise in the Black Forest. He joined the order of the Benedictines in the monastery of St Blaise in 1736, became priest in 1744, was soon thereafter appointed professor of theology, and was chosen abbot in 1764. From 1759 to 1762 he travelled in Germany, Italy, and France, chiefly with the view of obtaining access to the old collections of musical literature contained in the libraries of the monasteries. In 1774 he published two volumes *De cantu et musica sacra*; in 1777, *Monumenta veteris liturgiæ Alemannicæ*; and in 1784, in three volumes, *Scriptores ecclesiastici de musica sacra*, a collection of the principal writers on church music from the 3d century till the invention of printing. Although this work contains many textual errors, its publication has nevertheless been of very great importance for the history of music, by preserving writings which otherwise might either have perished or remained unknown. He is also the author of *Codex epistolaris Rudolphi I.*, 1772, and *Historia Nigræ Silvæ*, Cologne, 1783–1788. His interest in music led to his acquaintance with the composer Gluck, who became his intimate friend. He died 3d May 1793.

GERHARD, FRIEDRICH WILHELM EDUARD (1795–1867), a distinguished German archæologist, was born at Posen, 29th November 1795. After studying at Breslau and Berlin, he in 1816 took up his residence at the former town. The reputation he acquired by his *Lectiones Apollonianæ*, published in the same year, led soon afterwards to his being appointed professor at the gymnasium of Posen. On resigning that office in 1819, on account of weakness in the eyes, he travelled in Italy, and in 1822 he took up his residence in Rome, where, with the view of prosecuting his archæological studies, he remained for fifteen years. He there contributed to Platner's *Beschreibung der Stadt Rom*, then under the direction of Bunsen, and he was also one of the principal originators of the *Instituto di corrispondenza archeologica*, founded at Rome in 1828, and during his stay in Italy its director. After his return to Germany in 1837, he was appointed archæologist at the Royal Museum of Berlin, and in 1844 he was chosen a member of the Academy of Sciences, and a professor in the university. He died at Berlin 12th May 1867.

Besides a large number of archæological papers in periodicals, in the *Annali* of the Institute of Rome, and in the Transactions of the Berlin Academy, and several illustrated catalogues of Greek, Roman, and other antiquities in the Berlin, Naples, and Vatican Museums, Gerhard is the author of the following works:—*Antike Bildwerke*, Stuttg., 1827–44; *Auserlesene griech. Vasenbilder*, 1839–58; *Etruskische Spiegel*, 1839–65; *Hyperboreisch-röm. Studien*, vol. i., 1833; vol. ii., 1852; *Prodromus mytholog. Kunsterklärung*, Stuttgart and Tübingen, 1828; and *Griech. Mythologie*, 1854–55. His *Gesammelte akademische Abhandlungen und kleine Schriften* were published posthumously in 2 vols., Berlin, 1867.

GERHARD, JOHANN (1582–1637), one of the ablest and most learned exponents of Lutheran orthodoxy, was born of a good middle-class family in Quedlinburg, 17th October 1582. In his fifteenth year, during a dangerous illness, he came under the personal influence of Johann Arndt, author of *Das Wahre Christenthum*, and resolved to study for the church. Soon after entering the university of Wittenberg, however, in 1599, he began to waver in this determination, and ultimately gave himself for two years to the study of medicine, but in 1603 resumed his theological reading at Jena, and in the following year received a new impulse from Winkelmann and Mentzer at Marburg. Having graduated and begun to give lectures at Jena in 1605, he in 1606 received and accepted the duke of Coburg's invitation to the superintendency of Heldburg and mastership of the gymnasium; soon afterwards he became general superintendent of the duchy, in which capacity he was much and usefully engaged in the practical work of ecclesiastical organization until 1616, when he found a more congenial sphere in the senior theological chair at Jena, where the remainder of his life was spent. Though still comparatively young, Gerhard had already come to be regarded as the greatest living theologian of Protestant Germany; in the numerous "disputations" which characterized that period he was always protagonist, while on all public and domestic questions touching on religion or morals his advice was eagerly sought on all hands and by every class. It is recorded that during the course of his lifetime he had received repeated calls to almost every university in Germany, as well as to Upsala in Sweden. He died on the 20th August 1637. Personally he is said to have exhibited a rare combination of all the best elements of the Christian character; the only failing imputed to him by any one decidedly leans to virtue's side—an excessive love of peace.

His writings are very numerous, alike in exegetical, polemical, dogmatic, and practical theology. To the first category belong the *Commentarius in harmoniam historiæ evangelicæ de passione Christi* (1617), the *Comment. super priorem D. Petri Epistolam* (1641), and also his commentaries on Genesis (1637) and on Deuteronomy (1658). Of a controversial character are the *Confessio Catholica* (1634–68), an extensive work which seeks to prove the evangelical and catholic character of the doctrine of the Augsburg Confession from the writings of approved Roman Catholic authors; and the *Loci theologici* (1629), his principal contribution to science, in which Lutheranism is expounded "nervose, solide, et copiose," in fact with a fulness of learning, a force of logic, and a minuteness of detail that had never before been approached. The *Meditationes sacræ* (1621), a work expressly devoted to the uses of Christian edification, has been frequently reprinted in Latin and has been translated into most of the European languages, including Greek. The English translation by R. Winterton (1631) has passed through at least nineteen editions. There is also an edition by W. Papillon in English blank verse (1801). A *Vita Joh. Gerhardi* was published by E. R. Fischer in 1723.

GERHARDT, CHARLES FREDERIC, was born at Strasburg, August 21, 1816, and died there August 19, 1856. After his school years spent at home and in Carlsruhe, where his taste for chemistry was awakened, he was sent to Leipsic to learn business, but he attended Erdmann's lectures on chemistry as well. Returning home he very soon found that a commercial life was not to his taste, so, after a sharp dispute with a disappointed father, he enlisted in a cavalry regiment. In a few months a military career also became intolerable, and, being bought off by a friend, he went to Giessen to study under Liebig. There he remained eighteen months, displaying such entire devotion to chemistry that he found himself unable to obtain the customary degree. He again thought of entering trade, but Liebig persuaded him to go to Paris, where he arrived in 1838. His good appearance and address recommended him to Dumas and other chemists, and in a short time along with Cahours, who became his intimate friend, he published an important memoir on essential oils, distinguished especially by the new views it contained. He soon after left Paris and went to Montpellier, where he was professor in the faculty of science till 1848. He then returned to Paris and opened a school for chemistry, which, however, was not commercially a success. From 1848 to 1855 he resided at Paris, and it was during this time that he published the memoirs and carried on the controversies which have been of such importance in the development of scientific chemistry. In 1855 he was appointed professor at Strasburg, his native place; but he had held the office for but a short time when he died, after two days' illness. Gerhardt's contributions to chemistry are less discoveries of new facts, than of new ideas which organized and vitalized an inert accumulation of facts. He developed the notion of types of structure and reaction; he discovered the order of organic compounds, which led him to the doctrine of homologous and other series; and on theoretical grounds he remodelled the whole character of the combining weights upon the two-volume molecular basis. The bare statement, however, of his results gives no idea of the lucidity, the wealth of thought, the grasp of the entire subject which his memoirs and his longer works display. It was by his writings especially that Gerhardt's influence was felt. Although a thorough enthusiast in his subject, clear in his exposition, earnest in his work, weighty in his delivery, he seems to have wanted the qualities of a successful teacher. Nothing is heard of his lectures, or of his influence as a professor,—such influence as drew students round Liebig and other great masters. None the less, however, did he stir the thoughts of other chemists to the very depths; and although the unitary system has had its day, yet, in substance at least, if no longer in name chemistry is still Gerhardt's, and it is not impossible that chemists may return to some of his views which at present are not acceptable.

GERHARDT, PAUL (c. 1606–1676), the greatest hymnwriter of Germany, if not indeed of Europe, was born of a good middle-class family at Gräfenhainichen, a small town on the railway between Halle and Wittenberg, in 1606 or 1607,—some authorities, indeed, give the date March 12, 1607, but neither the year nor the day is accurately known. His education appears to have been retarded by the troubles of the period, the Thirty Years' War having begun about the time he reached his twelfth year. After completing his studies for the church he is known to have lived for some years at Berlin as tutor in the family of an advocate named Berthold, whose daughter he subsequently married, on receiving his first ecclesiastical appointment at Mittelwald (a small town in the neighbourhood of Berlin) in 1651. In 1657 he accepted an invitation as "diaconus" to the Nicolaikirche of Berlin; but, in consequence of his uncompromising Lutheranism in refusing to accept the elector Frederick William's "syncretistic" edict of 1664, he was deprived in 1666. Though absolved from submission and restored to office early in the following year, on the petition of the citizens, his conscience did not allow him to retain a post which, as it appeared to him, could only be held on condition of at least a tacit repudiation of the Formula Concordiæ, and for upwards of a year he lived in Berlin without fixed employment. In 1668 he was appointed archdeacon of Lübben in the duchy of Saxe-Merseburg, where, after a somewhat sombre ministry of eight years, he died on the 7th of June 1676. Many of his best known hymns were originally published in various church hymnbooks, as for example in that for Brandenburg which appeared in 1658; others first saw the light in Johann Crüger's *Geistliche Kirchenmelodien* (1649) and *Praxis Pietatis Melica* (1656). The first complete set of them is the *Geistliche Andachten*, published in 1666–67 by Ebeling, music director in Berlin. No hymn by Gerhardt of a later date than 1667 is known to exist.

The life of Gerhardt has been written by Roth (1829), by Langbecker (1841), by Schultz (1842), by Wildenhahn (1845), and by Bachmann (1863); also by Kraft in Ersch u. Gruber's *Allg. Encycl.* (1855). The best modern edition of the hymns, published by Wackernagel in 1843, has often been reprinted. There is an English translation by Kelly (*Paul Gerhardt's Spiritual Songs*, 1867).

GÉRICAULT, Jean Louis André Théodore (1791–1824), French painter, led the inevitable reaction which set in under the empire against the fixed and strictly limited aims of the school of David. He was born at Rouen in 1791. In 1808 he entered the studio of Charles Vernet, from which, in 1810, he passed to that of Guérin, whom he drove to despair by his passion for Rubens, and by the unorthodox manner in which he persisted in interpreting nature. At the Salon of 1812 Géricault attracted attention by his "Officier de Chasseurs à Cheval" (Louvre), a work in which he personified the cavalry in its hour of triumph, and turned to account the solid training received from Guérin in rendering a picturesque point of view which was in itself a protest against the cherished convictions of the pseudo-classical school. Two years later (1814) he re-exhibited this work accompanied with the reverse picture "Cuirassier blessé" (Louvre), and in both subjects called attention to the interest of contemporary aspects of life, treated neglected types of living form, and exhibited that mastery of and delight in the horse which was a feature of his character. Disconcerted by the tempest of contradictory opinion which arose over these two pictures, Géricault gave way to his enthusiasm for horses and soldiers, and enrolled himself in the *mousquetaires.* During the Hundred Days he followed the king to Bethune, but, on his regiment being disbanded, eagerly returned to his profession, left France for Italy in 1816, and at Rome nobly illustrated his favourite animal by his great painting "Course des Chevaux Libres." Returning to Paris, Géricault exhibited at the Salon of 1819 the "Radeau de la Méduse" (Louvre), a subject which not only enabled him to prove his zealous and scientific study of the human form, but contained those elements of the heroic and pathetic, as existing in situations of modern life, to which he had appealed in his earliest productions. Easily depressed or elated, Géricault took to heart the hostility which this work excited, and passed nearly two years in London, where the "Radeau" was exhibited with success, and where he executed many series of admirable lithographs now rare. At the close of 1822 he was again in Paris, and produced a great quantity of projects for vast compositions, models in wax, and a horse *écorché*, as preliminary to the production of an equestrian statue. His health was now completely undermined by various kinds of excess, and on 26th January 1824 he died at the age of thirty-three. That which he left us is effective only as a protest; his work, like his life, lacked the fixity of conscious purpose necessary to the task of reconstruction. Had he steadied himself and survived the abuse of his powers, he might have played an important part in determining the course of the modern school, for, though no colourist, he was in other respects richly endowed, and was possessed by a rare energy which redeemed even that tendency to undue emphasis which gives a theatrical character to much of the best French work. Géricault's biography, accompanied by a *catalogue raisonné* of his works, was published by M. C. Clément in 1868.

GERIZIM (הַר־גְּרִזִּים, "the desert hill," or, according to others, "the hill of the Gerizzites"[1]), the third highest mountain of Samaria,[2] is situated at the western extremity of the fertile plain of Mochna, and with Mount Ebal, which lies immediately to the north, forms a narrow valley in which lies the ancient town of Sichem or Shechem. As seen from this point Gerizim is distinguished from its tamer neighbour by the boldness of its crags, the richness of its verdure, and the number of its springs. Its southern slope however is much gentler than its northern, and both are almost bare of trees. On the summit stands at present a small Mahometan chapel, and there are besides numerous traces of a fortress and church possibly dating from the time of Justinian. But the spot regarded by the Samaritans as the holiest upon earth is a small level plateau situated somewhat to the south of this. Here it is believed stood the temple built by Manasseh, the son of the Jewish high priest in the days of Nehemiah,[3] and destroyed by John Hyrcanus 300 years afterwards (Jos., *Ant.*, xiii. 9. 1). According to the Samaritans and some modern writers, Gerizim was the scene of the incidents recorded in Genesis xxii. 9–13. Probably as being the hill on the right hand of the spectator who, standing in the valley of Shechem, looks to the sun rising, it was also the hill on which, according to Josh. viii. 33, 34 (comp. Deut. xi. 29, 30, and xxvii. 12–26), after the conquest of Ai, the tribes of Simeon, Levi, Judah, Issachar, Joseph, and Benjamin stood to pronounce the blessings connected with a faithful observance of the law, while the remaining tribes from mount Ebal confirmed the curses attached to specified violations of the divine commands. According to Eusebius and Jerome indeed, the Ebal and Gerizim described in Deut. xi. 30 were not the mountains now known by that name, but two smaller hills in the neighbourhood of Jericho. This view, however, may now be regarded as universally abandoned (see Stanley, *Sinai and Palestine*, p. 236, note).

GERMAN CATHOLICS (Deutschkatholiken), the name assumed in Germany towards the close of the year 1844 by certain dissentients from the church of Rome. The most prominent leader of the German Catholic movement was Johann Ronge, a Roman Catholic priest, who in October 1844 made a vigorous attack upon Arnoldi, bishop of Treves, for having made a relic, which he alleged to be the holy seamless coat of Christ, an object of pilgrimage and adoration. On Ronge's excommunication on this account, by the chapter of Breslau in December 1844, he received a large amount of public sympathy, and a dissenting congregation was almost immediately formed at Breslau with a very simple creed, in which the chief articles were belief in God the Father, creator and ruler of the universe; in Jesus Christ the Saviour, who delivers from the bondage of sin by his life, doctrine, and death; in the operation of the Holy Ghost; in a holy, universal, Christian church; in forgiveness of sins and the life everlasting. Within a very few weeks similar communities had been formed at Leipsic, Dresden, Berlin, Offenbach, Worms, Wiesbaden, and elsewhere; and at a "council" convened at Leipsic in March 1845, twenty-seven congregations were represented by delegates, of whom however only two or at most three were in clerical orders. Almost contemporaneously with the commencement of the agitation led by Ronge, another movement fundamentally distinct, though in some respects similar, had been originated at Schneidemühl, Posen, under the guidance of Johann Czerski, also a priest, who had come into collision with the church authorities on the then much discussed question of mixed marriages, and also on that of the celibacy of the clergy. The result had been his suspension from office in March 1844; his public withdrawal, along with twenty-four adherents, from the Roman communion in August; his excommunication im-

[1] See 1 Sam. xxvii. 8 (Keri.)

[2] Josephus (*Ant.*, xi. 8, 2) calls it the highest, but his assertion has been disproved by recent accurate measurement. According to Furrer, Tell 'Azur, Ebal, and Gerizim are 3566, 3375, and 3179 feet respectively above the level of the Mediterranean.

[3] In the days of Alexander the Great, according to Josephus (*Ant.*, xi. 8, 2); but there are good reasons for believing this to be inexact. See Neh. xiii. 28, and compare Bertheau on the passage.

mediately thereafter; and the formation, in October, of a "Catholic Apostolic Christian" congregation which, while rejecting various practices of the Roman Church, retained the Nicene theology and the doctrine of the seven sacraments. Czerski had been at some of the sittings of the "German Catholic" council of Leipsic; but when a formula somewhat similar to that of Breslau had been adopted, he refused to adhibit his signature because the divinity of Christ had been ignored, and he and his congregation continued to retain by preference the name of "Catholic Apostolic Christians" which they had originally assumed. Of the German Catholic congregations which had been represented at Leipsic some manifested a preference for the fuller and more positive creed of Schneidemühl, but a great majority continued to accept the comparatively negative theology of the Breslau school. The number of these increased with considerable rapidity, until in June 1846 in Silesia alone the members of the German Catholic communion were reckoned by thousands, while the congregations scattered over Germany amounted in all to 173. In Austria, however, and ultimately also in Bavaria, the use of the name German Catholics was officially prohibited, that of "Dissidents" being substituted, while in Prussia the adherents of the new creed were laid under various disabilities; these and other circumstances, among which the frequent occurrence of internal dissensions was perhaps the gravest, conspired to check at an early stage the prosperous career of a movement which in its beginnings had been looked upon by many intelligent observers with considerable hopefulness. In 1859 some of the German Catholics entered into a union with the "Free Congregations," when the united body took the title of "The Religious Society of Free Congregations." Before that time many of the congregations which were formed in 1844 and the years immediately following had been dissolved, including that of Schneidemühl itself, which ceased to exist in 1857. No very recent statistics of a trustworthy kind as to the numeircal strength of the German Catholics are accessible. Their total in Prussia was 6395 in 1861, and 10,920 in 1867, while in Saxony they numbered 1772 in 1849, and 3015 in 1871. At an early stage the movement attracted the attention of Gervinus, the eminent historian and critic, who in 1846 published a pamphlet entitled *Die Mission des Deutschkatholicismus*, to which, as well as to Kampe's treatise *Das Wesen des Deutschkatholicismus*, reference may be made. See also the article by Schmid in Herzog's *Realencyclopädie* (1878).

GERMANICUS, Cæsar, a distinguished Roman general and provincial governor in the reign of Tiberius, was born 15 B.C., and died 19 A.D. His name Germanicus, the only one by which he is known in history, he inherited from his father Claudius Drusus Nero, the stepson of Augustus, and the most famous of his generals. His mother was the younger Antonia, the daughter of Marcus Antonius and niece of Augustus, and he married Agrippina the grand-daughter of the same emperor. It was natural that a prince so intimately allied both by birth and connexion with the reigning family should be regarded as a candidate for the purple Augustus, it would seem, long hesitated whether he should name him as his successor, and as a compromise required Tiberius to adopt him, though Tiberius had a son of his own. When his uncle succeeded to the throne, Germanicus was the only rival that he feared; and the emperor's jealousy and suspicion of him not only cut short his career of conquest but embittered the last years of his life, and precipitated, if it did not indirectly cause, his unhappy and premature end.

For the facts of his life our chief and, except a brief notice in Suetonius, almost our sole authority is Tacitus. Germanicus forms the central figure of the first two books of the *Annals*, and in the minute and graphic record of his campaigns, the unravelling of the court intrigues to which he was subject, and the pathetic description of his last hours and of the outburst of grief and indignation which followed the news of his death, the historian has put forth all his powers. But a modern biographer, though compelled to trust to Tacitus for his materials, may yet be allowed to put upon them his own construction, to make allowance for the glamour which surrounded an amiable and ill-starred prince, and to discount the exaggerations of a master of rhetoric who has set his favourite hero in a blaze of light in order to deepen the shadows of his masterpiece Tiberius, the darkest and saddest portrait in all history. The following article will consist of a brief abstract of the life as related by Tacitus, and an estimate of the character as it presents itself to us in the foregoing records.

Of the early years and education of Germanicus little is known. That he possessed considerable literary abilities, and that these were carefully trained, we gather, not only from the speeches which Tacitus puts into his mouth, but from the reputation he left as an orator, as attested by Suetonius and Ovid, and from the fragments of his works which have survived. At the age of twenty he served his apprenticeship in the art of war under his uncle Tiberius, and was rewarded with the triumphal insignia for his services in crushing the revolt in Dalmatia and Pannonia. In 12 A.D. he was made consul, though he had neither attained the legal age nor passed through the grades of prætor and ædile. Soon afterwards he was appointed by Augustus to the important command of the eight legions on the Rhine. The news of the emperor's death found Germanicus at Lugdunum, where he was superintending the census of Gaul. Close upon this came the report that a mutiny had broken out among his legions on the lower Rhine. Germanicus hurried back to the camp, which was now in open insurrection. The tumult was with difficulty quelled, partly by well-timed concessions for which the authority of the emperor was forged, but mostly by the help of his personal popularity with the troops. Some of the insurgents actually proposed that he should put himself at their head and secure for himself the empire, but their offer was rejected with righteous horror. In order to calm the excitement and prevent further disaffection, Germanicus determined at once on an active campaign. Crossing the Rhine at the head of 12,000 legionaries and an equal number of allied troops, he attacked and routed the Marsi, and laid waste the valley of the Ems. In the following year he marched against Arminius, the conqueror of Varus, and reached the fatal battlefield in the Teutoburg Forest. The bones of the Roman soldiers still lay bleaching on the ground near the altars where their tribunes had been immolated, and the gibbets where the prisoners had been hanged. Having performed the last rites and erected a barrow to mark the spot, he led his army on, breathing vengeance against the foe. Arminius, however, favoured by the marshy ground, was able to hold his own, and it required another campaign before he was finally defeated. A masterly combined movement by land and water enabled Germanicus to concentrate his forces against the main body of the Germans encamped on the Weser, and to crush them in two obstinately contested battles. A monument erected on the field proclaimed that the army of Tiberius had conquered every tribe between the Rhine and the Elbe. Great as the success of the Roman arms had been, it was not such as to justify this boastful inscription. We read of renewed attacks from the barbarians, and plans of a fourth campaign for the next summer.

But no more victories were in store for Germanicus. His success had already stirred the jealousy and fears of Tiberius, and he was reluctantly compelled to obey the imperial summons and repair to Rome. The magnificence of a triumph and the idle honours of a consulship had little attraction for a general in mid-career of conquest, and a man of singularly simple habits and no political ambition. The enthusiasm with which he was welcomed, not only by the populace, which went in crowds to meet him as far as the twentieth milestone, but by the emperor's own prætorians, warned Tiberius that it might be equally dangerous to keep so popular a favourite at Rome, and the earliest pretext was seized to remove him from the capital. The recent death of Archelaus, king of Cappadocia, and a disputed succession in Parthia and Armenia, afforded a sufficient plea for Roman interference; and, a few months after his return, Germanicus was despatched to the East with extraordinary powers, and started on his mission without waiting to enter on his consulship. At the same time Tiberius took the further precaution of superseding Silanus, a connexion of Germanicus, in the government of Syria, and appointing in his stead one of the most violent and ambitious of the old nobility, Cneius Calpurnius Piso, in order to watch his nephew's movements, and if necessary to check his ambition. Germanicus proceeded by easy stages to his province, halting on his way in Dalmatia, where he conferred with Drusus, his brother by adoption, and visiting the battlefield of Actium, Athens, Ilium, and other places of historic interest. At Rhodes he met for the first time his coadjutor Piso, who had followed in his wake, and was seeking everywhere to thwart his policy and asperse his character. When at last he reached his destination, he found little difficulty in effecting the settlement of the disturbed provinces, notwithstanding the violent and persistent opposition of Piso. At Artaxata Zeno, the popular candidate for the throne, was crowned king of Armenia; to the provinces of Cappadocia and Commagena Roman governors were assigned; and Parthia was conciliated by the banishment of the dethroned king Vonones. After wintering in Syria Germanicus started next year for a tour in Egypt. The chief motive for his journey was love of travel and antiquarian study, and it seems never to have occurred to him, till he was warned by Tiberius, that he was thereby transgressing an unwritten law of the empire forbidding any Roman of rank to set foot in Egypt without express permission. On his return to Syria he found that all his arrangements had been upset by Piso. Violent recriminations followed, the result of which, it would seem, was a promise on the part of Piso to quit the province. But at this juncture Germanicus fell ill. Piso deferred his departure, and, when at length compelled to start, lingered in the neighbourhood of Syria, receiving with open exultation the bulletins which told of the prince's rapid decline. Germanicus on his side was fully convinced that he had fallen a victim to the arts of his unscrupulous enemy. He knew that he was dying, and believed that he was dying of poison. Even his gentle nature was stung to madness at the thought, and with his dying words he called on his friends and family to denounce his murderer and avenge his death. Whether these suspicions were true must remain an open question, yet the arguments in favour of a death from natural causes seem to preponderate. It is true that Piso desired his death, and, from what we know of their characters, neither he nor his wife Plancina were likely to stick at any means for procuring it. But a poisoner does not generally let his wishes be publicly known, nor show his exultation when they are attained. The evidence from the appearance of the corpse is still more uncertain. Suetonius indeed avouches that there were livid marks all over the body and foam at the mouth; but he adds as a further proof of poison that on the funeral pyre the heart remained unconsumed, which clearly shows that he was only retailing the vulgar gossip. Tacitus, though inclined to believe the worst of Piso, allows that the report of the symptoms varied with the prepossession of the observers.

The sad tidings of his death cast a gloom over the whole Roman empire. To the provincials he had endeared himself by his simple manners, his affability, his generosity, his justice. The legions mourned their comrade who had always stood their friend at need, their general who had never known a defeat. At Rome there was a universal outburst of sorrow and indignation. The natural grief at the loss of a favourite prince was aggravated by the suspicion of foul play, and by hatred of the emperor who was at least guilty of recklessly exposing him to danger, and who now sullenly refused to join the general mourning. Men recalled the forboding words which had been whispered at his departure, "Whom the plebs love, die young." Nor was he unworthy of this passionate devotion. He had wiped out a great national disgrace; he had quelled their most formidable foe; he had pacified distant provinces; and in his high estate he had so borne himself that all save one man had loved and honoured him. His private life had been stainless, and he possessed in a singular degree the gift of personal attractiveness. And yet an impartial biographer must add that for his fair fame his death was opportune. There were elements of weakness in his character which his short life only half revealed: an almost feminine impetuousness which made him twice threaten to take his own life; a superstitious vein which impelled him to consult oracles and shrink from bad omens; an amiable dilettantism which led him to travel in Egypt while his enemy was plotting his ruin; a want of nerve and resolution which prevented him from coming to an open rupture with Piso till it was too late. His very virtues, his elegant taste, his chivalrous sense of honour, his unsuspecting openness and candour, unfitted him for the stern times in which he lived. He was as little fitted to play the part of Augustus as that of Alexander, to whom Tacitus fondly compares him; and had he lived to succeed to the purple the historian might have been compelled to pronounce on him the epitaph of Galba, that all would have thought him fit to reign if he had not reigned. (F. S.)

GERMAN SILVER, or NICKEL SILVER, known also under the names of White Copper and Packfong, is an alloy of copper, nickel, and zinc, prepared either by melting the copper and nickel together in a crucible, and adding piece by piece the previously heated zinc, or by heating the finely divided metals under a layer of charcoal, by means of an air furnace of strong draught, and promoting the thorough solution of the nickel by stirring. To destroy its crystalline structure, and so render it fit for working, it is heated to dull redness, and then allowed to cool. German silver is harder than silver; it resembles that metal in colour, but is of a greyer tinge. Exposed to the air it tarnishes slightly yellow, and with vinegar affords a crust of verdigris. At a bright red heat it melts, and with access of the atmosphere loses its zinc by oxidation. At a heat above dull redness it becomes exceedingly brittle. German silver is much used in the arts. For the manufacture of imitation silver for knives and forks its composition is—nickel and zinc of each 2 parts, and copper 4 parts; for handles of spoons and forks the proportion of copper in this formula is increased by 1. For rolling, the most suitable alloy is copper 3 parts, zinc 1, nickel 1. Candlesticks, bells, spurs, and other cast articles are made of a German silver containing 2 or 3 per cent. of lead. The addition of 2 to $2\frac{1}{2}$ per cent. of iron, which must first be melted with part of the copper, makes an alloy which is whiter, but also more brittle and harder than ordinary German silver.

See COPPER, vol. vi. p. 351, and Watts, *Dict. of Chem.* ii. p. 51. On the electrical conductive capacity of German silver, see ELECTRICITY, vol. viii. p. 53.

GERMANY

PART I.—GEOGRAPHY AND STATISTICS.

GERMANY occupies the greater portion of central Europe, and has but few lines of natural boundary. If by the designation Germany is meant the territory inhabited by Germans, this is considerably larger than the German empire constituted in 1871, the former having an area of about 340,000, and the latter of 208,000 English square miles. The present German empire extends from 47° 16′ to 55° 53′ N. lat., and from 5° 52′ to 22° 52′ E. long. The eastern provinces project so far that the extent of the German territory is much greater from S.W. to N.E. than in any other direction. Tilsit is 815 miles from Metz, whereas Hadersleben, in Schleswig, is only 540 miles from the Lake of Constance. The difference in time between the eastern and western points is 1 hour and 8 minutes. The empire is bounded on the S.W. and S. by Austria and Switzerland (for 1170 miles), on the S.W. by France (275 miles), on the W. by Luxembourg, Belgium, and Holland (together 512 miles). The length of German coast on the North Sea or German Ocean is 300 miles, and on the Baltic 830 miles, the intervening land boundary on the north of Schleswig being only 53 miles. The eastern boundary is Russia (725 miles).

The total area of the empire, including rivers and lakes but not the "haffs" or lagoons on the Baltic, is 208,427 English square miles,[1] which is about the 18th part of Europe, the 250th part of the whole dry land, and the 853d part of the whole surface of the globe.

Physical Features.

Coast and Islands.—The length of the coast-line is scarcely the third part of the whole frontier, so that the Germans must be regarded as less a maritime than an inland people. Unlike the eastern states of Europe, the German empire has not only an inland sea-shore, but is also in direct communication with the great oceans by means of the North Sea. The coasts of Germany are shallow, and deficient in natural ports, except on the east of Schleswig-Holstein, where wide bays encroach upon the land, giving access to the largest vessels, so that a great harbour for men-of-war has been constructed at Kiel. With the exception of those on the east coast of Schleswig-Holstein, all the important trading ports of Germany are river ports, such as Emden, Bremen, Hamburg, Lübeck, Stettin, Dantzic, Königsberg, Memel. A great difference, however, is to be remarked between the coasts of the North Sea and those of the Baltic. On the former, where the sea has broken up the ranges of dunes formed in bygone times, and divided them into separate islands, the mainland has to be protected by massive dikes, while the Frisian Islands are being gradually washed away by the waters. On the coast of East Friesland there are now only seven of these islands, of which Norderney, a bathing-place, is best known, while of the North Frisian Islands, on the western coast of Schleswig, Sylt is the most considerable. Besides the ordinary waste of the shores, there have been extensive inundations by the sea within the historic period, the gulf of the Dollart having been so caused in the year 1276. Sands surround the whole coast of the North Sea to such an extent that the entrance to the ports is not practicable without the aid of pilots. Heligoland, which has belonged to England since 1814, is a rocky island, but it also has been considerably reduced by the sea. The tides rise to the height of 12 or 13 feet in the Jahde Bay and at Bremerhafen, and 6 or 7 feet at Hamburg. The coast of the Baltic on the other hand possesses few islands, the chief being Alsen and Fehmern off the coast of Schleswig-Holstein, and Rügen off Pomerania. It has no extensive sands, though on the whole very flat. The Baltic has no perceptible tides; and a great part of its coast-line is in winter covered with ice, which also so blocks up the harbours that navigation is interrupted for several months every year. Its three haffs fronting the mouths of the large rivers must be regarded as lagoons or extensions of the river beds, not as bays. The Oder Haff is separated from the sea by two islands, so that the river flows out by three mouths, the middle one (Swine) being the most considerable. The Frische Haff is formed by the Nogat, a branch of the Vistula, and by the Pregel, and communicates with the sea by means of the Pillau Tief. The Kurische Haff receives the Memel, called Niemen in Russia, and has its outlet in the extreme north at Memel. Long narrow alluvial strips called *Nehrungen*, lie between the last two haffs and the Baltic. The Baltic coast is further marked by large indentations, the Gulf of Lübeck, that of Pomerania, east of Rügen, and the semicircular Bay of Dantzic between the promontories of Rixhöft and Brüsterort. The German coasts are now well provided with lighthouses.

Surface and Geology.—In respect of physical structure Germany is divided into two entirely distinct portions, which bear to one another a ratio of about 3 to 4. The northern and larger part may be described as a uniform plain, covered generally by very recent deposits, but with small areas of Tertiary and Secondary formations protruding here and there. South and Central Germany, on the other hand, is very much diversified in scenery and in geological structure. It possesses large plateaus, such as that of Bavaria, which stretches away from the foot of the Alps, fertile low plains like that intersected by the Rhine, mountain chains, and isolated groups of mountains, comparatively low in height, and so situated as not seriously to interfere with communication either by road or by railway. Its geological structure corresponds to this diversity of surface. The most ancient rocks of Germany are the gneisses, schists, and granites which form the Bohemian and Bavarian plateau, and extend into Saxony. Another isolated mass of similar rocks rising into the heights of the Vosges and Black Forest has been cut through by the valley of the Rhine. Silurian rocks are but scantily developed in Germany. The Devonian system, however, occupies an extensive area, since it forms the high tableland of the Taunus, Hundsruck, and Eifel, which ranges westward into Belgium. Carboniferous rocks with productive coal-fields cover isolated areas, chiefly in north-western Germany, particularly in Westphalia, at Saarbrück, in Saxony, and in Upper and Lower Silesia (see COAL). Between the Devonian uplands of the Taunus and the crystalline rocks of Bavaria a vast area of western Germany is occupied by the Triassic system, which ranges from Hanover to Basel and from near Metz to Baireuth. The southern half of this vast Triassic basin is bordered by a belt of overlying Jurassic rocks which skirt the Danubian plain in Würtemburg and Bavaria. Cretaceous rocks occur chiefly in north Germany in scattered patches flanking older formations. They evidently underlie the great plain, since they are found rising up here and there to the surface between Westphalia and

[1] 1 English square mile = 2·5898945 square kilometres, or 0·0470352 German square mile; 1 German square mile = 21·26067 English square miles; 1 sq. kilometre = 0·3861161 English square mile.

Denmark. Older Tertiary formations are absent from Germany, save the portion of the Eocene Alps included within the territory of Bavaria. But Miocene deposits extend into numerous detached basins, including those of the Rhine below Bonn, and at Mainz, the country round Magdeburg, and the plains of Bavaria. These strata contain valuable seams of lignite. The vast plains of northern Germany are covered with glacial drift, which rises to heights of 1400 feet above the sea along the edges of the flanking hills. Igneous rocks of different ages have been erupted in many districts, and further diversify the geology. The best known are the Tertiary and post-Tertiary lavas and cones of the Eifel and Siebengebirge; others of more ancient date occur along the southern slopes of the Harz.

Mountains and Plateaus.—Bavaria is the only division of the country that includes within it any part of the Alps, the Austro-Bavarian frontier running along the ridge of the Northern Tyrolese or Bavarian Alps. The loftiest peak of this group, the Zugspitze (57 miles south of Munich), is 9702 feet in height, being the highest summit in the empire. The Upper German plain sloping northwards from the Bavarian Alps is watered by the Lech, the Isar, and the Inn, tributaries of the Danube, all three rising beyond the limits of German territory. This plain is separated on the west from the Swiss plain by the Lake of Constance (Bodensee, 1306 feet above sea-level), and on the east from the undulating grounds of Austria by the Inn. The average height of the plain may be estimated at about 1800 feet, the valley of the Danube on its north border being from 1540 feet (at Ulm) to 920 feet (at Passau). The plain is not very fertile In the upper part of the plain, towards the Alps, there are several lakes, the largest being the Ammersee, the Würmsee or Starnberg Lake, and the Chiemsee. Many portions of the plain are covered by moors and swamps of large extent, there called *Moose.* The left or northern bank of the Danube, from Regensburg (Ratisbon) downwards presents a series of granitic rocks called the Bavarian Forest (Bayerischer Wald), which must be regarded as a branch of the Bohemian Forest (Böhmischer Wald). The latter is a range of wooded heights on the frontier of Bavaria and Bohemia, occupying the least known and least frequented regions of Germany. The summits of the Bayerischer Wald rise to the height of about 4000 feet, and those of the Bohemian Forest to 4800 feet, Hoher Arber, about 49° N. lat., being 4842 feet. The valley of the Danube above Ratisbon is flanked by Jurassic plateaus sloping gently to the Danube, but precipitous towards the valley of the Neckar. The centre of this elevated tract is the Rauhe Alp, so named on account of the harshness of the climate. The plateau continuing to the north-east and then to the north, under the name of the Franconian Jura, is crossed by the valley of the winding Altmühl, and extends to the Main. To the west extensive undulating grounds or low plateaus occupy the area between the Main and the Neckar.

The south-western corner of the empire contains a series of better defined hill-ranges. Beginning with the Schwarzwald (Black Forest), we find its southern heights decline to the valley of the Rhine, above Basel, and to the Jura The summits are rounded and covered with wood, the highest being the Feldberg (10 miles S.E. of Freiburg, 4902 feet). Northwards the Black Forest passes into the plateau of the Neckarbergland (average height, 1000 feet). The heights between the lower Neckar and the Main form the Odenwald (about 1700 feet); and the Spessart, which is watered by the Main on three sides, is nothing but a continuation of the Odenwald. West of this range of hills lies the valley of the upper Rhine, extending about 180 miles from south to north, and with a width of only 20 to 25 miles. In the upper parts the Rhine is rapid, and therefore navigable with difficulty; this explains why the towns there are not along the banks of the river, but some 5 to 10 miles off. But from Speyer (Spires) town succeeds town as far down as Düsseldorf. The western boundary of this valley is formed in the first instance by the Vosges, where granite summits rise from under the surrounding red Triassic rocks (Sulzer Belchen, 4700 feet). To the south the range is not continuous with the Swiss Jura, the valley of the Rhine being connected here with the Rhone system by low ground known as the Gate of Mülhausen. The crest of the Vosges is pretty high and unbroken, the first convenient pass being near Zabern, which has been taken advantage of for the railway from Strasburg to Paris. On the northern side the Vosges are connected with the Haardt sandstone plateau (Kalmit, 2230 feet), which rises abruptly from the plain of the Rhine. The mountains south of Mainz (Mayence), which are mostly covered by vineyards, are lower, the Donnersberg, however, raising its head to 2262 feet. These hills are bordered on the west by the high plain of Lorraine and the coal-fields of Saarbrücken, the former being traversed by the river Moselle. The larger half of Lorraine belongs to France, but the German part possesses great mineral wealth in its rich layers of ironstone (siderite), and in the coal-fields of the Saar. The Devonian tract of the Hundsruck, Taunus, and Eifel is an extended plateau, divided into separate sections by the river valleys. Among these the Rhine valley from Bingen to Bonn, and that of the Moselle from Treves to Coblentz, are winding gorges excavated by the rivers. The Eifel presents a sterile, thinly-peopled plateau, covered by extensive moors in several places. It passes westwards imperceptibly into the Ardennes. The hills on the right bank of the Rhine also are in part of a like barren character, without wood; the Westerwald (about 2000 feet), which separates the valleys of the Sieg and Lahn, is particularly so The northern and southern limits of the Niederrheinisches Gebirge present a striking contrast to the central region. In the south the declivities of the Taunus (2890 feet) are marked by the occurrence of mineral springs, as at Ems on the Lahn, Nauheim, Homburg, Soden, Wiesbaden, &c., and by the vineyards which produce the best Rhine wines. To the north of this Gebirge, on the other hand, lies the great coal basin of Westphalia (the largest in Germany). In the south of the hilly duchy of Hesse rise the isolated mountain groups of the Vogelsberg (2530 feet) and the Rhön (3117 feet), separated by the valley of the Fulda, which uniting further north with the Werra forms the Weser. To the east of Hesse lies Thuringia, a province consisting of the far-stretching wooded ridge of the Thüringer Wald (with three peaks of upwards of 3000 feet high), and an extensive elevated plain to the north. Its rivers are the Saale and Unstrut. This plateau is bounded on the north by the Harz, an isolated group of mountains, rich in minerals, with its highest elevation in the bare summit of the Brocken (3743 feet). To the west of the Harz a series of hilly tracts is comprised under the name of the Weser Mountains, out of which above Minden the river Weser bursts by the Porta Westphalica. A narrow ridge, the Teutoburger Wald (1300 feet), extends between the Weser and the Ems as far as the neighbourhood of Osnabrück.

To the east the Thüringer Wald is connected by the plateau of the Frankenwald with the Fichtelgebirge. This group of mountains, occupying what may be regarded as ethnologically the centre of Germany, forms a hydrographical centre, whence the Nab flows southward to the Danube, the Main westward to the Rhine, the Eger eastward to the Elbe, and the Saale northward, also into the Elbe. In the north-east the Fichtelgebirge connects itself directly with the Erzgebirge, which forms the northern boundary of Bohemia.

The southern sides of this range are comparatively steep; on the north it slopes gently down to the plains of Leipsic, but is intersected by the deep valleys of the Elster and Mulde. Although by no means fertile, the Erzgebirge is very thickly peopled, as various branches of industry have taken root there in numerous small places. Around Zwickau there is a productive coal-field, and mining for metals is carried on near Freiberg. In the east a table-land of sandstone, called Saxon Switzerland, from the picturesque outlines into which it has been eroded, adjoins the Erzgebirge; one of its most notable features is the deep ravine by which the Elbe escapes from it. Numerous quarries, which supply the North German cities with stone for buildings and monuments, have been opened along the valley. The sandstone range of the Elbe unites in the east with the low Lusatian group, along the east of which runs the best road from northern Germany to Bohemia. Then comes a range of lesser hills clustering together to form the frontier between Silesia and Bohemia. The most western group is the Isergebirge, and the next the Riesengebirge, a narrow ridge of about 20 miles' length, with bare summits. Excluding the Alps, the Schneekoppe (5266 feet) is the highest peak in Germany; and the southern declivities of this range contain the sources of the Elbe. The hills north and north-east of it are termed the Silesian Mountains. Here one of the minor coal-fields gives employment to a population grouped round a number of comparatively small centres. One of the main roads into Bohemia (the pass of Landshut) runs along the eastern base of the Riesengebirge. Still farther to the east the mountains are grouped around the hollow of Glatz, whence the Neisse forces its way towards the north. This hollow is shut in on the east by the Sudetic group, in which the Altvater rises to almost 4900 feet. The eastern portion of the group, called the Gesenke, slopes gently away to the valley of the Oder, which affords an open route for the international traffic, like that through the Mülhausen Gate in Alsace. Geographers style this the Moravian Gate.

The North-German plain presents little variety, yet is not absolutely uniform. A row of low hills runs generally parallel to the mountain ranges already noticed, at a distance of 20 to 30 miles to the north. To these belongs the Upper Silesian coal-basin, which occupies a considerable area in south-eastern Silesia. North of the middle districts of the Elbe country the heights are called the Fläming hills. Westward lies as the last link of this series the Lüneburger Haide or Heath, between the Weser and Elbe, north of Hanover. A second tract, of moderate elevation, sweeps round the Baltic, without, however, approaching its shores. This plateau contains a considerable number of lakes, and is divided into three portions by the Vistula and the Oder. The most eastward is the so-called Prussian Seenplatte. Spirdingsee (430 feet above sea-level, and 46 square miles in area) and Mauersee are the largest lakes; they are situated in the centre of the plateau, and give rise to the Pregel. Some peaks near the Russian frontier attain to 1000 feet. The Pomeranian Seenplatte, between the Vistula and the Oder, extends from S.W. to N.E., its greatest elevation being in the neighbourhood of Dantzic (Thurmberg, 1096 feet). The Seenplatte of Mecklenburg, on the other hand, stretches from S.E. to N.W., and most of its lakes, of which the Müritzsee is the largest, send their waters towards the Elbe. The finely wooded heights which surround the bays of the east coast of Holstein and Schleswig may be regarded as a continuation of these Baltic elevations. The lowest parts, therefore, of the North-German plain, excluding the sea-coasts, are the central districts from about 52° to 53° N. lat., where the Vistula, Netze, Warthe, Oder, Spree, and Havel form vast swampy lowlands (in German called *Brüche*), which, during the last hundred years, have been considerably reduced by the construction of canals and by cultivation,—improvements due in large measure to Frederick the Great. The Spreewald, to the S.E. of Berlin, is one of the most remarkable districts of Germany. As the Spree divides itself there into innumerable branches, enclosing thickly wooded islands, boats form the only means of communication. West of Berlin the Havel widens into what are called the Havel lakes, to which the environs of Potsdam owe their charms. In general the soil of the North-German plain cannot be termed fertile, the cultivation nearly everywhere requiring severe and constant labour. Long stretches of ground are covered by moors, and there turf-cutting forms the principal occupation of the inhabitants. The greatest extent of moorland is found in the westernmost parts of the plain, in Oldenburg and East Frisia. The plain contains, however, a few districts of the utmost fertility, particularly the tracts on the central Elbe, and the marsh lands on the west coast of Holstein and the north coast of Hanover, Oldenburg, and East Frisia, which, within the last two centuries, the inhabitants have reclaimed from the sea by means of immense dikes.

Rivers.—Nine independent river-systems may be distinguished: those of the Memel, Pregel, Vistula (Weichsel), Oder, Elbe, Weser, Ems, Rhine, and Danube. Of these the Pregel, Weser, and Ems belong entirely, and the Oder mostly, to the German empire. The Danube has its sources on German soil; but only the fifth part of its course is German. Its total length is 1730 miles, and the Bavarian frontier at Passau, where the Inn joins it, is only 350 miles distant from its sources. It is navigable as far as Ulm, 220 miles above Passau; and its tributaries the Lech, Isar, Inn, and Altmühl are also navigable. The Rhine is the most important river of Germany, although neither its sources nor its mouths are within the limits of the empire. From the Lake of Constance to Basel (122 miles) the Rhine forms the boundary between the German empire and Switzerland; the canton of Schaffhausen, however, is situated on the northern bank of the river. From Basel to below Emmerich the Rhine belongs to the German empire—about 470 miles, or fourth-sevenths of its whole course. It is navigable all this distance, as are also the Neckar from Esslingen, the Main from Bamberg, the Lahn, the Lippe, the Ruhr, the Moselle from Metz, with its affluents the Saar and Sauer. Vessels sail up the Ems as far as Papenburg, and river craft as far as Greven, and the river is connected with a widely branching system of canals for turf-boats. The Fulda, navigable for 63 miles, and the Werra 38 miles, above the point where they unite, form by their junction the Weser, which has a course of 271 miles, and receives as navigable tributaries the Aller, the Leine from Hanover, and some smaller streams. Large steamers cannot, however, get as far as Bremen, and that commercial emporium has, in consequence, been obliged to form a seaport at Bremenhafen. The Elbe, after a course of 250 miles, enters German territory near Aussig, 482 miles from its mouth. It is navigable above this point to its junction with the Moldau. Hamburg may be reached by vessels of 10 to 11 feet draught. The navigable tributaries of the Elbe are the Saale (below Naumburg), the Havel, Spree, Elde, Sude, and some others. The Oder begins to be navigable almost on the frontier at Ratibor, 480 miles from its mouth, receiving as navigable tributaries the Glatz Neisse and the Warthe. Only the lower course of the Vistula belongs to the German empire, within which it is a broad, navigable stream of considerable volume. On the Pregel ships of 2500 tons reach Königsberg, and river barges reach Insterburg; the Alle, its tributary, may also be navigated. The Memel is navigable in its course of 113 miles from the Russian frontier. Germany is thus a country abounding in natural waterways, the total length of them being estimated at 7000 miles. But it is only the Rhine, in its middle course, that has at all times sufficient volume of water to meet the requirements of a good navigable river.

Lakes.—The regions which abound in lakes have already been pointed out. The Bodensee or Lake of Constance (186 square miles) is on the frontier of the empire,—portions of the northern banks belonging severally to Bavaria, Würtemberg, and Baden. The largest lake entirely on German territory is the Chiemsee (75 square miles); the Ammersee and the Würmsee are, however, but little less. A good many smaller lakes are to be found in the Bavarian Alps. The North-German plain is dotted with upwards of 500 lakes, covering an area of about 2500 square miles. The largest of these are the three Haffs,—the Oderhaff covering 370 square miles, the Frische Haff 332, and the Kurische Haff 626. The lakes in the Prussian and Pomeranian provinces, in Mecklenburg, and in Holstein, and those of the Havel, have already been mentioned. In the west the only lakes of importance are the Steinhuder Meer, 14 miles north-west of Hanover, and the Dümersee on the southern frontier of Oldenburg.

Climate.—The climate of Germany is to be regarded as intermediate between the oceanic and continental climates of western and eastern Europe respectively. It has nothing in common with the Mediterranean climate of southern Europe, Germany being separated from that region by the lofty barrier of the Alps. Although there are very considerable differences in the range of temperature and the amount of rainfall throughout Germany, these are not so great as they would be were it not that the elevated plateaus and mountain chains are in the south, while the north is occupied by low-lying plains. In the west no chain of hills intercepts the warmer and moister winds which blow from the Atlantic, and these accordingly influence at times even the eastern regions of Germany. The mean annual temperature of south-western Germany, or the Rhine and Danube basins, has in recent years been about 52° to 54°, that of central Germany 48° to 50°, and that of the northern plain 46° to 48°. In Pomerania and West Prussia it is only 44° to 45°, and in East Prussia 42° to 44°. The warmest districts of the German empire are the northern parts of the Rhine plain, from Carlsruhe downwards, especially the Rheinthal; these are scarcely 300 feet above the sea-level, and are protected by mountainous tracts of land. The same holds true of the valleys of the Neckar, Main, and Moselle. Hence the vine is everywhere cultivated in these districts. The mean summer temperature there is 66° and upwards, while the average temperature of January does not descend to the freezing point (32°). The climate of north-western Germany (west of the Elbe) shows a predominating oceanic character, the summers not being too hot (mean summer temperature 60° to 62°), and snow in winter remaining but a short time on the ground. West of the Weser the average temperature of January exceeds 32°; to the east it sinks to 30°, and therefore the Elbe is generally covered with ice for some months of the year, as are also its tributaries. The further one proceeds to the east the greater are the contrasts of summer and winter. While the average summer warmth of Germany is 60° to 62°, the January temperature falls as low as 26° to 28° in West Prussia, Posen, and Silesia, and 22° to 26° in East Prussia and Upper Silesia. The navigation of the rivers is regularly interrupted by frost. Similarly the upper basin of the Danube, or the Bavarian plain, has a rather inclement climate in winter, the average for January being 25° to 26°.

As regards rainfall, Germany belongs to those regions where atmospheric precipitation takes place at all seasons, but chiefly in the form of summer rains. In respect to the quantity of rain the empire takes a middle position between the humidity of north-western Europe and the aridity of the east. There are considerable differences between particular places. The rainfall is greatest in the Bavarian table-land and the hilly regions of western Germany. For the Eifel, Sauerland, Harz, Thüringer Wald, Rhön, Vogelsberg, Spessart, the Black Forest, the Vosges, &c., the annual average may be stated at 34 inches or more, while in the lower terraces of south-western Germany, as in the Erzgebirge and the Sudetic range, it is estimated at 30 to 32 inches only. The same average obtains also on the humid north-west coast of Germany as far as Bremen and Hamburg. In the remaining parts of western Germany, on the shores of Further Pomerania, and in East Prussia, it amounts to upwards of 24 inches. In western Germany there is a district famous for the scarcity of rain, and for producing the best kind of wine: in the valley of the Rhine below Strasburg, in the Palatinate, and also in the valley of the Main, no more than from 16 to 20 inches fall. Mecklenburg, Brandenburg, and Lusatia, Saxony and the plateau of Thuringia, West Prussia, Posen, and Lower Silesia are also to be classed among the more arid regions of Germany, the annual rainfall being 16 to 20 inches.

Vegetation, Animals, and Agriculture.

The flora of Germany comprises about 3000 species of phanerogamic and about 4000 cryptogamic plants. The country does not, however, form a single natural region, and cannot be characterized distinctively by any of the principal botanical types.

No uniform returns for the whole empire have been published, furnishing details regarding the distribution of the soil in respect of its cultivation, and thus statistics can only be collected from the official returns and estimates or valuations for separate districts. The following tabular statements must therefore be regarded as only approximately accurate:—

Cultivable and Uncultivable Area.

States or Groups.	Cultivable.		Uncultivable.	
	Square Miles.	Percent. of Total.	Square Miles.	Percent. of Total.
Prussia, including the minor states of North Germany	134,400	91·7	12,130	8·3
Thuringia	4,450	93·7	300	6·3
Saxony	5,570	96·0	230	4·0
Bavaria	27,500	93·8	1,800	6·2
Würtemberg	7,200	95·6	330	4·4
Baden	5,200	89·4	620	10·6
Alsace-Lorraine	5,200	90·9	520	9·1
Hesse	2,850	96·0	120	4·0
Total	192,370	92 3	16,050	7·7

Distribution of the Cultivable Area.

States.	Arable.		Meadows and Pasture Grounds.		Woodland.	
	Square Miles.	Percent. of Total.	Square Miles.	Percent. of Total.	Square Miles.	Percent. of Total
Prussia, &c.	74,150	50·7	26,870	18·3	33,380	22·7
Thuringia	2,500	52·6	440	9·3	1,510	31·8
Saxony	3,200	55·2	770	13·2	1,600	27·8
Bavaria	12,350	42·1	5,120	17·5	10,030	34·2
Wurtemberg	3,600	47·8	1,300	17 3	2,300	[illegible]
Baden	2,200	37·9	1,030	17·7	1,970	33·8
Alsace-Lorraine	2,770	48·5	660	11·6	1,770	30·8
Hesse	1,530	51·6	380	12 8	940	31·6
Total	102,300	49·0	36,570	17·6	53,500	25·7

From these tables it will be seen that the extent of uncultivable ground in Germany is inconsiderable; and that the arable land, including garden ground and vineyards, amounts to about one-half of the area.

Forests.—The woodlands form about one-fourth of the entire soil, the proportion of forest being far greater than in any other state in the west or south of Europe; the percentage for France is but 17, for Italy 12; for Great Britain about 3. The state forests alone occupy 17,600 square miles; and the greatest attention is paid throughout the empire to forest culture. Speaking generally, northern is not nearly so well wooded as central and southern Germany, where indeed most of the smaller mountains are covered with timber, as is indicated by the frequent use of the termination *wald* affixed to the names of the mountain ranges (as Schwarzwald, Thüringer Wald, &c.). The "Seenplatten" are less wooded than the hill country, but the eastern portion of the northern lowlands is well provided with timber. A narrow strip along the shores of the Baltic is covered with oaks and beeches; further inland coniferous trees are the most prevalent, particularly the Scotch fir; birches are also abundant. The mountain forests consist chiefly of firs, pines, and larches, but contain also silver firs, beeches, and oaks. Chestnuts appear on the terraces of the Rhine valley, and in Swabia and Franconia. The whole north-west of Germany is destitute of wood, but to compensate for this the people have ample supplies of fuel in the extensive stretches of turf.

Agriculture.—The same kinds of cereal crops are cultivated in all parts of the empire, but in the south and west wheat is predominant, and in the north and east rye, oats, and barley. To these in some districts are added spelt, buckwheat, millet, rice-wheat (*Triticum dicoccum*), lesser spelt (*Triticum monococcum*), and maize. In general the soil is remarkably well cultivated. The three years' rotation formerly in use, where autumn and spring-sown grain and fallow succeeded each other, has now been abandoned, except in some districts, where the system has been modified and improved. In South Germany the so-called *Fruchtwechsel* is practised, the fields being sown with grain crops every second year, and with pease or beans, grasses, potatoes, turnips, &c., in the intermediate years. In North Germany the mixed *Koppelwirthschaft* is extending, by which system, after several years of grain crops, the ground is for two or three seasons in pasture. No general statistics on the subject of crops have as yet been published, but, according to private estimates, a fair average season will yield 325 million quarters of rye,[1] oats 300, wheat and spelt 170, barley 100. In good seasons the production has been found sufficient to meet the native demand. Formerly the exports of the produce of the wheat and pulse crops exceeded the imports, but the importation of cereals has now for a number of years been constantly increasing. The potato is largely cultivated, not merely for food, but for distillation into spirits. This manufacture is prosecuted especially in eastern Germany. The Prussian provinces east of the Elbe, including Mecklenburg and Saxony, with a population of about 19 millions, produced 72 million gallons[2] of spirits in 1876, while the rest of Germany (population 24 millions) produced only 25 million gallons. The common

Years.	Manufactories.	Beet-root consumed.	Sugar produced
		Cwts.	Cwts
1846-47	107	5,600,000	331,000
1856-57	233	27,500,000	1,800,000
1866-67	296	50,700,000	3,900,000
1874-75	333	55,100,000	5,100,000
1875-76	332	83,200,000	7,100,000
1876-77	328	71,000,000	5,800,000

beet (*Beta vulgaris*) is largely grown in some districts for the production of sugar, which has greatly increased during the last thirty years. There are two centres of the beetroot sugar production: 231 factories, or more than two-thirds of the whole, are in Prussian Saxony, Hanover, Brunswick, Anhalt, and Thuringia, and there are 71 in Silesia, Brandenburg, and Pomerania, the principal centre of the latter group being Frankfort-on-the-Oder. Flax and hemp are cultivated, though not so much as formerly, for manufacture into linen and canvas, and also for the production of oil. The home supply no longer suffices for the native demand. The cultivation of hops is in a very thriving condition in the southern states of Germany. The soil occupied by hops was estimated in 1873 at 93,680 acres,[3]—a larger area than in any other country of the globe (Great Britain having about 70,000 acres). The total production of hops is 477,000 cwts., and of this 402,000 cwts. are grown in Bavaria, Würtemberg, Baden, and Alsace-Lorraine. Hops thus form one of the standard articles of exportation from Germany, as well as beer. The following table shows the number of breweries in different parts of the country, and the amount of their production:—

States.	Breweries.	Total.	Per Head.
		Gallons.	Gallons.
Northern Germany	12,186	448,000,000	14
Bavaria, not including Palatinate	6,703	269,000,000	59
Palatinate (estimated)	...	13,000,000	20
Würtemberg	7,777	85,300,000	46
Baden (estimated)	1,500	24,200,000	18
Alsace-Lorraine	241	17,600,000	11
Total, about	28,500	857,100,000	20

Tobacco forms the most productive and most profitable object of culture in many districts. The total extent under this crop in 1876 was 53,720 acres, no less than 32 per cent. of this being in Baden, 22 in Bavaria, 16 in Alsace-Lorraine, and only 30 per cent. in the rest of Germany. In the north the plant is cultivated principally in Pomerania, Brandenburg, and East and West Prussia. Of late years the production has on the whole diminished, the average amount having been 800,000 cwts. from 1872 to 1876.

The culture of the vine is almost confined to southern and western Germany, and especially to the Rhine district. The northern limits of its growth extend from Bonn in a north-easterly direction through Cassel to the southern foot of the Harz, crossing 52° N. lat. on the Elbe, running then east some miles to the north of that parallel, and finally turning sharply towards the south-west on the Warthe. In the valley of the Saale and Elbe (near Dresden), and in Lower Silesia (between Guben and Grünberg), the number of vineyards is small, and the wines of inferior quality; but along the Rhine from Basel to Coblentz, in Alsace, Baden, the Palatinate, and Hesse, and above all in the province of Nassau, the lower slopes of the hills are literally covered with vines. Here are produced the celebrated Rüdesheimer, Hochheimer, and Johannisberger. The vines of the lower Main, particularly those of Würzburg, are the best kinds; those of the upper Main and the valley of the Neckar are rather inferior. The Moselle wines are lighter and more acid than those of the Rhine. The total amount produced in Germany is estimated at 1000 million gallons,—Alsace-Lorraine turning out 400 millions, Baden 175, Bavaria, Würtemberg, and Hesse together 300, while the remainder, which though small in quantity is in quality the best, is produced by Prussia.

Live Stock.—The cultivation of grazing lands in Germany has been greatly improved in recent times, and is in a highly prosperous condition. The provinces of Pomerania

[1] 1 quarter = 2·90781 hectolitres; 1 hectolitre = 0·34388 quarter.
[2] 1 gallon = 0·22 litre.
[3] 1 acre = 0·40467 hectare; 1 hectare = 2·4711442 acres.

and Hanover are particularly remarkable in this respect. The best meadow lands of Bavaria are in the outer range of the Alps, those of Saxony in the Erzgebirge. The following table shows the results of a live-stock census in 1873:—

Horses	3,352,231
Cattle	15,776,702
Sheep	24,999,406
Pigs	7,124,088
Goats	2,320,002
Total	53,572,429

The breeding of domestic animals is prosecuted most extensively in Bavaria, and in the maritime provinces. There we find 1000 to 1500 head of the larger kinds (horses, cattle, sheep, goats, swine) for every 1000 inhabitants; in the rest of eastern Germany 600 to 800; and in central and southern Germany only 400 to 600. In the number of horses Germany ranks with Great Britain (about 80 for every 1000 inhabitants); and, although the production cannot satisfy the home demand, the imports being nearly 30,000 in excess of the exports annually, the breeding of horses has attained great perfection. The main centre is in East and West Prussia, where there are more than half a million of horses,—about 30 per English square mile; then follow the marsh districts on the Elbe and Weser, some parts of Westphalia, Saxony, and Upper Silesia, Lower Bavaria, Lower Alsace, and Lorraine. Cattle abound in most South-German states, especially Bavaria and Würtemberg, where there are 180 to 200 head for every square mile. In the northern and north-eastern districts, on the other hand, the numbers are small (in some districts only 30 to 50 head to the square mile), except Schleswig-Holstein and the marsh lands along the shores of the North Sea, whence there is a considerable exportation to England. The aggregate number of sheep in Germany is only exceeded in Europe by that in Great Britain and Russia. The principal sheep districts are Pomerania and Mecklenburg (300 per square mile). As a rule, sheep-farming is resorted to where the soil is of inferior quality and unsuitable for tillage and the breeding of cattle. Far more attention is accordingly given to the rearing of sheep in northern and north-eastern Germany than in Schleswig-Holstein, East Frisia, Westphalia, Rhineland, and South Germany. The exportation of sheep is considerable, amounting in 1871 to 1,460,000 head; in 1875, however, the number was only 1,000,000. At the same time the native demand for wool is not covered by the home production. The largest stock of swine is in central Germany and Saxony, in Westphalia, on the lower Rhine, in Lorraine, Hesse, &c. Central Germany (especially Gotha and Brunswick) exports sausages and hams largely, as well as Westphalia; but the excess of swine imported over the exports for the whole of Germany ranges from 600,000 to 800,000 annually.

Agricultural Population.—In the census returns of 1871 the number of persons entered as agriculturists (including persons engaged in rearing stock, in forestry, and the fisheries) was about 12,210,000, comprising 1,844,202 proprietors (1,690,931 males and 153,271 females), 2,101,005 agricultural labourers, &c., with 6,764,747 members of their families (2,338,174 males and 4,426,573 females), and about 1,500,000 (660,000 males and 840,000 females) engaged in household duties. Agriculture thus supports three-tenths of the population.

Wild Animals.—The number of wild animals in Germany is not very great. Foxes, martens, weasels, badgers, and otters are to be found everywhere; wolves are rare, but they find their way sometimes from French territory to the western provinces, or from Poland to Prussia and Posen. Among the rodents the hamster and the field-mouse are a scourge to agriculture. Of game there are the roe, stag, boar, and hare; the fallow deer and the wild rabbit are less common. The elk is to be found in the forests of East Prussia. The feathered tribes are everywhere abundant in the fields, woods, and marshes. Wild geese and ducks; grouse, partridges, snipes, woodcocks, quails, widgeons, and teal are plentiful all over the country. Geese and ducks are found mostly in the flat districts, where the great abundance of standing water affords ample scope for their increase. Tame geese are bred in large flocks, particularly in Pomerania. The length of time that birds of passage remain in Germany differs considerably with the different species. The stork is seen for about 170 days, the house-swallow 160, the snow-goose 260, the snipe 220. In northern Germany these birds arrive from twenty to thirty days later than in the south.

The waters of Germany abound with fish; but the genera and species are few. Carp and salmon tribes are the most abundant; after them rank the pike, the eel, the shad, the roach, the perch, and the lamprey. In addition to frogs, Germany has few varieties of Amphibia. Of serpents there are only two kinds, one of them being poisonous.

The rearing of bees is particularly attended to in the heathy districts of Hanover. The number of bee-hives may be estimated at 2 millions, and the produce of wax and honey at 100,000 cwts. The cultivation of silk-worms has been attempted, but has either entirely failed or had very indifferent success. In 1852–62 an attempt was made to extend the cultivation of the mulberry in the province of Brandenburg; but disease among the silk-worms, which it was found impossible to repress, rendered it unsuccessful.

Mines and Minerals.

Germany abounds in useful minerals, and in consequence takes a high place among industrial states. The production falls short, indeed, of that of England, but bears comparison with that of France and of the United States. The last annual report of the imperial statistical office (for the year 1876) classified the mineral produce of Germany under the following heads:—

Mineral Production in 1876.

Minerals.	Quantities.	Value.	Miners.
	Metric Tons.[1]	£	
Coal, including lignite	49,588,050	15,131,000	208,429
Iron ore	3,515,020	1,047,850	24,373
Zinc ore	503,360	650,340	11,680
Lead ore	12,060	1,019,300	16,929
Copper ore	30,450	356,250	7,077
Silver and gold ore	2,311	219,150	7,475
Tin ore	185	6,380	306
Cobalt ore	313	10,000	...
Nickel ore	1,222	5,780	100
Antimony ore	43	580	66
Arsenic ore	1,670	2,510	20
Manganese ore	11,651	28,240	79
Bismuth ore	28	13,650	824
Uranium ore	9	2,210	...
Tungsten ore	3	20	...
Iron pyrites	113,703	107,290	...
Alum ores	35,320	4,400	829
Salt	170,150	60,700	195
Potash, &c.	580,900	234,500	2,053
Total, about	55,000,000	18,900,000	280,401

The general value of the production has increased considerably during the ten years ending 1876, as will be seen by the following table:—

[1] 1 centner or 50 kilogrammes = 110·23 pounds = 0·9851 cwt. In round numbers the centner is taken as equivalent to the cwt., and the metric ton to the English ton; the exact value of the latter, however, is 19·702 cwts., or 0·9851 tons. £1 sterling = 20·4291 marks. In round numbers £1 is taken as 20 marks: the values given are therefore too large by 2·15 per cent.

		£		£
1867	Not including Lorraine.	19,720,700	1872	20,783,000
1868		11,248,000	1873	26,782,000
1869		12,021,000	1874	25,283,000
1870		12,412,000	1875	20,844,000
1871		15,708,000	1876	18,900,000

The metals extracted from ores in 1876 were thus classified:—

Metal Production in 1876.

Metals.		Quantities.	Value

Coal.—Coal-mining appears to have been first practised in the 14th century, at Zwickau (Saxony), and on the Ruhr. The production, which certainly did not exceed 500,000 tons in 1800, has vastly increased during the last thirty years, as may be seen from the following table (which does not include lignite):—

Coal Production, 1848 1877.

		Quantities.	Value
		Metric Tons.	£
1848	Lorraine not included.	4,381,000	1,284,000
1853		8,329,000	2,566,000
1857		11,279,000	4,137,000
1862		15,576,000	4,155,000
1867		23,808,000	6,371,000
1871		29,398,000	10,917,000
1872		33,306,000	14,833,000
1873		36,392,000	20,183,000
1874		35,919,000	19,359,000
1875		37,436,000	14,874,000
1876		38,454,000	13,184,000
1877		37,576,000	10,854,000

There are six large coal fields, occupying an area of about 3600 square miles, of which the most important occupies the basin of the Ruhr, its extent being estimated at 2800 square miles. Here there are more than 60 beds, of a total thickness of 150 to 200 feet of coal; and the amount in the pits has been estimated at 45,000 millions of tons, so that the basin, at the present rate of 17,500,000 tons raised per annum, would not be exhausted in 2000 years. Smaller fields are found near Osnabrück, Ibbenbüren, and Minden, and a larger one near Aix-la-Chapelle. The Saar coal-field, within the area enclosed by the rivers Saar, Nahe, and Blies (460 square miles), is one of great importance. The thickness of 80 beds amounts to 250 feet, and Von Dechen estimates the total mass of coal at 45,400 million tons. The greater part of the basin belongs to Prussia, the rest to Lorraine. A still larger field exists in the Upper Silesian basin, on the border-land between Austria and Poland, containing about 50,000 million tons. Beuthen is the chief centre. The Silesian coal-fields have a second centre in Waldenburg, east of the Riesengebirge. The Saxon coal-fields stretch eastwards for some miles from Zwickau. Deposits of less consequence are found in Upper Bavaria, Upper Franconia, Baden, in the Harz, &c.

Number and Production of Collieries in 1876.

Coal-Fields. (Not including Lignite).	Number of Collieries	Coal produced in 1876.
		Tons.
Ruhr (gov. districts, Arnsberg and Dusseldorf) ...	207	17,430,000
Upper Silesia......................	107	8,468,000
Saar	33	5,080,000
Zwickau	71	3,038,000
Lower Silesia	44	2,150,000
Aix-la-Chapelle	17	994,000
Osnabrück, Ibbenbüren, &c.	22	822,000
Minor fields	47	472,000
Total......... ..	548	38,454,000

The above tables do not include lignite, of which numerous beds are scattered over Germany. Extensive strata follow the course of the Oder, and a second group is spread over Lusatia, but the largest and most important deposit is in the Saale districts from Altenburg to the Harz. Smaller fields are situated round Cassel, northward of Frankfort, near Cologne and Aix-la-Chapelle, in the west of Hanover, and in the Upper Palatinate. The total production is stated in the official returns at 11,100,000 tons, representing a value of £1,922,000. Of this 8,780,000 tons are supplied by the fields in the Saale districts (province of Saxony, Anhalt, Brunswick, Saxe-Altenburg, and kingdom of Saxony). In North Germany turf also is of importance as a fuel; the area of the turf moors in Prussia is estimated at 8000 square miles, of which more than 2000 are in the north of Hanover. The coal produced supplies the home demand, although a considerable trade is carried on across the frontier. Through the ports of the North Sea and the Baltic more than 2 million tons of coals are imported annually from England, and nearly $2\frac{1}{2}$ million tons of lignite come from Bohemia. On the other hand, the Ruhr and the Saar basins export nearly 3 million tons of coal to the Netherlands, France, and Switzerland, and the Upper Silesian basin $1\frac{2}{3}$ millions to Austria and Russia. The following table gives a comparative view of the quantity supplied by the more important coal-producing countries in 1876:—

	Tons.		Tons.
Great Britain	135,612,000	France................	16,889,000
United States... ...	50,000,000	Belgium	14,329,000
Germany...	48,296,000	Austria-Hungary ..	13,362,000

Graphite is produced only in Lower Bavaria; the total amount in 1876 was 20,104 cwts., value £2090. *Asphalt* occurs near Hanover, in Brunswick, and in Alsace; total production in 1876, 720,000 cwts., value £15,300. *Petroleum* is found in limited quantity near Lüneburg, and in Alsace.

Iron Ore.—Germany abounds in iron ores, some of which are of superior quality. The production increased rapidly for a time, but in recent years there has been a very great decline.

About 35 per cent. is brown iron ore, 25 per cent. spathic iron, 18 per cent. black band, and 10 per cent. red iron ore. The rest consists of clay-ironstone, bog-iron ore (in the northern lowlands), and magnetic ores. Unfortunately but few mines are found in proximity to coal-pits, and important ore-deposits of great extent are far from coal, as, for instance, the iron districts of Nassau, of the Sieg valley, and of Hesse, Thuringia, Lorraine, Bavaria, and Würtemberg.

Iron Ore Production, 1848–1876.

	Quantities.	Value.
	Tons.	£
1848 } Lorraine	694,000	191,000
1853 } not	903,000	250,000
1857 } included.	1,962,000	583,000
1867	3,264,000	918,000
1872	5,896,000	2,118,000
1873	6,177,000	2,117,000
1874	5,137,000	1,430,000
1875	4,730,000	1,387,000
1876	4,712,000	1,181,000

Ores free of phosphorus, suitable for the manufacture of Bessemer pig-iron. are also very scarce.

The following table shows the number and production of furnaces in blast in 1876 :—

Government Districts.	Furnaces in Blast.	Pig-Iron made.
		Tons.
Arnsberg	37	337,640
Dusseldorf	21	278,110
Oppeln	32	223,750
Coblentz	27	212,470
Lorraine	18	193,450
Treves	10	103,080
Hildesheim	4	55,750
Osnabrück	4	45,200
Upper Palatinate	10	31,060
Wiesbaden	14	26,550
Cologne	3	25,130
Hesse (grand-duchy)	5	18,150
Würtemberg	5	10,810
Saxe-Meiningen	1	13,840
Other districts	34	37,690
Total	225	1,614 680

The iron manufacture has not been in a thriving condition since 1873; the total number of furnaces in Germany in 1876 was 435,—225 in blast as above, and 210 blown out. The following table shows the progress of pig-iron production, including castings :—

	Quantities.	Value
	Tons.	£
1848 }	200,000	1,230,000
1862 } about	640,000	2,630,000
1867 }	990,000	3,600,000
1871	1,421,000	5,946,000
1873	1,983,000	11,238,900
1874	1,660,000	7,243,000
1875	1,759,000	6,632,900
1876	1,615,000	5,232,000

Since the incorporation of Lorraine with the German empire the pig-iron production of Germany exceeds that of France. The following table shows the comparative increase in those countries, as well as in Great Britain and the United States :—

	Quantities of Pig-Iron.			
		Tons.		Tons
Great Britain	1866	4,596,000	1876	6,660,000
United States	,,	1,225,000	1877	2,351,000
Germany	,,	1,000,000	1876	1,615,000
France	,,	1,260,000	1877	1,453,000

Iron Industry.—While the produce of pig-iron has thus been advancing, similar progress appears in the iron industry, in some branches of which Germany has already emancipated herself from dependence on England. During the last few years, it is true, this trade has suffered severely from the overproduction of 1872 and 1873, as may be seen from the following table, showing the quantities and values of worked pig-iron in 1872 and 1876 :—

Articles.	1872.		1876.	
	Quantities.	Value.	Quantities.	Value.
	Cwts.	£	Cwts.	£
Wrought iron & rolled iron	19,194,000	12,255,000	15,515,000	5,013,000
Iron plate	2,348,000	2,007,000	2,190,000	1,095,000
Iron wire	2,053,000	1,695,000	2,650,000	1,392,000
Raw steel	2,703,000	2,333,000	2,680,000	1,104,000
Cast steel	3,542,000	2,840,000	4,877,000	2,488,000

The greatest advance has been made in the production of steel. In 1863 the quantity was only 1,400,000 cwts., but in 1872 it was about 6,500,000. The greater part of this is produced at the celebrated works of Krupp in Essen and the cast-steel works in Bochum. Many European states have for a considerable time been supplied by Krupp with cast-steel guns. The production of rails not only covers the home demand, but has allowed an annual exportation of 3,000,000 cwts. since 1877. Hardware also, the production of which is centred in Solingen, Heilbronn, Esslingen, &c., is largely exported. Germany stands second to Great Britain in the manufacture of machines and engines. There are in many large cities of North Germany extensive establishments for this purpose, but the industry is not limited to the large cities. It must be admitted that in agricultural machinery Germany cannot as yet compete with England. The locomotives and waggons for the German railways, however, are almost exclusively built in Germany; and Russia, as well as Austria, receives large supplies of railway plant from German works. In shipbuilding likewise Germany is becoming independent of England; and dockyards have been erected on the coast for the construction of large ironclads.

Silver and Gold.—Germany produces more silver than any other European state, and the quantity is annually increasing. Silver and gold are extracted from the ores in the mines of Freiberg (Saxony) and near the Harz; but silver is also refined from lead and copper ores in Upper Silesia, Merseburg, Aix-la-Chapelle, Wiesbaden, and Arnsberg. The gold-mining is of far less importance. The value of silver produced was, in 1867, £791,370; 1873, £1,539,590; 1876, £1,098,470; and that of gold, 1867, £11,750; 1876, £39,234.

Lead.—The quantity of the lead produced allows Germany to export from 300,000 to 400,000 cwts. annually. Nearly half the produce is obtained near Aix-la-Chapelle (651,273 cwts. in 1876); next come Upper Silesia (265,000 cwts.), Harz (176,550 cwts.), Nassau (143,770 cwts.), Saxony, Arnsberg, &c. The value in 1867 was only £898,140; but in 1876, £1,565,280; the quantity was 87,090 cwts. in 1867, and 1,512,000 cwts. in 1876.

Copper.—Although Germany yields more copper than any other European state, the native supply does not meet the demand. In recent years more than 200,000 cwts. have been imported. The Harz mountains and their environs (Mansfeld) alone produce five-sixths of the whole amount, which has been doubled during the ten years ending 1876:—1867, 77,440 cwts., value £312,750; 1876, 168,430 cwts., value £641,750.

Zinc.—About 90 per cent. of the zinc produced in Europe is yielded by Belgium and Germany. The exportation from the latter amounts to more than half a million of cwts. per annum. The production doubled during the period from 1850 (620,000 cwts.) to 1860, but has made only slow progress since that time. In 1867 it was only 1,277,000 cwts., value about £600,000; in 1876, 1,664,500, value £1,740,000. 70 per cent. is produced in Upper Silesia in the neighbourhood of Beuthen, the rest in Westphalia and the Rhineland.

Salt.—Germany possesses abundant salt deposits. The actual production not only covers the home consumption, but also allows a yearly increasing exportation, especially to Russia, Austria, and Scandinavia. In 1877–78 there were 77 salt works in operation, 8 of which were mining works for rock-salt. The provinces of Saxony and Hanover, with Thuringia and Anhalt, have 28 works, and produce half the whole amount. A large work is found at Strzalkowo (Posen), and smaller ones near Dortmund, Lippstadt, and Minden (Westphalia). In South Germany salt abounds most in Würtemberg (Hall, Heilbronn, Rottweil); the principal Bavarian works are at the foot of the Alps near Freilassing and Rosenheim. Hesse and Baden have 6 salt works; Lorraine and the Upper Palatinate, 6. The total yield now amounts to 8,318,000 cwts. boiled salt, 3,221,000 cwts. rock salt, and 256,000 cwts. of other kinds. The production has made great advance during the last thirty years, having in 1850 been only 5 million cwts., while in 1877 it was upwards of 11 million cwts.

Chloride of Potash.—A considerable amount of this substance is turned out by 15 works in Anhalt, where only the potash ores are found. The production there in 1876 was 816,000 cwts., value about £250,000.

POPULATION.

Till very recent times no estimate of the population of Germany was precise enough to be of any value. At the beginning of the present century the country was divided into some hundred states, but there was no central agency for instituting an exact census on a uniform plan. Even the formation of the German Confederation in 1815 effected but little change in this respect, and it was left to the different states to arrange in what manner the census should be taken. On the formation, however, of the German Customs Union or Zollverein between certain German states, the necessity for accurate statistics became apparent, since the amounts accruing from the common import duties were to be distributed according to the number of inhabitants in the several states. The Zollverein had its origin in a customs convention between Prussia and the grand-duchy of Hesse in 1828; and other states, as they gradually became convinced of the advantages afforded by a general customs frontier, joined it from time to time during the succeeding forty years. The following table shows the progressive territorial limits of the Zollverein—which may be regarded as the precursor of the present German empire:—

Population of the Zollverein.

Years.	States entering during the various Periods.	Area, Sq Miles.	Population of the Union States.
1828	Prussia, Hesse (grand-duchy)	112,000	13,295,254
1831	Hesse-Cassel	115,300	15,090,075 ('34)
1834	Bavaria, Wurtemberg, Saxony, Thuringia, &c.	163,900	23,478,120
1844	Brunswick, Luxembourg, &c.	171,900	28,498,136 ('43)
1851	Hanover, Oldenburg	191,800	32,559,055 ('52)
1868	Schleswig-Holstein, Lauenburg, Mecklenburg	205,500	38,277,939 ('67)
1871	Alsace-Lorraine	209.281	40,677,950

The returns made at different times by the separate states cannot be combined into an aggregate, showing precisely the former population of Germany. An enumeration was made every third year of the number of people that could be held as belonging to the different states comprised in the Zollverein; and it was only from 1867 that the returns gave the actual resident population. The following table gives the area and population of the twenty-six states of Germany as returned at the two last censuses (1871 and 1875):—

Population of the German Empire, 1871 and 1875.

States of the Empire.	Area. English Sq. Miles.	Population. Dec. 3, 1871.	Population. Dec. 1. 1875.
Kingdoms.			
1. Prussia	134,178	24,691,433	25,742,404

Principalities.			
16. Schwarzburg-Rudolstadt	364	75,523	76,676
17. Schwarzburg-Sondershausen	333	67,191	67,480
18. Waldeck	433	56,224	54,743
19. Reuss-Greiz	122	45,094	46,985
20. Reuss-Gera	320	89,032	92,375
21. Schaumburg-Lippe	171	32,059	33,133
22. Lippe	438	111,135	112,452
Free Towns.			
23. Lubeck	109	52,158	56,912
24. Bremen	97	122,402	142,200
25. Hamburg	158	338,974	388,618
Imperial Territory.			
26. Alsace-Lorraine	5,603	1,549,738	1,531,804
Total	208,425	41,058,792	42,727,360

The following table shows the rate of recent increase, the population of Alsace-Lorraine returned at the French census of 1866 being included in the statement for 1867:—

Years.	Population.	Total Increase.	Percentage for the period	Percentage per annum.
Dec. 3, 1867	40,108,029			
Dec. 3, 1871	41,058,792	950,763	2·4	0·6
Dec. 1, 1875	42,727,360	1,688,568	4·1	1·0

Comparing the census returns of 1871 and 1875, it is found that only Alsace-Lorraine (17,934), the two Mecklenburgs (together 5231), and Waldeck (1481) are decreasing; all other states are increasing, though at very different rates. A comparison cannot here be made, however, between the smaller and the larger states. Hamburg and Bremen, for example, have considerably increased, but these must be regarded as consisting of single large towns, and a similar increase is found in all the great cities of Germany. In southern Germany (Alsace-Lorraine not included), and also in Hanover, the growth of population has been insignificant, whereas the population in the eight old provinces of Prussia and in Saxony shows a marked increase.

It appears from the following table that the inhabitants of Prussia and Saxony have increased 60 to 70 per cent. in 40 to 44 years, and those of the other states only 18 to 23 per cent. And it is to be observed that this increase is not confined to the industrial districts, but that those provinces also which have few large cities and the population of which live for the most part by agriculture, such as

Pomerania, Prussia, Posen, have increased by 50 to 60 per cent. This is to be explained by the fact that there has been a very extensive immigration into Prussia since 1815, whereas emigration has been mostly from South Germany. But the surplus of births over deaths also has at all times been greater in the North.

Increase of Population in States.

Vital Statistics.—It is very recently that general registers of births, deaths, and marriages began to be kept for all the German states, but these prove the increase of the excess of births over deaths in recent years to have been considerable. The following table of returns for the whole of Germany during the period 1872–76 brings out a natural addition by births of upwards of half a million yearly :—

	Marriages	Births (incl. Still born).	Deaths (incl. Still born).	Still-born.	Surplus of Births.
1872	423,900	1,692,227	1,260,922	66,190	431,305
1873	416,049	1,715,287	1,241,459	67,166	474,012
1874	400,282	1,752,976	1,191,132	69,536	560,579
1875	386,746	1,798,591	1,246,572	74,179	552,019
1876	366,912	1,831,218	1,207,144	73,517	624,074
Mean...	398,778	1,758,059	1 229,606	70,117	528,378

The numbers of births, deaths, and marriages for every 1000 of the population of Germany during the period 1872–5 were as follows :—

	To 1000 Persons living.			To 1000 Marriageable Persons. *
	Births.	Deaths	Marriages	Marriages.
1872	41·1	30 5	10 3	39·9
1873	41·3	29·9	10·0	37 8
1874	41·8	28·4	9·5	36·0
1875	42·3	29·3	9·1	34·3
Mean...	41·6	29·5	9·7	36·7

In comparing this with similar tables for England, a great difference is obvious. While the average annual rate of births (41·6) has been much higher than in England (34·0) during recent years, the annual death-rate does not compare favourably with that of England (22·3) or of other states. Only Russia, Finland, Austria-Hungary, Italy, and Servia exhibit greater higher rates.

Sexes.—The numbers of the different sexes in 1871 and 1875 were as follows :—

	Males.	Females.	Excess of Females.	Females for 1000 Males
1871	20,154,109	20,906,737	752,638	1037
1875	20,986,701	21 740,659	753,958	1036

As in most European states, the surplus of females arises from their lower death-rate, for in Germany as elsewhere more boys are born than girls. The following table shows the numbers of births, including still-born :—

	Boys.	Girls.	Excess of Boys.	Boys for 1000 Girls.
1872	871,438	820,786	50,652	1062
1873	883,017	832,265	50,752	1061
1874	903,148	849,821	53,327	1063
1875	928,397	870,194	58,203	1067
1876	943,433	887,781	55,652	1063
Average	905,857	852,170	53,717	1063

Illegitimacy.—The number of illegitimate births is greater than in any other European state, except Sweden, Denmark, Austria, and Portugal. The rate of illegitimacy is about 9 per cent. of the births, the annual average for 1872–75 being 8·86. In Rhineland the proportion was 2·8 per cent., North-Western Germany, Oppeln, and Posen 5 to 6, South Western Germany 7 to 9, province of Saxony, Brandenburg (exclusive of Berlin), Pomerania, Schleswig-Holstein 9 to 10, Saxony, Thuringia, and Lower Silesia 12, Berlin 13·5, and Bavaria 14·6 per cent On the whole, illegitimacy has decreased of late, particularly in Bavaria.

Emigration.—The increase of population would have been still greater if emigration had not for years drained the country of considerable numbers of its inhabitants. The number of emigrants from Germany since 1820 may be estimated at 3,500,000, but this includes many Austrians, and it cannot be stated how many of the emigrants were natives of the German empire, as no authentic statistics of emigration were issued before 1873. The greater part of the emigrants take their passage *via* Bremen and Hamburg. The following statement, therefore, of the numbers of emigrants from these ports may afford a sufficient indication of the total emigration :—

	Emigrants		Emigrants.
Average 1836-44	14,653	1870	79,337
1845-49	36,706	1871	102,740
1850-54	77,165	1872	154,831
1855-59	54,433	1873	132,417
1860-64	41,665	1874	74,076
1865-69	107,672	1875	56,313
1870-74	108,675	1876	50,396
1875-77	49,786	1877	41,749

The following table, on the other hand, gives the number of emigrants from the German empire according to the official returns. The numbers are considerably lower than those of the last table. It will be seen that emigration has decreased greatly during recent years.

1873.............................	103.638	German Emigrants.
1874...................	45,112	,,
1875	30,773	,,
1876...	28,368	,,
1877.......	21,964	,,
Total...	229,855	,,

The greater part of the recent emigration has been from the maritime provinces. Out of 230,000 emigrants in the years 1873–77, 132,350 were from Prussia, Pomerania, Mecklenburg, Schleswig-Holstein, Hanover, Oldenburg, Bremen, and Hamburg. These states, with a total population (1875) of 9,245,000, accordingly lost $1\frac{1}{3}$ per cent., the rest of the country (33,482,000 inhabitants) only 97,500, or 0·3 per cent. It must be added, however, that the emigration from South Germany was formerly much more considerable. Alsace-Lorraine lost only 1193 inhabitants in 1873–77 by emigration to America. The great mass of

German emigrants go to the United States,—90·5 per cent. of the whole (207,974) having embarked for that country in 1873–76. According to the official returns of the board of statistics at Washington, more than 2,900,000 immigrants arrived from Germany at American ports during 1820–1877. The rest of the emigrants find their way to Australasia, Brazil, the Cape, &c.

Immigrants and Foreigners.—In comparison with the emigrants, the number of immigrants is inconsiderable. The bulk come from Belgium, Holland, and Russia. The following table shows the number of natives of the empire who after being abroad have re-established themselves at home, and also the number of naturalized foreigners:—

	Re-established.	Naturalized.
1872	897	2296
1873	1284	2381
1874	1514	6532
1875	3735	9604
1876	2007	3643
1877	651	5810
Total...	10,088	30,266

The number of foreign residents has considerably increased during 1871–75. In 1871 there were in the empire 40,852,037 natives and 206,755 foreigners; in 1875, 42,436,561 natives and 290,799 foreigners. The following table gives the native countries of the foreigners for 1871,—the latest date for which these statistics have been published:—

Austria-Hungary	75,702	Belgium	5,097
Switzerland	24,518	Luxembourg	4,828
Holland	22,042	France	4,671
Denmark	15,163	Italy	4,019
Russia	14,535	Turkey	504
Sweden and Norway	12,345	Spain	310
United States	10,698	Greece	192
Great Britain	10,104	Other countries	2,026

Density of Population.—The population is very unequally distributed, and the differences are far greater now than they were formerly. The mean density of the population had increased from about 120 inhabitants per square mile in 1820 to 150 in 1840, and to 205 in 1875. We have already pointed out the great increase of population during the present century in many agricultural provinces of Prussia. In South Germany, however, the density of population was considerable even at the beginning of the century. But Germany during this period has become an important industrial state, and, as in England, distinct industrial districts have been formed, where the inhabitants cluster in populous centres. Besides, the population of the cities has gone on increasing at the expense of the agricultural districts, so that the natural increase of the inhabitants

Classes of Towns.		Number of Towns.	Population.	Percent. of Total.
Large towns of more than 100,000 inhabitants...	1871	8	1,968,537	4·8
	1875	12	2,665,914	6·2
Middle-sized towns, from 20,000 to 100,000.....	1871	75	3,147,272	7·7
	1875	88	3,487,857	8·2
Small towns, from 5000 to 20,000	1871	529	4,588,364	11·1
	1875	592	5,132,971	12·0
Rural towns, from 2000 to 5000	1871	1716	5,086,625	12·4
	1875	1636	4,922,781	11·5
Town population	1871	2328	14,790,798	36·1
	1875	2328	16,209,523	37·9
Rural population	1871	...	26,219,352	63·9
	1875	...	25,517,837	62·1

in these districts by the surplus of births is neutralized by the steady migration of the people into the cities. In the accompanying official statistics all the inhabitants of communes with more than 2000 souls are designated "town population," and the term "rural population" is applied to those of the smaller places. But it must be remarked that in several provinces, such as Westphalia, Rhineland, and Oldenburg, there are many communes consisting of numerous small villages and hamlets which have not the character of a town, and the inhabitants of which are almost exclusively agriculturists. These rank as town population, which accordingly appears in the returns to be a little larger than it really is. The figures exhibit the extremely unequal increase of the different groups from 1871 to 1875.

Increase per cent. of Population, 1871–75.

Large towns	14·83
Middle-sized towns	12·41
Small towns	10·74
Rural towns	5·75
Town population	9·59
Rural population	0·79
Total for the empire	4·19

The following is a list of the 35 towns which had upwards of 50,000 inhabitants at the census of 1875. The first column exhibits the population within the boundaries of the municipal boroughs (Stadtgemeinde). The numbers in the second are not official, but include all suburbs of a really urban character. The latter therefore afford a better indication of the actual size of the several towns.

Population of the Principal Towns in 1875.

Towns.	Within the Municipal Boundaries.	Within the Topograph. Boundaries.
1. Berlin	966,858	1,062,000
2. Hamburg	264,675	348,447
3. Breslau (Silesia)	239,050	239,050
4. Munich (Bavaria)	198,829	212,376
5. Dresden (Saxony)	197,295	197,295
6. Elberfeld (Rhine)	80,589	167,091
Barmen (Rhine)	86,502	
7. Leipsic (Saxony)	127,387	160,686

9. Frankfort-on-Main (Hesse-Nassau)	103,136	134,776
10. Hanover	106,677	127,576
11. Magdeburg (Saxony)	87,925	122,789
12. Königsberg (East Prussia)	122,636	122,636
13. Bremen	102,532	111,039
14. Stuttgart (Würtemberg)	107,273	105,062
15. Dantzic (West Prussia)	97,931	ab. 99,000
16. Nuremberg (Bavaria)	91,108	94,878
17. Strasburg (Alsace)	94,306	92,379
18. Chemnitz (Saxony)	78,209	85,334
19. Altona (Holstein)	84,097	84,097
20. Stettin (Pomerania)	80,972	80,972
21. Düsseldorf (Rhine)	80,695	80,695
22. Aix-la-Chapelle (Rhine)	79,606	79,606
23. Essen (Rhine)	54,790	76,450
24. Posen (Posen)	60,998	66,505
25. Brunswick	65,938	65,938
26. Mülhausen (Alsace)	58,463	65,361
27. Crefeld (Rhine)	62,905	62,905
28. Halle (Prov. Saxony)	60,503	60,503
29. Dortmund (Westphalia)	57,742	57,742
30. Augsburg (Bavaria)	57,213	57,213
31. Cassel (Hesse-Nassau)	53,043	56,745
32. Mainz (Hesse)	56,421	56,421
33. Potsdam (Brandenburg)	45,003	54,186
34. Metz (Lorraine)	45,856	53,151
35. Erfurt (Prov. Saxony)	48,030	50,477
Total...	4,340,564	4,745,945

The inhabitants of these 35 towns amount to 10·1 or 11 per cent. of the entire population of the empire, according as we reckon by the municipal or the topographical boundaries. A similar proportion appears in France and

Belgium; but the towns of England and Wales of 50,000 inhabitants and upwards have nearly 9½ million inhabitants, or 44 per cent. of the whole population.

Density of Population.—The town population amounts in some districts, such as Gumbinnen (East Prussia) and Lower Bavaria, to only 11 to 12 per cent.; in others, as Zwickau, Leipsic, Düsseldorf, it reaches 50 to 66 per cent. Arranging Germany in 13 large divisions, we get the following table, the divisions being named after their principal provinces:—

Divisions.	Population 1875.	Per Sq. Mile.	Proportion per cent. of	
			Town Popul.	Rural Popul.
1. Prussia (East and West)	3,199,171	132	23·8	76·2
2. Pomerania, Schleswig-Holstein, Mecklenburg, &c.	3,665,289	144	42·3	57·7
3. Brandenburg (not including Berlin) and Posen	3,765,637	142	30·0	70·0
4. Hanover, Münster, Oldenburg, &c.	2,437,476	137	35·0	65·0
5. Bavaria (not including Palatinate)	4,381,136	163	25·0	75·0
6. Prov. of Saxony, Anhalt, Brunswick, &c.	3,123,643	228	40·8	59·2
7. Silesia	3,843,699	247	33·0	67·0
8. Hesse, Hesse-Nassau, Minden, Lippe	3,033,856	250	33·6	66·4
9. Würtemberg, Baden	3,455,150	250	33·9	66·1
10. Alsace-Lorraine, Palatinate	2,173,058	274	35·9	64·1
11. Rhineland, Arnsberg	4,823,215	355	60·2	39·8
12. Saxony and Thuringia	3,859,972	365	40·8	59·2
13. Berlin	966,858	...	100	...
Total	42,727,360	205	37·9	62·1

The most thinly peopled territories are found, not as might be expected in the mountain regions, but in some parts of the plains. There are not more than 50 persons to the square mile (about the same proportion as in the Scotch Highlands) on the moors of the Isar north of Munich, on the East-Frisian moors, and on the Lüneburg Heath. There are 50 to 100 inhabitants to the square mile on the Seenplatten of Pomerania and Mecklenburg, on the middle ridges of Schleswig-Holstein, in the northern districts of Hanover, in the Spreewald, &c. Leaving out of account the small centres, Germany may be roughly divided into two thinly and two densely peopled parts. In the former division has to be classed all the North German plain; there it is only in the valleys of the larger navigable rivers, and on the southern border of the plain, that the density reaches 150 to 200 inhabitants per square mile. In some places indeed it is far greater: at the mouths of the Elbe and the Weser, in East Holstein, in the delta of the Memel, 250 to 300, and in the environs of Hamburg even 400, inhabitants are found to the square mile. This region is bordered on the south by a very densely inhabited district, the northern boundary of which may be defined by a line from Breslau to Hanover, and its southern by a line from Coburg *via* Cassel to Münster. Here the density rises from 150 to 570 per square mile, for in this part of Germany there are not only very fertile districts, such as the "Goldene Aue" in Thuringia, but also centres of industry. The population is thickest in Upper Silesia around Beuthen (coal-fields), round Ratibor, Neisse, and Waldenburg (coal-fields), round Zittau (Saxony), in the Elbe valley around Dresden, in the districts of Zwickau and Leipsic as far as the Saale, in the Goldene Aue, on the northern slopes of the Hartz, and around Bielefeld in Westphalia. In all these places the density is greater than 350 inhabitants to the square mile, and in Saxony it exceeds 500. The third division of Germany comprises the basin of the Danube and Franconia (the Upper Main system), and sweeps to the north-west between the valleys of the Werra and the tributaries of the Rhine as far as Sauerland. The population of Franconia rises a little above that of the rest of this region, the density in the valley of the Regnitz between Nuremberg and Bamberg, and in the Main valley round Würzburg, reaching about 200 to 240 inhabitants per square mile. The fourth division embraces the valleys of the Rhine and the Neckar. In the latter and in the Upper Rhine plain agriculture has reached a high degree of perfection, and the soil is so fertile as to support a population of 400 per square mile. North of the Niederrheinisches Schiefergebirge, again, are rich coal-fields, —making this the most important industrial district in Germany. Here indeed, in the governmental district of Düsseldorf, the population amounts to 700 per square mile, —about the same proportion as in the West Riding of Yorkshire; but no such density as exists in Lancashire (1500 to the square mile) is found anywhere in Germany. West of the Rhine a thickly peopled district is grouped round the coal-field of the Saar basin, but there is only a scattered population in the surrounding country. On the Eifel there are scarcely 100 inhabitants to the square mile.

Houses.—The number of houses was estimated in 1871 at 5,330,000, so that the average number of inhabitants per house is from 7 to 8. In England and Wales it is only 5·3 (1871). The greatest proportion of dwelling-houses to the population is in Alsace (5·1 persons to one house) and in Swabia (5·4). All the larger cities of Germany consist largely of houses in which a number of families live together. In Berlin the proportion per house is 57 persons, while in London it is only 8. This marks one important point of difference in the habits of the two countries.

Occupations.—The census of 1871 distinguishes 8 principal classes of occupation, but does not subdivide these. The official returns give for each class the number of persons engaged in the several occupations comprised in that class, with the number of attendants and other members of the families of those so occupied. The following table presents an abstract of the returns. In the case of Alsace-Lorraine the attendants are not given in the separate classes, but are all returned under class D.

Occupations.		Engaged in the several occupations.	Attendants and other members of families.	Total.
A. Agricultural class	males	2,963,738	2,986,556	12,179,307
	females	976,669	5,247,344	
B. Industrial class	males	4,498,739	2,462,937	13,407,793
	females	1,086,071	5,360,046	
C. Commercial class	males	1,023,260	322,249	3,256,605
	females	201,641	1,709,455	
D Domestic class (and general labourers)	males	1,777,118	2,344,235	9,569,658
	females	936,901	4,511,404	
E. Army and Navy	males	430,800	20,654	508,413
	females	...	56,959	
G Other occupations	males	506,734	318,238	1,751,976
	females	98,974	828,030	
H. Persons not returned under any occupation	males	414,284	255,322	1,985,162
	females	620,881	694,685	
I. Not stated (poor, &c.)	males	...	...	437,968
	females	...	...	
Total:		15,540,610	25,080,214	41,058,792

This table does not admit of comparison with the census returns of England and Wales, the mode of classification being different. It will be seen that more persons belong to the industrial than to the agricultural class.

INDUSTRIES.

Some account of different industries has already been given in connexion with the productions of the empire. The principal textile manufactures have still to be noticed.

Cotton Manufacture.—Before 1871 the production of cotton fabrics in France exceeded that in Germany; but as the cotton manufacture is pursued largely in Alsace, more than 2 million spindles being employed there, the balance is now against the former country. In 1873 there were about 5 million spindles in Germany and 4,611,000 in France. From the subjoined table of imports and exports (gross weight, the net weight being about 4 per cent. less) of the raw material, it will be seen that this industry has not improved since 1873 :—

	Total Imports of Raw Cotton.	Total Exports of Raw Cotton.	Excess of Imports.
	Cwts.	Cwts.	Cwts.
1873	3,609,000	1,153,000	2,456,000
1874	3,490,000	848,000	2,642,000
1875	3,199,000	819,000	2,380,000
1876	3,518,000	705,000	2,813,000
1877	3,262,000	831,000	2,431,000
1878	3,289,000	973,000	2,313,000

Cotton spinning and weaving are not confined to one district, but are prosecuted in Upper Alsace (Mülhausen, Gebweiler, Colmar), in Saxony (Zwickau, Chemnitz, Annaberg), in Silesia (Breslau, Liegnitz), in the Rhine province (Düsseldorf, Münster, Cologne), in Erfurt and Hanover, in Würtemberg (Reutlingen, Cannstadt), in Baden, Bavaria (Augsburg, Bamberg, Baireuth), and in the Palatinate. The number of hands occupied in the mills in 1875 was 68,555 (34,385 males, 34,170 females) and in the weaving establishments 186,496 (124,732 males and 61,764 females). Of these 98,188 were in Saxony. The production of cotton yarn is not sufficient for the home demand, and for some years back the imports of the article have exceeded the exports by about 200,000 cwts., till 1878, when the excess was only 117,000 cwts.

Woollen and Worsted.—In this class of manufactures Germany is far behind France. First of all, the home production of wool is not sufficient. In 1873–75 the imports of wool exceeded the exports by 300,000 cwts. per annum, and in 1876–78 the excess amounted to 800,000 cwts. In 1875 there were about 1,200,000 spindles for carded woollen yarn,—about 700,000 of them in Prussia, and 320,000 in Saxony. For worsted spinning there were 450,000 spindles,—Upper Alsace having 180,000, and Saxony 110,000; nevertheless the production falls short of the demand, and from 150,000 to 250,000 cwts. must be obtained from foreign countries. The manufacture of woollen cloth is well developed, and is prosecuted for exportation. The cloth is valued as being well woven, durable, and cheap. The centres of its manufacture are the Rhine province, Brandenburg, Lower Silesia, Magdeburg, Thuringia, Saxony, Würtemberg, and Alsace. In 1875 there were altogether 192,452 persons engaged in the woollen industry.

Linen, Hemp, and Jute.—Germany, although linen was formerly one of her most important articles of manufacture, is now left far behind in this industry, not only by Great Britain and France, but also by Austria-Hungary. In 1874 there were 326,538 spindles at work in Germany for flax, hemp, and jute spinning, while there were 415,000 in Austria, 663,000 in France, and 1,670,000 in Great Britain. About 300,000 cwts. of linen yarn are imported into Germany annually, whereas Austria exports about 100,000 cwts. Hand-loom weaving is practised all over Germany, but centres principally in Saxony, Silesia, and Westphalia. In recent times also power-loom weaving has been extending. In 1873 there were 68 establishments in Germany, principally at Elberfeld and Barmen, with 3473 power-looms, including 7 factories, with 546 power-looms, for jute. The linen industry employed 187,793 persons in 1875. The demand for linen is nearly covered by the home production.

Silk.—Raw silk can scarcely be ranked among the products of the empire, and the annual demand has thus to be provided for by importation. It amounts to about 50,000 cwts., there being some superior silk-weaving establishments. The main centre of the silk industry is Crefeld and its neighbourhood; then come Elberfeld and Barmen, Aix-la-Chapelle, as well as Berlin, Potsdam, Chemnitz and Annaberg, Munich, Stuttgart, Saargemünd, &c. The exports of silk stuffs always exceed the imports.

General Census of Industries.—In 1875 a census of industrial occupations was taken in Germany. The following table gives the numbers of the different establishments and of the persons engaged in them :—

Classes.	Establishments.	Persons Engaged.
1. Horticulturists	13,072	24,893
2. Fishermen	15,636	19,623
3. Miners	7,893	433,109
4. Workers in stone, clay, glass	51,235	265,139
5. Workers in metal	164,328	420,445
6. Workers in machines, instruments, &c.	83,635	307,705
7. Chemical industry	8,640	51,739
8. Workers in lighting materials, soap, resins, &c.	8,947	42,318
9. Textile industry	380,918	925,457
10. Workers in paper and leather	56,614	187,174

19. Lodging and boarding	159,881	234,848
Total	2,936,572	6,467,570

Roads, Railways, and Canals.

Roads.—The construction of good highways has been well attended to in Germany only since the Napoleonic wars. The separation of the empire into small states was favourable to road-making, inasmuch as it was principally the smaller Governments that expended large sums for their network of roads. Thirty years ago the best roads were found in Hanover and Thuringia: the Thüringer Wald has been almost transformed into a park by its splendid roads. But some districts suffer even still from the want of good highways. The introduction of railways for a time diverted attention from road-making, but this neglect has of late been to some extent remedied. In Prussia the circles (*Kreise*) have now themselves undertaken the charge of the construction of the roads; but they receive a subsidy from the public funds of the several provinces. The total length of the public roads is now estimated at 72,000 miles.

Railways.—The period of railway construction was inaugurated in Germany by the opening of the line from Nuremberg to Fürth in 1835, but the development of the system was slow. The want of a central government operated injuriously here, for it frequently happened that intricate negotiations and solemn treaties between several sovereign states were required before a line could be constructed; and moreover the course it was to take was often determined less by the general exigencies of commerce than by many trifling interests or desires of neighbouring states. The state which was most self-seeking in its railway politics was Hanover, which separated the eastern and western parts of the kingdom of Prussia. The difficulties arising to Prussia from this source were experienced in a still greater degree by the seaports of Bremen and Hamburg. Until 1866 there was no railway from Bremen into the interior of Germany, while now there are four. Prior to 1865 the construction of railways advanced pretty uniformly, the average construction during the years from 1840 to 1865 having been from 340 to 370 miles per annum. Germany was at that time far outstripped in the extent of its railway system by England, Belgium, and Switzerland, and even by France. A new period of railway construction begins with the year 1866, and is closely connected with the economical and political progress of Germany. Numerous great undertakings were then set on foot, partly to remedy the defects of the existing system. Everywhere it became a primary object to establish the most direct lines of communication between important places of industry and commerce. As a consequence the German railway system was immensely enlarged, and from 1865–75 it has nearly been doubled. In 1872, 2000 miles were opened, the average from 1869 to 1877 being 1080 miles annually, so that Germany now owns a greater length of railways than any other state in Europe. On the 31st December 1877 Germany had 18,830 miles, Great Britain and Ireland 17,092, France 14,785. As regards proportion to the area and population, however, Belgium, Great Britain, and Switzerland are still in advance. In 1877 Belgium had 320 miles of railways to every 1000 square miles, Great Britain 273, Switzerland 155, and Germany 147. The following table exhibits the development of the German railways, including those of Alsace-Lorraine:—

Years. Dec. 31.	Length of Lines open for Traffic.	Of which double Lines.	Cost of Construction.
	Miles.	Miles.	£
1840	304		
1850	3,753		
1860	7,195		
1865	8,887		
1870	11,457	3,699	207,608,000
1875	17,061	5,622	339,225,000
1876	18,080	5,735	373,558,000
1877	18,830		

In recent years the multiplication of competing railways has greatly reduced the receipts of the older lines. The total amount of capital sunk in railway construction is estimated for the year 1876 at £373,558,000, or just about half the capital invested for the same purpose in Great Britain (£741,800,000). From the subjoined table it will be seen that the working expenses have considerably advanced during late years, and dividends accordingly have experienced a great decline. Railways formerly paying 15 to 18 per cent. have gone down to 5 to 6; the average dividend, which in 1870 was still 6 per cent., in 1876 had fallen to 4·4 per cent.

	Total Receipts.	Total Working Expenditure.	Net Receipts.	Proportion of Expenditure to total Receipts.
	£	£	£	Per cent.
1870	25,312,000	12,770,000	12,543,000	50·5
1875	42,151,000	26,534,000	15,617,000	63·0
1876	42,862,000	26,559,000	16,303,000	62·0

The making of railways has from the outset been regarded by some German states as exclusively a function of the Government. The South German states, for example, possess only state railways. In Prussia numerous companies have in the first instance constructed their systems, and the state has contented itself for the most part with laying lines in such districts only as were not likely to attract private capital. Yet, in order to establish a preponderating influence over the administration of all German railways, the Government has for some time been buying up private lines. Saxony not long ago purchased all the Saxon railways belonging to private companies. The following table gives the proportion of state and private railways at 31st December 1877, the minor North German states being classed along with Prussia. Of these Oldenburg alone possesses a greater length of railways belonging to the state than of those in the hands of private companies. The railways of Alsace-Lorraine are the property of the empire. The number of independent managements in 1878 was 67.

States.	State Railways.	Private Railways worked by State.	Private Railways.	Total.
	Miles.	Miles.	Miles.	Miles.
Prussia and minor German States	3,285	2,060	6,857	12,202
Bavaria	2,241	169	371	2,781
Saxony	1,035	23	170	1,228
Würtemberg	761	..	10	771
Baden	651	77	4	732
Hesse	179	...	270	449
Alsace-Lorraine	660	...	7	667
Total	8,812	2,329	7,689	18,830

Canals.—Germany cannot be said to be rich in canals. In South Germany the Ludwigs-canal was until the annexation of Alsace-Lorraine the only one of importance. It was constructed by King Ludwig of Bavaria in order to unite the German Ocean and the Black Sea, and extends from the Main at Bamberg to Kelheim on the Danube. Alsace-Lorraine had canals for connecting the Rhine with the Rhone and the Marne; the coals of the Saar valley were conveyed by canals to Lorraine. The North German plain has several canals, of which only the more important need be named. In the east a canal by which Russian grain is conveyed to Königsberg joins the Pregel to the Memel. The Netze canal unites the Vistula and Oder. The Upper Silesian coal-field is in communication with the Oder by means of a canal. The greatest number of canals is found around Berlin; they serve to join the Spree to the Oder and Elbe. Smaller canals are found also in the north-west. The Meuse and the Rhine are also connected by a canal. The 70 canals in Germany have a total length of only 1250 miles, a very small extent when the other canal systems of western Europe are compared with it.

Posts and Telegraphs.

With the exception of Bavaria and Würtemberg, which have administrations of their own, all the German states belong to the system of the reichspost. Since 1874 the postal and telegraphic departments have been combined. Both branches of administration have undergone a surprising development during the last 10 years, especially since the reduction of the postal rates. Germany, including Bavaria and Würtemberg, constitutes with Austria-Hungary a special postal union (Deutsch-Oesterreichischer Postverband), besides forming part of the international postal union. There are no statistics of posts and telegraphs before 1867, for it was only when the North German union was formed that the lesser states resigned their right of carrying mails in favour of the central authority. Formerly the prince of Thurn-and-Taxis was postmaster-general of Germany, but only some of the central states belonged to his postal territory. The seat of management was Frankfort. Of late years the number of post-offices has increased considerably, as will be seen from the following figures, in which the statistics of the Bavarian and Würtemberg post-offices are included, as well as those of the reichspost. In 1872 there were 7400 post-offices; in 1877, 8600. In the latter year therefore there was one post-office for every 23 square miles. In 1877 there were 3194 imperial post-and-telegraph offices, and 3746 imperial post-offices, while the Bavarian post-offices numbered 1243, and those of Würtemberg 499. The following table shows the increase of letter circulation, from 1872 to 1877:—

	Letters. Imperial Post.	Total in German Empire.	Average Number to each Person.
	Millions.	Millions.	
1872	352·0	407·8	10
1873	429·0	492·4	12
1874	456·6	521·9	13
1875	498·2	576·0	14
1876	516·4	596·3	14
1877	521·5	604·2	14

The average number of letters to each person is thus a little greater in Germany than it is in Ireland, whereas it is 26 in Scotland and 35 in England. The number of post-cards has increased from 26·5 millions in 1872 to 99·3 millions in 1877. The following table shows the general postal circulation during the three years 1875–77:—

	1875.	1876.	1877.
	Millions.	Millions.	Millions.
Letters	576·0	596·3	604·2
Post-cards	64·7	82·7	99·3
Printed papers	93·0	101·0	112·4
Newspapers	392·8	414·2	433·5
Samples	9·3	9·0	9·8
Money orders	33·5	39·8	...
Total amount of money orders and remittances	£840	£793	£784
Parcels	78·4	80·3	82·3
Total weight of parcels	℔ 559	℔ 583	℔ 915

Telegraphs.—By combining the postal and telegraphic departments Germany has been saved a large number of officials; but great sums are still spent annually on the extension of the telegraph system. Since 1876 important localities have been brought into communication with Berlin by subterranean wires. This plan is expensive, but under it a considerable saving is anticipated in repairs. The number of telegraph offices in 1877 was 7251, of which about 4600 belonged to the state, and the rest to private railways. The following table shows the progress of the telegraphic system between 1872 and 1877, and the number of messages in these two years:—

Telegraph Service.	1872.	1877.
	Miles.	Miles.
Length of line	23,350	33,660
Length of wire	77,870	121,810
Number of offices	4,038	7,251
Number of messages—		
Home service	8,478,000	8,994,000
International (includ. in transit)	4,945,000	5,203,000

The increase of messages is insignificant, a circumstance which must be attributed to the recent dulness of trade. On the whole the telegraph is not as yet used to a very great extent in Germany. The number of messages for every 100 inhabitants in 1877 was 33, as compared with 47 in Norway, 49 in Denmark, 54 in Belgium, 58 in the Netherlands, 64 in Great Britain, and 100 in Switzerland.

Shipping.

The German mercantile marine has always been distinguished by the excellence of its personnel. The seamen of Frisia are acknowledged to be among the best in the world, and the shipping of Bremen and Hamburg had won an everywhere respected name long before a German mercantile marine, properly so-called, was heard of. Many Hamburg vessels sailed under charter of English and other houses in foreign waters, especially in the Chinese. Since 1868 all German ships have carried a common flag—black, white, red—but formerly Oldenburg, Hanover, Bremen, Hamburg, Lübeck, Mecklenburg, and Prussia had each its own flag, and Schleswig-Holstein vessels sailed under the Danish flag. It is but lately that a uniform mode of measuring the hold tonnage of German ships has been introduced, and accordingly it is only since 1871 that it has been possible to give an exact statement of the position of German shipping. The official returns show that the marine is on the increase. The following table gives its position on the 1st of January in the years 1872–78. The tonnage is reckoned according to the English register ton.

	Sailing Vessels.		Steamers.		Total.	
	Number.	Tons.	Number.	Tons.	Number.	Tons.
1872	4,354	892,000	175	97,000	4,529	988,000
1873	4,311	869,000	216	130,000	4,527	999,000
1874	4,242	866,000	253	168,000	4,495	1,034,000
1875	4,303	878,000	299	190,000	4,602	1,068,000
1876	4,426	901,000	319	184,000	4,745	1,084,000
1877	4,491	923,000	318	181,000	4,809	1,104,000
1878	4,469	935,000	336	183,000	4,805	1,118,000

The lowest tonnage of vessels included in this return is 16 tons for sailing vessels and 11 tons for steamers. On comparing the state of the German marine with that of other countries we find that Germany ranks fourth in the list of maritime nations. Great Britain and the United States have considerably larger fleets. That of Norway also was even in 1871 greater than that of Germany, and it has increased much more rapidly than the other since that time; but on the other hand the mercantile marines of France and Italy, which in 1871 were larger than the German, are both now less. The following table shows the proportion of the mercantile shipping of Germany belonging to each of the maritime states on the 1st of January 1878. It must be borne in mind that Bremen and Hamburg properly consist only of one port each, whereas Prussia has hundreds of miles of coast-line both on the North Sea and on the Baltic.

States.	Number of Ports.	Sailing Vessels.	Steamers.	Total.
		Tons.	Tons.	Tons.
Prussia	243	464,477	31,573	496,050
Hamburg	2	137,347	84,127	221,474
Bremen	2	158,677	57,377	216,054
Mecklenburg	2	108,521	3,812	112,333
Oldenburg	21	61,774	27	61,801
Lübeck	1	3,760	6,463	10,223
Total	271	934,556	183,379	1,117,935
North Sea Ports	62	419 698	38,699	458,397
Baltic Ports	209	514,858	144,680	659,538

The number and the tonnage of steamers have, as in other countries, increased greatly, while those of sailing vessels have remained almost stationary. The aggregate horse-power of the steamers in 1871 was 23,287; in 1877 it was 50,603. The number of seamen employed in 1878 was 40,832, and of those 8173 served on board steamers.

In 1876 165 sailing vessels of 35,439 tons, and 14 steamers of 6200 tons, were built in Germany; and 8 sailing vessels of 3862 tons, and 1 steamer of 1910 tons, were built abroad. There were besides 50 ships with a total tonnage of 21,755 which had been bought in America, Holland, and Great Britain.

The shipping returns of German ports have lately fluctuated but little. The total amount was 13,311,000 tons in 1876. A striking difference will be observed in the following table in the returns between the numbers entering and clearing in ballast:—

Total Tonnage of Ships, 1876.

	With Cargo.	In Ballast.	Not for Trade.	Total.
	Tons.	Tons.	Tons.	Tons.
Entered	6,072,000	505,000	130,000	6,585,000
Cleared	4,100,000	2,619,000	128,000	6,726,000

Only 44 per cent. of the ships that trade with German ports sail under the German flag. British ships have a very considerable trade in German ports. They constitute 32 per cent. of the total tonnage, and as much as 47 per cent. of the tonnage of steam vessels. Denmark follows next with 7·2 per cent., Sweden 4·8, Norway 4·6, Russia 2·3, Holland 2·1, France 1·2, United States 1·2, Italy 0·5, other countries 0·4. The number of voyages in all made by German ships in 1876 was 45,492, of which 12,963 were made between German ports. Much more considerable, however, is the trade of German ships between the home ports and foreign countries, as the subjoined table will show, while no fewer than 9777 voyages were made in 1876 by German vessels without calling at any home port:—

	Number of Ships with Cargo.	Tonnage of Ships with Cargo.	Number of Ships in Ballast.	Tonnage of Ships in Ballast.
Home trade (average of entered and cleared ships)	12,963	577,000	5,194	220,000
Foreign trade { entd. into German ports	8,002	1,984,000	710	79,000
Foreign trade { cleared from " "	5,449	1,552,000	3,397	602,000
Voyages of German ships between foreign ports	6,950	3,314,000	2,827	880,000
Total..........	33,364	7,420,000	12,128	1,782,000

There were 5544 voyages made between non-German ports in Europe, the greater number being between one English port and another. Many German vessels also run between the Baltic ports of Russia and Sweden. From European ports 993 vessels sailed for non-European ports, and 869 returned thence to Europe. Here also the greater number ran from Great Britain to the United States, the West Indies, and South America. 2371 ships made their voyages without touching at European ports. Most of these were engaged in the coasting trade in the Chinese Seas, on the South American coasts, and in the West Indies.

As regards the shipping of the most important German ports, the following table will show the total tonnage of ships entered and cleared in 1876:—

Ports.	Tonnage	Ports.	Tonnage.
Hamburg..........	4,406,000	Kiel.................	608,000
Bremerhafen	1,300,000	Pillau	440,000
Stettin..............	1,144,000	Königsberg	418,000
Neufahrwasser (Dantzic)....	780,000	Geestemünde........	378,000
		Memel...............	352,000
Lübeck	646,000	Swinemünde	332,000

Commerce.

Statistics relating to the foreign trade of the empire are necessarily confined to very recent times. The quantities of such imported articles as are liable to duty have indeed been known for many years; and some years ago an attempt was also made to compile official tables showing the value both of imports and of exports. But when the results of these tables proved the importation to be very much greater than the exportation, the conviction arose that the valuation of the exports was erroneous, and below the reality. There is no compulsory declaration of such goods, and consequently the attempt to compute statistics of this nature has been abandoned since 1875. It must at the outset be observed that the customs frontier does not coincide with the political frontier of Germany, for it does not take in the free-port territories of Hamburg and Cuxhaven, Bremen, Bremerhafen and Geestemünde, &c. (in all, 129 square miles with 593,040 inhabitants; in 1875), besides some communes in Baden adjoining the Lake of Constance (22 square miles, 5236 inhabitants). On the other hand the grand-duchy of Luxembourg (998 square miles, with 205,158 inhabitants in 1875) and the small Austrian commune of Jungholz 206 inhabitants), near Füssen, belong to the German Zollverein. The collection of duties is a function of the empire. The following table shows the results of the official calculations of the imports into Germany for 1872–76, and also the values of the exports, but in the case of these it is only the figures for the years 1872–74 that are official. The numbers for 1875 and 1876 are those published by Professor Laspeyres in the *Économiste Français*.

Years.	Imports	Exports.	Transit.
1872	£173,400,000	£124,700,000	£54,700,000
1873	212,800,000	124,400,000	61,700,000
1874	183,700,000	121,600,000	
1875	176,500,000	127,400,000	
1876	190,200,000	127,600,000	
Average...	187,100,000	125,200,000	

The extremely slight variation which this table shows in the exports of the several years from 1872 to 1876 appears so improbable that we can hardly venture to make it a basis of calculation, or to draw a conclusion so unfavourable to the trading balance of Germany as the figures would suggest. The proportion per head of population is, as regards imports and exports respectively, about £4, 10s. and £3, whereas the proportion in Great Britain in 1876 amounted in the one case to £11, 10s. and in the other to £6, thus showing the German trade to be less than half that of England. The statistical tables do not specify the several foreign markets for imports and exports; they only give the value of imports on the different frontiers.

Frontiers.	Total Value of Imports.	
	1875.	1876.
	Millions.	Millions.
North Sea line, including Bremen and Hamburg..........................	£56·6	£62·4
Denmark	1·0	1·0
Russia	19·0	19·2
Austria	32·2	36·3
Switzerland	8·0	9·2
France	11·3	12·1
Belgium	16·3	16·3
Holland..	27·1	28·8
By post, or frontier not stated............	5·0	4·9
Total.................	176·5	190·2

According to the official trade returns of Great Britain, France, and other countries, the trade between Germany and these countries is very considerable. By the English tables the importation from Germany to British ports was in 1875–76 between £21,000,000 and £22,000,000; the exportation to Germany in 1875 was £23,300,000, and in 1876, £20,100,000. The movement of trade is shown in the following tables of the principal articles imported and exported. We begin with articles of consumption:—

Articles.	1872.		1877.	
	Imports.	Exports.	Imports.	Exports.
Animals, except horses..No	1,490,000	1,719,000	2,443,000	1,848,000
Grain and flour ....Cwts.	28,800,000	21,860,000	73,070,000	39,600,000
Herrings ....Barrels.	691,000	...	667,000	...
Coffee ....Cwts.	1,855,000	...	1,910,000	...
Sugar .... "	879,000	264,000	155,000	1,802,000
Wine............................ "	817,000	400,000	1,182,000	380,000
Beer .... "	100,000	590,000	300,000	1,280,000
Hops .... "	25,000	142,000	36,000	162,000
Tobacco .... "	1,128,000	140,000	1,043,000	120,000

The weights are stated in hundredweights (cwts.) net throughout (see *Statistical Abstract* published by the English Board of Trade, No. V., 1878). This table shows that of late years Germany has had to order considerable quantities of grain from abroad. The value of the importation, estimated at £14,000,000 in 1872, was nearly £36,000,000 in 1877. Similarly the value of the imported animals advanced from £4,400,000 in 1872 to £9,500,000 in 1877.

The following table gives the imports and exports of the principal raw materials:—

Articles.		1872.		1877.	
		Imports.	Exports.	Imports.	Exports.
Coal, lignite, &c.	Cwts.	71,600,000	76,395,000	95,000,000	100,184,000
Ores	"	8,200,000	5,300,000	6,655,000	16,140 000
Iron, pig	"	12,395,000	3,616,000	10,536,000	9,119,000
Lead, pig	"	163,000	433,000	60,000	649,000
Cotton, raw	"	2,830,000	614,000	3,130,000	798,000
Flax	"	786,000	667,000	1,380,000	1,010,000
Hemp	"	500,000	248,000	930,000	469,000
Wool, raw	"	1,070,000	357,000	1,370,000	445,000

With regard to the proper products of industry, the exports, with few exceptions, such as yarn, exceed the imports in every case, as is shown in the table below. The total value of all fabrics imported is estimated at about £30,000,000, that of those exported at from £42,000,000 to £45,000,000. But, even supposing the last figures to be too low, the difference between the German and the British trade is still very great, since the value of all the industrial products exported by Great Britain may be stated at £170,000,000 for the year 1875 (see *Almanach de Gotha*, 1877). The difference is greatest in the textile industries,—the value of tissues exported from England in 1875 being estimated at £100,000,000, while that of Germany did not rank higher than from £20,000,000 to £25,000,000. Articles of hardware are showing a great decrease of imports and a considerable increase of exports.

Industrial Products—Imports and Exports.

Articles.	1872.		1877.	
	Imports.	Exports.	Imports.	Exports.
	Cwts.	Cwts.	Cwts.	Cwts.

The principal ports of import and export are Hamburg and Bremen, and in these places the annual amount of shipping business has advanced step by step with the general development of German trade. As to the total value of goods entering Hamburg we have accurate statistics for several decades.

Imports of Hamburg.

		Total Imports, exclud. Bullion.		Total Imports, exclud. Bullion.
		Millions.		Millions
Average	1846-50	£20·5	1873	£85·3
Average	1851-60	33·5	1874	84·3
Average	1861-70	49·8	1875	85·1
	1871	77·3	1876	85·2
	1872	85·6	1877	88·8

The stagnation in the development of trade during the period 1871-77 is obvious; and with Bremen the case is the same. The following table states the total imports of Bremen by sea and from the interior. The importation from Germany or the Zollverein territory represents about one-third of the total amount. Bremen trades principally with the United States; Hamburg more with England, South America, &c.

Imports of Bremen.

Government.

The German empire is a union of 25 sovereign states,—4 kingdoms, 6 grand-duchies, 5 duchies, 7 principalities, 3 free towns. Alsace-Lorraine, ceded by France at the peace concluded 10th May 1871, forms a twenty-sixth constituent of the confederation, but it is administered by the central authority. The supreme direction of the military and political affairs of the empire has, by the vote of the reichstag or diet of the North German confederation, been vested in the king of Prussia, who accordingly bears the title of German Emperor (Deutscher Kaiser).

The imperial dignity is hereditary in the line of Hohenzollern, and follows the law of primogeniture. The emperor exercises the imperial power in the name of the confederated states. In his office he is assisted by a federal council or bundesrath, which represents the Governments of the individual states of Germany. The members of this council, 59 in number, are appointed for each session by the Governments of the individual states. The legislative functions of the empire are vested in the emperor, the bundesrath, and the reichstag or diet. The members of the latter, 397 in number, are elected for a space of three years by universal suffrage. Vote is by ballot, and one member is elected by (approximately) every 100,000 inhabitants.

As regards its legislative functions, the empire has supreme and independent control in matters relating to military affairs and the navy, to the imperial finances, to German commerce, to posts and telegraphs, and also to railways, in so far as these affect the common defence of the country. Bavaria and Würtemberg, however, have preserved their own postal and telegraphic administration. The legislative power of the empire also takes precedence of that of the separate states in the regulation of matters affecting freedom of migration (Freizügigkeit), domicile, settlement, and the rights of German subjects generally, as well as in all that relates to banking, patents, protection of intellectual property, navigation of rivers and canals, civil and criminal legislation, judicial procedure, sanitary police, and control of the press and of associations.

The executive power is in the emperor's hands. He represents the empire internationally, and can declare war if defensive, and make peace as well as enter into treaties with other nations; he also appoints and receives ambassadors. For declaring offensive war the consent of the federal council must be obtained. The separate states have the privilege of sending ambassadors to the other courts; but all consuls abroad are officials of the empire, and are named by the emperor.

Both the federal council and the reichstag meet in annual sessions convoked by the emperor who has the right of proroguing and dissolving the diet; but the prorogation must not exceed 60 days, and in case of dissolution new elections must be ordered within 60 days, and the new session opened within 90 days. All laws for the regulation of the empire must, in order to pass, receive the votes of an absolute majority of the federal council and the reichstag. The subjoined table gives the number of votes which the separate states have in the federal council. Each state may appoint as many members to the federal council as it has votes. The table also gives the number of the deputies in the reichstag. The official order of precedence of the 26 states is given in a former table (see p. 455); here they are arranged in the order of the number of their inhabitants.

The federal council is presided over by the chancellor of the empire (Reichskanzler). Imperial measures, after passing the federal council and the reichstag, must obtain the sanction of the emperor in order to become law, and must be countersigned, when promulgated, by the chancellor of the empire. All members of the federal council are entitled to be present at the deliberations of the reichstag. The federal council, acting under the direction of the chancellor of the empire, is also a supreme administrative and consultative board, and as such it has nine standing committees, viz.:—for army and fortresses; for naval purposes; for tariffs, excise, and taxes; for trade and commerce; for railways, posts, and telegraphs; for civil and criminal law; for financial accounts; for foreign affairs; and for Alsace-Lorraine. Each committee includes representatives of at least four states of the empire.

For the several branches of administration a considerable number of imperial offices have been gradually created. All of them, however, either are under the immediate authority of the chancellor of the empire, or are separately managed under his responsibility. The most important are the chancery office, the foreign office, and the general post and telegraph office. But the heads of these do not form a cabinet.

By the electoral law of 31st May 1869 every German of twenty-one years of age is entitled to be an elector, and every one who has completed his twenty-fifth year, and has resided for a year in one of the federal states, is eligible for election. The deputies are unsalaried, but during the session they have the right of travelling free by rail. The following table shows the political composition of the reichstag after the four elections from 1871 to 1878:—

Parties.	1871.	1874.	1877.	1878.

All the German states are constitutional, except Alsace-Lorraine and the two grand-duchies of Mecklenburg. The six larger states have adopted the two-chamber system, but in the composition of the houses great differences are found. The following table gives analyses of the membership for the sessions of 1878. As regards the lower house, 60,000 inhabitants elect one deputy in Prussia, 33,000 in Bavaria, 35,000 in Saxony, 20,000 in Würtemberg, 24,000 in Baden, 18,000 in Hesse.

The lesser states also have chambers of representatives numbering from 12 members (in Reuss) to 46 members (in Brunswick), and in most states the different classes, as well as the cities and the rural districts, are separately represented. The free towns have legislative assemblies, numbering from 120 to 200 members. In the so-called landtagen (diets) of Mecklenburg, which have but few privileges, 684 rittergüter (allodial estates) are represented and only 40 towns.

Finance.

The most important expenses which the budget of the German empire has annually to meet are those of the central administration, the army and navy, posts and telegraphs, the high court of justice, the foreign office, and some smaller items. For defraying these, all customs receipts and the net amount of certain excise duties are paid into the imperial treasury (reichskasse). Of the excise duties those on beet-root sugar, salt, and tobacco are common to all the states; but the imperial malt tax is not imposed in Bavaria, Würtemberg, Baden, or Alsace-Lorraine. The three first-named states are likewise exempt from the imperial excise on spirits. Additional receipts are derived from the duty on bill stamps, from posts and telegraphs (excluding Bavaria and Würtemberg), from the railways in Alsace-Lorraine, &c. These receipts are, however, insufficient to meet the expenses of the administration, and for that reason the separate states have to make contributions to the revenues of the empire, varying in proportion to their population. Bavaria, Baden, Würtemberg, and Alsace-Lorraine pay proportionally higher direct contributions, because they impose taxes on their own account on malt and spirits; so also do Bremen and Hamburg, because they are situated outside the customs territory. For the last few years the average contributions have ranged from £3,000,000 to £4,000,000; but they are increasing with the diminution of the funds available from the French war indemnity. These contributions press heavily upon the minor states.

The imperial budget is voted every year by the reichstag. The ordinary and extraordinary expenses for the financial year ending March 31, 1879, were distributed as follows:—

Expenditure, 1878-79.

	Ordinary.	Extraordinary.
Imperial chancery	£226,799	£116,516
Reichstag	6,100	1,500
Foreign office	305,233	26,350
Army	16,125,914	1,368,927
Navy	1,205,526	1,729,008

8. Imperial bank (share of profits)			100,500
9. Various revenues			381,509
10. Invalid fund			1,602,658
11. Interest of imperial funds			366,210
Total direct revenue			16,640,810
Extraordinary supply (loans, various funds)			5,826 753
Contributions of states to revenue			4,357,276
Total revenue to cover expenditure			26,824,840

The direct contributions of the principal states of the empire to the revenue for 1878-79 were as follows:—

Prussia	£2,074,730	Saxony	£228,786
Bavaria	984,137	Alsace-Lorraine	103,020
Würtemberg	340,330	Hesse	71,125
Baden	241,828	Mecklenburg	40,602

Customs Revenue.—The revenue from the customs duties has increased but little since 1872. In that year it was £5,534,000, and in 1873, £6,131,000; but in 1877-78 it was only £5,768,000. No export duties have been raised in Germany for many years. On the other hand, all imported goods were taxed till 1865, with very few exceptions. Since then free trade has been more in favour, and a considerable reduction has taken place in the number of taxed articles. There are still, however, according to the official lists, about 148 articles on which custom duties are levied under 43 divisions. Raw materials are duty free. Four-fifths of the receipts (£4,323,000) are derived from articles of consumption, coffee being the principal item, after which come tobacco, wine, spirits, &c. The subjoined table shows the customs receipts, in round numbers, from the following items in 1878:—

Coffee	£1,833,000	Herrings	£108,000
Tobacco	821,000	Pork	103,000
Wine and spirits	517,000	Sugar and molasses	101,000
Salt	259,000	Rice	83,000
Fruit	258,000	Miscellaneous	235,000

The preceding table shows great differences when compared with the corresponding list for Britain. The consumption of coffee is considerably larger,—Germany having imported 2,128,000 cwts. in 1876, Great Britain only 1,361,000. The duty is at the same time much higher than in England, where the revenue from coffee was only £200,000. On the other hand, tea yields only £36,000 duty in Germany, but in England £3,700,000; wine and spirits in Germany £517,000, in England £7,500,000; tobacco, in Germany £821,000, in England £7,800,000.

The German customs tariff serves as a protective duty for several industrial products, although in general a free-trade policy has prevailed in Germany during the last ten years. In 1873 the duties on iron were abolished; still its importation, owing to the stagnation of trade, has not increased. The following is a statement of the produce of the duties on specific manufactured articles in 1878:—

Textile fabrics	£604,000	Furniture, &c.	£23,000
Glass and earthenwares	50,000	Copper-wares	16,000
Oil	147,000	Iron-wares	10,000
Leather and leather-wares	62,000	Paper	12,500

In 1879, however, Germany has suddenly returned to an extreme protective system. The present import duties are much increased, and duties are imposed on many articles hitherto duty free. The Government hopes to make a gross revenue of about £8.000.000 by the new customs.

Excise.—The excise duties on articles of consumption have for the most part been considerably increased since 1872, especially the duty on sugar. The tax on tobacco is, however, still trifling (in 1877, £47,000). Bavaria, Würtemberg, and Baden are exempt from the duties both on spirits and on malt, Alsace-Lorraine from that on spirits.

Receipts from Excise Duties.

	Beetroot Sugar.	Spirits	alt.	Malt
	£	£	£	£
1872	1.726.000	1.631.000	1,644.000	601.000
1874	2.578,000	1.902.000	1,704.000	766.000
1877-78	3,274.000	2.632.000	1.786,000	922.000

Funds of the Empire.—The extraordinary funds, from which very large sums appear annually in the budget, were created after the French war. Part of the indemnity was invested for fixed purposes. The largest of these investments served for paying the pensions of the invalided, and amounted originally to £28,000,000. Every year not only the interest, but also part of the capital of this fund is expended in paying these pensions. Another fund, of about £5,200,000, serves for the construction and armament of fortresses; a third for building new houses of parliament; a fourth for the construction of railways in Alsace-Lorraine. Further, the empire has put aside £6,000,000 as a Reichs-Kriegs-Schatz, or imperial war reserve fund, which is not laid out at interest, but exists in coined gold and bullion at Spandau. The railways in Alsace-Lorraine are also the property of the empire,—France having paid an allowance to the Eastern Railway Company of £13,000,000 for the railways brought under the control of Germany. The following table shows the state of the imperial funds at 1st March 1878:—

Invalid fund	£27,870,700
Fund for armament of fortresses	6,515,800
War reserve fund	6,000,000
Parliament House building fund	1,456,400

Imperial Debts.—The loans contracted by the North German Confederation for the war with France have long since been paid off. The extraordinary expenditure of the empire was for several years paid out of the French indemnity, but that resource is now exhausted. Accordingly, for defraying the expenses of the army and navy, the extension of the subterranean telegraphs, &c., two new loans had to be raised in 1877 and 1878, amounting to £8,760,800. There exists, besides, an unfunded debt. The law allows the imperial chancellor to effect an issue of bills of exchequer for short terms to the extent of £7,500,000, and these are destined partly for the expenses of administration, and partly for the completion of the monetary reform. Since 1874 also a debt bearing no interest has been created in imperial treasury bills (Reichscassenscheine), which are to be substituted for the paper currency issued by the separate states. At that date only four states—Lippe, Lübeck, Hamburg, and Bremen—had no paper currency. Prussia had in 1872 only £3,000,000 of paper currency, or 2s. 6d. a head, but in the minor states the proportion was higher,—reaching in Saxe-Coburg-Gotha 10·3s. a head, in Anhalt 14s., in Mecklenburg-Strelitz 24·7s., and in Schaumburg-Lippe the very high figure of 34·8s. This inconvenience was remedied by an imperial law, ordering the states to call in their paper currency, and replacing it by the issue of imperial treasury bills, amounting to £6,000,000. For many of the smaller states this sudden withdrawal of their paper currency was too severe an ordeal. Accordingly, to these a further sum was advanced for a term of years in treasury bills; £8,338,000 was thus in circulation on the 30th September 1878.

Reform of the Currency.—The German empire adopted a gold currency by the law of the 4th December 1871. Subsequently the old local coinages (*Landesmünzen*) began to be called in and replaced by new gold and silver coins. The old gold coins, amounting to £4,550,000, had been called in as early as 1873; and the old silver coins have also been successively put out of circulation, so that none actually now remain as legal tenders but the thaler (3s.). Silver currency to the amount of £52,000,000 had been withdrawn up to the 30th September 1878, and copper coins to £157,600. To replace these there were coined up till the 30th September 1878—gold pieces, £81,900,000; silver coins, £21,330,000; nickel and copper, £2,237,800. The currency reform was at first facilitated by the French indemnity, a great part of which was paid in gold. But later on that metal became scarcer; the London gold prices ran higher and higher, while silver declined. The average rate per ounce of standard silver in 1866–70 was 60⅝d., in January 1875 only 57½d., in July 1876 as low as 49d. It rose in January 1877 to 57½d., but again declined, and in September 1878 it was 50⅜d. While, therefore, the proportion of like weights of fine gold and fine silver in 1866–70 averaged 1 to 15·55, it was 1 to 17·79 in 1876, and 1 to 17·18 in 1877, and the difference again increased in 1878.

Banking.—A new banking law was promulgated for the whole empire on the 14th March 1875. Before that date there existed 32 banks with the privilege of issuing notes, and on the 31st December 1872 £67,100,000 in all was in circulation, £25,100,000 of that sum being uncovered. The banking law was designed to reduce this circulation of notes; £19,250,000 was fixed as an aggregate maximum of uncovered notes of the banks. The private banks were at the same time obliged to erect branch offices in Berlin or Frankfort for the payment of their notes. In consequence of this regulation 13 banks resigned the privilege of issuing notes, so that at present there are in Germany but 19 note-issuing banks of which 5 belong to South Germany (Frankfort included). The Imperial Bank (Reichsbank) ranks far above the others in importance. It took the place of the Prussian Bank in 1876, and is under the superintendence and management of the empire, which shares in the profits. Its head office is in Berlin, and it is entitled to erect branch offices in any part of the empire. It has a capital of £6,000,000 in shares of £150. The following table exhibits the position of the German Reichsbank as compared with the other 18 banks at the 30th September 1878:—

Banks.	Notes in Circulation.	Bullion.	Excess of Notes.
	£	£	£
Reichsbank	33,551,350	23,452,150	10,099,200
18 private banks	9,395,850	7,209,450	2,186,400
Total	42,947,200	30,261,600	12,685,600

Subjoined is a comparison with the great banks of England, France, and Austria at the same date:—

Banks.	Notes in Circulation.	Bullion.	Excess of Notes.
	£	£	£
Bank of England	26,592,000	23,846,000	2,742,000
Bank of France	91,250,000	86,114,000	5,126,000
German Reichsbank	33,551,000	23,452,000	10,099,000
Austrian National Bank	29,698,000	13,836,000	15,862,000

Finances of the separate States.—The budgets of the different German states are so variously arranged that it is difficult to group them on uniform principles. We extract the following particulars from the scheme published by Prof. H. Wagner in the *Almanach de Gotha* for 1874. The expenses and receipts of the empire and those of the separate states are in the two tables taken together. The first table contains the net expenses for 1872–73, the charges of collection being deducted:—

Net Expenditure of German States, including the Empire.

1. Civil list and annuities to the princely families	£1,750,000
2. Diets	112,500
3. Civil service	20,200,000
4. Interest and management of the public debts	19,000,000
5. Army and navy	17,360,000
Total	48,422,500

Professor Wagner's second table gives the principal items of revenue:—

Revenue.	Gross Revenue.	Net Revenue.
I. *Revenue from public property and establishments managed by state.*	£	£
1. Crown land and state forests	...	5,300,000
2. Interest on consolidated funds, profits of issue, &c.	...	3,075,000
3. State lotteries	...	375,000
4. Produce of public mines and salt works	...	1,445,000
5. Various state establishments	...	353,000
6. Post-office, telegraph service, state railways, canals	...	6,285 000
II. *Taxes.*		
1. Direct taxes	11,175,000	10,680,000
2. Excise—		
Spirits and malt	4,865,000	8,800,000
Beetroot sugar	2,170,000	
Salt	1,865,000	
Tobacco	96,500	
Other articles of consumption	1,100,000	
3. Customs	6,075,000	5,500,000
4. Stamps of all kinds, and fees	5,700,000	5,385,000
5. Tolls, tonnages, &c.	...	450,000
Total	...	47,638,000

In the absence of trustworthy statistics the local taxes have not been taken into consideration in the above table. These, however, are very considerable in many cities in Germany, in consequence of recent expenditure on schoolhouses, sewage-works, &c.

A comparison of the foregoing tables with the corresponding statistics for the United Kingdom (1874) gives the following result. The payments on account of the national debt in Great Britain formed 42·2 per cent. of the total expenditure after deducting the charges of collection; in Germany only 18·14 per cent. The army and navy in England absorb 39·3 per cent. of the expenditure (or 68·0 per cent. after deducting the charges of debt), in Germany 35·6 per cent. (or 43·7). The expenses of the national debt in England are about 17s. a head, in Germany about 5s. The expenses of the army and navy in England are about 16s. a head, in Germany 9s. The public property in domains and forests is greater in Germany than in any other state of Europe, the area of the state forests being no less than 17,600 square miles. Many of the smaller states defray more than one-half of their expenditure by the revenue from domains and forests. From this source Germany is able to meet nearly one-fifth of her expenditure (17·3 per cent.), whereas in England only 0·6 per cent. is thus obtained. On the other hand, the expenses incurred by Germany for the civil lists and for annuities to the princely families are very considerable. Germany pays 3·6 per cent. of the national income to her princes, Great Britain only 1·04 per cent. In the minor states the princely households absorb 10 to 12 per cent. of the expenditure. The proceeds of establishments managed by the state cover 17·5 per cent. of the whole expenditure in Germany, but only 2·5 in England. The proportion of direct to indirect taxes is in England as 17 to 83, in Germany as 31 to 69. But on the whole the English are taxed twice as heavily as the Germans. The gross revenue in England was, in 1874, 42s. a head, in Germany 16·2s.; of these sums 13·2s. came, in England, from customs duties, and 13·3s. from excise on spirits and malt (apart from the customs duties), while in Germany the corresponding figures were only 3s. and 2·4s.

A considerable part of the public debt of the separate states was paid off by them after the war. In 1873 the total amount of all debts of the German states was only about £171,000,000. In this sum was included £9,500,000 of currency. The greater part of this liability has been incurred for productive purposes, particularly for the construction of railways. The railway debts (which are not directly charged on the population) were in 1873 about £96,500,000. Since then some states have gone on reducing their debts still further; Prussia, for example, has done so by more than £11,000,000. Others again, such as Bavaria, Saxony, Würtemberg, and Baden have contracted new loans for constructing railways, or, as Saxony, for purchasing them. The entire debt of all the German states, including the imperial debt, at 31st December 1877, may be estimated at £220,000,000, of which sum, however, more than £140,000,000 consists of railway debt. The average sum per head will accordingly be £5, whereas in Great Britain it is £23 to £24. When the railway debts are deducted the proportion is less than £2 a head in Germany.

Army and Navy.

By the constitution of 16th April 1871 every German is liable to service (wehrpflichtig), and no substitution is allowed (art. 57). Every German capable of bearing arms (wehrfähig) has to serve in the standing army for seven years—as a rule from the end of the twentieth till the commencement of the twenty-eighth year of his age. Three of these seven years he must spend in active service, and the remainder in the reserve; after quitting the latter he forms part of the landwehr for five years more—the full time of military service thus being twelve years. The strength of the army on a peace footing (friedensfuss) was fixed in the army bill of 1874 at 401,659 (or say 1 per cent. of the population at the census of 1871) for a term of seven years ending the 31st December 1881. The number of recruits levied annually is 145,000 men. All young men who reach a certain fixed standard of higher school training, however, are obliged to serve only for one year in the active army, and these are not included in the effective strength of the army on a peace footing. Collaterally with the army there has existed since 1875 the landsturm, to which all men liable to service and capable of bearing arms, between the ages of seventeen and forty-two, belong, if they are neither in the line, the reserve, the landwehr, nor the marine. The landsturm is only called to arms in the event of a hostile invasion of the imperial territory being threatened or effected.

By the articles of the constitution the whole of the land forces of the empire form a united army in war and peace under the orders of the emperor. The sovereigns of the chief states are entitled to nominate the lower grades of officers, and the king of Bavaria has reserved to himself the special privilege of superintending the general administration of the two Bavarian corps d'armée; but all appointments are made subject to the emperor's approval. The 64th article of the constitution enacts that all German troops are bound to obey unconditionally the orders of the emperor, and to take the oath of allegiance accordingly. The emperor is empowered to erect fortresses in any part of the empire.

Organization of the Army.—The imperial army consists of 18 army corps, viz., the Prussian garde-du-corps, 13 Prussian corps (including the troops of the minor states in military convention with Prussia—Nos. 1 to 11 being Prussian, while Nos. 14 and 15 are the Baden and Alsace-Lorraine corps respectively), the Saxon corps (No. 12), the Würtemberg corps (No. 13), and the 2 Bavarian corps. One army "inspection" comprises from 3 to 4 corps. Generally 1 army corps consists of 2 divisions, each of which includes 1 horse and 2 foot brigades. As a rule the infantry brigade consists of 2 infantry regiments and 2 landwehr regiments, the cavalry brigade of from 2 to 3 cavalry regiments. An infantry regiment consists of 3 battalions of 4 companies each; a cavalry regiment has 5 squadrons. There are many exceptions, however, to these rules, *e.g.*, the garde-du-corps and the Saxon corps d'armée consist each of 1 cavalry and 2 infantry divisions, the 11th contains 3 divisions, &c. Some divisions also are stronger than others. Altogether the German army numbers 40 divisions, of which 6 are infantry, 3 cavalry, and 31 both combined. There are in all 74 infantry and 38 cavalry brigades, and 148 infantry and 93 cavalry regiments.

Besides the troops above named, each army corps generally includes (*a*) 1 jäger or light battalion (the Bavarian army has, however, 10 of them); (*b*) 1 field artillery brigade; (*c*) 1 foot artillery regiment; (*d*) 1 engineer battalion; (*e*) 1 train battalion. The garde-du-corps has, in addition, two railway battalions, 1 instruction infantry battalion (Lehrbataillon), &c. The several field artillery brigades are not uniformly constituted, but in 12 of the 18 army corps the brigade consists of 2 artillery regiments. One of these with 8 batteries is attached to the division, while the other remains under the orders of the corps commander. This latter consists of 2 sections (Abtheilungen) of 3 batteries each, and a mounted division of 3 batteries. Each battery has as a rule 4 guns. A foot artillery regiment has 2 battalions of 4 companies each. There are in all 36 field artillery regiments with 301 batteries and 1206 guns, and 13 foot artillery regiments. In war time several corps are combined as "armies," the entire military force consisting then of the field or battle army, the reserve or supplementary troops (Ersatztruppen), and the garrison troops (Besatzungstruppen).

The following tables exhibit the strength of the German army on a peace footing and on a war footing respectively.

There are other 25,975 men who are not included in the latter sum-total but whose cost is defrayed by army grants. They include 4653 physicians, 838 veterinary surgeons, 1600 paymasters, &c. Nor does the table take account of the troops of the field reserve and of the landsturm, regarding the organization of which no details have been published; the former, which is drawn from the landwehr, is estimated at 250,000 men. It is calculated that Germany may put in arms at any given time two millions and a half of armed men without having recourse to the last reserves. The maximum strength of the army in the war with France was 1,350,787 men and 263,753 horses.

Fortresses.—Since the Franco-German war the fortress system has been entirely remodelled. A number of old and useless fortresses have been dismantled; several new ones have been erected along the sea-coast; and most of those flanking the land frontiers have been enlarged. The empire is divided into nine fortress districts, each including a certain number of fortified places. The Baltic coast fortresses are Memel, Pillau, Dantzic (first-class fortress), Colberg, Swinemünde, Stralsund, Travemünde, Kiel, Friedrichsort, Sonderburg-Düppel. On the North Sea are Wilhelmshaven and the fortresses by which the mouths of the Elbe, Weser, and Ems are guarded. The eastern frontier is protected by the first-class fortresses of Königsberg, Dantzic, Thorn, and Posen; and by the secondary ones of Marienburg and Dirschau on the Vistula, and of Glogau on the Oder, which are especially intended for the protection of the railways. For the southern frontier there exist only the fortresses of Neisse, Glatz, and Königstein on the Elbe. The old inland fortresses have been abolished, except the first-class ones of Küstrin, Magdeburg, Spandau, and (for railway protection) Torgau on the Elbe. Ulm and Ingolstadt on the Danube, both first-class fortresses, are also maintained. On the western frontier Strasburg and Metz have been fortified by a wide range of outer fortifications, and there is besides an outer line of smaller fortified places, consisting of New Breisach, Bitsch, Saarlouis, and Thionville. A second line runs along the Rhine, where there are large fortresses serving as encampments at Rastadt, Mainz, Coblentz, and Cologne, and smaller ones for the protection of the Rhine bridges at Germersheim, Ehrenbreitstein opposite Coblentz, Düsseldorf, and Wesel. The empire thus possesses 16 fortified places of the first class serving as camps, and 27 other fortresses.

Navy.—The German navy is but of recent origin. In 1848 the German people urged the construction of a fleet. Money was collected, and a few men-of-war were fitted out; but these were subsequently sold, the German bundestag (federal council) not being in sympathy with the aspirations of the nation. Prussia, however, began laying the foundations of a small navy. To meet the difficulty arising from the want of good harbours in the Baltic, a small extent of territory near Jahde Bay was bought from Oldenburg in 1854, for the purpose of establishing a war-port there. Its construction is now practically completed, although at enormous expense, and it was opened for ships by the emperor in June 1869 under the name of Wilhelmshaven. In 1864 Prussia, by annexing Holstein, obtained possession of the excellent port of Kiel, which has since been strongly fortified. From the time of the formation of the North German confederation the navy has belonged to the common federal interest. Since 1st October 1867 all its ships have carried the same flag,—black, white, red, with the Prussian eagle and the iron cross.

From 1848 to 1868 the increase of the navy was slow. In 1851 it consisted of 51 ships with 188 guns (among which there were, however, 36 small gunboats of 2 guns each), and with 1180 hands in all. In 1868 it consisted of 89 vessels of 563 guns, among which number there were 2 ironclads, and 43 other steamers. Since then a definite plan for the development of the navy has been set on foot, and great activity has been displayed in fitting out ships and in augmenting the personnel.

The following table shows the increase that has occurred in the navy budget since 1868:—

	Ordinary.	Extra-ordinary.		Ordinary.	Extra-ordinary.
	£	£		£	£
1868	851,000	394,000	1874	692,000	1,976,000
1869	885,000	897,000	1875	902,000	454,000
1870	470,000	630,000	1876	1,053,000	238,000
1871	539,000	660,000	1877	1,083,000	1,428,000
1872	886,000	685,000	1878-79	1,205,000	1,729,000
1873	668,000	730,000			

The personnel of the navy consisted in 1878 of 965 officers and 0265 men. There are 2 sailors divisions (Matrosendivisionen) of 79 officers and 6029 seamen and boys, a ship-boys department (Abtheilung) of 400 hands, 2 dockyard divisions (Werftdivisionen) with 148 officers and 1718 men, and 1 battalion of marines with 1035 men. The sailors and marines are levied by conscription from among the seafaring population, which is on this account exempt from service in the army. The total sea-going population of Germany is estimated at 80,000, 48,000 of whom serve in the merchant marine at home, and about 6000 in foreign service. Great inducements to enter the navy are held out to able seamen. The following table gives the state of the navy in August 1878:—

Ships.	Number.	Guns.	Tonnage.	Horse-Power
Armour-clad ships—				
Frigates	7	85	3,400 to 5,900	3,500 to 8,000
Corvettes	3	20	2,400 to 5,000	3,000 to 5,600
Floating batteries	7	12	780 to 1,200	700 to 1,200
Non-armour-clad ships—				
Floating battery	1	23	3,300	3,000
Decked corvettes	11	166	1,700 to 2,800	1,500 to 4,800
Corvettes	7	62	1,000 to 1,600	800 to 2,400
Despatch vessels	5	6	330 to 1,500	350 to 3,000
Gunboats	12	30	600 to 1,200	600 to 1,100
Torpedo ships	11	...	24 to 900	80 to 2,300
Transport steamer	1	...	425	320
Sailing vessels	4	28	2,800	...
Total	70	399	91,500	110,000

Religion.

In the official census it has been usual to return the religious creed of the inhabitants, though a few states, such as Prussia and Hamburg, omitted this particular in 1875. Official estimates indeed have been made of the religious profession of the people in these states for 1875 also, but only the census of 1867 and that of 1871 can be accurately compared. The number of persons styling themselves of no religion, or refusing to state their religion, is very small. The following table gives the results of the three last enumerations:—

Creeds.	1867 Census.	1871 Census.	1875. Partly estimated.
Protestants	24,921,000	25,581,623	26,718,823
Roman Catholics	14,564,000	14,867,600	15,371,227
Dissenters	117,000	82,156	100,608
Jews	499,000	512,160	520,575
Other creeds	6,000	176	16,127
Religion not stated		16,980	
Total	40,107,000	41,058,722	42,727,360

Almost two-thirds of the population belong to the Evangelical Church, and rather more than a third to the Church of Rome. The dissenters are very inferior in numbers, amounting to only about 100,000 souls, but the Jewish element, represented by half a million ($1\frac{1}{4}$ per cent.), is more considerable than in any other state of West, North, or South Europe. The following table gives the proportion of Protestants, Catholics, and Jews in every 1000 inhabitants:—

	Rate to 1000 Inhabitants.		
	Protestants.	Catholics.	Jews.
1867	621	363	12·4
1871	623	362	12·5
1875	625	360	12·2

The Protestants have increased in number by 0·4 per cent. of the population since 1867. This increase, however, must not be attributed to conversions, but rather to the greater increase of population in the Protestant provinces of Germany as compared with the Catholic ones; though at the same time the official returns of Prussia prove that conversion to the rival communion is much more frequent with Catholics than with Protestants. Three states in Germany have a decidedly predominant Catholic population, viz., Alsace-Lorraine, Bavaria, and Baden; and in four states the Protestant element prevails, but with 23 to 33 per cent. of Catholics, viz., Prussia, Würtemberg, Hesse, and Oldenburg. In Saxony and eighteen minor states the Catholics number only from 1 to 3·3 per cent. of the population. The following table gives the respective numbers of Protestants and Catholics according to the census of 1871:—

States.	Protestants.	Roman Catholics.	Rate per 1000 of Population.	
			Prot.	Cath.
Alsace-Lorraine	270,699	1,235,097	175	797
Bavaria	1,342,592	3,464,364	276	712
Baden	491,008	942,560	336	645
Prussia	16,041,215	8,268,309	650	335
Würtemberg	1,248,860	553,542	687	304
Hesse	585,399	238,080	686	279
Oldenburg	240,962	71,027	766	226
Saxony and minor states	5,360,808	94,621	978	17
Total	25,581,623	14,867,600	623	362

From the above figures little can be inferred as to the geographical distribution of the two confessions. On this point it must be borne in mind that the population of the larger towns, on account of the greater mobility of the population since the introduction of railways and the abolition of restrictions upon free settlement, has become more mixed,—Berlin, Leipsic, Hamburg, &c., showing proportionally more Catholics, and Cologne, Frankfort, Munich, &c., more Protestants than formerly. Otherwise the geographical limits of the confessions have been but little altered since the Thirty Years' War. In the mixed territories those places which formerly belonged to Catholic princes are Catholic still, and *vice versa.* Hence a religious map of South Germany looks like an historical map of the 17th century. The number of localities where the two confessions exist side by side is small. Generally speaking, South Germany is predominantly Catholic. Some districts along the Danube (province of Bavaria, Upper Palatinate, Swabia), in southern Würtemberg and Baden, and in Alsace-Lorraine are entirely so. These territories are bordered by a broad stretch of country on the north, where Protestantism has maintained its hold since the time of the Reformation, including Baireuth or eastern Upper Franconia, Middle Franconia, the northern half of Würtemberg and Baden, with Hesse and the Palatinate. Here the average proportion of Protestants to Catholics is two to one. The basin of the Main is again Catholic from Bamberg to Aschaffenburg (western Upper Franconia and Lower Franconia). In Prussia the western and south-eastern provinces are mostly Catholic, especially the Rhine-province, together with the government districts of Münster and Arnsberg. The territories of the former principality of Cleves and of the countship of Mark (comprising very nearly the basin of the Ruhr), which went to Brandenburg in 1609, must, however, be excepted. North of Münster, Catholicism is still prevalent in the territory of the former bishopric of Osnabrück. In the east, East Prussia (Ermland excepted) is purely Protestant. Catholicism was predominant a hundred years ago in all the frontier provinces acquired by Prussia in the days of Frederick the Great, but since then the German immigrants have widely propagated the Protestant faith in these districts. A prevailingly Catholic population is still found in the district of Oppeln (89 per cent.) and the countship of Glatz, in the province of Posen (64 per cent.), in the Polish-speaking "circles" of West Prussia, and in Ermland (East Prussia). In all the remaining territory the Catholic creed is professed only in the Eichsfeld on the southern border of the province of Hanover, and around Hildesheim.

Protestant Church.—The adherents of Protestantism are divided by their confessions into Reformed and Lutheran. To unite these the "church union" has been introduced in several Protestant states, as for example in Prussia and Nassau in 1817, in the Palatinate in 1818, and in Baden in 1822. Since 1817 the distinction has accordingly been ignored in Prussia, and Christians are there enumerated only as Evangelical or Catholic. The union, however, has not remained wholly unopposed,—a section of the more rigid Lutherans who separated themselves from the state church being now known as Old Lutherans. In 1866 Prussia annexed Hanover and Schleswig-Holstein, where the Protestants were Lutherans, and Hesse, where the Reformed Church had the preponderance. The inhabitants of these countries opposed the introduction of the union, but could not prevent their being subordinated to the Prussian oberkirchenrath (high church-council), the supreme court of the state church. Subsequently the official returns have been thus classified:—

	1875.
(*a*) Members of the Evangelical State Church	16,636,990
United 13,266,620	
Lutherans 2,905,250	
Reformed 465,120	
(*b*) Separatist Lutherans (Old L.)	40,630
(*c*) Separatist Reformed	35,080

The separatists are thus not numbered among dissenters. A synodal constitution for the Evangelical State Church was introduced in Prussia in 1875. The oberkirchenrath retains the right of supreme management. The ecclesistical affairs of the separate provinces are directed by consistorial boards. The parishes (*pfarreien*) are grouped into dioceses (*sprengel*), presided over by superintendents, who are subordinate to the superintendent-general of the province. Prussia has sixteen superintendents-general. The ecclesiastical administration is similarly regulated in the other countries of the Protestant creed. Regarding the number of churches and chapels Germany has no exact statistics, but in 1867 it was estimated that there were 12,959 places of worship in Prussia.

Roman Catholic Church.—There are six archbishoprics within the German empire:—Breslau (where the archbishop has the title of prince-bishop), Gnesen-Posen, Cologne, Freiburg (Baden), Munich-Freising, and Bamberg. The eighteen bishoprics are—Ermland (see at Frauenburg, East Prussia), Kulm (see at Pelplin, West Prussia), Fulda, Hildesheim, Osnabrück, Paderborn, Münster, Limburg, Treves, Metz, Strasburg, Spires, Würzburg, Ratisbon, Passau, Eichstädt, Augsburg, Rottenburg (Würtemberg). An apostolic vicariate exists in Dresden. In recent years numerous convents, especially in Prussia, have been suppressed. The order of the Jesuits is interdicted in Germany.

Old Catholics.—After the infallibility of the pope had been proclaimed as a dogma by the Vatican council in 1871, several communities as well as individuals declared their secession from the Roman Church. They are called Old Catholics, and they have selected a bishop who has been acknowledged by most of the states. At the 1st of January 1877 the denomination had 121 congregations with 56 clergymen and 16,557 adult male adherents, so that we may fairly estimate the total number of Old Catholics at a little more than 50,000.

The number of Greek Catholics was 2660 in 1871.

Dissenters.—There is no uniformity in the state returns of the several denominations, and detailed statements are wanting for Würtemberg, Alsace-Lorraine, and eight of the lesser states. In the sixteen remaining states there were in 1875 21,000 Mennonites (particularly in East and West Prussia and the Palatinate), 10,451 Baptists, 3000 Irvingites, 4000 Herrnhuter (Moravian brethren), and 1600 members of the Church of England. The Mennonites had increased from 14,000 in 1871. Besides these there were about 6800 German Catholics, 3600 Freethinkers, and more than twenty-five sects represented by from 100 to 500 members.

Jews.—It is in the towns that the Jewish element is chiefly to be found. They belong principally to the mercantile class, and are to a very large extent dealers in money. Within the last thirty years their wealth has grown to an extraordinary degree. They are increasingly numerous in Hamburg, Berlin, Frankfort, Breslau, Königsberg, and Fürth. Though still, in fact at least, if not also by law, excluded from many public offices, especially from commands in the army, they nevertheless are very powerful in Germany, the press being for the most part in their hands. Some towns of the Marienwerder and Posen districts contain from 20 to 30 per cent. of Jews. By far the greater number are found among the Slavs in the east; in the west they appear chiefly in Hesse, Baden, and Alsace.

Languages.

The German-speaking nations in their various branches and dialects are found to extend in a compact mass along the shores of the Baltic and of the North Sea, from Memel in the east to a point between Gravelines and Calais near the Straits of Dover. On this northern line the Germans come in contact with the Danes who inhabit the northern parts of Schleswig within the limits of the German empire. A line from opposite Sonderburg in the isle of Alsen to Tondern in the west will nearly form the boundary between the two idioms. The German-French frontier traverses Belgium from west to east, touching the towns of St Omer, Courtrai, and Maastricht. Near Eupen, south of Aix-la-Chapelle, it turns southward, and near Arlon south-east as far as the crest of the Vosges mountains, which it follows up to Belfort, traversing there the watershed of the Rhine and the Doubs. In the Swiss territory the line of demarcation passes through Biel, Freiburg, Saanen, Leuk, and Monte Rosa. In the south the Germans come into contact with Rhæto-Romans and Italians, the former inhabiting the valley of the Vorder-Rhein and the Engadine, while the latter have settled on the southern slopes of the Alps, and are continually advancing up the valley of the Adige. Carinthia and Styria are inhabited by German people, except the valley of the Drave towards Klagenfurt. Their eastern neighbours there are first the Magyars, then the northern Slavs and the Poles. The whole eastern frontier is very much broken, and cannot be described in a few words. Besides detached German colonies in Hungary, the western parts of that country are held by Germans. The river March is the frontier north of the Danube from Presburg as far as Brünn, to the north of which the German regions begin near Olmütz,—the interior of Bohemia and Moravia being occupied by Czechs and Moravians. In the Prussian provinces of Silesia and Posen the eastern parts are mixed territories, the German language progressing slowly among the Poles. In Bromberg and Thorn, in the valley of the Vistula, German is prevalent. In West Prussia some parts of the interior, and in East Prussia a small region along the Russian frontier, are occupied by Poles (Kassubians in West Prussia, Masurians in East Prussia). The German tongue is also fast invading the Lithuanian territory, and in a short time no people speaking that idiom will be found to the left of the river Memel. The total number of German-speaking people, within the boundaries wherein they constitute the compact mass of the population, may be estimated, if the Dutch and the Flemings be included, at 56 millions.

The geographical limits of the German language thus do not quite coincide with the German frontiers. The empire contains about 3⅓ millions of persons who do not make use of German in everyday life, not counting the 290,000 resident foreigners. The non-German languages have their representatives only in Prussia, Saxony, and Alsace-Lorraine. No census since 1861 has given the statistics of the different languages spoken in the first-mentioned country; and, in regard to Alsace-Lorraine also, the figures are based upon estimates only. The following table gives the results of semi-official estimates for 1875:—

Languages.	Persons.	Proportion to 1000 Persons.
German	39,100,000	921
Polish	2,600,000	66
Wendic	140,000	
Czech	50,000	
Lithuanian	150,000	4
Danish	150,000	4
French	250,000	6
Total—Natives	42,440,000	
Foreigners	290,000	

From this it will be observed that the Poles form a considerable part of the population,—about 60·1 per cent. in the district of Oppeln, 59·3 in Posen, 49·6 in Bromberg, 37·8 in Marienwerder, 27·3 in Dantzic, 21·9 in Gumbinnen, 17·1 in Königsberg, and 4·3 in Breslau. The Wends, who inhabit Lusatia, are decreasing in number,—in the Saxon district there were 52,097 in 1871, and in 1875 only 50,737. The Lithuanians are likewise diminishing on the eastern border of East Prussia. Czechs are found only in Silesia on the confines of Bohemia. The French are represented in Lorraine and Upper Alsace, and on the Belgian frontier.

Education.

In point of intellectual culture Germany ranks high. Much is done by the Government for the promotion both of primary and of secondary education; there are no exact statistics, however, of the educational establishments, or of the expenditure incurred in connexion with them. In regard to the latter the sums which figure in the Government budgets are not the only contributions which must be considered; for in most of the states the several local communities provide from their own resources for primary instruction and for many of the higher schools, while many of the superior institutes have funds of their own not included in the budget. School instruction is obligatory on the whole people, but in many districts there is still a scarcity of teachers and some want of efficient control. The total number of primary schools is estimated at 60,000, and that of pupils at 6,500,000, or 150 pupils to every 1000 inhabitants. Some provinces exhibit a larger proportion; in Saxony, Thuringia, Brunswick, Rhineland; and Westphalia there are from 165 to 175 pupils to every 1000 inhabitants. In Bavaria, Posen, East and West Prussia, Brandenburg, on the other hand, there are only from 120 to 130. A good criterion of the school instruction is to be found in the statistics of the annual levies of recruits. The following table shows the number of recruits during the years 1876–78 who were unable to read and write:—

	Number of levied Recruits able to write and read.		Number of levied Recruits unable to write and read.	
	In German Language.	In other Languages only.	Number.	Rate to 10,000 Recruits.
1875–76	130,176	6,368	3,311	237
1876–77	130,939	6,283	2,975	212
1877–78	134,189	6,292	2,476	173

It will be seen from the above that the number of illiterate recruits has considerably decreased during the last three years. The figures given compare very favourably with those of other European countries. In 1872 the number of illiterates was 4·6 per cent. in the army, and 2·3 in the navy the corresponding numbers in France being 23 and 14 per cent. In England 23 per cent. of the marines could neither read nor write in 1865, 4 per cent. could only read, and 37 per cent. could write but imperfectly. In Austria only 28 per cent. of the recruits could write, and in Russia scarcely 10 per cent. had any school education. But the provinces of Germany differ much from one another in this respect. Education is very inferior in the eastern Polish districts. During the three years from 1875-78 in the districts of Posen, Bromberg, and Oppeln there were in all 10·7, 9·24, 8·02 per cent. of illiterates among the recruits, in the provinces of West and East Prussia 8·77, 8·66, 7·80. After these the rate takes a long leap to 3·18, 3·17, 1·94 in Alsace-Lorraine and the Palatinate. In 1877-78 there was no considerable district in Germany which sent so many as 1 per cent. of illiterates. The most satisfactory state of matters is to be found in Saxony, Thuringia, Baden, and Würtemberg, and especially in the last two. Würtemberg had only one recruit among 6000 that was unable to read.

The census in Prussia in 1871 proves primary school instruction to be much better among the Protestants than among the Catholics, as will be seen in the following table:—

Illiterates of 10 Years and under.	Males.	Females.	Percentage of corresponding Population.		
			Males.	Fem.	Total.
Protestants	390,117	693,400	4·9	8·3	6·7
Catholics	464,755	685,535	11·3	16·4	13·2
Jews..................	7,976	15,648	4·9	9·4	7·2
Others	995	2,846	3·7	9·4	5·2
Total......	863,843	1,396,434	7·1	11·1	9·2

Unremitting attention is being paid to the improvement of primary schools (*volksschulen*), although many of the eastern districts are still destitute of these in the rural localities. Not long ago the position of teachers of primary schools was very unsatisfactory; and the supply of masters was unequal to the demand. In recent years much has been done in all the states to effect a reform on this state of matters. In 1875 there were 170 seminaries in Germany for the training of schoolmasters. But this number is insufficient, for it may be estimated that 5000 to 6000 new appointments are required annually, if one master is not to have charge of more than 60 children. Saxony has the greatest number of institutions of this kind (15). Within the last few years many municipalities have begun to found schools of a somewhat higher rank for the lower classes of the town population, called middle schools.

There are four different kinds of schools for the higher branches of education. The gymnasia supply preparatory training for the universities, the foremost place in the course of instruction being assigned to the classical languages; but French, English, and mathematics are also taught, and some attention is given to natural science, history, and geography. Their constitution dates back to very remote times, and but few and slight alterations have been made in their schemes of study since the beginning of the present century. Officials, judges, clergymen, teachers, and physicians for the most part receive their early education at the gymnasia. In 1878 there were 360 gymnasia in Germany, or 1 for every 600 square miles and every 117,000 inhabitants. Central Germany has the largest proportion, 1 for every 75,000 inhabitants. To these must be added the progymnasia, about 90 in number. The same studies are prosecuted in these, but the highest classes of a gymnasium are wanting. Of more recent growth is the system of *realschulen*, where Latin is the only ancient language taught, the other branches being modern languages, especially French and English, mathematics and natural philosophy, geography, and modern history. These schools have long enjoyed great popularity. They are classified as of the first and of the second order. In the former a pupil remains generally for nine or ten years, as in the gymnasia; and those who pass the highest examination are allowed to enter the universities, but only to study the modern languages, mathematics, and natural sciences. In 1878 there were 129 realschulen of the first order, mainly in Saxony, Rhineland, Berlin, and Hanover. The realschulen of the second order prepare pupils for those professions which do not require a university course. On the average a pupil leaves school in the seventeenth year of his age. Besides these institutions, which are increasing every year, there is a considerable number of technical schools (gewerbeschulen). Their purpose is purely industrial; drawing, mechanics, mathematics, physics, and chemistry are among the subjects of instruction, languages being excluded. There are, moreover, schools of commerce, navigation, and agriculture in different towns. The military law relating to the one year's volunteers has had an important influence on the attendance at all these institutions. In 1879 there were 878 schools with the privilege of furnishing pass certificates to such volunteers; of these 360 were gymnasia, 129 were realschulen, and about 40 were private schools. Exact and uniform statistics of the higher schools do not as yet exist. Many of the last-mentioned institutions are maintained partly or entirely at the expense of the municipalities, and by far the greater number are denominational, Protestant ones prevailing. The following table shows the number of Prussian schools in 1875 maintained severally by the Government, by the municipalities, and by other funds:—

Denomination.	Number of Middle Schools in Prussia maintained by		
	Government.	Municipalities.	Private Funds.
Protestant ,......	100	199	16
Mixed	18	38	..
Catholic	43	..	2
Jewish	...	...	2
Total......	161	268	20

Universities and Higher Technical Schools.—Germany owes its large number of universities, and its widely diffused higher education to its former subdivision into many separate states. Only a few of the universities date their existence from the present century; the majority of them are very much older. Each of the larger provinces, except Posen, has at least one university, the entire number at present being 21. All have four faculties except Münster, which has no faculties of law and medicine. As regards theology, Bonn, Breslau, and Tübingen have both a Protestant and a Catholic faculty; Freiburg, Munich, Münster, and Würzburg are exclusively Catholic; and all the rest are Protestant. The following table gives the names of the 21 universities, the dates of their respective foundations, the number of their professors and other teachers, and of the students attending their lectures during the summer session 1878, arranged according to the numbers in attendance:—[1]

[1] The teaching staff was classified as follows: ordinary professors 957, extraordinary professors 403, honorary professors 41, private teachers (privat-docenten) 438, language and exercise masters 39. The following table gives the number of the students in the different faculties for 1878:—

1. Students of Protestant theology 1,738
2. „ Roman Catholic theology 689
3. „ law, politics, and forestry 5,156
4. „ medicine, surgery, and pharmacy 3,727
5. „ philosophy, philology, history, geography, mathematics, and natural science 7,237
6. Unmatriculated students (chiefly at Berlin) 2,280

Universities.	Dates of Foundation.	Number of Professors and Teachers.	Number of Students.
1. Berlin, Prussia	1810	215	4,331
2. Leipsic, Saxony	1409	160	2,948
3. Munich, Bavaria	1826	136	1,396
4. Breslau, Prussia (1702)	1811	106	1,250
5. Tübingen, Würtemberg	1477	88	1,144
6. Bonn, Prussia	1818	100	1,075
7. Gottingen, Prussia	1737	120	1,009
8. Würzburg, Bavaria	1402	66	960
9. Halle, Prussia	1697	107	944
10. Heidelberg, Baden	1386	110	808
11. Strasburg, Alsace-Lorraine	1872	90	736
12. Konigsberg, Prussia	1544	89	671
13. Jena, Thuringian states	1558	78	570
14. Greifswald, Prussia	1456	61	534
15. Marburg, Prussia	1527	71	458
16. Freiburg, Baden	1457	57	454
17. Erlangen, Bavaria	1743	64	415
18. Giessen, Hesse	1607	55	347
19. Münster, Prussia	1780	30	332
20. Kiel, Prussia	1665	69	264
21. Rostock, Mecklenburg	1419	41	157
Total		1,913	20,826

A number of technical high schools rank along with the universities; they all took their rise in the course of the present century, and usually bear the name of Polytechnicum. To the number of these belong the academies of industry (founded 1821) and of architecture (1798) in Berlin, and the polytechnica at Hanover, Brunswick, Aix-la-Chapelle, Darmstadt, Carlsruhe, Stuttgart, Munich, and Dresden.

Among the remaining higher technical schools may be mentioned the mining academies of Freiberg in Saxony, of Berlin, and of Clausthal in the Harz, and the academies of forestry at Neustadt-Eberswalde, Münden on the Weser, Tharand near Dresden, and Hohenheim near Stuttgart, and at Brunswick, Eisenach, Giessen, and Carlsruhe. Schools of agriculture have also been attached to several universities, the most important being at Berlin, Halle, Göttingen, Königsberg, Jena, Poppelsdorf near Bonn, Munich, and Leipsic.

Libraries.—Mental culture and a general diffusion of knowledge are extensively promoted by means of numerous public libraries established in the capitals, the university towns, and other places. The most celebrated public libraries are those of Berlin (800,000 volumes), Munich (800,000 volumes and 22,000 manuscripts), Göttingen, Dresden, Stuttgart, Hamburg, Strasburg, Frankfort-on-the-Main, Breslau, Gotha, and Wolfenbüttel.

Societies.—There are also numerous societies and unions, some being of an exclusively scientific character, and others being designed for the popular diffusion of useful knowledge. The academies of science in Berlin, Munich, Göttingen, and Leipsic are Government institutions. Ample provision is made for scientific collections of all kinds in almost all places of any importance, either at the public expense or through private munificence.

Observatories.—These have in recent years been considerably augmented. There are 22 observatories in the empire, viz., at Altona, Berlin, Bonn, Bothkamp in Schleswig, Breslau, Dantzic, Düsseldorf, Gotha, Göttingen, Hamburg, Kiel, Königsberg, Leipsic, Lübeck, Mannheim, Marburg, Munich, Potsdam, Schwerin, Spires, Strasburg, and Wilhelmshaven.

Book Trade.—This branch of industry, from the important position it has gradually acquired since the time of the Reformation, is to be regarded as at once a cause and a result of the mental culture of Germany. Leipsic is the centre of the trade. The number of booksellers in Germany was not less than 5196 in 1878, among whom were 1546 publishers. The following table will show the recent progress of German literary production, and its proportion to that of other European states:—

	Number of Published Works.			
	Germany.	France.	Gt. Britain.	Italy.
1868	10,563	11,267	4,439	4,084
1870	10,058	8,831	5,082	4,318
1872	11,127	10,559	4,812	6,429
1877	13,925			
1878	13,912			

Newspapers.—While in England a few important newspapers have an immense circulation, the newspapers of Germany are much more numerous, but individually command a far more limited sale. Leaving out of account insignificant local papers, Germany in 1878 possessed 600 newspapers published daily, or two to three times a week; of these only 90 were published in South Germany Berlin alone produces 44 newspapers. Most readers receive their newspapers through the post-office or at their clubs, which may help to explain the smaller number of copies sold. Only 50 of the 600 daily newspapers print more than 10,000 copies, and only 20 more than 20,000.

Fine Arts.—There are many academies which have for their object the promotion of a taste for painting, sculpture, architecture, and music, and the improvement of the technique of art. The largest academy is now that of Berlin. The three schools of painting (*malerschulen*) are represented by the academies of Berlin, Munich, and Düsseldorf. Other academies for painting are to be found in Dresden, Carlsruhe, Weimar, and Königsberg. The chief musical academy is at Leipsic. Numerous museums of art and collections of pictures exist in the country, but there is no concentration of these as in London or Paris. Although the collections in Berlin have of late years been considerably enriched, they do not equal in their number of celebrated originals the galleries of Dresden, Munich, and Cassel. An archæological institute is maintained by the imperial Government at Rome and at Athens, and recently Germany has done much for the advancement of archæology by the part she has taken in the excavations at Olympia.

Bibliography.

Maps.—The topographical maps of Prussia and of some North German states (scale 1:100,000) are not yet quite completed. The South German states have for the greater part finished their topographical maps, scale 1:50,000. Other good special maps, though not quite completed, are—the maps of Central Europe by Reymann (1:200,000) and by Liebenow (1:300,000), and of Germany by Stieler (1:750,000) and by Ravenstein (1:800,000).

Physical Geography.—There is still wanting a sufficiently detailed work on the physical geography of Germany as a whole, although there are some excellent descriptions of the separate provinces. For general information we may mention—Cotta, *Deutschland's Boden*, 2 vols., 1853; Daniel, *Deutschland*, 1878; Kutzen, *Das deutsche Land*; Von Klöden, *Geographisches Handbuch*, vol. ii., 1875; Neumann, *Das deutsche Reich*, 2 vols., 1874; Peschel and Andree, *Atlas der deutschen Reiches*, 2 parts, 1876-78.

Statistics.—Since the year 1871 there has been established in Berlin an imperial office for statistics which does excellent work. Most of the figures in the foregoing article have been derived from these official returns. From 1871 to 1878 the same office has published 30 volumes in 4to, under the title of *Statistik des deutschen Reiches und Monatshefte der Statistik des deutschen Reiches.* But the returns do not give statistics under all the heads in which the separate states collect them. Much valuable geographical, statistical, and topographical information is given in Neumann's *Das deutsche Reich.* The most recent summaries are to be found year by year in the *Almanach de Gotha.*

Topography.—Rudolph's *Vollständiges Ortslexicon von Deutschland*, 2 vols. 1870, is exact and very ample. The separate states have published lists of all places (towns, villages, hamlets, farms), according to the census of 1871. *Das Reichs-Postgebiet*, issued by the General Post-Office, 1878, containing about 7000 places, exclusive of Würtemberg and Bavaria, forms an excellent topographical and statistical handbook. (H. WA.)

PART II.—HISTORY OF GERMANY.

Authentic history carries us no farther back toward the origin of the Germans than to a period but a short time before the beginning of the Christian era. It is true Herodotus, in the Fifth century B.C., mentions a tribe of Persian Germanii, but the traveled Greek merely refers to them as an aggregation of barbarians and leaves them. The terrible hordes of Cimbri and Teutones who, toward the close of the second century B.C., burst out of their northern forests and precipitated themselves upon Roman territory, left behind them no other record than the ravaged fields of Italy and Gaul, and the decaying heaps of their own slain in the vast slaughters of Aquæ Sextiæ and Vercellæ.

Until the time of Julius Cæsar — a marvelously acute observer in the interest of his own ambition — Germany to the then civilized European world remained a terra-incognita and the fierce blue-eyed Germans a dreaded but unstoried race.

Modern linguistic research, however, has in some slight degree drawn aside the curtain of obscurity and revealed a few details of their primitive life at a time far antedating all purely historical statement. By the philologers and ethnologists of the present day the Germans are classed with that branch of the Aryan stock designated *Yavana*, or "Young Ones." They are thus distinguished from their kinsmen who, retaining the title *Aryan*, subsequently conquered India.

Perhaps not less than three thousand years B.C. the Aryan or Indo-European division of the human family were concentrated not far from the district in Central Asia to which the traditions of the white race point as the source from whence issued its various tribes. The *Yavana*, by whom Europe was subsequently peopled, occupied the western part of Bactria. To the southwest were the Pelasgic tribes, the ancestors of the Greeks and Latins, whose advanced guard, the Celts, are supposed to have first moved westward, taking the route south of the Caspian and thence through the defiles of the Caucasus into Europe.

The tribes from whom are descended the Germans inhabited the country south of the Oxus. At an early period these two great races crossed the Oxus and spread themselves over the plains of Scythia to the north. Here they probably remained for many centuries before receiving the impulse which carried them into Europe.

In this remote age their life was chiefly pastoral, although they had some knowledge of agriculture. They possessed horses, oxen, sheep, pigs, goats, dogs, and other domestic animals. Oxen and horses were placed in the yoke, and were also harnessed to wheeled vehicles, but there is no evidence that these nomads were acquainted with the art of riding on the backs of horses. Gold, silver and bronze were known to them, but the race had not yet become iron-workers, and their knowledge of working the precious metals extended no farther than the manufacture of rude jewelry in the form of necklaces and rings. Their weapons were lances, javelins and arrows, and for defense the buckler or shield was generally in use. Of the sword they seem to have been ignorant. Unlike the Scythians, who lived in wagons, and both the ancient and modern Arabs of the desert, with whom the tent has always been a favorite abode, they knew how to build fixed habitations, which enclosed the family hearth and were provided with doors and roofs. Their food consisted mainly of grain ground into flour and the flesh of animals, and they employed salt as a condiment. They had also learned to construct small vessels for service on the water. These boats were propelled by paddles or oars, for they had not yet reached a knowledge of the use of masts and sails. The periodical revolutions of the moon furnished them with an imperfect standard of time measurement, and they were acquainted with the decimal scheme of numeration.

The basis of all social organization was the family. Marriage was a consecration and was preceded by betrothal. After the marriage, which was celebrated by the joining of hands and the pronouncing of a certain formula, the father of the bride presented a cow to his son-in-law, and the wife was conducted to the abode of her husband, where she was received with a present of fire and water. In her new home, while subject to the authority of her husband, which was supreme, she was treated with affection and respect. The birth of a male child was welcomed as the coming of one who gives joy, and the tenderness lavished on the son was extended to the daughter.

Naturally the union of families descended from the same stock produced the tribe, at whose head was the patriarch, or chief. From collision with hostile aliens and strife among themselves the art of war sprang up, and the foreign prisoner became a slave. It is probable that the Liti, or freedmen, who appear in the political organization of the Germanic race in Europe in later days, were the descendants of prisoners of their own race taken in the wars among themselves. The head of the tribe administered justice, but in doubtful cases the decision was referred to the judgment of God. This was the origin of the ordeal, which was in use among the Germans down to the beginning of the middle ages. There were two forms of the ordeal by fire. In one the accused was made to pass through a trench filled with live coals, and if not burned he was declared innocent. In the other, he was compelled to carry a redhot lance-head or ball of metal a certain distance, and without injury to himself, or suffer the penalty of guilt. In the judgment by water, a ring was thrown into boiling water and the accused was required to take it out without being scalded; or he was thrown into a pond of cold water, and if he floated without effort he was decided to be guilty. Both forms of the ordeal by water were practiced by the Germans in the time of the Merovingian kings.

The primitive religion of the Germans, as well as that of the other Indo-European peoples, was founded on a belief that everything proceeded from one God. By contact with other races this purity of religious faith was tainted with the polytheism which appears in their mythology on their introduction to the Roman power. It is probable also that they were led to personify the forces of nature as presented in the sun, the moon, the winds, the clouds, lightning, thunder and rain, the unexplanable growth of vegetation, the apparent conflict between day and night, and other natural phenomena. And as they saw these forces seemingly engaged in strife, they easily fell into a belief in the existence of the two principles of good and evil forever warring the one with the other.

Various external forms of worship existed, chief among which was sacrifice. On ordinary occasions the oblation offered consisted of pastoral products, such as curdled milk or butter, with grains of barley, and when in solemn ceremonies blood was required, victims were taken from the flocks, but the highest offering was that of the horse, the noblest of all the domestic animals. It does not appear that in this early age human beings were offered in sacrifice.

Such, in brief, is the imperfect presentation made by modern research of the condition of the Germanic and kindred tribes prior to their final dispersion. Through what lapses of time they remained on the Asiatic side of the Ural, whether they migrated to the west in a body, or as to what cause impelled them to forsake their cradle-land, neither history nor tradition furnishes a clew. Possibly their own increase, which necessitated the occupation of a greater area for the sustenance of their flocks and herds, the pressure of the Turanian populations to the eastward, and the restless, migratory spirit which in historic times has characterized the race, exercised a potent influence in this regard. Certain it is that with the exception of the notice of the *Germanii* by Herodotus and a reference by Pytheas of Massilia (Marseilles) in the time of Alexander the Great to the Teutones and Guthons on the Baltic, there is no direct evidence of their passage across the continent of Europe. An attempt has been made to identify with the Germanic peoples the European Scythians inhabiting the territory north of the Black Sea, among whom Darius Hystaspes made a campaign in 508–506 B. C., but the testimony is insufficient to furnish a safe foundation for anything stronger than conjecture.

German tribes in Europe.

Our knowledge of the geographical distribution and the social and political condition of the Germanic tribes when they first appeared on the European stage is derived mainly from the statements of Julius Cæsar, Pliny, Diodorus Siculus, Strabo, Ptolemy, Tacitus and other Roman writers of lesser note. The Germans in their then state of barbarism had no literature, and, beyond their traditions, which were communicated orally by father to son, there could be no record except that of the more civilized nations with whom they came in contact.

Ethnologists are agreed that the Scandinavians and the Germans are closely related, and that at the time of their migration from Asia into Europe they formed one people, but when the separation occurred and what caused it are points which have thus far eluded modern investigation

As to the name *German*, various accounts are given. Cæsar calls them *Germanen*, a valiant or warlike people, probably from *ger*, a spear or lance. According to other authorities the aboriginal name by which they designated themselves was *Deutsch*, from the word *Diot* (in the Gothic, *Thiudu*), which means *Nation*. This title, however, is found in very few records before the ninth century A. D. By other writers the name is said to signify *neighbors*, or *shouters*.

The earliest account we have of the location of the race in Germany is that of Pliny, who places the *Windilli* (Vandals, and probably including the Goths) about the estuary of the Vistula. To the westward, as far as the mouth of the Ems, was the country of the *Ingavonians*. The *Istavonians* had their seat in the neighborhood of the Rhine, extending to the Maine, and in the middle of Germany were the *Hermionians*. In the districts of the lower Danube, as far as Dacia, Pliny locates the *Peucinians* and Basiarnians. Tacitus, receiving his information mainly from the Germans, mentions three of these names—the Ingævones, who bordered on the northern sea coast; the Hermiones, who inhabited the midland country, and the Istavones, who were spread along the Rhine and its tributaries. These people, by their own account, were descended from the god Tuisco, who was born of the Earth and Man, or Mannus, his son (compare Mannus with the Chaldean *Manes* of Berosus and the Egyptian *Menes* of Manetho.)

Of the Saxon tribes, the *Sigambri* inhabited the country in the neighborhood of the Sieg and farther inward toward the mountains of Westphalia. They were among the first who felt the power of the Romans and were scattered. Those of them who remained around their original home are supposed to have been the ancestors of the Salian Franks who were the leaders in the Frankish confederation. The *Usipeti* and the *Tencteri* occupied in Cæsar's time the district between the Maine, the Rhine and the Lahn. The *Bructeri*, a powerful tribe, dwelt in the country north of the Lippe, and probably occupied part of the territory south of that river. Possibly they derived their name from the marshes (bruchen) included within their territorial limits. It appears that the *Marsi* were a Westphalian tribe, located not far from the Rhine, though there is some dispute on this point. The *Tubanti*, who were neighbors of the Bructeri, are placed by some authors in the vicinity of the present Paderborni and by others to the northwest of the Rhine. Southward of the Tubanti were the *Chamavi*. North of the Bructeri lived the *Ansibari*, and the *Chasuari* and *Chattuari* lay north of the Marsi. In the neighborhood of the Weser were the *Dulgibini*, who appear to have belonged to the confederation of the *Cherusci*, from whom sprang the great German liberator Arminius, or Hermann. The extent of the domain of the Cherusci, who were a noted tribe, cannot be definitely stated, but approximately it included the area reaching from the Saale and the Elbe northward to the Aller, westward to the Weser and southward to the Thuringian forest. The *Fosi*, who had their seat in the Brunswick of the present day, were confederates of the Cherusci. The *Chauci* dwelt in the low country on the Baltic, from the estuary of the Ems to the Elbe, and the *Angrivari*, their allies, were settled on both sides of the Weser below Minden. On the Atlantic coast north of the mouths of the Rhine and eastward towards Denmark were the *Frisii*, who joined in the invasion of England with the Angles, Saxons, and Jutes in the fifth century of our era. The Cimbri, who subsequently formed part of the host which first of the German tribes invaded Italy, were found in the present Jutland, still called the Cimbrian peninsula. The warlike *Chatti*, who were in frequent conflict with the Romans, were spread over the territory extending from Hanau to the Thuringian forest, to the southwest as far as the Franconian Saale, thence in a northerly direction to the country about the junction of the Werra and the Fulda, and northwest to the heights of the Wester forest. At a later period the Chatti joined the confederation of the Franks. In the present Nassau were located the *Mattiaci*, who were conquered at an early date by the Romans.

Of the Suevic tribes, the Semnones are placed between the Elbe and the Oder and as far south as the frontier of Bohemia. The Longobardi (Lombards) were first known in the tract lying westward of the middle Elbe, from whence they spread to the eastward of that river and to the west as far as the Rhine, overrunning the *Cherusci*, the *Tubanti* and the *Marsi*. The popular tradition in regard to the origin of the name *Lombard*, is that when the tribe were about to start south to find a new home, they prayed to Frigga, the wife of Woden, for good speed in their quest. The Goddess bade them stand forth in the rising sun, which they did with their long hair let down over their faces. "Who are these longbeards?" asked Woden. "Thou hast given them a name," said Frigga, and they were henceforth called *Longbeards* or *Lombards*. On the authority of some writers, they derived their name from their halberds, and by other authorities it is claimed that they received it from the *long borde*, or fruitful plain which they occupied on the Elbe. To the north of the Longobardi, in the present Lauenburg, Mecklenburg, and Pomerania, dwelt, according to Tacitus, a number of Suevic tribes, among them the *Varini* and the *Angli*, from the latter of whom is derived the name of England. The *Hermunduri*, a division of the race who frequently changed their locality, were know to Tacitus as friends of the Romans, occupying the territory on the northern shore of the Danube, their domain extending from that river to the Maine, across the present Franconia. From the middle of the second century they appear only under the collective name of *Suevi*, and it is suggested that they are the people who have preserved that name in the appellation of the Swabians. The *Marcomanni*, the most important of the southern Suevic tribes, guarded the boundaries of Germany between the Rhine, the Maine and the

Danube. This tribe furnished two names to history, Ariovistus, who was conquered by Cæsar, and Marboduus, who waged a desperate war with the Slavic Boii in Bohemia and overcame them. In the present Austria and Moravia were located the *Quadi*, whose territory stretched along the Danube as far as the river Grau in Hungary, where they joined the Sarmatian tribe of Jazygi. After their wars with the Romans, of whom they were implacable enemies, the Quadi were merged with the Suevi, among whom in latter times they are mentioned in Spain. In the lower portion of Silesia, eastward from the Riesengebirge, were established the *Marsingi*. The *Lygi* in eastern Silesia and part of Poland, were considered by Tacitus as Suevi, though their manners and mode of life resembled those of their Sarmatian neighbors. They were allied with Marboduus in his campaigns and were subjugated in the third century A.D., by the Roman Emperor Probus. Afterward those who remained in their original seat allied themselves with the Goths. Among the Lygian tribes Tacitus names the Ari (which seems to refer to their Aryan origin), the *Helveconi*, the *Buri* and the *Elysi*. Their home was at the sources of the Oder and the Vistula. The Goths, or Gothones, reckoned by Tacitus among the Suevi, and by Pliny among the Windilli, were placed by Pytheas about 300 B.C., around the estuary of the Vistula. Four hundred years later Tacitus locates them on the Vistula, but no longer extending to the Baltic Sea. Ptolemy, 50 years afterward, places them on the Vistula, but entirely removed from the sea coast. In the third century A.D. they are found far to the south in Dacia, and at this time they are divided into the two great branches, the East and the West Goths. The *Gepidi*, the *Mosogothi* and the *Thervingi*, are named as offshoots of the Gothic stem. Pliny places the Burgundians at the head of the Vandals, but Tacitus does not mention them. Ptolemy establishes them in the neighborhood of the Warthe, between the Oder and the Vistula. Driven from this country by the *Gepidi*, they divided and part of them settled in the island of Bornholm, between Denmark and Sweden. The other fragment, after long wanderings, received from Ætius, in the beginning of the fifth century, a dwelling place in south-eastern Gaul, where the name still continues. Of the Gothic family, the *Rugi*, the *Heruli* and other smaller tribes were located on the Baltic. They were allies of Attila in his great invasion of western Europe, and afterward planted themselves in Austria and Hungary. Odoacer, who destroyed the Western Roman Empire, was a chief of the Heruli. West and south of the Rhine, Tacitus places the *Vangioni*, the *Nemeti* and the *Triboci*, who lived in the lands between Bingen and Briesach. The *Ubi*, pressed by the Suevi, crossed the Rhine in the time of Julius Cæsar and were ever afterward the faithful allies of the Romans. Cologne, the birthplace of Agrippina, daughter of Germanicus, and consort of the Emperor Claudius, is in the country west of the Rhine formerly occupied by the Ubi. The *Batavi*, who dwelt in the country about the mouths of the Rhine, were fast friends of the Romans until the revolt of Civilis, in the year 70 A.D., when they turned against their former friends. Other small tribes of the trans-Rhenish territory were the *Treviri* and the *Nervi*.

To an alien, the Roman Tacitus, the Germans are indebted for the best extant account of the character and manner of life of their ancestors. His descriptions of the persons and appearance of the Germanic race entirely agree with those of Cæsar. By the Romans the Germans were considered as an aboriginal, pure and unmixed race of people. They were wide and strong in the chest; the hair of the adults was yellow, and that of the young children was dazzling white. Their skin was white and they had blue eyes, which were bold and piercing. With large powerful bodies, they possessed great strength and agility. The bodies of their youth were hardened by all the means within their reach. Infants were dipped in cold water immediately after birth, and the cold bath was used as a strength renewer by both sexes through life. The dress of the men was a short mantle made of coarse cloth, or the skins of beasts, and notwithstanding the rigor of their winter climate, portions of the body were left uncovered at all seasons. They despised effeminacy, and placed the highest value upon courage and strength. The women were dressed in linen robes spun and woven by themselves and ornamented with a purple band as a girdle. With all their fierceness, the Germans were eminently hospitable. In this regard no distinction was made between a friend and an entire stranger. Their principal vice seems to have been the at times immoderate use of liquor, which habit, together with their practice of carrying arms in all their assemblies, frequently led to scenes of violence. Atonement for homicide was made by a certain number of cattle, and the penalty for injuries was adjusted by a settled measure of compensation. Their beverage was a liquor fermented from barley or wheat, and their food was the flesh of animals, both wild and domestic, coagulated milk and such fruits as grew in their country, and, among the agricultural communities, the products of their farms. They had but few public spectacles; these consisted mainly of dancing by bands of young men among pointed swords and javelins. Funerals among them were conducted with simplicity. The funeral pile was made of wood, the arms of the deceased was committed to the flames with his body, and sometimes his horse was immolated. To adopt the quarrels of relatives was held to be an indispensable duty.

Organization of tribes for war.

Physically there seems to have been a marked difference between the mode of life of the nations characterized as Suevi, who inhabited the highlands in the interior, and those who dwelt in the lowlands near the coast. The Suevi had early banded themselves together in a union, the purposes of which were distinctively those of war and conquest. Their love of arms was assiduously cultivated and they were essentially a race of warriors. Their lands were held in common, and were divided yearly by the leaders among their followers, no one being permitted to retain the same allotment for two consecutive years. This arose from their antipathy to agriculture, which it was believed would destroy the desire for war and glory. War was carried on systematically by a division of the men into hundreds, half of whom each year took the field under their chiefs, while the other half remained at home to superintend the cultivation of the soil. In the following year an exchange of employments was made and the farmers became warriors, while the fighting men of the last year took charge of the fields and flocks. In the lowlands near the coast the tribes had made agriculture a regular occupation, and they lived in settled dwellings. Their farms were marked by boundaries, usually a hedge and a bank of earth. Nobles, freemen, freedmen, or peasants, and slaves composed the body politic of all the divisions of the race. Such legislation as existed was under the control of the nobles and freemen. The freedmen were permitted to bear arms, but they were excluded from participation in legislation and government. The slaves were at the absolute disposal of their masters, and in law were classed with the beasts. Originally the nobles appear to have been selected from among the freemen, because of conspicuous valor or the possession of great wealth in herds and flocks.

The civil organization led from the family, the head of which was lord and priest on his own holding, up to the community, composed of several proprietors, who in turn, bound themselves together in districts under the name of *gau*. The highest body of all was the national assembly, of which every freeman was a member.

In peace, a majority of the tribes had a very simple constitution of confederacy, perhaps not higher than the gau. In war, each tribe elected as chief one of their own number distinguished for courage and wisdom, on whom they bestowed the title of Herzog, or Duke. It has not been ascertained whether the chiefs of tribes or confederations bore the title of king. The leaders of great confederations were called by the Romans *kings* to distinguish them from the dukes, whose authority usually ceased with the close of the war, at the beginning of which they were elected. Frequently an ambitious chief would raise a miscellaneous force for the purpose of conquest. If successful in the acquisition and retention of territory, his followers gave him the title of king. Among the Saxon peoples, whose wars at first were chiefly of a defensive character, a common general was required only while the conflict lasted, while among the Suevi, whose principal business was war, generals with the title of King are found at an early date.

When a common danger threatened, the people formed themselves into a confederation, at the head of which was the most powerful tribe. Examples of this are seen in the Cheruscan alliance against Rome and in the confederations of the Goths, the Franks and the Allemanni. Unless called together by a sudden alarm, the assemblies of the people were held either at the time of the new or full moon. All the members of the assembly took part in the proceedings, and when any proposition not agreeable to them was made, it was rejected with a general murmur of disapprobation. Approval was expressed by brandishing their javelins and by shouts. The punishment for treason or desertion was hanging on a tree, but the coward, or one convicted of an infamous crime, was plunged under a hurdle into a bog and there suffocated.

Among all the ancient Germans was found a strong love of nature. They likened towns to prisons and avoided building them. Their huts were constructed of logs shaped by the ax, the sides being chinked with straw and lime. This structure was covered by a thatched roof and the interior was decorated with earths of brilliant colors. One of the noble characteristics of these early Germans was their proud and independent spirit, which frequently led them to suicide for the purpose of escaping captivity. The favorite occupation of the men was war, and next to war the chase; when not engaged in either, idleness was the rule. Agriculture and the care of the herds and flocks, as well as domestic occupations, were left to the women and slaves. It seemed manlier to attack their enemies than to cultivate the earth and reap the harvests. The youth were practiced in the use of arms from childhood. The sanctity of marriage was maintained among them almost as strictly as it was by their ancestors in Asia. The young man married the maiden of his choice at a time in life when his physical and moral natures had attained their equilibrium, and his wife was usually about his own age. The marriage presents given by the husband to the bride were a horse, a yoke of oxen and arms, the latter signifying that the woman was expected to fight when necessary. The new made wife in return gave her husband a present of arms. The marriage state was one of affection and constancy, although the husband was the absolute lord of his own household. The women frequently accompanied the armies, and in the battle hour encouraged the men by their actions and cries. To the German there was something in woman that was sacred and prophetic, out of which belief grew the importance of the Velledas, or prophetesses, who were listened to as oracles. The practice of polygamy was limited to a few, mostly princes, who strove in this way to strengthen themselves by alliances with powerful houses. The children of freemen and of slaves were reared together until the time came for the freeman to assert his title to freedom by the bearing of arms and participation in the proceedings of assemblies. The arms of the race consisted of spears, swords, axes, bows and arrows and clubs. Their shields, constructed of wood, were painted with gaudy colors, and their helmets were often made to resemble the open mouths of wild beasts or other fear-inspiring forms. The formation for battle was in the shape of a wedge, somewhat after the manner of the Macedonian Phalanx, or in a square. Among the horse companies were distributed the most agile footmen, who, in rapid evolutions, seized the horses by the mane, and were able to maintain the speed of the horsemen. In the infantry, however, lay the main strength of their armies. In action, relatives fought side by side, thus inciting each other to more heroic deeds. Before going into battle, and while advancing upon the enemy, they sang war-songs relating the deeds of their ancestors and the celebrity of their fatherland. Among their military musical instruments were drums and also horns made of brass, or fashioned from those of the wild bull. There was no loss of honor in retreating, but to lose one's shield was held to be an inexpiable disgrace.

As to their manufactures, it appears that they made their own implements not only of war and the chase, but of agriculture, which, however, could not have required much skill. There were iron mines in various parts of their country, but the Germans of that age do not seem to have had much knowledge of the art of working this metal, though copper was largely used. They had long known how to make chariots and vessels. With the latter they engaged in naval battles with the Romans in German waters. Spinning and weaving were certainly carried on, which would indicate that they were acquainted with the loom. During the period of their early contact with the Latins they learned the use of coined money, and later they had close trade relations with their Roman neighbors.

The religious system of the Germans was closely associated with the phenomena of nature. They built no temples, but groves and woods were consecrated to holy purposes. They all believed in the great god Woden, the supreme spirit of nature. He was all-wise. The sun and the moon were his eyes, and the wolf and the raven were sacred to him. He supported the vault of the sky and the clouds, and rode on the wings of the storm followed by his furious host. Another side of his nature reveals him as the god of the harvest. He also granted favors to men and ruled the world. His son Donar (the Scandinavian Thor) was the god of war and the tempests. He is represented brandishing a mighty hammer and accompanied by Tiw, the one-armed god of the sword. The Germans also worshiped a goddess of earth and heaven bearing the name Hertha, or *Nerthus*, as she is called by Tacitus, who places her abode in an island in the north sea, from whence she issues at times bearing peace and joy to the world. She was the guardian of the home and hearth, and took charge of children who died unborn. The forces of nature were personified in many forms, especially in dwarfs and giants. Unfortunately we have but scanty fragments of the theogony of the early Germans. It is believed by scholars that the Scandinavian Eddas (see Edda) present the mythology of the Germanic tribes in a form much nearer the original than the accounts of Roman writers which have come down to us. The Eddas inculcated the doctrine that the universe would perish, and as this thought was deeply impressed upon the minds of a large part of the German race, it went far toward preparing them for the reception of the Christian doctrine of the unknown God who alone was immortal.

In the year 113 B.C., the Roman world was startled by the appearance in front of their advanced guard in the Alps of a wild race hitherto unknown. They had with them their wives and children, and were evidently looking for a country in which to locate. These were the Cimbri and Teutones migrating from their seat in what is now Denmark, and coming for the first time within the range of authentic history. They had overrun the Celtic tribe of the Scordisci, who appealed for aid to Papirius Carbo, the Roman consul. This commander, in dealing with the barbarians, preferred to use dissimulation instead of force. Pretending friendship for the formidable strangers, he furnished them with false guides who led them astray in the mountains, while he advanced by a shorter road and surprised them. Thrown at first into confusion, they rallied and inflicted upon the Roman troops a severe defeat. This battle was fought at Noreja (Klagenfurth) in Carinthia, and marked the advent of the race which was destined to overthrow the Roman empire. After the battle the Cimbri and Teutones, failing to pursue their advantage, turned to the westward between the Danube and the Alps and forced a passage into Gaul. On the march they were joined by other tribes from Germany and Switzerland. From the Romans they demanded a country in which to settle, and upon the refusal of that haughty power, they determined to win a home by the sword. In five battles they defeated the Roman armies with great slaughter. They passed into the south of Gaul and through the passes of the Pyrenees into Spain, but returned toward Italy for the purpose of making an attack on Rome. In this expedition they divided into two bodies, the Cimbri marching up the Rhone and advancing through Switzerland and the Tyrol toward the plains lying south of the Alps. The Romans, under Marius, moved forward to meet the Teutones. At Aquæ Sextiæ, now Aix, near Marseilles, a great battle was fought in which the Romans won a decisive victory, practically destroying this branch of the barbarians. Latin historians assert that more than one hundred thousand of the invaders were killed or taken prisoners in this savage contest. In the meantime the Cimbri had overthrown a Roman army under the consul Catullus in upper Italy and spread themselves over the fertile plains between the mountains and the Po. Marius was at once recalled from Gaul, and in a desperate battle at Vercellæ utterly defeated the enemy, putting sixty thousand of them to the sword. When the Romans, pursuing the beaten enemy, arrived at the camp of the Cimbri, they beheld a terrible scene. Dressed in black, the wives of the Germans stood upon their wagons killing the fugitives with their own hands, mercilessly slaughtering their own children to save them from captivity, and then killing themselves. Many of the men also slew themselves, fearing slavery more than death. Sixty thousand prisoners taken in the battle and the pursuit were carried to Rome as slaves. The fear bred in Rome by the prowess of the barbarians, and the relief felt at their repulse, were such that Marius was crowned with high honors, and was decreed the third founder of the city.

The terrible slaughter of the Cimbri and Teutones appears to have deterred the Germans for a number of years from making incursions into Roman territory, but the race was too aggressive to be permanently excluded. About forty years after Vercellæ, Ariovistus, the king or leader of the Marcomannic Suevi, who occupied the country between the Danube and the Neckar, crossed the Rhine, driving before him several Gallic tribes, and took possession of Burgundy. Here he encountered Julius Cæsar, who was engaged in the conquest of Gaul. A sanguinary conflict followed, in which the Romans were victorious, and Ariovistus with a few of his followers escaped from the massacre by swimming the Rhine. The two wives and one of the daughters of the German chief were killed, and his other daughter was taken prisoner. Continuing his operations for the subjugation of the Celtic tribes in Gaul, Cæsar learned that she Usipeti and the Tencteri to the number of four hundred and thirty thousand, with their wives and children, their slaves and herds, had crossed the lower Rhine to escape from the Chatti, and were establishing themselves in northern Gaul. Cæsar invited their leaders to a friendly interview and treacherously murdered them. He then fell upon the German camps and drove the great host with frightful butchery back across the Rhtne. To put an end to the invasions of the German hordes, the Roman general determined to attack them, in their own country. In the year 55 B.C., he built a bridge across the Rhine, near the mouth of the Moselle, and passed over it with his army into the country of the Chatti, whom Cæsar, by mistake, terms the Suevi. The Germans fell back through the forests and concentrated their forces on chosen ground in the center of their domain. Cæsar did not follow them far enough to bring on a battle, but remained eighteen days in their country, devastating it with fire and sword, and then re-crossed the river. Soon afterward he constructed a second bridge, but as the Germans pursued the same tactics as before, he did not advance into the country. Cæsar had acquired a respect for the fighting qualities of the barbarians which led him to enlist numbers of them in his legions, where they rendered him material assistance in his subsequent campaigns. From this time forward Germans were found in the Roman service, and some of the Emperors used them as body-guards.

When Augustus became Emperor, after the assassination of Cæsar and the subsequeut disorders in Rome, he inaugurated a war against the tribes in the Tyrol and Austria, and at the end of the struggle in the year 15 B.C., the Romans had conquered the country north to the Danube, having either exterminated the inhabitants or reduced them to slavery. Between the years 12 and 9 B.C., the Emperor's stepson, Claudius Drusus (the first Germanicus), made four campaigns in Germany. Although he was not successful in permanently attaching any great area to the Roman possessions, he adopted a system of fortifying as he advanced, and had he lived he would, perhaps, have subjugated the whole country. His campaigns were made in the summer. The severity of the climate compelled him to fall back in the winter, while a sort of guerrilla warfare was maintained against him by the Germans. Several battles were fought, and, although the Romans were the victors, they were often in great peril. In pursuance of his plan, Drusus built fifty forts along the Rhine, and others in various parts of Germany, and also cut a canal from the Rhine to the Yssel for the passage of his fleet. One of the incidents of this war was a naval battle in which the Romans defeated the Bructeri, near the mouth of the Ems. In the fourth campaign the Roman commander penetrated to the Elbe, where, as the tradition runs, he was met by a Velleda, or prophetess, who warned him that his life was near its end. On his return from the campaign he fell from his horse and died a few weeks afterward. In this war Drusus fought principally with the Suevi, Chatti, Sigambri, Usipeti, Tencteri, Bructeri and Cherusci, and was aided by the Frisi. After the death of Drusus, his brother, Tiberius, subsequently Emperor of Rome, took up the work, and, by craft and duplicity as well as arms, obtained many advantages over the barbarians. For the easier passage of his troops he built a road from the Rhine to the Ems, and scattered among the Gallic tribes large numbers of his prisoners. Many of the noble German youths had gone voluntarily, or been carried to Rome, and from the Romans learned the arts as well as the vices of the more polished Italians. So much of Germany as was under Latin control was organized on the Roman provincial model, by which the natives were reduced to a state of dependence. Among others who fretted under the yoke was Marboduus, a noble youth of the Marcomannic Suevi. He was tall and stately in person, and also ambitious and of vigorous intellect. He had been educated at the court of Augustus. Upon his return to his own country, convinced that his people could not maintain themselves against the Roman power, he led the Marcomanni into Bohemia, and after driving out the Boii he established there a kingdom with his capital either at the present Prague or Budweis. The Hermunduri, Longobardi and Semnones came under his sway, and he ruled the country from the Danube across the center of Germany to the Elbe. His army consisted of seventy thousand infantry and four thousand cavalry, and his purpose was conquest. The Romans looked upon him as a most dangerous neighbor, and in the year 7 A.D., dispatched against him an army of two hundred and nine thousand, under the command of Tiberius. A rebellion in Pannonia, however, called off the Roman forces, and a peace was concluded between Augustus and the Marcomannic king which materially increased the latter's domain. Though founded on ambition, this kingdom of Marboduus was the result of one of the first attempts at a unification of the German-speaking peoples.

The effect of Roman civilization upon the Germans in that part of the country under Latin domination began to be seen in all directions. The national manners and habits were changed, and in some places obliterated, and the minds of many of the leading men had been poisoned by Roman seductions; but among the mass of the people still existed a desire for that liberty from foreign dominion which had been theirs from time immemorial. This desire, taking on action, led at last to the bloodiest butchery which had yet befallen the Romans in their contests with the barbarians. In the year 6 A.D., Quintilius Varus became Governor of Germany and attempted to weld still more closely the fetters of slavery upon the subject race. While the work of subjugation was progressing, an avenger of his people's wrongs was being raised up. Arminius, or Hermann, a prince of the Cherusci, who had been educated at Rome, organized an insurrection among the north German tribes. Morboduus was invited to participate in the redemption of his countrymen, but refused his aid. The rebellion sprang into flame among a small tribe at a distance from the Roman camp on the Weser. Varus, accompanied by Arminius, who still pretended friendship for the Roman Governor, marched to reduce the revolted tribe. In the midst of the Teutoberg forest, near where Detmold is now situated, Arminius left the Latin camp, and with the united Germans fell upon the army of Varus. After skirmishing and fighting three days the whole Roman army, consisting of the three best legions of the Empire, was mercilessly slaughtered, Varus falling on his own sword to escape capture. With victory and the annihilation of the invading force the German coalition fell apart.

Overthrow of Arminius.

The Second Germanicus invaded Germany in the year 14 A.D., and, after several successful battles with the Chatti, Chausi, Cherusci and other tribes, reached the scene of Varus' disaster, and gave burial to the bones of the slain. In the meantime Thusnelda, the wife of Arminius, was taken prisoner by her own father, who was the Liberator's enemy, and carried to the Roman camp. Again Arminius called upon the tribes who had defeated Varus, and at their head assailed the Romans, who narrowly escaped destruction. In the year 16 A.D., Arminius was overthrown by Germanicus in a battle near the present Minden, and at the Steinhuder Lake, but Germanicus also lost heavily, and was forced to retire. The Romans made no further attempt to subdue Germany by force. Tiberius, who had become emperor in the year 14 A.D., adopted a policy of bribery and the fostering of jealousies among rival German families and tribes in order to weaken, and, if possible, destroy the bond which consanguinity had hitherto maintained amongst the German people. Roman fortresses and cities arose on German territory, and the people became accustomed to peaceful commerce and intercourse with the southern race. The people retained their own local laws and customs, and justice was administered by their own officers, but the influence of the Empire was everywhere felt.

In the meantime Arminius quarreled with Marboduus in consequence of the refusal of the latter to join in the national rising which had resulted in the massacre of the army of Varus. The Longobardi and the Semnones revolted from the Bohemian king and brought on a war in which he was defeated and driven out of his kingdom. Arminius himself was slain by his own kinsmen, and his death destroyed the last bond of union among the North German tribes. Subsequently the Cherusci, the Chatti, and the Bructeri wasted away in civil strife.

Under Claudius Civilis in the year 69 a league was formed by the Batavi, the Frisi, the Tencteri and part of the Bructeri to drive the Romans out of Gaul, but after a short-lived success the German army was defeated by Vespasian.

In the two first centuries of the Christian era, Roman influence in Germany, resulting from the wars and the Latin system of colonization, increased wonderfully, but while changing the manners and customs of the people it did not deprive them of their language. Among the cities of the present day which sprang into existence during this period are Cologne, Bingen, Bonn, Treves, Augsburg and Vienna. On the Rhine and the Moselle vineyards blossomed; superior orchard fruits and vegetables were cultivated and a complete system of agriculture was introduced, which extended among the yet independent tribes. In the interior, Roman merchants purchased horses and cattle and the various products of the soil. Iron mines were opened and industries of various kinds were established. The Roman civilization not only invaded the wildernesses but softened the character of the people. In exchange for their products the Germans received from Rome ornaments of gold and silver, Roman coin, fine cloth and the rich wines of the South. Large numbers of the youths took service in the Imperial armies and became associated throughout the Empire with the Roman soldiery. Their tales of the magnificence of the outer world led still others into the armies of the Emperors, where they learned not only the art of war but the weakness of the Empire which men of their race were eventually to overthrow. Before the end of the third century Germans had ceased to fear Rome, and, indeed, they soon began to look upon it as their prey.

Confederations.

In the third century the German peoples politically presented a new aspect. Many of the old tribal distinctions had been lost and new names made their appearance. Great confederations were formed by the concentration of tribes, stimulated perhaps by the example of the Roman power which emphasized the strength that lay in organization. The history of the period in which these confederations were formed is extremely obscure. The Roman historians furnish but little information and the alleged histories by subsequent German writers are so mixed with incredible traditions as to be worthless.

The first of the northern tribes who established kingdoms in the south were the Goths. From their seat along the Vistula they had spread in the third century to the shores of the Black Sea. At this time they were divided into the East Goths (Ostrogoths) and the West Goths (Visigoths). They made terrible inroads into the Roman provinces of Mœsia and Thrace, and the Emperor Decius fell fighting them. They also built ships and ravaged the coasts of the Black Sea and the eastern Mediterranean. Under Ehrmanric in the fourth century they were united, but were scattered by the invasion of the Huns led by Attila. The Allemanni, a mixed race descended from the Suevi and other tribes, starting from eastern Germany in the third century, drove the Romans from a part of their territory and established themselves in the country now included within the limits of Baden, Wirtemburg and northeastern Switzerland. About the same time the Thuringi, sprung from the remnants of the Hermunduri, appear united under a king and occupying a large tract in central Germany. The Saxon confederation dwelt in the plains of north Germany between the Hartz and the sea, and from the Elbe nearly to the Rhine. Confederated with them were descendants of the old Cherusci. The name of the Saxons was derived from the short sword (sahs) with which they were armed. They still retained the ancient order of government by districts and communities.

Subsequently the Saxons appear divided into three circles: That of the Eastphalians, the Westphalians and the Engerians. They were navigators of the seas and committed many piracies on the northern and western coasts. The Franks, a mixture of Bructeri, Chatti, Batavi and Sigambri, were recognized as a distinct nation before the end of the third century. They were at that time neighbors and allies of the Saxons, and like them were pirates, extending their voyages to Britain, Gaul, Spain, and even into the Mediterranean as far as Sicily. The peaceable Frisians occupied the shores of the North Sea and the islands.

About this time Christianity began to take root amongst the Germans, but their religion was only a part of their state policy, and it in no wise hindered them from the predatory incursions of earlier ages; on the contrary, with organization came a desire for permanent conquest, and we shall soon see Germans absorbing the power of Rome which, in its attempts to enslave them, had furnished them with the civilization and discipline that were used to its own overthrow. The Empire itself had lost much of the vigor of its old days of conquest, for the ownership of the world was a luxury which was steadily sapping the vitality of the Roman power. As early as the year 235 the Gothic Maximin was made Roman Emperor, and from that time on all positions of dignity were within the reach of ambitious Germans. In the Fourth century Ulphilas, a Christian of Asia Minor, who had been carried into captivity by a band of Gothic pirates, introduced Christianity to that people and is said to have invented the Meso-Gothic alphabet which he used in his translation of the Bible. This translation is the oldest monument of German speech extant.

The Huns. In the latter part of the Fourth century Europe as far west as Gaul was overrun by the Huns. These were a Turanian race who had for many centuries wandered over the steppes of northeastern Asia. So dangerous were they that the Chinese built the Great Wall as a defense against their invasions. Migrating to the West, the Huns entered Europe early in the Christian era and threw themselves upon the Slavs and Germans. In the year 375 they subdued the Alans, a tribe of mixed German and Tartar descent, and then attacked the East Goths who were defeated with great slaughter, their aged king, Ehrmanric, falling upon his own sword. The effect of the Hunnish invasion was a crowding to the west of the Slavs upon the Germans and of the Germans upon themselves and the Latins. In the year 428 Attila, then King of the Huns, established his capital in the present Hungary between the Theiss and the Danube and gathered about him beside his own people many of the heathen German tribes. From his capital he moved to the west, proposing to make himself master of the continent. Against him Christian Europe united under the Roman eagles, and in 451, near Chalons, in what is now France, a tremendous battle was fought, the result of which was the defeat and retirement of the Huns. Their Empire was subsequently disrupted and they ceased to be a menace to civilization. It is supposed that the Szeklers of eastern Hungary are the descendants of these formidable warriors.

At the close of the migrations caused by the Hunnish invasion the Vandals are found in Africa, having traversed all of south central and western Europe and crossed the straits of Gibralter. In Africa they set up a kingdom, whose ruler, Genseric, about 455, captured Rome. That part of the Suevi who had accompanied the Vandals to Spain established themselves there. The East Goths had been subdued by the Huns, but a part of the West Goths were received by Valens, the Emperor of the Roman Empire of the East, who gave them homes in the country south of the Danube. The exactions of the Roman governors drove them to rebellion and they overthrew Valens and his army. Under Alaric, their king, the West Goths invaded Italy twice and in their last invasion seized Rome and sacked it. Subsequently they moved to Spain, drove out the Suevi and founded there a kingdom. An army composed of various German tribes under their general, Radagaise, broke into Italy, but they were defeated by Stilico. Bands of Saxons, Angles, Jutes and Frisians crossed the North Sea and took possession of England, driving into Wales and northern Scotland the old Celtic population. From this German invasion sprang the present British Empire.

In the year 456 Rome, the capital of the Western Empire—the Roman possessions having been divided by Diocletian into the Eastern and Western Empires—fell before Odoacer at the head of the Heruli and confederated German tribes. The Herulian chief assumed the title of King of Italy. Among the new names which now appear is that of the Bavarians, probably descendants of the Marcomanni and other tribes, who are found in Rhœtia. On the death of Attila the East Goths regained their independence. Passing into Italy they overthrew Odoacer, after which their king Theodoric assumed the title of Emperor of Rome, with Ravenna for his capital. Theodoric formed a plan of uniting the Germans in a national league, but this was found to be impracticable. In the Sixth century the kingdom founded by Theodoric was destroyed by Belisarius and Narses, generals of the Eastern Empire. Belisarius also overthrew the Vandal monarchy in Africa.

The Franks, improving the opportunity afforded by the disruption of the Roman Empire, took possession of part of Gaul. They were divided into two branches, the Ripuarians and the Salians. With the Salian Franks originated the famous Salic law, by which no female could ascend the throne.

The Thuringi, the Allemani and the main body of the Saxons retained their possessions in the interior of Germany. The Longobardi were approaching the Danube, and at this time occupied Moravia, from whence they afterwards moved into Italy and there founded the Lombard kingdom. The Slavs of eastern Europe moved into the territory left vacant by the migrations of the Germans and took possession of the country as far west as the Elbe.

The Germans of this period seem to have fallen back almost into their original barbarism. With a passionate contempt for learning they united a ferocity which depopulated or reduced to slavery the countries through which they passed. Notwithstanding this deterioration their language was cultivated in poetical forms and their minstrels sang of the great deeds of the German heroes. The historical instinct seems to have been lacking, for the Nibelungenlied, not at that time written, but memorized, brings together with mythical heroes real personages who were separated in their lives by centuries of time. Many of the German soldiers who had participated in the conquest of the Roman possessions received grants of land and held their former lords in subjection, but after their first ebullition of savagery they appear to have been mild masters. The two races did not readily coalesce, mainly because of differences in their religious beliefs. The Romans were Athanasians, believing in the absolute divinity of Jesus Christ, while the mass of the Christian Germans held to the Arian belief that the Savior, while immeasurably above men and angels in dignity and power, was yet a finite being created by God.

The first Germanic monarchy which had a firm foundation was that of the Salian Franks. Clovis, the first king of note, was the grandson of Merovæus (Meerwing), who gave the name *Merovingian* to the dynasty. Clovis was but fifteen years of age when he came to the throne in 482. When only 20 years old he attacked the remnants of the Roman power in Gaul, and by a victory over the Latin governor, Syagrius, at Soissons, acquired control of the country south to the Loire. He then made war on the Allemanni and overcame them in the famous battle of Zülpich. The consort of Clovis, Clotilde, was the Christian daughter of a Burgundian prince. She had long sought to convert her pagan husband, but without success. In the heat of the battle, Clovis, having failed to secure victory by calling upon his own gods, fell upon his knees and vowed that if the God of his wife would save him from defeat he would become a Christian. The Allemanni were beaten, and Clovis caused himself and three thousand of his noblest Franks to be baptized in the Catholic faith at the next Easter festival. This summary wholesale conversion to Christianity was merely nominal, but it was the beginning of that influence of the Church of Rome which subsequently became so powerful among the Germans. Clovis continued his conquests until his rule was acknowledged east to the Rhine and south as far as the Garonne. Anastasius, Emperor of the East, sent a message of congratulation to the King of the Franks, and nominated him to the dignity of a Roman patrician and consul, and Clovis wore with pride the purple robe which symbolized this once noble but now emasculated office. Clovis made Paris his capital and died there in the year 511, leaving four sons, who divided the kingdom among themselves, but maintained toward other nations the attitude of a single power.

The Merovingian kings were with few exceptions monsters of cruelty and vice. Their people were sunk in moral degradation, but the power of the kingdom increased until it included the territory between the Saxon frontiers on the north and the Alps on the south. The Frisians and Saxons alone remained independent. The conquered lands within the Frank kingdom were distributed by the monarchs among their chiefs, who held the gifts as *fiefs* or loans, for which they were obliged to do military duty on the command of the king. The feudatories took the name of liege subjects or *vassals*, and those of them who stood close to the king were named *administrators*. These great vassals distributed from their own lands portions to poorer individuals, who were called *Arriere vassals*. The freemen, who were only obliged to serve in great national wars, held an *allodial* or free inheritance. Under this system arose an aristocracy composed of the great vassals and those who held under them. The frequent wars of the Merovingian kings wasted the strength of the monarchy and in time the great vassals assumed powers and dignities which properly belonged to the king—a state of things which led in the end to the deposition of the dynasty. Grants of land were also made to the higher clergy, which contributed to the erection of an ecclesiastical aristocracy. Most of the priests were of the subject Latin race, but their religious office and their large possessions soon raised them to an importance which permitted them to mingle on equal terms with the military lords of the land. In the course of time many of the smaller proprietors found it to their advantage to surrender their grants of land either to the church or to some powerful nobleman, and to have them returned with additions when they became vassals. In this way the freemen decreased in number and the whole order of society was changed.

In Austrasia, the eastern division of the Merovingian kingdom, the power of the noblemen was constantly increasing, because of their great distance from the seat of the king; and while they held in check the authority of the monarch, they continually extended and strengthened their power over their own subjects. In the western division, or Neustria, the authority of the head of the state was generally acknowledged and obeyed until a time arrived when the weakness of the king loosened his grasp of the sceptre and it fell into the strong hand of his chief officer. Among the vassals who immediately surrounded the throne were the royal Treasurer, the Marshal, the Steward and the Butler, and to these were added the Pfalz-grafen, or king's deputies, who exercised the royal prerogative in the absence of the ruler, and the Major Domus, or Mayor of the Palace who commanded the king's knights. This officer soon became the most important dignitary in the kingdom.

In the Seventh and Eighth centuries the heathen Allemanni, Thuringians and Bavarians in the wilds of the interior of Germany, and part of the Saxons and Frisians on the coast of the North Sea, were converted to Christianity by missionaries from Ireland, England and Scotland. The best known of these missionaries are St. Columban and Boniface. The latter established bishoprics, or regulated those already existing, at Salzburg, Passau, Ratisbon, Wurzburg, Erfurt, and other places. The celebrated abbey of Fulda was founded by his follower, Sturm, and he also planted at Ohrdruf a school for religious teachers, in which, in connection with doctrinal teachings, instruction was given in the arts of agriculture and horticulture. Boniface presided over the Council held at Soissons in 742. After a long life of missionary labor, during which he received promotion to high ecclesiastical office, he suffered martyrdom at the hands of heathen Frisians in the year 755. In view of the subsequent development of the national mind and conscience, the work of these missionaries cannot be overestimated, but at the time the conversion of many of these pagans was not of that quality which would commend itself to a modern religious devotee. The morals of the people were frightfully corrupt; the old-time sanctity of marriage was almost annihilated and the word humanity seems to have been thrust out of the language. Regular assemblies were still held, but instead of consisting as formerly of the whole body of the freemen, they were now composed mainly of the nobility. Courts were held in the open air, and verdicts were rendered by a body of men who combined in themselves the functions of both judge and jury. When human judgment failed to arrive at a finding in cases brought before this tribunal, a verdict was obtained through the agency of the ordeal by fire or water or by single combat.

In the year 613 the sub-kingdoms of Austrasia and Neustria were united by Clotaire, under whom and his son Dagobert comparatively good government was maintained. After Dagobert, who died in 637, the authority of the throne declined, and the power of the "Lazy Kings," as they are called, passed into the hands of the Mayors of the Palace, while the titular rulers became mere puppets. The real power of the early medieval German Empire may be said to have begun with Pippin of Landen, from whom sprang the line which produced Charles Martel and Charlemagne. Pippin, who was Mayor of the Palace in Austrasia under Dagobert, was related to the Merovingian kings. The office had become hereditary, and the power of the Mayor was so great that Pippin's son, Grimoald, attempted to depose the current Merovingian king and place his own son on the throne. The ambitious father and his son were both killed in the struggle, the Frank nobility having not yet sufficiently departed from their reverence for their royal house to consent to its overthrow. One of Grimoald's sisters was married to the son of the Latin Bishop of Metz. Her son, Pippin of Heristal, in whom both Latin and German blood were mingled, became Mayor of the Palace in Austrasia. In the famous Battle of Testri, fought in the year 681, he overcame the king of Neustria, and the divisions of the Frankish kingdom were re-united. Warned by the fate of his uncle, Pippin made no attempt on the throne but was content to wield the power of the united kingdom. Charles Martel (the Hammer) was the son of Pippin of Heristal.

Pippin of Landen.

The Mohammedan power, which had extended from Mecca through northern Africa to Spain, was preparing for the destruction of Christianity in Europe and the imposition of its doctrines and government upon the people of that continent. While a Saracen fleet and army assailed Constantinople, the capital of the Eastern Roman Empire, a Moslem army under Abderrhaman advanced across the Pyrenees against the Christians of Western Europe. As in the time of the

Hunnish invasion, the forces of Europe were concentrated and battle was offered to the invaders. In 732 the two armies met in the plain between Tours and Poitiers in southern France, and after a sanguinary contest lasting through seven days the Christians were victorious and Europe was saved from the rule of Islam. But while the thorough military organization, which was made possible by the power of the Mayor of the Palace, had undoubtedly preserved Europe in the great conflict, the independence of the individual was materially impaired and its place was taken by feudal allegiance.

After adding East Friesland to the kindgom, Charles Martel died in 741, leaving two sons, Carloman and Pippin the Short. Carloman retired to a convent, and Pippin, seeing the time ripe for a change of dynasty, inquired of Pope Zacharias: "Who ought rightly to be king; he who sits at home in idleness, or he who bears the toils and dangers of government?" The Pope was in difficulty at the time with his neighbor, the Lombard king, and secured the aid of Pippin by sanctioning the deposition of Childeric III, the last Merovingian monarch, and the coronation of the Frank Mayor of the Palace. The decision of the Pope contained a statement to the effect that the throne was the gift of the Church, and also a threat of the ban of the Church upon anyone who opposed the accession of Pippin. In this way began the assumption of temporal authority by the Pope over the kings of Christendom. The head of the new dynasty was crowned in 752 at Soissons by Boniface, two hundred and sixty-six years after Clovis at the same place founded the Frank kingdom. In aid of Pope Stephen, Pippin marched into Italy in 754, defeated the Lombard King at Susa and Ravenna and presented to the head of the Church the territory which formed the nucleus of the Papal States. Pippin died in 768 and was succeeded by his sons Charles and Carloman. Carloman died in 777, and Charles, subsequently named Charlemagne, the greatest monarch yet produced by Germany, reigned alone.

By the death of his brother, Charles came into possession of a kingdom more extensive than that of the Merovingian Kings. Bavaria and Thuringia had been annexed. Brittany, Aquitaine and Bavaria still retained their native dukes, but all the other provinces were governed by officers of the crown. In early life Charles had married a princess of the Franks but he subsequently put her away and married a daughter of Desiderius, the Lombard King. This second wife he afterward divorced on the protest of Pope Stephen III. During his reign he espoused five wives, all of whom he divorced, apparently viewing the marriage tie with contempt. Nor does he seem to have been troubled with scruples because of anything he did in his long reign; but on the other hand, the ruthless genius which enabled him to consolidate his imperial power was also exerted for the civilization and enlightenment of his subjects.

In 772 Charles made war on the Saxons, and at Eresburg he destroyed the celebrated Irmansul. This was the figure of a warrior standing on a marble pillar, bearing in one hand a rose and in the other a pair of scales. The warrior's crest was a cock. There was a figure of a bear on his breast and on his shield was a lion in a field of flowers. The Irmansul was an object of worship among the Saxons, who propitiated the divinity by human sacrifices. The Saxons submitted to the Frank King and promised him their allegiance, but without any intention of keeping their promise; in fact, several campaigns were required to bring them under his power. The divorce of the Lombard King's daughter and the denial by Charles of the rights of his own nephews—sons of Carloman—together with an appeal by the Pope to the Frank King for aid against Desiderius, involved him in war with the latter. Assembling a great army at Geneva, he invaded Lombardy, captured Desiderius and the sons of Carloman in Pavia and compelled them to enter a convent. He then annexed the Lombard kingdom to his own, leaving the people their own laws and their native dukes, but he himself assuming the iron crown and proclaiming himself king of Italy. At a later date insurrections in Lombardy caused the deposition of the Lombard dukes, and the people were afterward governed by counts appointed by the king of the Franks. At this time began his intimate relations with the papal power, out of which grew the close connection that for many centuries existed between the German Empire and the affairs of Italy. In his reign Charlemagne's great genius was directed to the building up together of the absolute monarchy of the Franks and the spiritual power of the Church. He was convinced that Christianity was the means by which his people were to be advanced in civilization, and he proposed to use the strong religious influence of Rome as a buttress for his own power.

Charlemagne was continually hampered in his plans for universal dominion by the onslaughts of the heathen Saxons, who, under their duke Witikind, resisted all attempts to deprive them of their freedom and their religion. In retaliation for the destruction of one of his armies in Saxony, Charlemagne barbarously ordered the decapitation of four thousand five hundred Saxon prisoners, an act which fanned into fury the passions of that people. After years of desperate struggle the pagan Saxons were reduced, and in 797 their popular assembly was dissolved, the arms-bearing population was made liable to be drafted into the Frankish army and the country was brought into complete subjection. Finding his new subjects bitterly opposed to his rule, Charles, partly as a political measure and following the example of Boniface, established numerous bishoprics among them. Sees were founded by him and his successor at Paderborn, Münster, Osnabrüch, Bremen, Minden, Verden, Halberstadt and Hildesheim.

Roland

Among other acts of his reign was an expedition into Spain against the Saracen power there which had risen on the ruins of the Visigothic kingdom. He captured Pampeluna and Saragossa and formed the country between the Pyrenees and the Ebro into a vice-royalty or march. In the pass of Roncesvalles, on his return, the Basque mountaineers fell upon his rear guard and slew many of Charles' bravest noblemen, among them Roland, Count of the March of Brittany. The death of Roland has passed into legend and song, and the glory of the great Paladin and the fabulous deeds ascribed to him have been kept fresh to the present day.

The Empire enlarged

Thassilo, Duke of Bavaria, having incurred the displeasure of Charlemagne, was overthrown and driven into a convent and his country was incorporated into the Frank kingdom. The annexation of Bavaria completed the reduction of Germany to the rule of Charlemagne. It will be remembered that after the Hunnish invasion the Slavs had moved into the vacated German lands westward to the Elbe. Charlemagne addressed himself to the task of subjugating these people, who by the Germans were called Wends. In one campaign he conquered the *Avari* in the territory extending from the Ems to the Raab and planted there a colony of Bavarians. The country was attached to the ecclesiastical province of Salzburg and became the germ of the Austrian Empire. In the Saxon march lay the germ of Brandenburg, the modern Prussia. Other parts of the Slav region were overrun by the armies of Charlemagne, but it was many centuries before the oldtime control of the country between the Oder and the Vistula was established in German hands. For protection against the Slavs he built the fortresses of Halle on the Saale and Magdeburg and Buchen on the Elbe.

The state built up by Charlemagne embraced within its boundaries all the people of German descent except the Anglo-Saxons and the Northmen of Scandinavia. His possessions in Italy reached to the Garigliano, and in Spain to the Ebro. On Christmas day in the year 800, Charlemagne was crowned Emperor of Rome by

Pope Leo III. who at the same time bestowed upon him the title of Guardian of the Christian Church and of the True Faith. The relations between the Empire and the Church were of a peculiar nature. The Pope in a secular sense was a subject of the Empire, but he was also the spiritual Father from whom all Christian monarchs received their crowns with reverence. The ecclesiastical power of Rome and the physical power of the Empire were to support and serve each other, and for a time this relation was sustained. The civil constitution of the Empire was the result of a complete change from the old order of things. The whole country was divided into districts ruled by counts appointed by the king. A further division was made into circuits resembling the ancient hundreds, governed by officers who were afterward called viscounts. High courts of justice were held each month by the counts in the king's name, and here the law was administered in all cases involving life, liberty and estate. In time of war the count commanded the military force of his district. Upon the borders were erected "marches," or marks, which were organized as military districts for the protection of the Empire from external assault. The counts of the marches necessarily had a greater latitude in the use of power than their peers in the interior of the Empire, and in subsequent reigns several of them strongly resisted the Imperial authority. In the body of the Empire the executive power of the emperor was represented by his sheriffs, and judicial power by royal judges. All the officers were paid in land, which was held by feudal tenure. The officers were visited four times a year by imperial deputies, who communicated to them the emperor's will, and also reported their conduct to him. This inspection, however, was not sufficiently strict to prevent abuses. In war the emperor first summoned his vassals, who led to him their forces, composed of the subordinate vassals and the freemen of the Empire. The general assembly of the freemen was still held, but the rights of the individual had passed into the hands of the great spiritual and secular vassals and it was an assembly of freemen only in name. No regular taxes were levied; the court was supported by the tributary gifts of the subjects and the revenues derived from the crown lands.

Charlemagne traveled through the whole Empire, but he spent much time at Ingelheim, Mainz, Nimeguen and Aix-la-Chapelle (Aachen). He had no fixed capital, but was specially attached to Aix, where he built a splendid residence and a cathedral. In person, Charlemagne was very tall and of generous proportions. His eyes were large and bright, he had an abundance of fair hair which was white in his old age, and a fine forehead. He had a passion for labor, war and danger, and this quality joined with a lofty intellect made him one of the great princes not only of his own age but of all time. His far-seeing mind had caught from Rome the conception of a universal state, but his wisdom saved him from copying Roman models except in so far as they were adapted to the genius of his race. He gathered about himself learned men from all countries, and established the School of the Palace, as it was called, presided over by Alcuin, a learned Anglo-Saxon, the emperor himself taking part in the discussions. He founded schools in all the convents and introduced Roman teachers of music, but he required that sermons should be preached in the German language. Under his direction a German grammar was compiled. In every way possible he forwarded the cause of education, which was not then a German accomplishment. He caused to be preserved the ancient heroic songs of the minstrels, but these were destroyed by the religious fanaticism of his son Lewis the Pious, who ascended the throne after him. The Church was cherished in the reign of Charlemagne as it had never been before. He granted tithes to the clergy and himself selected many of the abbots and bishops. Simple in his own attire, he had little patience with the luxurious habits of his courtiers and scoffed at their gorgeous raiment. All his public acts—even the slaughter of the Saxons at Verden—were done in accordance with a policy which looked to the establishment of a German Christian Empire. The great emperor was never cruel upon impulse; on the contrary, in his private intercourse with those about him he was mild, cheerful and benevolent. His cruelties sprang from an unbounded ambition, to which the Germans are indebted for the partial unification of the race which is not yet complete. The impulse he gave to the German power was felt through the middle ages, and it may not be too much to say that it is still a living force. The principal weakness of the Empire was to be found, perhaps, in the system of feudalism which in the reign of Charlemagne was firmly established. This system raised the nobles almost to the dignity of kings, and correspondingly debased the freemen. In his own strong hand its cutting edge was turned away from the monarch, and by it he was enabled to build around his throne the greatest state of Europe, but the authority delegated to the lords of the provinces permitted them to so strengthen their power that soon after the sceptre passed out of his dead hand, his weak successors were unable to maintain themselves and the great structure fell to pieces.

In 813 Charlemagne caused his son Lewis (Ludwig) to be crowned joint emperor, with the provision that he should be sole emperor on his father's death. At the same time the crown of Italy was decreed to Bernard, the son of Charlemagne's second son Pippin who died in 811. Charlemagne died in 814, leaving his vast empire to Lewis, then aged 36. The new emperor had been educated by the church and was a cowardly, weak ruler, whose sole desire seemed to be to serve the papacy. In French history he is known as "Louis le Debonnaire," and among the Germans he is styled "Ludwig the Pious." He relaxed the strict regulations devised by his father for the levying of troops, and in other ways neglected to exercise his rights over his vassals; and this to the extent that with them imperial authority began to sink into contempt. In order to remedy this, on the counsel of his priestly advisers he associated with himself in the government his three sons and partitioned the realm among them. Lothair, the eldest, was made joint emperor with his father. Lewis took Bavaria and Bohemia, and Pippin was intrusted with Aquitaine, Lewis and Pippin ruling in their domains as subordinate kings to their elder brother and their father. Bernard, to whom Charlemagne had given Italy, was ignored, and threatened to rebel. He soon submitted, but he and three of his nearest friends were condemned to lose their eyes. He died soon afterward. The emperor's wife dying, he married Judith, daughter of the Bavarian Count Welf. Of this union was born a son, who is known to history as "Charles the Bald." The emperor proposed to make a new division for the benefit of the infant, whereupon Lothair and Pippin rebelled. Lewis of Bavaria and Bohemia at first joined his brothers, but subsequently led his forces to the assistance of his father and secured the victory for him. The emperor divided the empire in 833, giving Aquitaine, which had been taken from the rebellious Pippin, to Charles the Bald; the Pope, in the interest of Lothair, induced the military commanders to abandon the emperor, who submitted and consented to read in church a "confession of his sins," which was, in effect, an abdication of the throne. Indignant at the humiliating treatment of their father, the younger sons restored him to his imperial dignity. A further effort by the emperor to extend the territory of Charles the Bald at the expense of his son Lewis brought on another war, in the course of which the old monarch died on an island in the Rhine, A.D. 840. On his death-bed he was asked to forgive his son Lewis, and replied: "I do forgive him, but let him know that he has brought me to my death." History presents few spectacles so pitiable as the strife between this father and these sons.

The Emperor's strife with his sons.

Lothair. Lothair succeeded to the title of emperor. In an effort to make himself sole master of the empire, in which he was aided by the clergy, he was opposed by Lewis the German and Charles the Bald, who demanded a partition. Lewis and Charles were supported by the Bavarians, Saxons and Swabians, and also by the northeastern Franks, who united to throw off the clerical domination which had been established over the empire. The struggle eventuated in a battle at Fontenay in 841, in which Lothair was totally defeated. He protracted the war for a time by stirring up the Saxon subjects of Lewis against that prince, and he also endeavored to enlist in his cause the piratical Northmen, who had already begun to scourge the coasts of the empire. Driven to extremities, he at last gave up the contest, and in 843 signed the Treaty of Verdun, by which he retained the title of emperor, with an empire composed of Italy, Friesland, and a strip of land extending from the Mediterranean to the North Sea, along the rivers Rhone, Saone, Rhine and Maas. This peculiarly carved domain was called Lotharingia (Lorraine), and was so formed to give him the two capitals of Charlemagne, Aix and Rome. To Charles the Bald fell the Western Kingdom, with boundaries almost coincident with those of modern France; and to Lewis was given Germany, with the districts on the left bank of the Rhine, which had belonged to the Archbishopric of Mainz. The Treaty of Verdun is generally assigned as the foundation of the German and French kingdoms. The empire of Charlemagne was in fragments. Nor was the political division the only line drawn between the three kingdoms. Languages and customs alien to the purely German were coming into life. In France, Latin continued to be the language of learning and the church, but among the people was spoken a patois composed of a mixture of Latin and German, which afterward became French. In Italy a similar change was taking place by a union of corrupted Latin with foreign elements. In Spain the Visigoths had long since abandoned the German language for a Neo-Latin tongue, a branch of which became the language of Portugal. In Germany there was a division into the High and the Low German. The gulf between the languages of the different parts of the empire was already so wide that, when the brothers and their vassals met at Strasburg in 846 to renew the oaths of friendship exchanged at Verdun, the Knights of Austrasia and those of Neustria could not understand one another. The oath taken at that time by the Neustrians has been preserved, and is the only existing record of the new-born French language.

Lothair died in 855. He was succeeded by his son Lewis II, who, dying without heirs, was followed on the throne by another son of Lothair, called Lothair II. On his death in 869, his domain was divided between Lewis the German and Charles the Bald. In this division Lewis received the dioceses of Utrecht, Strasburg and Basle, and the ecclesiastical provinces of Treves and Cologne.

Lewis ruled in Germany until 876, his reign being disturbed by family dissensions similar to those which had disrupted the empire of Charlemagne. The bold incursions of the Northmen and the increasing strength and aggressiveness of the Slav kingdom, which had been established in Moravia, caused the emperor much anxiety. Charles the Bald, having obtained the title of emperor, attempted to extend his authority over Germany and Italy, but was defeated at the battle of Andernach by Lewis' second son, also named Lewis, and his schemes were thwarted. Lewis the German died in 876, and his two eldest sons dying—Carloman in 880 and Lewis in 882—the kingdom passed to his youngest son Charles, known in history as Charles the Fat.

Charles the Bald died in 877, leaving a ruined kingdom to his son Lewis the Stammerer, who, after a troubled reign of two years, was succeeded by his sons Louis II and Carloman. These princes lived but a short time, and the West Frank kingdom fell into the hands of Charles the Simple, then but five years of age. Refusing to accept the child, the French nobles elected as their king Charles the Fat, who made himself master of Italy also. He was crowned as Emperor by the Pope, and for a short time the empire of Charlemagne was renewed. In Italy the power of the popes was increasing and they were claiming secular as well as spiritual supremacy. Their pretensions were founded on what were called the "Decretals of Isidore," which were clumsily forged documents purporting to be decrees of ancient councils of the Church declaring that the Bishop of Rome was superior to the other bishops and that the spiritual power was entirely independent of temporal authority. In 879, Bozo of Vienne, a Frank noble, who had married a grand-daughter of the Emperor Lothair, set up the kingdom of Burgundy, and was supported by Pope John VIII. Charles the Fat.

Charles the Fat was too weak in character to maintain himself against the evils which threatened his empire. Swatopluk, king of a Slavonic kingdom in Moravia, made inroads upon the eastern borders of the empire. The Saracens, crossing the Mediterranean from Africa, took possession of Southern Italy and Sicily, and the Northmen of Scandinavia ravaged the western shores of the empire, making their way up the rivers and plundering cities which lay far inland. The invasions of the northern Vikings were at first merely predatory incursions, but there was danger that the comparative immunity with which they were made would encourage the pirates to attempt permanent conquests of the lands which they harried; and this, indeed, occurred. In the reign of Lewis the Pious they had burned Hamburg and afterwards sacked Aix (Aachen), stabling their horses in the cathedral erected by Charlemagne. Cologne, Nimeguen, Treves and other cities were burned. They took Rouen and besieged Paris, where they were bought off. From Charles the Simple they received a cession of land which afterward became the dukedom of Normandy. In Sicily and Southern Italy, as early as 1016, they founded a kingdom, and one branch of them under Rurik, established in Russia the monarchy which was the beginning of the present Russian Empire. Instead of fighting for the honor and integrity of his domain, the distressed and vacillating emperor bought temporary peace from the pirates by the payment of a heavy tribute; and when their demands increased he gave them lands for permanent settlement. In the interior of the empire law had fallen into contempt and there was scarcely any rule but that of might. The people, oppressed by the nobles, either joined the forces of their tyrants or formed themselves into bands of robbers. Piracies by the Northmen. Norman kingdoms. Anarchy.

The German nobles, disgusted with the weakness of their emperor, deposed him in 887, and placed upon the throne Arnulf of Carinthia, a natural son of Carloman and grand-son of Lewis the German. At the same time the French nobles called to the throne of the Western kingdom Count Eudes (Odo) of Paris the son of a valorous German knight who had married a daughter of Lewis the Pious. Charles the Fat survived the last indignity of dethronement but a few months, dying January 12th, 888. His followers, many of whom existed in Southern Germany, invited Duke Conrad, a nephew of Judith, the wife of Lewis the Pious, to be their king. He accepted the invitation and set up a new kingdom of Burgundy between the Alps, the Jura and the Rhine. This kingdom, which was afterwards called Upper Burgundy, became the present Switzerland. Charles the Simple was crowned at Rheims in 893 in opposition to Eudes. After a short war between the rivals peace was made, Charles receiving a part of Flanders with a pledge that the whole kingdom should pass to him on the death of Eudes. That event occurred in 898, and Charles be- Arnulf.

came king of France in the same year. Under him and his weak successors the kingdom remained until 987, when the death of the last Carlovingian ruler in France, Louis the "Lazy," left the throne vacant, and Hugh Capet, Count of Paris, was elected king.

Unlike the Carlovingian kings, Arnulf had no intention of submitting to the ravages of the Northmen, or the aggressiveness of the Moravian state. On foot, at the head of his army, he utterly defeated the pirates at Lowen; then, turning to the Moravians, with the assistance of the Magyars he conquered a peace. On the invitation of the Pope he went to Italy, and in 896 was crowned emperor, but family troubles and sickness—said by some to have been caused by poisoning—brought him to his death in 899.

Arnulf's successor on the throne was "Lewis the Child," then nine years of age. The government of this prince was conducted by Hatto, Bishop of Mainz, the unsavory hero of the rat story in legend and poesy. In the reign of Lewis the Child, German civilization was threatened with extinction by an invasion of the Magyars. These were Tartar nomads of the same race as the Huns, and like the terrible warriors of Attila, they were bent on the subjugation of the continent. In the disorganized state of the empire, combined opposition to their assaults seemed to be impossible.

Magyar wars.

The dukes of Germany, each at the head of his vassals, fought heroically with the invaders, but only to sustain defeat. Surging continually to the west, the barbarians reached Saxony and Lorraine, appearing to have universal dominion almost within their grasp.

Last Carlovingian king in Germany.

The king himself was forced to pay them tribute. In 911, in the midst of this misery and disaster, Lewis the Child, the last of the Carlovingian kings in Germany, passed to the tomb.

Assailed from within and without, Germany was apparently at the point of disruption, but the national danger appealed to the fears and the patriotism of the great noblemen and measures were at last taken to avert the threatened calamity. Both Franks and Saxons insisted on the election of a king, and in an assembly held at Forchheim, Conrad of Franconia, related to the House of Charlemagne through a female branch, was elevated to the throne. Taking advantage of the confusion in Germany, Charles the Simple had annexed Lorraine to France and held it through the reign of Conrad I. The latter, however, secured Alsace. The new monarch of Germany had only a limited authority, for the power of the dukes was nearly as potent as his own. Personally Conrad was mild and gentle, but in the beginning of his reign he ruled with vigor and harshness, having before his eyes the restoration of the power of the kingdom. He became involved in a quarrel with the Dukes of Bavaria and Swabia and overcame them. The Duke of Bavaria fled to the Magyars, who had penetrated as far to the northwest as Bremen and were overrunning large districts of the country in the south. Conrad marched against them, but was wounded and defeated. He also quarreled with the Saxon Henry, to whose father he was indebted for his election as king. Henry, who subsequently received the title of "The Fowler," had succeeded his father in the dukedom of Saxony, but Conrad refused to confirm to him his feudal possessions. The young Duke of Saxony made war on Conrad and fought him down to a disastrous defeat at Merseburg. Notwithstanding his errors and failures Conrad was true to his country. With all his plans dissolving, conscious that he had miserably failed in nearly all his undertakings, yet, with a patriotism seldom seen in like circumstances, on his deathbed he directed that his crown be delivered to his enemy, Henry of Saxony, as the only German prince who could save the state from its peril. Conrad's principal fault seems to have been a surrender to the counsels of his priestly advisers, who, being extremely jealous of the secular power of the dukes, persuaded him to employ his authority for their humiliation. Conrad died in 918, and in accordance with his wish Henry of Saxony was elected his successor.

Saxon emperors

Henry's accession to the throne was a fortunate event for the autonomy of the German kingdom. He was an able sovereign.

Henry the "Fowler."

At his coronation he declined anointment by the papal representative, the Archbishop of Mainz, basing his declination on the ground of his own unworthiness, but the truth probably was that he was determined to divorce the physical power of the empire from the dominion of Rome, which, in Germany, had become both spiritual and secular. This purpose seems clearer in the light of his reservation to himself of the right to designate the German bishops. In order to secure harmony in the kingdom, he conciliated the dukes of Bavaria and Swabia. He had a personal conference at Ratisbon with the Bavarian duke, and restored to him the possessions which had been forfeited by Conrad. In the seventh year of Henry's reign, Lorraine was incorporated into the German Kingdom. Fortunately for the country, in the first years of the work of consolidation the Hungarians (Magyars) had suspended their attacks, but after a short respite they came against it with renewed fury. In 924 they drove Henry to take refuge behind the Oeker morasses, but one of their princes was left a captive in German hands. In exchange for the freedom of this prisoner the Hungarians agreed to an armistice of nine years, during which period Henry continued to pay them tribute.

Armistice with the Hungarians.

While the armistice lasted, although the barbarians renewed their incursions into Swabia, Bavaria and Franconia, they kept the terms of their agreement as to Saxony and Thuringia. These nine years of comparative peace were improved by Henry in strengthening his army and building up the defenses of the kingdom. On the eastern borders of Saxony and Thuringia he established fortresses and garrisoned them by drafting every ninth man of the population for that purpose. The other eight of each group of nine cultivated the fields and deposited one-third of the crops in the fortresses. He also required all the markets and public festivals to be held in the cities, in order to accustom the people to a social life, which was impossible among their scattered hamlets.

War measures.

To meet the horsemen, of whom the Hungarian armies were composed, he formed a large body of cavalry, and is said to have instituted tournaments for the purpose of perfecting them in cavalry exercises. Having raised his army to a high state of efficiency, he led them to actual service in expeditions against the Wends, east of the Saale and the Elbe, and other Slavonic tribes. In 928 he conquered the Havelli, and, moving over the frozen lakes by which their city of Brennabor (Brandenburg) was surrounded, captured it, and reduced them to subjection. In Bohemia he overthrew Wratislaw,—who had apostatized from Christianity and formed an alliance with the Hungarians,—and installed Wenceslaus as Duke of that province. At Lenzen, in 929, his generals defeated several revolting Slavic tribes, thereby securing the northeastern frontiers of Germany. In a council which he held with his Saxon nobles, it was determined that the time had come to throw off the Hungarian yoke, and when, in 932, the agents of that power appeared at Henry's court to receive the annual tribute, they were given only a mangy dog and a message of defiance. The Hungarians in great force at once invaded the kingdom, sweeping with flame and carnage over Thuringia, and advancing into Saxony. Henry, who was receiving large reinforcements, avoided battle with the enemy until a lack of provisions compelled them to divide into two armies, one of which remained in Thuringia, and the other moved to the north. The Germans immediately fell upon the Hungarian force in Thuringia and destroyed it. The other division, marching to avenge the defeat of their fellows, was overthrown and dispersed. In the following year, 933, the Hungarians returned in immense force, but in a desperate battle fought near Merseburg they were almost annihilated. From this time on for a number of years the Hungarian invasions were mere raids for the purpose of plunder and destruction. Henry restored the ancient frontiers on the north, which had been violated by the Danes, and added Schleswig to his kingdom. This province, which, with Holstein, afterward furnished one of the complicated questions in German affairs, remained a part o Germany until the year 1032, when it was ceded by Conrad II to the Anglo-Danish king, Canute. Christianity was preached to the Danes under Henry's protection, and many converts were made. In addition to his skill in war, Henry the Fowler possessed qualities which stamp him as a great ruler. In the midst of the strife which marked his reign he was engaged with plans for the welfare of his people, encouraging husbandry and the arts, and also the commerce of the nation. A stroke of apoplexy warning him that his death was near, he summoned his nobles and exacted from them a pledge that his son Otto should be his successor. Dying in 936, he was deeply lamented by all Germany.

Schleswig.

Otto I.

Otto I, the new king, called "Otto the Great," was crowned in the cathedral at Aachen by the Archbishop of Mainz, and the dukes of Germany did him homage. Taking Charlemagne for his model, he attempted to depose the dukes from the position accorded them by his father—that of almost independent princes—and to make them his dependent vassals, as in the early days of feudalism. To this curtailment of their power they were decidedly averse. Another cause of trouble was his interference in Italian affairs and a re-assumption of German influence in the peninsula. Expeditions into Italy were disliked by both nobles and people, for with rare exceptions attempted control of the Italian kingdom by German rulers was ever a source of kingly misery and national misfortune.

Otto's first duty led him to the frontiers, which were being overrun on one side by the Wends, and on a -other by the Bohemians. Against the former he was successful, but the latter secured their liberty and maintained it for twelve years. During this time Otto was occupied in the reduction of his refractory noblemen to a condition of dependence on the throne and submission to the will of the king. A rebellion in Bavaria led to the deposition of the Duke Eberhard. A conspiracy organized in North Germany was headed by Thankmar of Saxony, Otto's half-brother, who, in conjunction with the Duke of Franconia, devastated Westphalia and captured Otto's brother Henry. The rebellion was overthrown by the captu e of Eresburg. Thankmar being killed beside the altar in the church. The Duke of Franconia was forgiven on the intercession of his prisoner, the king's brother, Henry. This same Henry thought he should be the sovereign instead of Otto, because he had been born after their father became king, while Otto was born when Henry the Fowler was only a duke. In an insurrection fomented on this claim Henry was aided by the Duke of Lorraine. Otto defeated their forces at Birthen, west of the Rhine. Henry organized a second conspiracy, in which he was joined by the Archbishop of Mainz, but their designs came to naught. The list of Henry's conspiracies ended with a third, in which he was worsted by the king, whose pardon the permanently penitent prince sought and obtained. The power of the great secular vassals now lay at the feet of the king.

Otto married his son Ludolf to a daughter of the Duke of Swabia, a union by which the government of that province soon passed into Ludolf's hands. Lorraine was made over to Conrad, a Frank noble who had assisted the king, and Bavaria was given to Henry of the three conspiracies. Each of these rulers held as vassals of the king in the old sense. Otto governed the Franks, Saxons and Thuringians in person. Christianity and German manners were imposed on the Wends, and among them bishoprics were established at Oldenburg, Havelberg, Brandenburg, Merseburg, Meissen and Zietz. The See of Posen was also set up among the Poles. Harold Bluetooth, the Dane, was driven to the northern extremity of Jutland; Henry of Bavaria pushed his conquests to the eastward as far as the Theiss, and to the southwest into Istria and Friaul. Lewis IV, of France, Otto's brother-in-law, becoming involved in difficulties with his nobles, sought the aid of the German king, who marched with an army to Paris, where he helped the French sovereign temporarily out of his troubles. Otto also interfered in the affairs of Italy, and was the means of re-introducing the Italian element into the German polity—a course which was productive of great evils. The Lombard king, Berengarius, wished to marry his son to Adelheid, or Adelaide, widow of Lothair, the last Carlovingian king of Italy. When she refused he imprisoned her in a castle, from which she was rescued by a monk named Martin. She appealed to Otto, who, in 951, marched an army to Canossa, where Berengarius was besieging her, and overthrew the Lombard potentate. The German king married Adelheid, and obtained with her the old Carlovingian claim to the crown of Italy, which he assumed. Ludolf became apprehensive that the birth of a son to Otto by this marriage would interfere with his own accession to the German throne, and conspired against his father with the Archbishop of Mainz and Conrad of Lorraine. In the war which resulted from the conspiracy, the king outlawed and deposed the two dukes. The rebellion was crushed at length, and Lorraine was divided into two provinces called Upper and Lower Lorraine, which were governed by the king's brother, Bishop Brun, of Cologne. While these dissensions were in progress the Magyars invaded Germany with a large army, bent on the permanent conquest of the country. In a fiercely fought battle on the Lech, near Augsburg, in 955, Otto so completely defeated the enemy that the river, it is said, ran red with the blood of sixty thousand men, and the half-dozen Magyars who escaped returned to their country with slit noses and ears. Among the dead on the German side were Conrad, formerly of Lorraine, and many of the noblest knights of the kingdom. This was the end of the Hungarian invasions. The king's brother, Henry of Bavaria, died soon afterward, and his death was followed by that of Ludolf, the king's son.

Ludolf's conspiracy

Lorraine.

Magyar invasions.

After the close of the Hungarian war, Otto was invited by Pope John XII to Italy, where he went and rescued the Head of the Church from the assaults of the Lombard king Berengarius. In return for this service the Pope conferred upon Otto the imperial crown of the Cæsars and the German king was hailed as the Emperor of the Holy Roman Empire. From this time the German emperors claimed the imperial crown and with it supreme secular authority in the Christian Catholic world. It is true this dignity brought with it innumerable miseries and in the end caused the dismemberment of the empire, but it was not without attendant benefits. The intimate and long-continued intercourse which then began between the rude Germans and their polished southern neighbors led to the introduction among the former people of all that Italy possessed in the fine arts, in science, in trade and in government. One of the principal evils was the calling away of the emperors from the affairs of their own land to attend those of Italy; but while the autonomy of the empire was from this cause destroyed, the connection with Italy was not an unmixed curse, for the German people were not exterminated, their intellectual horizon was enlarged, and they exist today a potent factor in the affairs of Europe.

In consequence of troubles in the Roman kingdom, Otto went there several times to direct matters with the hand of the master. He called a council which tried and deposed Pope John XII, in whose chair Otto seated Leo VIII, and compelled the Romans to take an oath that no pope should be ordained without the emperor's ratification. On the last of his visits to Rome in 966 his son Otto, then six years of age, was crowned as emperor by the Pope. In 972 Otto established a sort of alliance with the Greek empire by the marriage of his son to Theophano, daughter of the Byzantine emperor. This union seems to have been productive of but little more than the importation of the corruption of the Greek court into the German empire.

Otto II.

Otto II, eighteen years of age when he ascended the throne in 973, on the death of his father, was much under the influence of his empress and that of his mother, Adelheid. He had an ambition which overvaulted that of his father and grandfather, but he lacked their genius and determination. The first thorn in his crown was the rebellion of his cousin Henry of Bavaria, called the "Contentious." Henry made an alliance with the eastern Slavs, the Bohemians and the Poles, but was defeated by the Emperor, who gave Bavaria to Otto of Swabia, son of the dead Ludolf, and granted to Luitpold of the family of Babenbergs the East Mark, which afterward became the foundation of Austria. Continuing his career of rebellion, Henry was captured and placed in confinement at Utrecht. The Emperor in 974 made a campaign against the Danes. At Aachen in 976 he and his empress narrowly escaped capture by Lothair II, of France, who was making a stealthy attempt to possess himself of Lorraine. After his escape

War with France.

Otto sent word to Lothair that he would reply to his secret attack by open war, and invaded France in 978. His army was unable to take Paris, but he gave the treacherous French monarch a lesson which was not soon forgotten. Two years later the German emperor

France renounces Lorraine.

and the French king entered into a treaty of peace by which Lothair in behalf of France renounced all claims to Lorraine. In the meantime Italy was a horrible nightmare of family feuds and assassinations. Otto turned to this land of horrors with the hope of subject-

The emperor in Italy

ing the whole peninsula to his rule. After a short stay in Rome he passed into southern Italy, where, in 981, he met and easily defeated the forces of the Greek emperor who occupied the country. In the following year he fought a battle at Cotrone in Calabria with the Saracen allies of the Greek empire and was disastrously defeated. Improving their opportunity, the Slavs of eastern Germany, in league with the Danes, rose in revolt, having for their object not only the destruction of the empire but the abolition of the Christian religion. The Danes were reduced, but the Slavs maintained themselves against the German power. An army was collected in Germany and sent to Italy to aid the emper-

Death of Otto II.

or. Stricken with the sickness which caused his death, Otto summoned his nobles to him at Verona, where they chose as emperor his son, who is known as Otto III. He then attempted to lead his army into southern Italy, but died at Rome and was buried there in 983—the only emperor of the Holy Roman Empire who received sepulture in the Imperial City.

When the news of the sovereign's death reached Germany, the princes of the empire had just crowned the infant Otto III at Aachen. As the result of a dispute among the relatives of the emperor in regard to the possession and control of the royal child, he was at first placed in the hands of Henry the Contentious, who had previously been released from his confinement at Utrecht. Afterward, on the suspicion that Henry was aiming at the Imperial dignity, the child was surrendered to his own mother, Theophano, Henry receiving his old dukedom of Bavaria. As regent Theophano showed considerable ability in the art of government, but the great nobles were asserting their independence of the crown, and many of the provinces returned to the ancient custom of electing their own dukes. Theophano died in 991, whereupon the dukes of Bavaria, Saxony, Swabia, Tuscany, and Meissen, constituting the body of the great princes of the empire, took upon themselves the conduct of the government, with the young emperor's grandmother, Adelheid, as regent. Otto III was carefully educated by his mother and grandmother and the learned Gerbert of Rheims—whom Otto afterward made Pope with the title of Sylvester III—but the education of the youth was mainly in the foreign culture of Constantinople and Rome. He was a dreamer who constructed in his imagination a universal empire with his capital at Rome and himself ruler of the world. He did but little more than dream, and while indulging in these phantasms of universal rule he lost a great part of his actual domain. In 995, when fifteen years of age, he was declared to have attained his majority and the control of the empire was placed in his hands. After going to Rome, where he seated his cousin Bruno on the papal throne as Gregory V and receiving from that pontiff the crown of the Cæsars, he returned to Germany. His first act in the field was a movement against the revolted Wends, but he accomplished nothing save the establishment of the Polish kingdom under Bolesilaus. Other nations which had acknowledged allegiance to his immediate predecessors on the throne were also acquiring their independence. Hungary embraced Christianity, and under St. Stephen began the formation of an independent kingdom. Denmark, which had also adopted the Christian faith, was moving in the same direction.

Otto III died in 1002 without issue, nor was there left any direct descendant of Henry the Fowler, and the crown was claimed by three dukes—Henry of Bavaria, son of Henry the Contentious; Hermann of Swabia, and Eckart of Meissen. Eckart was assassinated, Hermann was already an old man, and the crown was decreed by the nobles to Henry of Bavaria, who reigned with the title of Henry II. The new monarch set about the task of consolidating the empire. He made war on Bolesilaus, the chief of the Polish kingdom, and after three campaigns was successful in reaching a peace by which Bohemia remained a province of the empire, and Bolesilaus received Meissen and became a vassal of the emperor. In Mecklenburg and Holstein he was not so fortunate, for these provinces were lost to the crown, and the inhabitants returned to heathenism. Henry made three campaigns in Italy against Arduin of Ivrea, who wished to make the whole peninsula independent of German authority. In Italy Henry was crowned king of the Romans and also king of the Lombards, having overcome Arduin, who died in a convent. At this time and afterward the German rulers were crowned four times: First, at Aachen (Aix-la-Chapelle), where they became kings of the Germans; second, at Pavia, where they took the title of kings of Italy; next at Monza, as kings of the Lombards, and finally at Rome, as emperors of the Holy Roman Empire. Henry waged wars in Flanders, Luxemburg and Burgundy. He had been named as the heir of Rudolph III of Burgundy, who was yet living, but old and childless. The heirship of the German emperor was opposed by the Burgundian nobles, and Henry went against them with his army. In two

Conquest of Burgundy

campaigns he conquered Burgundy, which included the greater part of what is now Switzerland and a portion of the valley of the Rhone. The country, however, was not then annexed to Germany, that event not occurring until the death of Rudolph. In the meantime the vassals of the empire in the heart of Germany were returning to their ancient independence. They declared their dignities hereditary, and the emperor was compelled to make them large concessions. In opposition to the growing power of the secular princes he fostered the spiritual authorities in the empire, and for a time the ecclesiastic strength was a counterpoise to that of the great secular feudatories. The wisdom of this course, however, was challenged by subsequent events.

End of the Saxon dynasty.

When Henry II died, in 1024, the line of the Saxon emperors was extinct. In the same year the clerical and noble orders met at Oppenheim for the purpose of electing a successor to the dead emperor. After a long

The Franconian line

struggle, in which the choice lay between two Conrads of Franconia—descended from a daughter of Otto the Great—each of whom agreed that he would submit to the result of the election, the elder of the two, known as Conrad the Salic, was declared king with the title of Conrad II. This sovereign began the Franconian line, as it is termed in history. In the first year of Conrad's reign the Polish kingdom, which had been extended far to the east by Bolesilaus, began to fall to pieces. The Poles were driven out of Lusatia and Bohemia. Canute, the Danish king who ruled Norway, England and Denmark, was conciliated by a marriage between his daughter and Henry, the son of the German monarch. Schleswig, which Henry I had conquered, was ceded to Canute, and the northern boundary of the empire was fixed at the Eider, as in the time of Charlemagne. A threatened war in Burgundy, growing out of the refusal of Rudolph III to make good his promise to Henry II, was averted by the submission to Conrad of Rudolph's stepson, Ernest of Swabia, who, as the nearest relative of the Burgundian ruler, claimed the kingdom for himself. In 1027 Conrad was crowned at Rome by the Pope. Passing into southern Italy the emperor confirmed the Normans in the possessions which they had seized there and returned to Germany. Ernest of Swabia made a second effort for the possession of Burgundy, but he was overcome and slain. When Rudolph died, in 1032, Conrad formally annexed the kingdom of Burgundy to his dominion, but his sovereignty in the new territory was more nominal than real, because of the almost kingly power of the great Burgundian nobles.

Burgundy annexed.

Political measures.

Conrad had a keen appreciation of the danger to his crown growing out of the strength of his principal vassals in Germany proper, and endeavored to neutralize it by cultivating the friendship of the minor nobility. One of his measures to this end was a decree making the fiefs of the tenants of the feudal lords hereditary and perpetual. By thus fostering the partial independence of the smaller feudatories he was enabled to hold somewhat in check the assumptions of the princes. Another step in this direction was the appointment of his son Henry to the dukedoms of Swabia and Bavaria, which confirmed, to that extent at least, the direct control of the sovereign. He also built up his power on the spiritual side of the realm by selecting his own relatives for high church offices. During his reign he had his son Henry crowned as his heir. After an expedition into Italy to put down a rising in Milan, in which attempt he failed, he came back to Germany and died in 1039.

Character of Conrad II

Conrad was a powerful sovereign, who governed with a strong hand; often harsh and cruel, and open to the charge of selling church offices for political service; ambitious and avaricious, but, on the whole, a ruler who conserved the national unity, and gave his people what may be termed a good government for the time in which he lived.

Henry III.

Henry III, when he succeeded his father, was twenty-three years of age. One of his first enterprises in war was undertaken against Bretislaus, Duke of Bohemia. This prince had received his title from Conrad II, as a reward for services rendered in driving the Poles out of Bohemia and Lusatia. He now desired to erect an independent kingdom, but Henry reduced him to submission. In Hungary the successor of Stephen had been driven from the throne by a rebellion, and asked the German monarch for assistance in regaining his kingdom. Henry restored him, but required of him a cession of land. The emperor also erected the Margraviate of Austria, which was given to Leopold of Babenburg. Subsequently Henry compelled Peter, the Hungarian monarch, to hold his domain as a fief of Germany. One of the acts of Henry III, which had for a time the effect of reducing the volume of lawlessness that prevailed in Germany, was his procurement in the Diet of Constance of a decree that the right of private vengeance, which had come down from the days of barbarism, should give way to the forms of law. He enforced this decree so vigorously that comparative internal peace was established. He strengthened himself in France by a marriage with Agnes, daughter of the Duke of Poitiers, and was not without hope of re-uniting the French kingdom with the empire.

In Henry's reign the sanguinary genius of the age seemed to have a momentary surfeit of human slaughter. Violence ruled everywhere, and the papacy, which should have been the saving leaven of society, was itself wallowing in a mire of vice. In the Burgundian convent of Cluny, pious men, for an amelioration of the evils of the times, originated a movement which gave rise to the partial peace known as the "Truce of God." The church at last recognized the effort by an injunction, on penalty of excommunication, that from Wednesday evening of each week until the following Monday morning all fighting, both public and private, should cease. Henry was an ardent friend of this measure, which was to some extent concurred in by the people, thus mitigating the horrors of war and individual violence. Regarding himself as an instrument commissioned for the reformation of the church, Henry took an army into Italy, caused the passage at the Council of Sutri of a decree giving the emperor the right to nominate a successor to St. Peter and deposed the three rivals who claimed the papal chair. By virtue of the Sutri decree he placed four popes in succession at the head of the church, and was assisted by them in the work of reform.

Deposition and appointment of Popes.

Revolts in Hungary, wars in Italy and Lorraine, and discontent and conspiracy in Germany clouded the last years of his reign. Close upon the news of a defeat sustained by his army in a battle with the Wends, came his death in 1056.

Henry IV.

Henry IV, son of the dead emperor, was a child, and the empire was ruled in his name by his mother, the Empress Agnes. A conspiracy to deprive her of the conduct of affairs and to place it in the hands of the great nobles was successful in so far that the young prince was abducted by Hanno, Archbishop of Cologne. The empress retired and Hanno as regent succeeded her in the government.

Regency of Hanno and Adelbert.

Suspicious of Hanno, Henry sought the friendship of Adelbert, Archbishop of Bremen, by whom he was crowned when sixteen years of age. By indiscreet measures the young ruler alienated the loyalty of the princes of the empire. Extravagant in his habits, he fell into want. He scandalized the Christian world and corrupted the morals of the people by confiscating church estates and openly selling ecclesiastical offices. He built fortresses in Saxony, which led the people to think he intended them for prisons.

Rebellion in Saxony

A general conspiracy, which ripened into open rebellion in Saxony, compelled him to fly from the palace in Goslar, which had been the residence of himself and his immediate predecessors. Taking refuge in Worms, which remained faithful to him, he was there prostrated by a sickness which threatened his life. On his recovery, finding the cities loyal, he cultivated their friendship and was soon in a position to restore his impaired authority. As his power increased he was joined by the Archbishop of Mainz and the dukes of Lorraine, Bohemia, Bavaria and Swabia. By a victory over the revolted Saxons and Thuringians at Langensalz he made himself master of all Germany. His sovereignty, however, was imperiled, and indeed for a time overthrown, by a conflict which sprang up between him and the stern, incorruptible Hildebrand, who had been elevated to the papal throne in 1073 as Gregory VII. This Pope determined to assert the supremacy of the Church over the Empire and to reform the flagrant abuses which existed among the clergy. From the nature of their office, the influence of the priests was very strong in the family. Organized, they would become a power the authority of whose head would be superior to that of the Emperor. In order to organize them, it was necessary that natural human feelings and passions should be suppressed and the whole priestly life and ambition devoted to the glory of the church. The first act of the pontiff to this end was a decree enforcing the rule of celibacy amongst the priests, which had fallen into desuetude. This was followed by a decree, issued in 1075, declaring that the investiture of bishops—the conferring on them of the ring and staff which symbolized their office—should be no longer the prerogative of any layman. The bishops were to be elected by the cathedral chapters, subject to the confirmation of the Pope alone. This was a direct challenge to the Emperor, who, in accordance with the custom established several reigns before, had made all appointments of bishops without previous conference with the Pope. The enforcement of the decree would not only transfer to the Pope an authority claimed and exercised by the Emperor, but would cut off the revenues which he received from his merchandizing in the church offices and estates. Rendered confident by the issue of the struggle with his revolted subjects, Henry was not averse to the conflict. Lances and swords, however, were but feeble weapons against the terrific power which, in the eyes of the people, held the keys of heaven and hell. In the year following the issuance of the decree of investiture by Gregory, Henry convened at Worms a council of German bishops who deposed the Pope. Gregory replied with the ban of excommunication, releasing the Emperor's subjects from their allegiance to their secular ruler. The princes of the empire, who were fretting under their submission to the sovereign, saw their opportunity and gave him notice that they would consider him deposed unless the ban were removed within a year and a day. Henry's friends fell off from him like dry husks and he found himself alone, confronting the awful authority of spiritual Rome wielded by her uncompromising champion. By an act of humiliation unheard of until then, the emperor made his peace with the Pope. Gregory was at Canossa. Hither came the monarch of Germany, who, bare-footed, clad in a coarse hair shirt, stood three days in the snow before the gate of the castle begging an audience with the Head of the Church. On the morning of the fourth day he was admitted. The haughty pontiff relinquished none of his assumed rights, but finally forgave his suppliant and removed the ban on conditions which made the empire a dependency of the papacy. Soon after this the German princes deposed Henry and declared the crown not hereditary but elective. In pursuance of this policy they elected as their king Rudolph of Swabia. The people refused to ratify the election, and the Pope demanded that the dispute should be referred to him for arbitration. Had Henry been destitute of kingly qualities, as was supposed, he would have been crushed, but all the man and all the king in him was roused, and with a spirit as unyielding as that of the arrogant Hildebrand he set his face against his evil fortune. The struggle was long and bloody and when finished the Pope was dead in exile. Henry, indeed, retained his throne, but his power was materially weakened by the distrust which existed between him and his nobles. He was also under a second ban of excommunication which had been hurled at him by the pontiff during the conflict. Nor was the principle enunciated by Gregory permanently set aside. His successors re-affirmed it, and for centuries it was a source of desperate contention between the emperors and the popes.

Canossa.

In Henry's reign occurred the first of the crusades. Many of his subjects followed the preaching of Peter the Hermit, but he himself held aloof from the movement. The latter years of the emperor's life were embittered by his strife with his sons Henry and Conrad and the refractory nobles. The rival emperor, Rudolph, was killed in battle and two other claimants of the crown were overthrown. The emperor's sons were discomfited, but, by cunning, that one of them who became Henry V made his father prisoner and compelled him to abdicate the crown. Henry IV died in 1076, and as he was yet under the ban of excommunication, several years elapsed before his body was permitted to lie in consecrated ground.

Henry V, son of the late emperor, owed his crown to the papal party and the nobles, but manifested no disposition to give up the right of investiture. He went to Italy and overawed Pope Paschal II, who yielded to him in the investiture controversy and crowned Henry emperor in 1113. This led to war, the emperor being excommunicated by the French clergy and the cardinals. Returning to Germany, he confronted a rising of the Saxon and Thuringian nobles, and reduced them to submission. He then gave his father a magnificent funeral at Spires and in 1114 married Matilda of England. Insurrections among the Saxons and Thuringians led to a war in which the emperor was defeated. All of north Germany fell away from him and he was deserted by nearly the whole German church. In south Germany he had two staunch friends in the Hohenstaufen princes, Frederick, Duke of Swabia, and Conrad, Duke of Franconia. The breach between the sovereign and the rebellious princes was bridged by a treaty which provided that the emperor should maintain peace in the empire and uphold the civil power independent of the clergy. After the death of Paschal II in 1118, Henry set up an anti-pope against Gelasius, the successor of Paschal II, and maintained his appointee in Rome. In Germany the emperor was threatened with deposition and returned to that country. After four years of struggle, the question of investiture was settled by the Concordat of Worms, by which the Pope was given the right of investiture with the ring and crosier, the bishops to be elected in the presence of the emperor or his representative, and to receive their estates as fiefs of the crown by the touch of the emperor's sceptre before ordination. This solution of the question left the emperor in control of the estates of the church in Germany, while the allegiance of the clergy was recognized as being due to the Pope. Henry V died at Utrecht in 1125, without issue, and the Franconian dynasty came to an end.

Concordat of Worms.

End of the Franconian dynasty.

Putting aside the claims of Conrad and Frederick, who were the next of kin to Henry V, the electors met at Kamba in August, 1125, and chose as emperor Lothair of Saxony, who had long been the champion of the church and the nobles against Henry V. Lothair at once renounced his right to have the bishops elected in his presence, and otherwise indicated his zeal for the interests of the church. He then demanded from the Hohenstaufens certain estates of Henry V, which had been siezed by them as heirs of the dead emperor. They resisted and for a time maintained a successful defense against the sovereign. Lothair finally secured an alliance with Henry the Proud of Bavaria by giving him his daughter Gertrude in marriage. Henry the Proud, a grandson of Welf (Guelph) to whom Henry IV had given the fief of Bavaria, afterward received Saxony from Lothair and administered the government of Germany during the absence of the emperor in Italy. In 1134 Lothair captured and destroyed Ulm, the ducal capital of the Hohenstaufens, who submitted to the rule of the emperor. Lothair made several expeditions into Italy and died while returning from that country December 3, 1137.

Emperor Lothair.

The succession was to have been decided by an election in May, 1138, Henry the Proud conducting the affairs of the empire during the interregnum. Three months before the time set for the election the Archbishop of Treves proclaimed Conrad of Hohenstaufen with the title of Conrad III, and a papal legate crowned him at Aachen. Henry the Proud, whose claims were ignored because it was feared he would become too powerful to please the nobles, was compelled at the time to submit to the election of his rival. Conrad deprived him of Saxony and gave it to Albert the Bear. In the war which followed Henry was abandoned by his Bavarian nobles and died in 1139, leaving a son ten years of age, who was afterward known as Henry the Lion. The war was continued by Welf, brother of Henry the Proud. During his advance to the relief of Weinsburg were first heard the war cries of "Welf" and "Waibling," or "Guelph" and "Ghibbeline," as they were transformed in Italy. *Welf* was the name of the family to which Henry the Proud belonged, and Waiblingen was the birth-place of the Hohenstaufen Frederick. Subsequently in the political and religious arena the Welfs were adherents of the papal party and the Waiblings upheld the German nationals. In this campaign the women of Weinsburg were the heroines of the touching story which has given them fame. The city surrendered to the emperor, who pledged his word that before it was sacked the women would be permitted to leave, bearing whatever of their possessions they could carry away with them. The women appeared carrying their fathers, brothers and lovers on their backs, a spectacle which drew tears from the eyes of the stern warrior and saved their loved ones' lives. Conrad overcame his opponents in this war, and when peace was made in 1142 he granted Saxony to the young Henry the Lion, detaching from the dukedom its northern mark, which was given to Albert the Bear with the title of Margrave of Brandenburg This Margraviate afterward became the kingdom of Prussia. To the Margrave of Austria, Henry Jasomirgott, was given Bavaria. Conrad III was invited to participate in the second crusade and led to Asia Minor an army of 70,000. They were wasted away by disease and conflict with the Saracens, and the emperor returned to Germany in 1499 with only the skeleton of the magnificent host with which he had departed. His son Henry died in 1150, and the emperor himself went to his death in 1152. Germany had profited during the crusade by the absence of the robber knights, who, after being a grievous burden to the realm, had donned the cross, and most of them were slain in Asia bearing the sacred emblem.

Conrad's nephew, Frederick Barbarossa (Red-beard), a powerful ruler, just, in his conception of the word, and a great captain in war, was crowned at Aachen immediately after Conrad's death. Frederick's mother being a Welf, and he himself a Waibling on the side of his father, he endeavored to reconcile the two factions, whose wars disturbed the peace of the empire. The feudal system had reached its completest development. Frederick recognized the rights of the great feudatories, but was determined to enforce his claims upon their allegiance, having in view the restoration of the empire to the power it had enjoyed in the days of Charlemagne. He arbitrated a dispute between Sweyn and Canute, each of whom claimed the Danish throne, awarding the crown to Sweyn and receiving from him an oath of allegiance. The Duke of Bohemia was elevated to the rank of king. Through his own marriage to the niece and heiress of the Count of Burgundy, that state was added to the emperor's hereditary lands. Henry the Lion was conciliated by the gift of Bavaria, which was taken for that purpose from Henry of Austria, for whom, however, Frederick erected Austria nto a duchy. Passing into Italy to the rescue of the Pope, who was besieged by his rebellious subjects, the emperor reduced Rome, where he was crowned by Adrian IV. On his return to Germany he punished the robber knights—whose spoliation of travelers and traders rendered the roads unsafe — and adopted other measures for the public security. Henry the Lion, now the most powerful nobleman in the empire, conquered Mecklenburg, built cities there and introduced Saxon colonies into the newly acquired territory. Albert the Bear was engaged in similar work in Brandenburg and the adjacent country. In 1158 Frederick went again to Italy, and while there called together a body of Italian lawyers who prepared a code of the Roman civil law, which was afterward introduced into Germany. Milan, refusing to receive Frederick's governors, was destroyed, and with this fearful example before them, the other cities submitted to the emperor's rule. After his return to Germany he interfered in a Polish dispute and annexed Schleswig. Pope Alexander III having formed a confederacy of the northern Italian cities in opposition to the German emperor, Frederick invaded that country, but was compelled to retreat in consequence of a pestilence which carried off the best part of his army. Milan was rebuilt in his absence. In 1174 the emperor went to Italy with a large army to recover control of the revolted cities, but fortune was against him. Being reduced to extremities, he called on Henry the Lion for aid. Henry refused, and thus laid the foundation of a bitter enmity, which resulted in his humiliation. At the battle of Legnano in 1176 the German army was utterly defeated by the confederated Lombard cities. Humbled by his defeat, the emperor sought a reconciliation with Pope Alexander III, who accepted his friendship and in his interest negotiated the Peace of Constance, by which the confederated cities, while acknowledging allegiance to the emperor, became practically free. Frederick was crowned King of Burgundy at Arles in 1178. The alleged tyranny of Henry the Lion over the smaller nobles in his dominions gave the emperor an opportunity to retaliate for the refusal by Henry of Frederick's application for aid in Italy, which was assigned as the cause of the defeat at Legnano. Henry's possessions were divided among faithful adherents of the emperor, and Henry himself was compelled to humble himself before his sovereign. Of all his ducal possessions he was permitted to retain only his family estates, and he was banished for three years. Saxony was divided, the name of the duchy being attached to the eastern district, which was given to Bernard, son of Albert the Bear. Frederick also decreed that the sees of Regensburg, Bavaria, Salzburg and Passau should be independent of all minor authority, and elevated the Tyrol and Styria to independence under the crown. Peace being restored, he visited Italy, where he was received with reverence. In 1186 he married his son Henry to Constance, daughter of the Norman king of Sicily and acquired an interest in that kingdom which was disastrous to his successors. The last act of the emperor's life was his participation in the third crusade. While bathing in the river Seleph in Asia Minor he was drowned, June 10th, 1190, and his death caused the failure of that attempt to rescue the Holy City from the hands of the Saracens. During his reign Frederick had given his subjects substantial peace at home and enlarged the empire by foreign conquest. He encouraged the arts and sciences as well as the industries of the empire. As a popular hero, he was sincerely lamented by his people.

Henry VI, son and successor of Frederick I, came to the throne at the age of 25. He was a severe, ambitious monarch who was spurred by a desire to emulate the career of his father. His first expedition was to Italy, where he received the crown of the Cæsars in 1191. An attempt by him to enter into possession of his wife's inheritance of the Norman kingdom in southern Italy was resisted by the people, and in Germany his troubles began with an endeavor by Henry the Lion to regain his possessions. This prince made an alliance with Richard I of England, who was then engaged in a crusade in Palestine. The English monarch returning from Palestine to his own country through Austria, was seized by Leopold and delivered to the emperor. Henry received from Richard a heavy ransom and Henry the Lion was reinstated in his dignities. In 1194 the emperor secured the Norman kingdom in Italy and assumed the crown at Palermo. He also had his son Frederick crowned as emperor at Rome in 1196. In 1197, while revelling in dreams of universal rule as wild as those of Otto III, Henry died, leaving the throne to his young son Frederick. Ignoring Frederick's claims, the electors chose as emperor Philip of Swabia, the young prince's uncle; Otto, son of Henry the Lion, was also set up as emperor with the title of Otto IV. Civil war ensued between the adherents of the rival emperors. Pope Innocent III, a learned, gloomy-minded, ambitious priest, claimed the right to decide the question of the succession and awarded the throne to Otto. Philip was killed and Otto was chosen king in 1208 at a diet in Frankfort. Otto was a Welf; in order to conciliate the Waibling party he married the daughter of Philip and was crowned by the Pope as emperor in 1209. Otto's cruelty and avarice earned him many enemies, who welcomed a new claimant of the throne in the person of Frederick, son of Henry VI. Frederick was called to Germany from the Norman-Italian kingdom where he had been reared, and soon made himself master of the southern German provinces. Otto allied himself with the English king John—who was then at war with Philip Augustus of France—and was defeated at the battle of Bouvines. He died in poverty and humiliation at Hartzburg, in 1218.

In the meantime Frederick II had been crowned at Aachen, in the year 1215. He was a brilliant, intellectual sovereign, but had little affection for Germany, to which country and its genius he was a stranger. He abandoned to the Danish king all the land north of the Elbe in order to secure an alliance with Waldemar of Denmark, who immediately took possession of Holstein, Mecklenburg and Pomerania. The people in the territory adjacent to Brandenburg were converted to Christianity and German settlements there carried civilization with them throughout its extent. Owing his throne to Pope Innocent III. Frederick had promised that pontiff at his own coronation that he would be content with the German crown, and would make a crusade in the Holy Land. He put off the crusade on various pretexts, and so far from confining himself to the German crown, he assumed control of the Norman kingdom in southern Italy. At length in 1228 he departed on a crusade, in which he negotiated a truce with the Sultan of Egypt and had himself crowned King of Jerusalem. He then returned to southern Italy and substituted for the feudal system in that country a form of government resembling a constitutional monarchy. Meanwhile his son Henry, chosen King of Germany in 1222, acted as Frederick's viceroy in that country. Henry had been promised the Norman kingdom, and because his father had taken it himself, thought he was wronged. In 1234 he declared his purpose of governing Germany for himself, but Frederick came back from Italy in 1235 and overthrew him. Henry was pardoned by his father, but renewing his designs on the throne, he was cast into prison and died there in 1242. Frederick having lost two wives, married Isabella, daughter of the English king. He subdued an insurrection led by Frederick of Austria, the last of the Babenburgs. At the Diet of Spires, held in 1237, Frederick secured the election as king of his son Conrad, the fourth of that name. The emperor then returned to Italy and did not return to Germany. In Italy he attempted to establish his dominion over the whole peninsula, and was engaged with the popes in a furious war not only of arms, but of words. Attacking the doctrine of temporal sovereignty in the papacy, he in return was characterized as the "Apocalyptic Beast." "Guelph" and "Ghibbeline" became the war-cries respectively of the friends of the Pope and those of the emperor. In this strife Frederick was engaged for the last thirteen years of his life, dying in 1250. Such a terrible enemy was he of the papacy that on hearing of his death Pope Innocent IV exclaimed: "Let the heavens rejoice and let the earth be glad." In Germany Conrad's power declined day by day; the duchies, the cities and even the large landed proprietors asserted and maintained their independence of the crown. In 1241 the Mongols under the successors of Genghis Khan made an irruption into Silesia, but were beaten back without the assistance of Conrad, by Henry the Pious, Margrave of Liegnitz. In 1246, on the instigation of the Pope, the ecclesiastical princes of the Rhine declared the deposition of Frederick and chose Henry Raspe of Thuringia as emperor, but this rival was overthrown by Conrad and died in 1247. Count William of Holland, another claimant of the throne, through an election by the spiritual princes, engaged Conrad in puerile war and overcame him in 1251. The defeated king took refuge in Sicily with his half-brother Manfred—who had seized the throne on the death of Frederick II—and died in 1254. He left a son, Conradin, who was brought up in Swabia. After the death of Manfred in battle with Charles of Anjou, to whom the Pope had promised the southern Italian kingdom, Conradin attempted to establish himself as sovereign in Naples and Sicily, but was taken prisoner by Charles, and the last of the Hohenstaufen line was executed on the scaffold.

Rebellion of Frederick's son Henry.

War with the papacy.

With the fall of the Hohenstaufen dynasty in Germany, the empire was broken into fragments. The ancient dukedoms were divided and a new order of society was established. Had the lesson taught by the fate of former dynasties been heeded in time—that the hope of Germany lay in confining itself to Germany and relinquishing all thoughts of dominion south of the Alps—the empire might, perhaps, have been maintained on a firm foundation. Aside from this, one of the principal obstacles to stable rule was the ungovernable ambition of the great nobles, who aspired to absolute sovereignty in their own provinces, and whenever the sceptre was held by a weak hand, attained it. The great ecclesiastical lords were seldom in complete accord with the reigning monarch, for their spiritual allegiance at least was due to an authority which with them stood higher than the national government, and which was frequently in conflict with it. The lower classes had entirely lost the independence of the earlier days, and were fallen into the condition of peasants and serfs. Robber barons whose revenues were insufficient to support their style of living, literally took to the road and levied blackmail on all who passed through their territories. Every man's hand seemed to be turned against his neighbor, and chaos appeared to have come again. The spirit of chivalry gilded the surface, but in the depths the cankerworm of national decadence was gnawing its way into the vitals of the state.

Condition of society.

The period of 22 years from the deposition of Conrad IV, in 1251, to the election of Rudolph of Hapsburg in 1273, is termed "The Great Interregnum." During this time, out of the ruins of the old system was formed a patchwork state which had no adhesive quality, no competent central head, and, indeed, no other tie than that of common blood. In the new arrangement the manipulators of the political machine which succeeded the great interregnum were called "The States of the Empire." First came the princes, who, after a time, secured to themselves the sole right of electing the German king. This house of electors was composed of the three Archbishops of Cologne, Treves and Mayence, and the four temporal princes of Bohemia, Bavaria, Saxony and Brandenburg. With these princes the sole object appeared to be the aggrandizement of their several houses without regard to the welfare of the state. They established for themselves the principle of heredity, but, fearing the power of dynasties, they denied it to their king. They also hampered their sovereign at his election by pledges which to a great extent nullified the royal decrees. Below these princes came in order of rank the dukes, margraves, landgraves, counts and barons, and knights of the empire. On the spiritual side of the realm were archbishops, bishops, abbots and commanders of religious orders. In addition to these were the free cities, which were practically independent, aristocratic republics. In the exercise of their freedom, the cities formed alliances with one another, constituting a powerful confederation, which in time waged war and administered government in its own name. The cities which were not free were dependent on some feudal lord. About this time the Hanseatic League—a union of maritime cities for the protection of commerce,—came into prominence, and subsequently developed into a great power. The mass of the people were peasants, bearing the burden but receiving none of the honors of government. Each of

The house of electors.

these classes was for centuries engaged in a struggle for power or freedom.

William of Holland, who overthrew Conrad IV, was acknowledged as emperor by several of the vassals of the empire, but he wielded scarcely the power of a modern sheriff. Engaging in a war of conquest among the free Frisians, he was defeated and killed in 1256. The lack of national spirit was so pronounced that the princes were willing to go on without any king, but the free cities, which had risen to great importance, demanded a head of the state. The princes were compelled to yield, but preferred a foreigner for the strange reason that having no feudal estates in Germany, he would not be likely to take much interest in its affairs. In 1257 the Archbishop of Cologne and the electors of Mayence and Bavaria set up Richard Duke of Cornwall, brother of the English king, while the electors of Bohemia, Saxony and Brandenburg in conjunction with the Archbishop of Treves, elected King Alfonso of Castile. These rival emperors paid very little attention to their imperial dignities. Alfonso never saw Germany; Richard visited the country four times, departing the last time by stealth and in disgrace. Richard of Cornwall died in 1272 and the election of a king was demanded by the people as a method of release from the anarchy which prevailed. The Pope, whose revenues from Germany were decreasing, and who wished to find a counterpoise to the growing strength of the House of Anjou in southern Italy, called on the German people to elect a ruler.

Rudolph of Hapsburg. In 1273 the electors came together at Frankfort and chose as emperor Count Rudolph of Hapsburg, then in his 55th year. This monarch, to whom perhaps Austria is indebted for her prominence in Europe, was a wise ruler, simple and kindly in his private life, but valiant in the field, and a statesman of no mean order. Rudolph immediately began to gather into his hands the imperial rights and property which had been alienated in the reign of the last Hohenstaufen. He was supported by the best of the electors, and by Pope Gregory X, with whom he had an interview and whom he vowed to protect and defend. Rudolph had a bitter Ottocar enemy in Ottocar, King of Bohemia, who had expected to be elected Emperor of Germany. Ottocar had built up a mixed German and Slavonic kingdom, which included not only Bohemia and Moravia, but Austria, Styria, Carinthia and Carniola, parts of Hungary and Poland, and extended on the northeast to Konigsburg which he had built on the Baltic. He refused to acknowledge Rudolph as emperor, and the latter, after some delay in organizing his forces, overthrew him in a great battle on the Marchfeld near Vienna in 1278. Ottocar was killed on the field. His son Wenzel acknowledged Rudolph and married one of his daughters. In 1282 Rudolph gave Austria, Styria and Carniola to his own son Albert, and Carinthia to Meinhard of Gortz. [Internal administration.] The emperor then addressed himself to the administration of internal affairs, restoring order and law by the hanging of the robber barons and by other measures. Eleven years after his election he married Isabella of Burgundy, but obtained no control of that kingdom, nor was he successful in extending his power over Hungary. Rudolph died in 1291 and was buried at Spires. During his life he had endeavored to secure the election of his son Albert as emperor, but the electors were too jealous of hereditary lines to accede to his request.

When the throne became vacant in 1291, the electors chose Adolphus of Nassau, a bold, unscrupulous ruler. He made an alliance with the King of England against the French monarch, who was endeavoring to get possession of German territory along the Rhine. With the large sum of money furnished him by the English king for use against France, regardless of the terms of the alliance, Adolphus purchased Thuringia and Meissen from Albert the Degenerate. Adolphus entered the two provinces with his army, but was resisted by the sons of Albert, who maintained themselves against him. The emperor then violated his compact made with the electors by an attempt to win the cities to his cause through the abolition of the tolls on the Rhine. A majority of the electors deposed him and chose in his stead Albert of Austria, son of Rudolph of Hapsburg. In a battle at Gollheim in 1298, Adolphus was killed by Albert in a hand-to-hand combat. The previous election of Albert being deemed irregular, he was re-elected and crowned in 1298.

Albert I was a gloomy, calculating ruler, bent on the restoration of the German monarchy and the aggrandizement of the House of Austria. At first he had serious differences with Pope Boniface VIII, but they were afterwards reconciled and he became a devoted adherent of the Roman pontiff. Albert abolished the tolls on the Rhine in order to secure the assistance of the confederated cities, promised the vassals of the princes the "Freedom of the Empire" in return for their support, and employed every means within his reach to weaken or destroy the power of the great nobles. He claimed Holland and Zealand as a vacant fief, but his attempted usurpation was defeated. Bohemia was declared a fief of the empire and given to the emperor's son Rudolph with the title of king. Rudolph died a few months afterward and the people of Bohemia refused to accept an Austrian as their ruler. The emperor's claim to Thuringia was disputed and his army there was defeated. Albert was assassinated in 1308 by his nephew John, called "The Parricide" because of this crime.

Henry, Count of Luxemburg, was elevated to the throne as Henry VII in the fall of 1308. He determined to become emperor in the old sense. After placing his son John on the throne of Bohemia, he revived the ancient imperial practice of the journey to Rome, where the crown of the Cæsars was placed on his head. He was also crowned at Milan. Hatred of German rule leagued the princes of Italy against him; the Pope excommunicated him, and he died suddenly in 1313, not without a suspicion of having been poisoned —the favorite Italian method of removal, which was considered less honorable, but was certainly not less effectual than the German method along the road of insurrection to the sword or the dagger.

The claimants for the vacant throne were Frederick the Fair, Duke of Austria and son of Albert I, and Lewis, Duke of Bavaria. Each was elected by a faction of the House of Electors. The outcome of the struggle between the rivals was materially influenced by the battle of Morgarten, which also laid the foundation of Swiss independence. The forest cantons had been confirmed in the freedom of the empire by Henry VII. The Swiss were partisans of Lewis, and Frederick's brother Leopold undertook to subdue them. In the famous battle of Morgarten the Swiss peasants routed Leopold's forces, thus cutting off an important element of Frederick's strength. Pope John XXII claimed the right not only of deciding the election, but of governing the empire. His claims were ignored with contempt, for a time had arrived when the Germans were determined to rule their own country without papal interference. The war which followed between the rivals continued with varying fortune until 1322, when Frederick's army was decisively defeated in the battle of Muhldorf. The victory was secured for Lewis by a charge of Bavarian cavalry led by Seifrid Schweppermann. The gratitude of the victor is illustrated by an incident which is said to have occurred on the night after the battle. The king's steward announced that a small number of eggs had been procured for the evening meal. "An egg apiece," exclaimed the monarch, "and two for the faithful Schweppermann!" The war was sustained a short time by Leopold, but was ended by his death in 1326. A reconciliation took place between Frederick and Lewis in 1325, and an agreement was made by which, while Lewis bore the imperial title, Frederick shared with him the administration of the government. This

Lewis IV.

Crowned emperor by "The Roman Republic."

arrangement was continued until 1330, when Frederick died and Lewis reigned alone as Lewis IV. He obtained the imperial crown from the people of Rome, who had expelled Pope John XXII and styled themselves "The Roman Republic." On his return from Italy Lewis was reconciled to Albert and Otto, sons of Albert I, and carried on a war with Pope John, who held his court at Avignon in France, and was supported by the French king. At this time the abuses in the church were laid bare by the writings of the Franciscan monks, and the exposure led to a general belief in the necessity of a reformation. Frederick was not a great statesman. Failing absolutely to detect the trend of thought and the forces which were moving among the people. carrying them forward to the great reformation, he endeavored to conciliate the Pope and abased himself before the Head of the Church, but without effect. In 1338 he called a Diet of the Empire at Frankfort, which included not only the princes but the lower nobility, the knights and the representatives of the cities. To the latter he had given many privileges which materially increased their power and permitted them to largely develop their varied industries and commerce. At this diet the solemn declaration was made which divorced the temporal power of Germany from the spiritual power of the papacy. They declared that "the King of Germany received his authority solely from God. and by the choice of the German electors; the Pope has no right of decision, confirmation, or rejection in the election." In 1324 Lewis declared the fief of Brandenburg vacant and bestowed it upon his son Lewis, then an infant. He also made an enemy of King John of Bohemia. Through the influence of the Pope, Lewis was deposed by a part of the electors in 1346 and Charles of Luxemburg, son of the Bohemian king, was elected sovereign of Germany by the same electors. Charles was crowned at Bonn, but was not efficiently supported. The old King of Bohemia, with his son Charles, went to France to assist Philip VI in his war with England. At the battle of Crecy, John was killed and his knightly motto, "Ich dien" (I serve) was adopted on that field by the victor, Edward the Black Prince. The motto is still borne by the Prince of Wales. Charles returned to Germany to fight or negotiate for his crown.

Repudiation of temporal papal power.

Charles IV.

Gunther.

Lewis died in 1347, and the claimant as Charles IV, bought his way to the throne by gifts of money to the electors and promises of subserviency to the Pope. He was opposed by Gunther of Schwarzburg, who was put forward by Lewis of Brandenburg, son of the dead sovereign. Gunther was deserted by his followers and was compelled to renounce his claim to the throne, which he did two days before his death, June 14th, 1349. Charles IV was a schemer and a trader rather than a warrior, and he accomplished a great deal by the use of money which could not have been won by arms. In Italy he was crowned emperor, but sold all the rights of the empire still existing in that country, and returned to Germany. The only one of his acts for which Germany was grateful was the issuance of the "Golden Bull," for it established among other things the membership of the House of Electors, which did much to prevent the strife that had become almost a custom from the setting up of rival emperors by fractions of the electoral body. The following were declared to be the legitimate electors: The Archbishops of Cologne, Treves and Mayence, the King of Bohemia, the Count Palatine of the Rhine, the Duke of Saxony, and the Margrave of Brandenburg. The House of Wittenburg was to hold and cast the vote of Saxony, a right which had been claimed by the Lauenberg branch, and the dispute as to the Electoral Palatinate was settled by giving its vote to the House of Wittelsbach. To the electors were given certain powers in their own domains superior to those of the king. In regard to the family title and the possessions of the electors, the law of primogeniture was to prevail. In his own territory each elector was the supreme judicial arbiter, and he had there the exclusive right to work the mines, coin money and tax the Jews. These enterprising sons of Shem, being cut off from public place, were wholly given to trade and were in a fair way to absorb the business of the realm. Frankfort was named as the place of election, and Aix as that of the coronation of kings. The Golden Bull remained in force until the middle of the seventeenth century, and was of considerable effect in preventing contests over elections. Having regulated this important matter, Charles set about the acquisition of territory and added to his hereditary domain Brandenburg, the upper Palatinate, Pomerania, Mecklenburg and Silesia. In his reign the "Black Death" swept through Europe, carrying off in Germany alone not less than one hundred and twenty-four thousand victims. Europe is supposed to have lost one-fourth of its population by this pestilence. In the ignorance of the people, the Black Death was ascribed to the Jews and thousands of them were slaughtered. In many places large bodies of this unfortunate race put themselves to death rather than face the infuriated populace. The moral effect of the pestilence was felt in the license practiced by the living, who, in the belief that the world was to be depopulated, adopted the principle "Eat, drink and be merry, for tomorrow we die." The use of gunpowder became common in this reign, and was an efficient factor in the "War of the Cities." In these black, flamy grains, knighthood with its cumbrous armor met its doom. Charles gave good government to Bohemia, but to some extent neglected the remainder of Germany. He fortified Prague and established there in 1348 the first German university. Charles IV died in 1378.

Use of gunpowder

Wenzel.

Wenzel, the son and successor of Charles IV, began his reign by a division of South Germany into four circles for judicial purposes, and afterwards created seven circles, but in the disturbed state of the empire his efforts in this direction were not at first successful. The Swiss struggle for independence continued, and for a time the freedom of the mountaineers was secured by the victory of Sempach—where Arnold von Winkelried earned his fame with his life—and that of Nafels. The War of the Cities was maintained until 1388. When the Municipals were defeated at Doffingen in that year, the emperor dissolved all city leagues. The political power of the cities was almost crushed, and the authority of the princes proportionately increased. Wenzel, who saw in the imperial dignity but little more than an opportunity to indulge his taste for hunting and carousal, neglected the affairs of the empire to such an extent that a conspiracy was organized against him, which was finally successful. On his loss of the imperial throne in 1400, he retired to Bohemia. which he continued to rule as king.

Battle of Sempach.

Deposition of Wenzel.

Rupert.

Rupert of the Palatinate, who occupied the throne until his death in 1410, accomplished nothing except the carrying on of fruitless war with the adherents of Wenzel. After Rupert's death, three claimants of the crown appeared—Wenzel, who was still living; Jobst, Margrave of Moravia, and Sigismund, King of Hungary and Poland. Jobst died in 1411, Wenzel's candidacy amounted to nothing, and Sigismund, by the skill of Frederick of Hohenzollern in obtaining the acquiescence of the electors, was called to the throne in 1411. At this time the prostitution by the Popes of their high office was shameful. One pope at Avignon and another at Rome vied the one with the other in the employment of measures which brought the church into contempt. Intermixed with excommunications of each other, they encouraged the sale of indulgences and the use of other vicious devices for the raising of money with which to prosecute their schemes. The evil at last led to the calling by the cardinals of the Council of Pisa, which elected a Pope and deposed the other two, who, however, refused to obey the decree of the council. A thrill of spiritual awakening ran through the people, and the new doctrines proclaimed by Wickliffe, Jerome of Prague and John Huss heralded the reformation which culminated with Martin Luther. The whole Christian world sent representatives to the Council of Constance, which assembled in 1414. The Patriarch of Constantinople was represented in the council; the Emperor gave it the authority of his presence, and its early deliberations were attended by Pope John XXII. Under a safeguard signed by Sigismund, John Huss appeared and for three days before the church fathers denounced the abuses in the papacy and defended his own position. The Council condemned him to death, and, in utter disregard of the safety promised him by Sigismund, had him burned at the stake and his ashes flung into the Rhine. The three Popes were deposed by the Council, which asserted its authority in the election of Pope Martin V. The Emperor at this time ceded to Frederick of Hohenzollern the Electorate of Brandenburg. The first effect of the action of the Council of Constance was a furious rebellion in Bohemia to revenge the death of Huss. When, on the death of Wenzel, Bohemia fell to Sigismund, the Bohemians refused to receive him because of his treachery to Huss. Before John Ziska. the blind leader of the Bohemians, and others who followed him, the Emperor's armies were destroyed, and in 1431 he gave up the attempt to quell the insurrection. Sigismund was crowned at Rome and Milan in 1431. By a treaty with one of the parties into which the revolted Bohemians were divided, the Emperor assured them their religious freedom, and was acknowledged as King of Bohemia. He bequeathed the crowns of Hungary and Bohemia to his son-in-law, Albert of Austria, and died in 1437. From his reign dates the beginning of the importance of the great rival kingdoms of modern Germany, Prussia and Austria. Sigismund was a ruler of considerable intellectual attainments, but notably weak character. He is remembered in modern times better, perhaps, from the odium attaching to his name because of his treacherous surrender of Huss than from any other act of his reign.

Albert II, who succeeded his father-in-law on the imperial throne in 1437, proceeded at once to organize the empire for resistance to the Turks, who were on the eve of the capture of Constantinople, and had already pushed their advance into Hungary. He led an army as far as the Theiss, but died in 1439, having reigned less than two years.

Albert's successor, Frederick of Styria, who continued the Austrian line of emperors, took the title of Frederick III. He occupied the throne from 1440 to 1493, and through this long period of fifty-three years his indecision of character brought many miseries upon the empire. He first made an attempt to regain possession of Switzerland, but failed. In 1446 he ordained a "National Peace" for five years, but the old custom of private feuds continued without interruption. The Electors, disheartened by the condition of the country, caused by his neglect of affairs, threatened to depose him and proposed to place on the throne George Podiebrad, the Hussite King of Bohemia. Pope Pius II, who was bitterly opposed to the recognition of a heretic, made an alliance with Frederick, by which not only were the plans of the Electors frustrated, but an intimate association was formed between the Imperial Throne and the Papacy. Meanwhile affairs in the interior of the empire were in confusion and lawlessness prevailed. In 1449 a war broke out between the Margrave of Brandenburg and the City of Nuremburg. In the course of the struggle Nuremburg was joined by seventy-two imperial towns and a detachment of eight hundred men from the Swiss League. The Margrave was assisted by the princes of Austria, Baden, Wurtemburg, and others. The war lasted seven years and the advantage lay with the princes, but they were not entirely successful. for the power of the cities was not destroyed. The authority of the Emperor was so slight that numerous private wars were engaged in without interference from the head of the empire. Charles the Bold of Burgundy, taking advantage of the weakness of the Emperor, attempted the conquest of Lorraine and Switzerland. Charles captured Nancy, the chief city of Lorraine, but after several campaigns in Switzerland his army was defeated and he was left dead on the field. Torn by internal strife, the empire was threatened with dissolution by the rapid advance of the Turks toward the centre of Europe. Having taken Constantinople in 1453, they pushed to the north and west into Carinthia and Carniola. In Bohemia and Hungary the cause of the emperor steadily waned. In the former country George Podiebrad acquired a dangerous power; the Hungarians under Matthias Corvinus seized Vienna and were not expelled until a short time before Frederick's death. The Poles and Lithuanians advanced on the northeastern frontiers, but were held in check by the Hohenzollern Frederick II of Brandenburg. While the cup of Germany's misery was overflowing, the Emperor, by the marriage of his son Maximilian to Mary of Burgundy, brought into his family the great possessions of Charles the Bold. Maximilian was crowned "King of the Romans" (German king) in 1486, and was immediately associated with his father in the administration of the government. In 1488 the "Swabian League" was formed for the preservation of peace. This league, which was at first composed of several imperial cities and knights of the empire, was subsequently joined by a number of the princes, and in some measure restrained the disorder of the times. By the vigorous efforts of the emperor's son, the Hungarians were driven out of Vienna and peace in the empire was substantially established. Frederick had been crowned Emperor by Pope Nicholas V in 1452, but the title brought with it neither honor nor power. He was the last emperor who made the journey to Rome for the purpose of receiving the crown of the Cæsars. He died in 1493, and the imperial power was quietly assumed by Maximilian. The reign of Frederick III was marked by the organization of local diets throughout the empire, composed of the lower order of nobles and the representatives of the cities. These diets were a growing power, which did much to carry on government in an empire the head of which was better fitted for the cloister or the laboratory than the throne.

Charles the Bold

Maximilian

Maximilian I was a bold monarch, a man of noble disposition and persistent activity, but his strength was wasted in adventures which, while they redounded to his personal fame, were of no benefit to his people. As a knight-errant he would have won great renown; as an emperor he was a failure. Imbued with a chivalrous spirit, he was unable to comprehend the genius of the age, which was that of progress and reformation rather than the glory of the tournament and the fierce pleasure of war. The first Imperial Diet called by Maximilian was held at Worms in 1495. The Emperor's object in calling it was to procure for himself the whole power of the empire to be used in foiling the machinations of the French king in Italy. The diet, however, thought more of securing the peace of the realm at home than a resumption of German authority south of the Alps. This body proclaimed "The Public Peace" as a law, and the right of private revenge was forever abolished. An Imperial Chamber of Justice was established on a basis of independence so far as the Emperor was concerned. It was to have power to pronounce the ban of the empire of its own motion, with or without the sanction of the Emperor. The jurisdiction of this tribunal was supreme in matters of controversy among the nobility. The Diet levied an Imperial tax, the Emperor having no control of either its collection or expenditure, both of which were under the authority of the General Assembly of the States of the Empire. The Assembly of the States was also to have, independent of the Emperor, the right to begin war, and was to be convoked every year. This constitution was gradually recognized and became efficient in the preservation of peace. but it came too late to prevent the disintegration of the empire. Maximilian thus became virtually a constitutional monarch, but his parliament. the States General, was almost entirely independent of him. The Cities, the Princes and the Electors composing it. were jealous of one another. Maximilian's hot desire to begin the work of war in Italy was neutralized by the Assembly, which failed to furnish him with either money or men for that purpose. At one time during his reign he contemplated a union of the spiritual and temporal power of the Christian world by having himself elected Pope. Charles VIII of France, reviving the claims of the house of Anjou to the south Italian kingdom, had gained possession of Naples. Maximilian allied himself with the Pope and Ferdinand of Aragon and compelled Charles to retire. At this time the emperor negotiated the marriage of his son Philip with Juana, Infanta of Spain, from which union issued Charles V, who ruled half of Europe. In 1498 Maximilian invaded Upper Burgundy and Champagne, but was forced to make the peace of Basle (1499) by which Switzerland was practically released from all allegiance to the Empire. At the Diet of Augsburg, held in 1500, a scheme was adopted of levying an army by taking one man from each four hundred of the emperor's subjects. A permanent Imperial Council was formed, and for judicial purposes the Empire was divided into six Circles. The Imperial Council, in which the emperor was simply presiding officer, was a supreme court with both civil and criminal jurisdiction. The first act of this body was to conclude an armistice with France, yielding Milan as a fief of that country, much to the indignation of the German Emperor. Subsequently, however, he was furnished with troops and money and in 1508 marched into Italy. At Trient he proclaimed himself "Roman Emperor-elect," which title was sanctioned by Pope Julius II, although there was no coronation. Maximilian was driven out of Italy by the Venetians, whom he had attacked. In 1509 he changed his policy and concluded with Louis XII of France the "League of Cambray," which had for its object the humiliation of Venice and a division of her possessions. The diet refused to sustain the Emperor in this dishonorable scheme. He continued the war with the resources of his Austrian dominions until 1510, in which year the League of Cambray was broken by a quarrel between him and the French king. He then made an armistice with Venice and returned to Germany, where he immediately became involved in disputes with the "States General," but at the Diet of Treves in 1512 he surrendered most of his claims. The judicial circles were ordered to be increased to ten, and the diet adopted other measures for the peace of the country. The war with Venice was resumed in 1512 on the conclusion of the armistice, and continued for several years. Maximilian died in 1519.

Freedom of Switzerland.

The "League of Cambray."

During this reign, the minds of men in Germany were bent on political reform and the suppression of internal disorder, into which the country had relapsed, none of those in high place appearing even to dream of the mighty revolution in thought which was close upon the Christian world. The conditions in Germany were better adapted to the success of what is called the "Great Reformation" than in any of the other nations. With comparatively few exceptions, the human race demands a holding-ground in religious belief. The ideal of religion is placed far above human conception. and especially was this so among the early Germans. Their gods were regarded as too great to dwell in temples made by human hands; only the groves made by the Deity himself were His fit places of worship on earth. With Christianity came a transfer of their adoration to the dwelling-place and the representative of the new faith, and thus to them Rome was the Holy City par excellence. The sentiments of loyalty and fidelity which characterized the race operated to make them the devoted liege-men of Jesus Christ. whom they followed as they followed their military leaders: for it is a singular fact that in the early days of Christianity among the Germans they attached but little importance to the vicarious sufferings and atonement of the Savior, regarding Him rather as a tribal chief or feudal lord to whom they owed their allegiance and their lives. With this idea of personal devotion. their reverence was supreme for all that pertained to Him—Rome. the Pope, the clergy and the ordinances of the church. The struggle for power between the emperors and the popes, which brought into conflict their loyalty to their temporal sovereign and that which they owed to the Head of the Church on earth, created doubts of the infallibility of the spiritual power and inclined them to the belief that it was not the true agent of the Almighty. The humiliation of the national dignity in the person of the people's representative at Canossa, and the repeated attempts at usurpation of authority by the papacy, still further relaxed their faith. The corruptions in the church, which were visible in the sale of indulgences and the dissolute lives of the priests, resulted in bringing sacred subjects into contempt and created new breaches which the ecclesiastical power made no effort to fill, and which finally became impassable. The sublime structure upon which the people had been accustomed to lean was felt to have been built upon sand, and, sorrowing, as children who turn from the treachery of a once loved and honored parent, they drifted away from the unquestioning faith and obedience which they had accorded it for centuries. Their faith being dead in that which claimed to represent their spiritual Liege-Lord, but with the religious impulse still a living force within them, they wandered uncertainly about, compelled by an inherent necessity of their being to lay hold on some substitute for the belief which they had rejected. Atheism, philosophy and the arts, which followed in the train of the Renaissance, were not for the common people, although to the educated minds of the day they furnished to a limited extent a source of relief. To the lower classes, burdened with toil, to whom came no other reward for continuous labor than the maintenance of a miserable existence, the consolations of religion were beyond value; yet even they had learned to laugh at the vices of the priesthood. Beyond question, the Church of Rome had done noble work for the world. She had lifted out of barbarism many of the tribes of ancient Europe; she had preserved nearly all there was of art, and had held together the few threads of civilization and humanity which ran through the savagery of the early and middle ages; but under the ever-ruling principle which requires present works, she had been weighed and found wanting, and her glorious record was obscured by the mildew of her own degeneracy. No one had yet risen to declare for the abolition of the old creed and the introduction of a new form of faith. To the intelligent, it seemed that the remedy lay in a reformation within the church. In the travail of the times, earnest souls began to look beyond the established forms to the origin of the church and the purity of its primitive faith. Adrift on a sea of doubt, the race lacked only a bold leader to shape their course toward a new ideal. The time was favorable. Germany was divided into numerous principalities, the chief of any one of which could foster a change in religious belief without apprehension of the certain doom which would have been decreed by a united state wedded to the papacy. The western world had been discovered; the art of printing was just coming into use—and it is indicative of the hold which religion had on the minds of men that the first book produced by the new method was the Bible. The practical use of gunpowder was the knell of chivalry; the invention of printing assisted the spiritual awakening of the people in giving the death-blow in Germany to the power of Rome. The movable blocks of Guttenberg were mightier than the awful ban of the Church; more impressive than the hoary dignity which nearly fifteen hundred years of existence imparted to papal Rome. As the Jews looked for their Messiah through long years of oppression, so the people now looked for the prophet of a new faith; and he came.

Martin Luther. One morning in 1517, the people of Wittenburg in Saxony found nailed to the door of their church ninety-five propositions signed by Martin Luther. The theses were directed at the principle which underlay the sale of indulgences by John Tetzel and others for the Pope. Tetzel, a Dominican friar, had established himself at Juterbock, and with trumpet and drum called the people to him to buy indulgences for the remission of sin. "God willing," exclaimed Luther, "I will beat a hole in his drum"—and the ninety-five propositions constituted the sledge-hammer with which the hole was beaten, not only in the instrument of Tetzel, but in the doctrine of the power of the church to forgive sin. "The Pope's absolution has no authority in and for itself," wrote Luther in effect. "If the sinner is truly contrite he receives complete forgiveness, not from the Pope, but from God himself, without the mediation of any human being." This was an attack on a vital point. In the struggles of the emperors with the popes, the assumptions of the latter in matters of faith had never been denied, but Luther flung in the teeth of the papacy a denial of the vicegerency under which it claimed the power to pronounce the forgiveness of sin. The news of Luther's bold step spread rapidly throughout the empire and the new doctrine was received by thousands. Tetzel fled to Frankfurt, where he published a set of counter-theses and publicly burned those of Luther. The students of Wittenburg committed Tetzel's theses to the flames and were applauded by the people for the act. The Elector of Saxony was called upon to compel Luther to renounce his heresy, but out of friendship for the author of the Wittenburg theses he refused to interfere. At first Pope Leo X paid little attention to the threatened revolution, but the vital importance of the subject was seen by some of the cardinals. They urged their views on the Pope, and Luther was summoned to Rome. The Elector would not permit him to thus place himself in the power of his enemies, and he remained in Germany, where a papal legate came to receive the retraction which the Pope ordered Luther to make. This Luther refused. Then followed his memorable discussion with Eck and the issuance of the papal pull. Luther took more advanced ground as time progressed and attacked the whole doctrinal system of the Church of Rome and its pretensions to supremacy. Thus the Reformation was fairly launched, and out of the convulsions of the struggle came the second great schism in the Christian church.

Charles V, grandson of Maximilian, came to the throne in the first throes of the religious strife. The claims of Charles to the crown were disputed by Henry VIII of England and Francis I of France. There was no vitality in the candidacy of the English king, and as between Francis and Charles the question was soon settled by the election of the latter. The young monarch entered upon his reign wearing the crowns not only of Germany but of Spain and the Two Sicilies; he was heir to the territories of Burgundy and the Austrian possessions, with a prospect of obtaining Hungary and Bohemia. As King of Spain he held the lands discovered by Columbus in the new world. In him the house of Hapsburg reached its highest point of importance. The dangers to his sovereignty lay, first, in the pretensions of the French king to territories in Burgundy and Italy, and, second, in the threatening advance of the Turks, who had spread their conquests from the Bosphorus to the borders of Austria and Hungary. With a united empire, the cold and calculating Emperor might have entertained with some hope of realization the visions of Otto III, but the Reformation, which soon took on a political aspect, materially weakened his power. Charles was a devoted supporter of the papacy, but, while he deferred to the church in spiritual matters, both by nature and policy he was bound to insist upon his rights as a sovereign. He was crowned at Aix in 1520. In 1521 he convoked a diet at Worms, in which the affairs of the Church and the Empire were to be arranged. Two papal legates were present demanding that Luther be punished by the Empire for his heresy. Frederick of Saxony, Luther's friend, obtained a safeguard for the Wittenburg professor, and he went to the diet, although warned by the fate of Huss. The ban of the Empire was issued against him by the diet and he was given twenty days to return to Wittenburg. On his journey he was abducted by friends, who feared that his safeguard would be violated, and he was secluded nearly a year in the castle of Wartburg, where he began his translation of the Bible. Charles, thinking the Reformation could be crushed by the civil power, forbade the printing of Luther's books and threatened with the ban of the Empire anyone who harbored him. The agitation in Germany was intense. The intelligence of the country was generally with Luther, and among the peasantry the belief grew up that the movement would produce an amelioration of their condition. This led the latter to violence. An outbreak of the lower classes in Wittenburg was subdued by Luther himself, who announced his opposition to all violent measures among his partisans. He also declared against the introduction of the Reformation into politics, but here he was powerless, for religious and political matters had been too closely allied to be separated in a day. In 1522 a conspiracy was organized by a young noble, Ulrich Von Hutten, who proposed to overthrow the existing government and substitute a close union of the states with the Emperor at its head. In this way the papal power was to be overthrown, the nobles confirmed in their rights and the peace of the Empire maintained. After a bloody war, Hutten's forces were defeated.

In 1524 the peasants in Swabia and Franconia rose in a revolt which extended over the whole of south Germany. Having the power, they turned with ferocity on the nobles and put many of them to death with great cruelty. In the following year the "Peasants' War" was suppressed and the insurrectionists were not only reduced to their late condition of servitude, but the most inhuman outrages were inflicted upon them. Thomas Münzer, a scholar who thought Luther did not go far enough in his differences with Rome, proclaimed in Thuringia a socialistic republic. He was joined by thousands of the peasants. They burned monasteries, tortured the nobles who fell into their hands, and committed atrocities at which men of all shades of faith shuddered. Both Catholic and Protestant princes united against them, and at Frankenhausen dispersed a body of nine thousand, putting five thousand to the sword. The Anabaptists of Münster also broke out into violence in 1534, but were put down in a short time. One of the measures of reform proposed by Luther was the marriage of the priests, which had been forbidden by Hildebrand. Luther himself married an escaped nun, Catherine Von Bora, a member of a noble family in Meissen.

In the meantime Charles was absent in Italy warring with the French king for possession of that country, while the government of Germany was conducted by the Imperial Council. The effect of Luther's preaching was such that the diet permitted the new doctrine to be expounded in the churches of Nuremburg, notwithstanding the demand of the papal legates that it be prohibited. Philip of Hesse and John of Saxony protected the Lutherans. The Diet of Spires in 1526 decreed that "in respect of religion every one shall act as he will venture to answer for it before God and the Emperor." This was a recognition of liberty of religious thought, which stirred the Emperor into demanding of the diet the enforcement of the ban against Luther; but the diet refused to do more than to call for a general council of the church to consider the question. Between 1525 and 1532 the Lutheran Church was established in Saxony, the electors of which were fast friends of the Reformation. Albert of Brandenburg, Grand Master of the German Knights, embraced the new faith. The emperor's brother, Ferdinand of Austria, became King of Hungary and Bohemia in 1526. The Turks appeared before Vienna three years afterward, and the necessity under which the Emperor lay of support from the people led to a cessation for several years of the persecutions with which the Lutherans had been pursued. The Emperor overcame his antagonist, Francis I, in Italy, and, capturing him, compelled him to sign a humiliating peace. When hostilities again broke out, an imperial army, composed mainly of German Lutherans, captured Rome, and Charles received the crown of the Cæsars from the Pope at Bologna in 1530. The Diet of Spires in 1529 resolved to attack the Reformation. Nineteen states of the empire, led by Saxony, protested, their action on this occasion earning for the reformers the name of "Protestants." At the Diet of Augsburg in 1530 the protesting members presented their confession of faith, since known as "The Augsburg Confession," which is regarded as the foundation of Protestantism. An attempt to reconcile differences failed, and both parties prepared for war. In 1531 the Protestant leaders formed the "Smalcald League" at the town of that name in Thuringia. The affairs of Spain called Charles to that country, but before he went he caused the election by the Catholic electors of his brother Ferdinand as German Emperor. An attack on Austria by the Turks led the Emperor to make terms with the Protestants in "The Religious Peace of Nuremburg" in 1532. In the ten years which followed a number of the German princes joined the Protestants. The Smalcald League, which was renewed in 1537, now contained nearly all the Protestant princes. A Catholic league, headed by Bavaria, was formed in opposition, but it accomplished little against the overwhelming odds which confronted it. Even the Catholic princes of the empire attempted to reform the abuses in the church, but without any sympathy with the Reformation. In 1534 Pope Paul III took his seat in the papal chair. Recognizing the impossibility of reuniting the church by force, he undertook to accomplish that end by policy. A conference between the reformers and the church dignitaries ended in a violent controversy, and the whole matter was referred to the council which subsequently met at Trent in the Tyrol. Meanwhile the Reformation had spread beyond Germany into Norway, Sweden, Denmark, the Netherlands, England, France and Switzerland, although the movement in those countries, as in Germany, had a political as well as a religious aspect. In 1544 the Emperor, with the assistance of Henry VIII of England, compelled Francis I to make the Peace of Crespy, which left the German monarch free to carry out his projects of breaking down the power of the princes and bringing the empire back to its old allegiance to the Church of Rome. The two leaders in the Smalcald League were placed under the ban of the empire. The Protestants collected an army, but were deserted by the Electors of Brandenburg and the Palatinate and the Dukes of Mecklenburg and Pomerania. This was but the beginning of defection. Luther died in 1546. In 1547 all south Germany had given its adhesion to the Emperor. Charles invaded Saxony, beat the protestant army at Muhlberg and captured Wittenburg. By his successes the empire was placed firmly in his hands. The princes and the imperial cities were humbled, and the fate of the new doctrine seemed to be at his disposal. Acting with moderation, he permitted the Lutheran doctrine to be preached. In 1548 he caused to be prepared the "Augsburg Interim," a system of doctrine and practice which yielded nothing to the Protestants but the sacrament in both kinds and the marriage of the clergy. The Interim gave no satisfaction to either party. The Spanish troops introduced by Charles scoffed at the Lutheran doctrine and perpetrated outrages upon its professors. The war was resumed between Charles and France, which enabled Maurice of Saxony and other princes to contract an alliance with the French king, Henry II. In exchange for French aid Henry was to take possession of four German towns on the western border of the empire—Metz, Cambray, Verdun and Toul. In 1552 Maurice marched against the Emperor, who was then at Innspruck in the Tyrol. The march was made so secretly that Charles narrowly escaped capture. At the same time the French king invaded Germany, and Charles was compelled to sign the Truce of Passau, which provided for toleration of Lutheranism. In 1555 he signed the "Religious Peace of Augsburg," which contained a provision that the princes and barons should have religious freedom and the right to promote the Reformation in their own territories. Church estates were not to be secularized, and the ecclesiastical princes were to tolerate the Protestant worship. If a prelate adopted the reformed faith, he must give up his clerical estates and dignities. This last clause was the subject of much future dissension, for the Lutherans insisted that it was invalid, and several prelates who subsequently went over to Lutheranism retained their secular estates. The followers of Zwingli and Calvin were not included in this peace. Charles V abdicated the throne in 1556 and retired to a monastery in Spain, where he remained until his death in 1558. To his son Philip he had given Spain and the Netherlands with Naples and Sicily, while Ferdinand remained Emperor of Germany.

"The Augsburg Confession."

Progress of the Reformation.

Ferdinand I became sole ruler of Germany in 1556. He was an ardent Catholic, devoted to the promotion of the interests of the church. He gave material assistance to the Jesuits in their efforts to produce a reaction in favor of the papacy, which met with some success in the period of comparative inaction that succeeded the fierce strife of the early Reformation. He attempted also to bring about a reconciliation between the Protestants and Catholics. His reign had no important effect on German history. Ferdinand I died in 1564.

Maximilian II, the son of Ferdinand I, was suspected of leaning toward Lutheranism. While he did not join the Protestants, he gave them religious liberty not only in the empire generally but in his hereditary state of Austria, where every departure from the Catholic faith had hitherto been rigorously dealt with.

Maximilian II died in 1576 and was succeeded by his son Rudolph II. This prince had been educated by the Spanish Jesuits, and, so far as his weak will permitted, he was their agent in the attempted destruction of Protestantism. Regardless of the guaranties of religious freedom given by his father, he resumed the persecutions, which led to so much disorder that in 1606 the imperial government was taken from him and given to his brother Matthias. Rudolph continued to rule in Bohemia, but was compelled by his subjects to grant them religious freedom. He died in 1612. In Germany, the war on the Protestants was led by Bavaria, whose duke was an earnest Catholic. The reign of Matthias was an unfortunate period for the new doctrine. The Emperor was almost a nonentity, but the imperial power in the hands of the Jesuits was used with terrible effect on the adherents of Lutheranism. The principal agents of this zealous order were Maximilian of Bavaria and Ferdinand of Styria, who had both been educated by the Jesuits and were fierce enemies of the Reformation. Styria was wholly Protestant when Ferdinand assumed control of affairs in that province. "Better a desert than a country full of heretics," was his favorite expression. He marched through Styria with an army, closing the Lutheran churches, burning Protestant Bibles, and setting up Catholic ceremonials everywhere. He also introduced a band of Capuchin friars, who secured an apparent re-conversion of the Styrians to the Catholic faith. The breaking up of a Catholic procession in Donauworth gave Maximilian, of Bavaria, an excuse for seizing that free evangelical city. The Protestants of south Germany formed a league called "The Union" for protection against Maximilian, who himself built up a "League" composed of Catholic princes. An alliance was contracted between "The Union" and the French king Henry of Navarre, who was interested in breaking down the power of the Austro-Spanish family of the Hapsburgs. The assassin Ravaillac, who murdered Henry, prevented a general war. The Union and the League came to terms in 1610 because of Maximilian's jealousy of the house of Hapsburg, whose power he did not wish to increase. Matthias drove his brother Rudolph out of Bohemia and procured the election of Ferdinand of Styria as the future king of that country. Ferdinand promised the Bohemians religious liberty, but the promise was not kept. Hussite churches were torn down, and on appeal to the Emperor the Protestant nobles were met with threats. Believing Matthias to have been influenced in his action by two of his councillors, Martinetz and Slavata, the nobles threw the latter out of the windows of the castle at Prague. The councillors fell eighty feet, but were not killed, and their escape was regarded by the Catholics as a miracle. This act of violence, which immediately preceded the Thirty Years' War, occurred in 1618. The Bohemians at once took arms to protect themselves from the vengeance of the Emperor. Actual hostilities began under his successor.

The Protestant "Union" and the Catholic "League."

Ferdinand II.

Matthias died childless in 1619 and Ferdinand of Styria, cousin of Rudolph II, was chosen emperor with the title of Ferdinand II. He was a fierce bigot, determined to restore the papacy to its ancient authority in Germany.

Thirty Years' War.

The Thirty Years' War has been divided into four periods, the Bohemian, Danish, Swedish and French. First is that of Bohemia, where the war began. The Bohemians refused to acknowledge Ferdinand, and chose as their king the Elector Palatine, Frederick IV. Frederick, who was a Calvinist, was immediately involved in difficulties with the Hussites, who preserved many of the old Catholic forms, which were repugnant to their king. Ferdinand was aided by Maximilian of Bavaria, who was now left at liberty by a Peace with the Union. With the forces of the League under the command of Tilly, and an army raised by threats from other German princes, together with some Hungarians, Spanish and Italian troops, he advanced into Bohemia. Frederick's army retired before him to Prague, where, on the White Hill, November 6th, 1620, was fought a battle which decided the campaign. Frederick was defeated, and barely escaped capture. Ferdinand brought into use in Bohemia the methods he had employed in Styria for the destruction of the heretics, and it is estimated that when peace came three-fourths of the population of the kingdom had been massacred or driven into exile.

Ferdinand as emperor declared Frederick deposed from his Electorate of the Palatinate. This was an assumption of authority which the north German nobles resented, and they formed an alliance with Christian IV of Denmark, who, as Duke of Holstein, belonged to the Circle of Lower Saxony. Under Tilly and Maximilian the troops of the Emperor devastated the Protestant lands and cities of the Palatinate and began the ravages which marked the Thirty Years' War. The Protestants retaliated, with the result that the country was almost depopulated. In 1622 the Emperor's forces were victorious, the Union was dissolved, and Maximilian received the Palatinate as his reward. Tilly was then sent into north Germany, where he defeated Christian IV and restored the Catholic religion. Ferdinand, being embarrassed by his obligations to Maximilian, sought the assistance of Wallenstein. This general was born of a Protestant family in Bohemia, but became a Catholic to further his own ambitious purposes. He was a man of great military talent, tall and thin in person, mysterious, stern, and pitiless. Acquiring wealth by marriage, he had obtained princely estates and rank by purchase from the Emperor at the time of the Bohemian confiscations. Wallenstein proposed to subsist his army by plunder, and on these terms took service under the Emperor. Christian IV opposed the imperial armies under Tilly and Wallenstein. Tilly defeated the Danish king at the battle of Lütter in 1626. Wallenstein pursued the Protestant general Mansfeld into Hungary and, returning, joined Tilly in the north. The Danes were driven to the islands in 1627 and Wallenstein supported his army at the expense of Mecklenberg and Pomerania. Here he formed a scheme to crush Sweden and to obtain control of the northern seas by the capture of the Hanse towns. His plan was frustrated by the heroic defense of Stralsund. Believing himself invincible, Ferdinand in 1629 issued the "Edict of Restitution," requiring the return of all Catholic property which had been secularized since the treaty of Passau. In addition to this, the private possessions of all the princes were threatened, and the estates of six thousand noblemen were declared forfeited. In the matter of religion, only those who accepted the Augsburg Confession were to be permitted in the realm. The Danes were humbled and signed the treaty of Lubeck in 1629. In 1630 a diet of princes was held at Ratisbon, where, in exchange for a promise of his son's succession, the Emperor relieved Wallenstein from command. The latter retired to his estates and as Duke of Friedland awaited the call of the Emperor, who, he believed, would soon need him.

Gustavus Adolphus, King of Sweden, a man of lofty character, great prudence and fine military ability, was brought into the struggle by a desire to aid the cause of Protestantism, and also to acquire the territory lying along the Baltic, to which he had a claim. Tilly's soldiers captured Magdeburg in May, 1631, and subjected that unfortunate city to a sack, the horrors of which have given it special prominence even in the history of outrages and butcheries. Gustavus met Tilly at Breitenfeld, near Leipsic, in September, 1631, and obtained a decisive victory, which restored the Protestants to confidence and gave the Swedish king a prospect of conquering all Germany. In the spring of 1632 he again defeated Tilly in a battle on the Lech and dispersed his forces. Tilly was wounded in the battle and died a few days afterward. Wallenstein was again placed in command, but was defeated in a battle fought November 6th, 1632, in the great plain of Lutzen. The victory was dearly purchased, for the heroic King of Sweden was slain. The command of the Protestant army fell to Bernard of Weimar. The war continued with varying success. Wallenstein was suspected of a design to usurp supreme power, and was assassinated in 1634. With assistance from France, sent by Cardinal Richelieu, who coveted the Rhine provinces, Bernard maintained the war until the battle of Nordlingen in 1634, where he was defeated. He afterward obtained successes, but died in 1639. The Swedes were defeated in battle, and were forced to retreat to the Baltic.

Ferdinand II died in 1637, and was succeeded by his son, Ferdinand III, who pursued the policy inaugurated by his father. Under the Swede Torstensten a number of victories were gained over the imperial troops in Saxony.

In the meantime the French, under Turenne and Condé, were fighting the Emperor's armies on the Rhine and in south Germany. A junction was effected between Turenne and the Swedish army. Together they invaded Bavaria and overthrew Maximilian. In 1648 the war ended where it began, at Prague, in a battle which gave the Protestant army a part of the city and the royal castle. Negotiations, which were begun in 1640 continued until October 24th, 1648, when a treaty of peace was signed between all the belligerents.

Treaty of Westphalia.

By this treaty (Treaty of Westphalia) religious freedom was accorded to Lutherans, Calvinists and Catholics. Germany lost large territories by the war, and also a great part of her influence as a political power in Europe. Upper and Lower Alsace were ceded to France, which power was also confirmed in its possession of Metz, Verdun and Toul. Sweden relinquished Pomerania east of the Oder, receiving the part west of that river, together with four islands, including Stettin, a very important city from both a military and commercial point of view. An indemnity, amounting to five million dollars, was also paid to Sweden. Switzerland and the Netherlands were recognized as independent countries. In the interior the status of 1624 was fixed as the basis of settlement. By this arrangement the Catholic gains in Bohemia were confirmed. The Protestant Elector Palatine was reinstated, ceding to the Catholic Duke of Bavaria the upper Palatinate. The edict of Restitution was revoked. The Pope declared the treaty void, but his fulmination received no more attention than was given by the comet of 1456 to the bull issued against it by Pope Calixtus III. The Treaty of Westphalia secured peace, and was the basis of the legal relations of the states of Europe for a century and a half, but the disintegration of the empire was complete, and in many places the face of the country was a desert.

Ravages of the War.

It has been estimated that in the first half of the seventeenth century two-thirds of the people of Germany perished from war, pestilence and famine. One of the effects of the war was the destruction of almost all trade and commerce. The Hanseatic League fell to pieces, and the interior industries of the realm were paralyzed. The decline of the Hanseatic cities was not altogether due to the Thirty Years' War. The changed relations caused by the discovery of America and the ocean route to India aided in depriving the German coast cities of their importance, which was transferred to Antwerp, Lisbon and other southern ports. The people of Germany relapsed into a condition of serfdom, and the princes asserted a royal authority in their dominions. The states acknowledged but a slack allegiance to the imperial crown, and the cities abandoned themselves either to the government of cliques, or accepted the rule of the nobles. The tastes of the people were changed by the introduction of vicious foreign customs.

National decadence.

The Germanism of the princes was vitiated by foreign travel and a desire to imitate the luxury of France and other southern peoples. In the midst of these signs of decadence two principles were left alive which alone gave promise for the future. These were the indomitable race vigor—weakened, it is true, but not destroyed—and the spirit of the Reformation. On this joint foundation was built the power of the modern German Empire, which, with Prussia at its head, is one of the principal states of Europe. While the empire remained for a long time inert, the little state of Brandenburg, under its Great Elector, William, was building up a conserving power.

Ferdinand III was succeeded in 1658 by his son, Leopold I, a cold, Jesuitical prince, weak in character and limited in intellect. The government was nominally in the Emperor, but really in the hands of a quarrelsome and factious diet. The ambition of Louis XIV of France and the weakness of Germany spurred the French king to active interference in the affairs of the empire. By conquest and negotiation he made himself master of Franche-Comte and various cities on the borders of the Netherlands, with the fortress of Freiburg and the duchy of Lorraine. These lands and cities were ceded to him by the Peace of Nimeguen in 1678. While the members of the diet were disputing about matters of etiquette, Louis in 1681 seized Strasburg and other cities, all of which were confirmed to him by treaty. The national honor was sustained only by Frederick William of Brandenburg, who, through an alliance with Sweden and the Duke of Brunswick, put a stop to the designs of the King of Denmark on Holstein and Hamburg. Subsequently Louis XIV was compelled to give up his claim to a number of the cities, but retained Strasburg. On the east the empire was threatened by the Turks, who overran Hungary and Transylvania, and in 1683 appeared before Vienna. Neither the Emperor nor the diet made any effort to protect the Capital of Leopold's hereditary state; but the duty which they neglected was ably discharged by other hands. The Electors of Saxony and Bavaria moved in person to the relief of the beleaguered city; the Great Elector sent eight thousand soldiers. Charles of Lorraine at last brought up the imperial army, which was joined by the heroic king of Poland, John Sobieski. The Turkish army was destroyed and Europe was relieved from the menace of Moslem rule. Within a century Austria repaid the inestimable services of Sobieski by the partition of Poland. Hungary having joined the Turks in the war, that kingdom was severely punished. At the Diet of Presburg in 1687 the Hungarians yielded their right to elect a king, and declared the crown of their country hereditary in the male Hapsburg line. In 1701 Brandenburg was erected into a kingdom, with Frederick I, son of the Great Elector, as sovereign.

The crown of Hungary

On the death of Charles II of Spain, who was the last Hapsburg of that branch, Louis XIV, who had married a sister of Charles, intrigued to secure the succession for his grandson, Philip of Anjou. Leopold claimed Spain for his own son as a descendant of Ferdinand, brother of Charles V. The German emperor formed an alliance against France with England and Holland, both of which powers were jealous of the increase of strength of Louis XIV.

"War of the Spanish succession."

This alliance brought on the "War of the Spanish Succession," which lasted from 1701 to 1713, and resulted in the Treaty of Utrecht, by which the Spanish crown was given to Philip of Anjou, but with a renunciation by him for himself and his heirs of all claims to the throne of France. Prussia obtained the province of Guelders, and was recognized by France as a kingdom. Savoy was also recognized as of royal dignity, and received the addition of Sicily.

Joseph I

Leopold died in 1705. His son, Joseph I, had a short reign, in which he sustained the War of the Spanish Succession, and died in 1711.

Charles VI

As he left no son, the crown went to his brother, Charles VI. Austria had not taken part in the treaty of Utrecht, but continued the war with France for another year. In 1714, by the treaty of Rastatt, Austria relinquished all claim to Spain, but received the Netherlands, the Duchy of Milan, the Kingdom of Naples, and Sardinia. The latter was ceded to Savoy in 1720 in exchange for Sicily, and Savoy was from that time known as the Kingdom of Sardinia.

Pragmatic Sanction

To Charles is due one of the four Pragmatic Sanctions of history. The Austrian throne was held under the Salic law, which forbade the coronation of a female. Having no son, Charles endeavored to secure the succession in Austria to his daughter, and for that purpose prepared a Pragmatic Sanction, or solemn ordinance, settling his dominions on the Arch Duchess Maria Theresa. This was confirmed by the diet and guaranteed by most of the European powers. In 1733 Charles engaged in war with France in support of the claim of the Elector of Saxony to the throne of Poland. The treaty of Vienna in 1735 secured for the Elector the Polish throne, but deprived the Emperor of the two Sicilies which went to Spain, and the Fortress of Landau. The rival claimant of the crown of Poland, Stanislaus Leszczynski, received as compensation the Duchies of Lorraine and Bar, which he immediately ceded to France. In this reign Prince Eugene of Savoy maintained the glory of the imperial arms against the Turks, driving them out of Hungary and capturing the city of Belgrade. In 1739, after Eugene's death, the Emperor by a disgraceful treaty relinquished to the

Turks not only Belgrade, but the whole southern frontier which had been conquered by the great imperial general. Charles VI appeared to have but a slight regard for the interests of Germany beyond his own hereditary possessions, and when he died in 1740 the people of the empire felt but little regret. Under the provisions of the Pragmatic Sanction, Maria Theresa at once ascended the throne, with no opposition except a protest from Bavaria; she immediately associated with herself in the government her husband Francis Stephen, Grand Duke of Tuscany.

Germany had ceased to have an important influence among the European nations; the local sovereignty of the states had been secured by the Peace of Westphalia, and the title of Emperor was but little more than an empty honor. From the entire empire, outside of his hereditary territories, the sovereign received an annual income of not more than five thousand dollars. The days of the great vassals of the crown were long since passed, and interest centers in the struggles for supremacy between the great states of Austria and Prussia. The Imperial Court was located at Vienna, but exercised no political influence beyond the possessions of the Hapsburgs. Among other changes which occurred was the elevation of the Elector of Hanover to the throne of England in 1714 as George I. His wife was the granddaughter of James I of England, upon which relationship was founded his claim to the throne of Great Britain. In 1697 Augustus of Saxony had become king of Poland. In the southwest the former circles of the empire, Swabia, Bavaria and Franconia, were still of some importance, because in them lay the military strength not of the states, but of the shadowy empire. The internal condition of Germany was deplorable. The extravagance of the Imperial and State officers was supported by the unrequited toil of the people, but there were glimpses of the dawning of that broad intellectual life which in the following century gave to Germany a greater glory than had ever been achieved by her arms.

In 1740 Frederick II ascended the throne of Prussia. His father, Frederick William, an obstinate, parsimonious monarch, had organized a splendid army, and accumulated a great hoard of treasure. The young king, afterward known as Frederick the Great, was 28 years of age when he assumed the crown. His early reign was characterized by a reckless ambition with which were united a military genius and an executive talent of the highest order. Reviving an old claim to the Duchy of Jagendorf and other territories in Silesia, he invaded that province with an army of one hundred thousand men and proposed to hold it as security for his claim. Advantage was taken at the same time of the supposed weakness of the woman Maria Theresa by the Elector of Bavaria, who claimed the whole of the Austrian hereditary possessions. A secret alliance was made in 1741 by France, Bavaria, Prussia, Spain, Sardinia and Saxony to despoil the Austrian queen of her possessions. The arrangement was that she should retain only Carinthia, Carniola, Styria, Hungary and Lower Austria. England, Holland and Russia declared in favor of Maria Theresa. After obtaining possession of Silesia, Frederick offered to uphold Maria Theresa under the Pragmatic Sanction if she would recognize his claims to the province which he had occupied. The high-spirited queen refused Frederick's offer, and appealed to the Hungarian nobles, who rallied enthusiastically to her support. A Bavarian and French army moved down the Danube and occupied Linz, while a French and Saxon army invaded Pomerania.

In 1741 Charles Albert, Elector of Bavaria, became King of Bohemia and Bavaria, and in 1742 received the Imperial Crown as Charles VII. In the same year Maria Theresa concluded with Frederick the Great a peace by which Silesia and the County of Glatz were confirmed to the Prussian king and his heirs. She then made vigorous war on the other allies, driving Charles Albert out of her territories and also out of his own kingdom of Bavaria. The Peace of Breslau followed, guaranteeing to the Austrian queen all her possessions except Silesia. An alliance formed by her with other powers in 1743 led Frederick to believe that she intended the recovery of Silesia, and he espoused the cause of Charles Albert. In 1744 the Prussian king began the second Silesian war by an invasion of Bohemia. The campaign ended in his forced withdrawal to Silesia, where he was followed by the Austrian army. Here he sustained himself and in 1745 made a treaty with the Austrian queen, Frederick retaining Silesia and annexing to his kingdom all of East Friesland.

Charles VII died in 1745. His successor was the husband of Maria Theresa, Francis I. The Prussian king, after the close of the war, turned his attention to the development of his domain, and on the conclusion of the ten years of peace which followed found himself at the head of a formidable power. In 1748 Maria Theresa negotiated with France a treaty of peace, Austria losing some territory in Italy but coming out of the struggle with honor. The Austrian empress, as she was called, gave herself up to regrets for the loss of Silesia, and her people grew jealous of the rising power of Prussia. The emperor, her husband, was a mild, benevolent man, but with no talent for government, the whole burden of which fell upon his wife. The genius of Frederick the Great alarmed other crowned heads than that of Austria. In 1755 their fears culminated in an agreement for the partition of Prussia, in which France, Russia, Saxony and Austria, and eventually Sweden, took part. Out of this compact grew the Seven Years' War, for Frederick, without waiting to be attacked, dashed into Saxony hoping to catch his adversaries unprepared. (See Austria).

During the war, which lasted from 1756 to 1763, the Prussian monarch, with a population of not more than five millions, made head against nearly all Europe and placed Prussia on a foundation of greatness which, with a short interval during the Napoleonic wars, she has since maintained. Regarding the nobles as the principal support of his throne, Frederick set himself to the task of repairing their fortunes, which had been shattered by the war. Ruling with vigor and yet with kindness, he inaugurated and maintained a system of economical administration in the kingdom which soon healed the wounds of strife. His army was kept ever ready for war, for it could hardly be hoped that the rival state of Austria would neglect any opportunity to recover the leading position it had lost to Prussia. In 1764 the Prussian king contracted an alliance with Russia, each power guaranteeing to the other the integrity of its possessions for eight years. During this period Russia showed a disposition to acquire Poland, which unhappy country, rent by civil strife, had fallen into a deplorable state of weakness. On the death of Emperor Francis in 1765, the Imperial Crown passed to his son, Joseph II, who had been elected in 1764. In order to prevent the great Northern Empire of the Czar from absorbing the whole Polish kingdom, Frederick joined with Austria and Russia in the first partition of Poland. The Prussian king asserted to this iniquitous transaction for the purpose of restraining Russia, and Maria Theresa was forced into it only by the sternest political necessity. By this act Prussia received an addition to her territory of about nine thousand square miles, with a population of six hundred thousand; Austria obtained Galacia and Lodomira, in all about sixty-two thousand square miles, while the remainder, more than eighty-seven thousand square miles, went to Russia. In 1786 the Prelates of Cologne, Treves, Mayence and Salzburg agreed to renounce the supremacy of Rome and form an independent German Catholic Church—so wide had become the gap between the papacy and even the Catholics of Germany. The lower classes of Germany, with the exception of those in the dominions of Maria Theresa, were sinking into a state of servitude but little short of slavery. In her possessions she introduced many reforms which alleviated the misery of the peasants; she also supported schools and churches, and provided educational institutions for the nobles, who were in a lamentable state of ignorance. In 1777–79, and again in 1785, Frederick resisted attempts of Joseph II to possess himself of parts of Bavaria, and prevented him from accomplishing his designs. After the operations of 1785 Frederick observed a growing friendship between Austria and Russia, and, to counteract it, founded the "Confederation of German Princes," which was a combination of the smaller states under the lead of Prussia. Frederick the Great died in 1786, and the Prussian throne fell to his nephew, Frederick William II. Maria Theresa died in 1780, and Joseph II wore the crown of Austria as well as that of the Empire. He had visions of reform which were impracticable. His failures depressed his spirits and an attack of malarial fever carried him to the grave in 1790.

Confederation of German princes.

Frederick William II.

Leopold II, brother of Joseph and Grand Duke of Tuscany, came to the throne in a time of gloom for the monarchs of Europe. That wonderful though savage outbreak of the lower classes in France which is styled the "French Revolution," was viewed with alarm throughout Europe as presaging a general downfall of thrones. The "Divine Right" of Kings was indeed questioned outside of France, but the fidelity of the peasantry to their rulers and the hopelessness of a struggle with the disciplined forces of royalty held the mass of the people in check. Frederick William of Prussia hoped to profit by disorders in Austria, but the common danger to European crowns compelled a cessation of his projects and led to a compact in 1791 between the two sovereigns to support the cause of the French king, Louis XVI, against the Revolution.

Emperor Leopold II.

French Revolution.

Leopold died in 1792, and was succeeded by his son Francis I of Austria and Francis II of Germany. The National Assembly of France in 1792 demanded that the French emigrants in Germany should immediately disperse or war would be declared. The German emperor naturally refused and war followed at once. The alliance between Austria and Prussia was strengthened by the accession of the other states of the empire. In 1793 occurred the Second Partition of Poland, which was made by Russia and Prussia. The Third Partition, which was made in 1795 between Russia, Austria and Prussia, erased Poland from the map of Europe. On the execution of Louis XVI in 1793, Russia, England and Holland joined the German alliance against France. The French took possession of Holland, and Prussia withdrew from the coalition. The young French general, Napoleon Bonaparte, led an army into Italy in 1796 and fought his way to Klagenfurt in Styria, and in 1797 compelled Austria to make the Peace of Campo Formio.

Emperor Francis II.

Second and third partitions of Poland.

Campo Formio.

Frederick William II was succeeded on the Prussian throne in 1797 by Frederick William III, whose reign extended to 1840. In 1799 war was renewed with the French Republic, Austria acting in concert with England and Russia, while Prussia refused to join the coalition, hoping to profit by the disasters of Austria. The Austrians were beaten at Marengo and Hohenlinden and begged for peace. Napoleon, now First Consul, and soon to be Emperor of France, exacted from Germany twenty-four thousand square miles of territory, occupied by three million five hundred thousand people. The boundaries of Germany were established at the Adige in Italy and along the Rhine on the west. Napoleon also formed the states on the eastern bank of the Rhine, which was now under his control, into a territory that he regarded as a barrier against Austria and Prussia. The Peace of Amiens, concluded in 1803 between England and France, secured a cessation of conflict on the Continent, but it was the quiet between the paroxysms of a fever, for the French Emperor (elected in 1804) had undoubtedly determined to make himself master of all western and central Europe. In 1804 Francis II recognized Napoleon as Emperor of France; Prussia also acknowledged him, but England, Turkey, Russia and Sweden refused the title recognition. The aggressions of the French emperor brought on a war in 1805 between a coalition composed of nearly all the European powers except Prussia, against the French, who were assisted by Bavaria, Wurtemburg and Baden. Napoleon immediately advanced into Germany and at the battle of Austerlitz, fought December 2, 1805, shattered the Austrian and Russian armies. By the Peace of Presburg, which followed, Germany was humiliated as never before. Venice was ceded to the kingdom of Italy, the Tyrol and Vorarlburg to Bavaria, and other territories to Wurtemburg and Baden. Bavaria and Wurtemburg were erected into kingdoms, the "Confederation of the Rhine" was formed by the French conqueror, and the German Empire was broken up, Francis II abandoning the title of emperor. Up to this time the Prussian king had remained quiet, but seeing in Napoleon's actions a desire to readjust the relations of the whole of Europe, and consequently danger to his own kingdom, made ready for war. Napoleon, who had heard with ill-concealed anger the Prussian boasts of the invincibility of the "Soldiers of Frederick the Great," eagerly embraced the opportunity, and himself at Jena and Marshal Davoust at Auerstadt on the 14th of October 1806, cut to pieces or captured the larger part of the Prussian army. By the Treaty of Tilsit in 1807, made between the Russian emperor and the Prussian king on one side, and Napoleon on the other, the territories of Prussia were reduced nearly one-half, and its monarch treated with contempt. An attempt by Austria in 1809 to recover her lost position led to the defeat of her army at Wagram, and by the subsequent Peace of Schonbrunn Austria was compelled to relinquish large tracts of her territory. The immense losses of the French in their invasion of Russia in 1812, and the constant waste of Napoleon's resources by the savage war in Spain, so weakened his strength that the Germans entertained hopes of deliverance from the bondage to which he had subjected them. The coalition formed by Austria, Russia and Prussia in 1813–14 beat Napoleon at Leipsic and forced him back to France. At Fontainebleau he abdicated and was sent to Elba. Returning in the spring of 1815, he was definitively overthrown at Waterloo and imprisoned at St. Helena, where he died in 1821. The Congress of Vienna, which began its labors on the first abdication of Napoleon and concluded them after Waterloo, restored with several changes the boundaries of the German states. Prussia received more than half of Saxony, the Rhine province with its old possessions in Westphalia, Posen and other small acquisitions, but lost its Slavonic populations in the east. It was now a strictly German state. To Austria were given the Bavarian and Italian Tyrols, Lombardy and Venice, which states, under the astute management of Metternich, gave the Hapsburg empire a predominating influence in Italy. Bavaria was guaranteed its territory, receiving in exchange for the Tyrol the Grand Duchy of Wurzburg and the Palatinate on the left bank of the Rhine. Hanover was increased by an addition of territory which gave that kingdom control of the mouths of the Elbe, the Ems and the Weser. The kingdom of the Netherlands was enriched by the annexation of Luttich and the Grand Duchy of Luxembourg, Hamburg, Lubeck, Bremen and Frankfurt-on-the-Main became free cities. The new "German Confederation" consisted of thirty-nine states, including the two great monarchies of Austria and Prussia, four Kingdoms, one Electorate, seven Grand Duchies, nine Duchies, ten Principalities and four free Cities. The territories of each state were guaranteed by the others; the citizens

of each had certain rights in all, and freedom of religious opinion was established. Disputes between states were to be settled by a diet sitting at Frankfurt, with an Austrian for permanent president. Immediately after Waterloo the Emperors of Russia and Austria and the King of Prussia executed a peculiar compact called the "Holy Alliance," by which they bound themselves as the representatives of the three branches of the Christian church to treat one another as Christian brethren and to govern their people on the basis of Christian principles. The Pope and the Sultan were ignored, but the other monarchs of Europe were invited to join the alliance and did so, with the exception of England, whose Prince Regent could not act without the direction of the Parliament.

As might have been foreseen, the jealousies and divisions of the German states deprived that country for a long time of any weight in European politics, but internal peace was secured and the ravages of the Napoleonic wars were covered over by the industry of the people. The condition of the masses was improved physically, but a new force was moving among them and they were beginning to aspire to something higher than submission to kingly decrees. The French democracy which sprang into action out of its bloody cradle was diffused throughout central Europe by the passage of the French armies, and wherever they penetrated they left with the people an aspiration for freedom. Recognizing this sentiment in their peoples, the rulers of the German states endeavored to retain the old supremacy of the Throne. To them, the political agitation of the years succeeding the Napoleonic wars was but a continuation of the struggle, although the enemy was now their own subjects. In 1816 the Prussian government suppressed a democratic journal which demanded fulfilment of the royal promises to the people, given after the return of Napoleon from Elba. Popular leaders remonstrated against the suppression and demanded constitutional freedom, but the Prussian government refused to fulfil its pledges until compelled by the revolution of 1848. A few states which granted constitutions so restricted them that they were practically inoperative. In Austria, Metternich, the efficient instrument of the Throne, labored to silence every voice raised against absolute monarchy. Repressed at home, German liberalism extended its sympathies to all peoples who strove to throw off the yoke of despotism. The assassination of the dramatic author, Kotzebue, in 1819, on the suspicion that he was a Russian spy, did the cause of freedom much harm, for this act was used as an argument in favor of the repressive measures which the governments of the states at once adopted to crush the popular aspiration for liberty. The Carlsbad Resolutions of 1819, the "Final Act" of 1820, and subsequent measures confirmed the power of the Holy Alliance and made it an engine for the oppression of the people. The French revolution of 1830 found a sonorous echo in the Rhine provinces. In 1832 thirty thousand men gathered at Hambach in the Palatinate to consider means for the emancipation of Germany, but the Bavarian troops put an end to the demonstration. Disturbances in Frankfurt, Brunswick, Cassel and Saxony were quickly put down. Hanover in 1833 granted a liberal constitution to its subjects. Francis of Austria died in 1835 and the crown passed to his son Ferdinand. Liberal government was expected from him, but he adhered to the principle of absolutism. His subjects continued their demands for reform, but obtained nothing. In 1837, on the death of William IV of England, who was also King of Hanover, the latter kingdom was separated from the British crown and given to the Duke of Cumberland, who overthrew the constitution and banished its principal supporters. Prussia was prosperous in her industries and trade. Her schools became models for the other nations of Europe. The old universities were fostered and a new one was founded at Bonn. Religious toleration was the rule; in 1817 an Evangelical union was formed through a reconciliation of the Lutheran and Reformed Churches. Between 1828 and 1834 the German states, with the exception of Austria, united in the "Zollverein" or Customs-Union, with Prussia at its head. Under this union the commerce and trade of Germany were rapidly developed. The steamship and the locomotive were adopted at once by the commercial centers, and the German merchant navy rose to the third rank, standing next to those of the United States and Great Britain.

Frederick William III was succeeded in 1840 by his son, Frederick William IV. This sovereign had a sincere desire for progress, but the revolutionary party in Prussia was not satisfied with the concessions made by him, and the political agitation increased. In self-defense he turned back to his kingly prerogative, and the result was an alienation from him of the affections of his people. The French revolution of 1848 rolled into and over Germany with a force before which the thrones were powerless. In an endeavor to avert the ruin of their states, the various rulers made large concessions to the liberal party, but without avail. Berlin and Vienna were captured by the populace, and it seemed as if the bloody scenes of '93 in France were about to be repeated. Hungary and Austrian Italy were aflame with insurrection. Frederick William gave way to the demands of the radical party, and in a proclamation pledged himself to maintain the freedom of the press and also to strive for a union of all Germany in a federal state. A national parliament met at Frankfort, but the delegates split into two factions and did little else than quarrel among themselves. The republicans were too radical, and the constitutionalists too conservative, to furnish any hope of united action. The Italian insurrection was put down by Marshal Radetzky, and the revolutionists in Vienna were suppressed with an iron hand by Prince Windischgratz. The Emperor Ferdinand abdicated and was succeeded by his nephew Francis Joseph, then eighteen years of age. By a decree promulgated in 1849, Austria became a constitutional monarchy. General Wrangel quelled the disturbances in Berlin, and a constitution was given to the kingdom of Prussia. The National Parliament elected the Prussian king, Frederick William, Emperor of Germany, but he declined the imperial crown. After changing its place of meeting several times, the National Parliament came to an end at Stuttgart in 1849, having accomplished nothing. In Hungary the insurrection became formidable and assumed the character of a race war. At first the Magyars were successful, and Louis Kossuth was proclaimed President of the Hungarian Republic. The Austrian emperor appealed for aid to the Czar of Russia, who immediately sent a large army into Hungary, and in 1849 the Maygars were overcome. Many of the leaders were exiled and others were put to death by Marshal Haynau, who, by his atrocities, earned the title of the "Hungarian Butcher." Schleswig and Holstein had been annexed to the Danish kingdom, but contained a large German population, who had attempted to set up an independent sovereignty. Their scheme was thwarted by the Danish king in 1846. In 1848 Schleswig and Holstein revolted, and with the assistance of Prussian troops expelled the Danes from the provinces and invaded Jutland. England and Russia threatened to interfere, and the war flagged. Prussia concluded a peace with Denmark, which the people of Holstein rejected and renewed the war. Austria and Prussia ordered that hostilities should cease, and an Austrian army in 1852 disarmed the duchies and surrendered them to Denmark. The question was disposed of for the moment by foreign influence, evidenced by a document called the "London Protocol." Other revolts in north Germany which grew out of the agitation of 1848 were suppressed by Prussian troops.

The prominent part taken by Austria in the Schleswig-Holstein matter added to the bitterness of feeling in Prussia against the former power. After the excitement caused by the outbreaks of 1848 the question of supremacy in Germanic affairs took definite form.

Struggle for leadership between Prussia and Austria.

Prussia endeavored to form the "League of the Three Kings"—Prussia, Saxony and Hanover—in order to provide a center around which to rally the north German states against Austria. The latter power called on the south German governments to renew the Federal Diet. Austria was joined by Bavaria and Wurtemburg, and also by the northern powers of Saxony and Hanover, and the diet was declared restored in 1851. A trifling conflict of authority between the people of Hesse and their Elector was used as a stepping-stone by Austria, whose troops invaded the principality to sustain its ruler. Prussian troops occupied Cassel, and war between the two principal powers of Germany seemed imminent. An effort was made to enlist the Russian emperor on the side of Prussia, but the czar not only refused to act, but made threatening declarations against the northern German power. Manteuffel, the Prussian minister, met the Austrian minister Schwarzenberg at Olmutz, and in the negotiations Austria was triumphant, but in the end she paid bitterly for her victory. King Frederick William also withdrew his opposition to the Federal Diet. The true sentiments of the Austrian ruler with regard to a liberal government were now displayed. Confident in his strength, the Emperor abolished the constitution granted during the insurrections of 1848–9 and restored the power of the Romish church. Austria also directed at Prussia a blow in the form of an attempt to weaken and dissolve the Zollverein, in which the influence of Prussia was predominant. As in Austria, the constitution of Prussia was regarded as a menace to the throne, and although it was not withdrawn, it was so weakened and hampered as to be useless as a measure of reform.

Constitutional government virtually abolished.

Encouraged by the example of Austria and Prussia, the smaller potentates withdrew their concessions to the people and absolutism became the rule of government throughout Germany. None of the states took part in the Crimean war until near its close, when Austria assumed such a threatening attitude toward Russia that the latter was forced into a humiliating peace.

William I Prussia.

The mind of Frederick William IV succumbed and in 1857 his brother, William I, assumed the government as regent, and on the death of the king in 1861 he received the crown. On taking the regency he had declared that "Prussia is ready everywhere to protect the right," and dismissed the Manteuffel ministry. This was a significant act, because it was supposed to refer to the surrender of the Germans in Schleswig-Holstein to Denmark.

The Italian War.

In 1859 the position of Austria in German affairs was materially weakened by the outcome of war with Sardinia and France. The Germans generally looked on the Italians as an oppressed people, and to a certain extent their sympathies were with them, but the dominant influence was a fear of the aggrandizement of France. Austria demanded the support of Prussia, which was refused. Later, Prussia took alarm at the prestige and power of Napoleon III and put her army on a war footing, but failed to appear on the field. After William I came to the throne he began to prepare for the inevitable struggle with Austria. Dimly in the future was seen a unified Germany, whose destiny should be controlled by the leading German state. Prussia was determined to occupy this position, while Austria, although relegated to the second place by the conflict in Italy aspired to her old-time leadership. William I met with great opposition in his preparatory measures, seemingly because of his assumption that "The King received his crown from God," and not from the people. Fortunately for Prussia's ascendency, William in 1862 placed at the head of his ministry Count Otto Von Bismarck, then Prussian Ambassador at Paris, one of the most daring and unscrupulous statesmen to be found in history. With a firm belief in the great destiny of a united German people, and devoted to the interests of Prussia, he bent every energy of his powerful mind and iron will to the accomplishment of the task before him. In the direction of German unity he was sure of the support of the German masses, who had seen with pleasure the movement of the people south of the Alps toward Italian unification. With the aspirations of his race to political freedom, Bismarck had no sympathy. Prussia was engaged in a constitutional struggle, and Austria took advantage of the consequent distraction to increase her own influence. On the invitation of Austria, a congress assembled at Frankfort in 1863 and declared that a Parliament should be established, composed of a House of Princes and a House of Delegates, the latter to be selected by the legislative houses of the several states, one-third by the hereditary family of each state, and two-thirds by a popular vote. Control of the whole machine was to be in the hands of Austria. Prussia refused to participate in the congress, and was supported by several of the smaller states. The movement came to naught. With contemptuous audacity, Bismarck advised the Austrian minister Rechberg to transfer the capital of Austria to Hungary, *outside* of Germany.
