

Guernsey Horticultural Society.

NEW RULES FOR THE LIBRARY.

In consequence of several valuable Works being missing from the Library, the following Amended Rules have been unanimously adopted, and the Fines modified, in order to their being strictly enforced in future:—

I.

The Library to be open to Members only, for reading and reference, every day, except Sundays.

II.

New Books to remain on the Table, from fourteen days to one month, according to size, before being circulated. All Periodicals to remain there one month.

III.

Books to be taken out, renewed, or returned every Wednesday and Saturday, from nine to two o'clock only; and, in no case, without the presence of the Clerk, under a fine of 5s.; and not more than One Volume to be taken at the same time, under a fine of 2s. 6d.

IV.

Any Books kept out longer than one week, to pay 6d. for the first week, and 1s. for each ensuing week beyond the time allowed.

V.

Any Members lending a Work belonging to the Society to a non-Subscriber, to forfeit 5s. for each offence.

VI.

Any Member losing a Work or Volume belonging to the Society, shall be bound to replace it within a month under a fine of 10s. beyond the value of the Book lost; and if the Volume should belong to a series, the whole Work must be replaced, unless the missing Volume be procured within the time above stated.

VII.

Any Member who shall appear to have wilfully or carelessly injured or defaced any Book belonging to the Library shall be fined one-third of its value.

PART III.

AGRICULTURE AS PRACTISED IN BRITAIN.

3385. In the first Part of this work we have endeavoured to give a concise view of the actual state of agriculture in every country, with a view to interest the reader in the subject, and prepare him for entering in detail on the elementary principles of the art. In the second Part, these principles and elementary departments of agricultural knowledge have been developed in successive views of the nature of vegetables, animals, and soils, and the mechanism and science of agricultural implements and operations. As far as these elementary principles go, they are applicable to the agriculture of every part of the world, with the modifications required by different physical and geographical circumstances; but as such an application is not required, in a work designed principally for this country, we limit this part of our work to *the agriculture of Britain*, in its most improved mode of practice. In the extensive sense in which we have applied the term Agriculture, this will include, 1st, the valuation, purchase, and transfer of landed property; 2d, its laying out, or arrangement; 3d, its improvement; and 4th, its management; 5th, the planting and stocking of farms; 6th, the culture of farm lands; and 7th, the economy of live stock and the dairy.

BOOK I.

OF THE VALUATION, PURCHASE, AND TRANSFER OF LANDED PROPERTY.

3386. *On the existence of property depends all human improvement.* Personal property is the first acquirement of man; but scarcely any progress is made in civilization till property in land is established and rendered secure. Landed property, indeed, is the basis on which every other material property is founded, and the origin from which it has sprung. The landed estates of Britain, as a species of property, may be considered in regard to tenure, valuation, and transfer.

CHAP. I.

The different Kinds and Tenures of Landed Property in the British Isles.

3387. *As landed property is somewhat different as to tenure in the three kingdoms, we shall notice the leading features in each separately.*

SECT. I. *The Kinds of Landed Property, and its different Tenures, in England.*

3388. *Territorial property in England*, Marshal observes, aptly separates into two principal divisions;—namely, into possessory property, or the actual possession of the lands and their appurtenances; and into abstract rights arising out of them.

3389. *Possessory property* comprises the soil or land itself; the minerals and fossils it covers; the waters annexed to it; the wood and herbage it produces; and the buildings, fences, &c. thereon erected.

3390. *Abstract rights* are, seigniorial, as chief rents, &c.; manorial, as quit-rents, fines, &c.; prescriptive, as common rights; predial, as tithes; parochial, as taxes.

3391. *Advowson and parliamentary interest* might be added, as they are not unfrequently attached to landed property.

3392. *Possessory property is further liable to analysis, and to more particular distinctions.*

3393. *Freehold.* If lands are held unconditionally, and in full possession, without any other superior than the constitution and laws of the country, they are termed *freehold*; a term which admits of still further distinctions.

3394. *Feefarmhold.* If they are liable to regular and fixed annual payments, beneath their rental value, and without being liable to fine, heriot, or forfeiture, they are *feefarmhold*, or other inferior holding.

3395. *Copyhold*. If they are held of a superior, as part of a royalty, honour, or manor, and are liable to fines, or other outgoings, on account of deaths, transfers, or other circumstances, they are *copyhold*; and are also subject to the ancient customs of the royalty, honour, or manor, of which they are respectively a part.

3396. *Leasehold*. If they are held by special agreement for a definite term, whether of lives or years, they are *leasehold*; which admits of various distinctions; namely,

Long leasehold, as for a thousand years.

Life leasehold, with a fine certain, or under certain limitations, on renewal.

Life leasehold, with an uncertain fine, payable to a proprietor or other superior, who has merely reserved a conventional rent; the tenant having paid down a sum of money to obtain the lease and the right of alienation, agreeably to the practice of the west of England.

Life leasehold, with an uncertain fine, payable to a proprietor, who receives the full rent of the land, at the time of granting the lease; the lessor having a power of alienation, according to the practice of Wales and some parts of England.

Leasehold for an ordinary term (as for less than a hundred years), with the power of alienation.

3397. *Tenure* is the general term for these several holds, or rights of possession. Even the lowest of them gives a sort of temporary property in the land, which is thereby rendered liable to bargain and sale as property. That species of holding which is given by a lease, without the power of alienation or transfer, being merely the right of occupancy, will be classed among other holdings of a similar nature, in treating of leases and tenancy. (See Book II.)

3398. Legal possession of landed property is gained, by *grant*, as from the crown; by *prescription*, or long usage; by *descent*, as from an ancestor; by *deed of gift*, or settlement; by the *testament* of the deceased owner; by *forfeiture*, as to a mortgagee; by *purchase*, either entered on a court roll, or ratified by a deed of conveyance.

3399. *The title*. Through whatever legal channel possession is obtained, the tradition, record, or deed, that witnesses the fact, gives the title of the possessor; by which he is enabled to hold his lands, and legally to convey them to another. Such is the tenure of lands in England.

SECT. II. *The Kinds and Tenures of Landed Property in Scotland.*

3400. *The kinds of landed property in Scotland* are the same as in England, except that manorial rights apart from the right to the soil are unknown.

3401. *The tenure of lands in Scotland* differs very little from the English tenures. All lands are either held *allodially*, that is, independently of any superior; or they are held by feudal tenures, by which all lands are considered theoretically as belonging to the crown. The different descriptions of these are termed feu-holding, blanch-holding, burgage, and mortmain. There are also some local tenures, as that of Udal, Lochmaben, &c.

3402. *Feu-holding*. The most ancient feudal tenure in Scotland was by military service; for all vassals were at first obliged, by the nature of their grant, to serve the superior in war, in such manner, and as often, as his occasions called for it. This species of holding, which was known under the name of *ward-holding*, is now abolished (by 20 Geo. 3. c. 50.), and requires no farther explanation.

3403. *Blanch-holding*. Where the vassal, in place of feu-duties and personal services as above described, only pays a small duty to the superior, in full of all demands, and merely as an acknowledgment of his right, whether in money, as a penny Scotch, or in some other article, as a pair of gilt spurs, a pound of wax, &c., it is called blanch-holding. This tenure deviates, more than any other, from the original nature of feus; but next to *feu*, it has now become the most general species of holding. The payments are entirely illusory, being never demanded.

3404. *Burgage-holding* is a tenure by which royal burghs hold of the sovereign the houses and lands that lie within the limits described in their several charters of erection. The proprietor of the burgage lands is liable to pay the municipal taxes; but all the political rights are vested in the magistracy, or town-council of the burgh. It is very limited in its extent.

3405. *Mortmain* is described by Erskine as the tenure by which any feudal subjects are held, which have been granted in donation to churches, monasteries, or other corporations, for religious, charitable, or public uses. Strictly speaking, the only lands now held in mortmain, are a few bursaries belonging to the universities, the tenure having been declared superstitious, and the other lands held by it given to the crown. Lands now destined for charitable purposes are vested in trustees, and held by feu or blanch.

SECT. III. *The Kinds and Tenures of Landed Property in Ireland.*

3406. *The kinds of landed property in Ireland* are limited to freehold and leasehold; there are no manorial rights apart from the soil as in England, nor feudal rights or holdings as in Scotland.

3407. *The tenure of lands in Ireland* is very simple. It is in general derived from grants made by the crown on the payment of a certain quit-rent received by the excise

collector of the district. This is the fundamental tenure, and the only other is leases granted by such proprietors; some of these leases are for ever, or on lives renewable for ever on payment of a certain fine for the insertion of a new life when one drops, or for leases of 999 years, and almost every variety of term with and without lives between that and twenty-one years. There are no feudal tenures in Ireland; the only abstract right being that of tithes and parochial or other taxes. (See *Wakefield's Account of Ireland.*)

CHAP. II.

Valuation of Landed Property.

3408. *When lands are valued with a view to sale or purchase*, the tenure is the first subject of attention. The nature of the tenure often occasions some difficulty in ascertaining its value; but by ascertaining the value of the fee-simple, or freehold tenure, the value of inferior holdings may be found by known rules of calculation, the principal of which we have already noticed. (3340.)

3409. *The fee-simple value* of lands is liable to fluctuation from general causes; and is likewise affected, and in much higher degree, by local circumstances. Lands of the selfsame quality are of fivefold value, in one situation, comparatively with what they are worth in another: not merely, though principally, on account of the rental value, or the current price they will let for, to tenants, in different situations; but through other less permanent causes; — as the quantity of land at market, and the number and value of purchasers, in a given district; as well as the temporary spirit which prevails in it, with respect to the possession of landed property, at the period of sale; — circumstances that are worthy of attention, from a purchaser whose views are not confined to any particular spot.

3410. *The usual method of coming at the fee-simple value of land* is to ascertain its fair rental value, or price by the year, and to multiply this by the number of years' purchase which the existing demand for land will bear, in the given situation, at the time of sale.

3411. *The number of years' purchase*, or the ratio between the rent and the sale value of lands, varies greatly, as from twenty to forty, twenty-five to thirty being the more ordinary numbers. Thus, a parcel of land, whose fair rental value is one hundred pounds, is, in common cases, worth from two thousand five hundred to three thousand pounds.

3412. *But the real rental value*, which is the only firm groundwork to proceed upon, whether in the purchase or the management of landed property, cannot easily be obtained. Speaking generally of the lands of England, it is what very few men are able to set down. It is true, that, in every district, and almost every township, there are men who tolerably well know the rate at which the lands of their respective neighbourhoods are usually let. But interchange them, reciprocally, into each other's districts, and their errors would be egregious, for reasons already suggested. Nor can a mere provincialist, especially in a district which is unenlightened by modern improvements, be aware of the value, even of his own farm, under the best course of management of which it may be capable: nor can he see, through the double veil of ignorance and prejudice, the more permanent improvements that may be made upon it, so evidently as one who has a more general knowledge of rural subjects, and is in the habit of detecting and prosecuting such improvements. Yet it very materially concerns an intending purchaser, in these improving times, to know, before he make his last offer for an estate, whether it is or is not capable of being improved beyond its existing value; and what, if any, is the probable amount of improvement: for he is else liable to lose a valuable purchase, through his being out-bidden by a better-informed candidate. These facts being evident, it follows, that before an offer be made, especially for a large purchase, it is no more than common prudence, in a man who is not himself a judge, to call in twofold assistance: a provincial valuer, to estimate its fair market price to the tenants of the neighbourhood in which it lies; and a man of more general knowledge, to check his valuation, and to estimate the improvements of which the lands are evidently capable.

3413. *The leading particulars which affect the value of an estate*, and which require to be considered in its estimation, are quantity, quality, situation, state, outgoings, and abstract rights.

3414. *The quantity of the land* is the groundwork of the estimate; though it has little weight in the scale of valuation. The fee-simple value of an acre of land may be less than twenty shillings, or it may be more than a hundred pounds. Nevertheless, it is on the quantity the rental value is calculated; and it is usual for the seller to exhibit a

“particular” of the estate on sale; showing, or which ought to show, not only the aggregate quantity, but the number of acres that each piece or parcel contains; and ought, most particularly, to specify the distinct quantities of the lands of different qualities, in order that their several rental values may, with greater accuracy and ease, be ascertained.

3415. *The intrinsic quality of the land* is another essential basis of calculation. But even this, in a general view of the value of lands throughout the kingdom, is often of secondary consideration; for, in many cases, their values are given by situation, rather than by soil and substrata. In some cases, as has been already said, the value of the situation may be fivefold that of the intrinsic value of the land. This excessive influence of situation, however, is limited in its effects, and is chiefly confined to the environs of towns, and other extraordinary markets for produce: a great majority of the lands of England owe their values less to situation than to intrinsic quality; and to come at this, with sufficient accuracy, is the most requisite, and, at the same time, the most difficult part of valuation, as it depends almost wholly on extemporary judgment, exercised on the frequently few data which rise to the eye in passing over the field of estimation. It is almost needless, therefore, to observe, that, to acquire the degree of judgment necessary to this critical task, it is requisite to know the productiveness of lands of different appearances: a species of knowledge which scarcely any thing but mature practice, in the cultivation of lands of different qualities, can sufficiently teach; though long habit may do much, in ordinary cases, towards hitting off the value of lands, without an extensive knowledge of the practice of agriculture. There are, however, cases in which we find both of these qualifications insufficient to give an accuracy of judgment, even among provincial valuers; and a man who ventures to step forward as a universal valuer, should either have an extraordinary talent for his line of profession, or should, after a suitable initiation, have had great experience in rural concerns in various parts of the kingdom.

3416. *On situation*, the value of lands, aggregately considered, depends less, than on intrinsic quality; though, without doubt, situation has great influence. Thus, land whose intrinsic quality renders it, in an ordinary situation, worth twenty shillings an acre, would not, in some districts, be worth more than fifteen shillings; while in others it would bear to be estimated at twenty-five shillings, or a higher rent, to a farmer on a large scale, and away from the immediate environs of a town, or any populous district of manufacture; for reasons that will appear in examining the different particulars of situation.

3417. *In the temperature of situation*, whether it is given by elevation, aspect, or exposure, we find a powerful influence, which is capable of altering exceedingly the value of lands. The same soil and subsoil, which we not infrequently see on exposed mountains, and hanging to the north, and which in that situation are not worth more than five shillings an acre, would, if situated in a sheltered vale district, and lying well to the sun, be worth twenty shillings, or a greater rent. Even on climate, something considerable depends. In the south of England, harvest is generally a month earlier than in the northern provinces; though it is not regulated exactly by the climate or latitude of places, a circumstance that requires to be attended to by those who estimate the value of estates; for an early harvest is not only advantageous in itself, but it gives time to till the ground, or to take an autumnal crop, which are advantages that a late harvest will not so well admit of. And another kind of temperature of situation has still more influence on the value of lands; namely, the moistness of the atmosphere. A moist situation not only gives an uncertain and often a late harvest, but renders it difficult and hazardous, as too frequently experienced on the western coasts of this island.

3418. *Even in the turn of surface* we find exercise for the judgment. Lands lying with too steep or too flat surfaces, especially retentive arable lands, are of less value than those which are gently shelving, so as to give a sufficient current to surface water, without their being difficult to cultivate. Steep-lying lands are not only troublesome and expensive, under the operations of tillage, but in carrying on manures and getting off the produce. Lands lying with an easy descent, or on a gently billowy surface, may be worth more by many pounds an acre, purchase money, than others of the same intrinsic quality, hanging on a steep.

3419. *A supply of water* for domestic purposes, for the uses of live stock, and for the purpose of irrigation, is another consideration of some weight in valuing an estate. There are situations in which a copious stream of calcareous water would enhance the fee-simple value of a large estate some thousand pounds.

3420. *A sufficient supply of manure*, whether dung, lime, marl, or other melioration, at a moderate price, and within a moderate distance of land carriage, materially adds to the intrinsic value of lands.

3421. *The established practice of the country* in which an estate lies, is capable of enhancing or depressing the value of it exceedingly. Even the single point of practice of ploughing light and loamy lands with two oxen, or two active horses, instead of four heavy ones, is capable of making a difference on good land, which is kept alternately in herbage and corn crops, of five to ten shillings an acre a year; or ten pounds an acre purchase money.

3422. *The price of labour* is another regulator of the marketable price of land in a given district. It is always right, however, to compare this with the habits of exertion and industry which prevail among farm workmen, before the net amount of labour can be safely set down.

3423. *The price of living*, or expense of housekeeping prevalent among farmers, has its share of influence on the value of lands. In the more reclusive parts of the north of England, farmers and their servants are fed, clothed, and accommodated, at nearly half the expense of those of a similar degree in many parts of the more central and southern provinces. It is not here intended to intimate how husbandmen, their servants, and labourers, ought to live. As they are the most valuable members of the community, they are well entitled to such enjoyments as are compatible with care and labour. All that is meant, in stating this fact, is to convey a hint to the purchasers of estates. For, in a country where frugality prevails, lands of a given quality will ever bear a higher rent than they will where a more profuse style of living has gained a footing. Rent is higher, in proportion to the gross produce, on the small farms in Ireland, and the west of Scotland, than in other parts of the united kingdom; and yet the landlord is seldom a gainer,

as such rents are not so regularly paid, and the tenant, having no reserve of capital, is in bad seasons often unable to pay any rent at all.

3424. *The spirit of improvement*, or the prejudice against it, which prevails in a district of sale, is a circumstance of some value to a purchaser: for if the former is in a progressive state, especially if it is still in the earlier stages of its progress, a rapid increase of rent may, with a degree of certainty, be expected; whereas, under the leaden influence of the latter, half a century may pass away, before the golden chariot of improvement can be profitably put in motion.

3425. *In markets*, more than in any other circumstances, we are to look for the existing value of lands. Their influence is not confined to towns and populous places of manufacture: for in ports, and on quays, whether of inlets, estuaries, rivers, or canals, markets are met half way; even by good roads, their distance from the farm-yard may be said to be shortened.

3426. *In this detail of the particulars of situation*, with respect to the value of landed property, we perceive the attentions requisite to be employed by a valuer who is called upon to act in a country that is new to him. A provincialist, or even a professional valuer, who acts in a district, the existing value of whose lands he is sufficiently acquainted with, determines, at sight and according to the best of his judgment, on their respective values: for he knows, or ought to know, their current prices; what such and such lands let for in that neighbourhood; what he and his neighbours give, or would give, for lands of the same quality and state, without adverting to the particular circumstances of situation (they being given, in the established current prices which have arisen out of these circumstances); resting his judgment solely on the intrinsic quality and existing state of each field or parcel as it passes under his eye. But let his skill be what it may, in a country in which he has acquired a habit of valuing lands, he will, in a distant district, the current market prices of whose lands may be ten, twenty, or fifty per cent. above or below those which he has been accustomed to put upon lands of the same intrinsic qualities and existing states, find himself at a loss, until he has learnt the current prices of the country, or has well weighed the circumstances of situation; to which, in every case, he must necessarily attend, before he can determine their value under an improved practice, or venture to lay down general rules for their improvement.

3427. *The existing state of lands*, or the manner in which they lie, at the time of sale, is the next class of circumstances which influences their marketable value.

3428. *Their state with respect to enclosure* is a matter of great consideration. Open lands, though wholly appropriated, and lying well together, are of much less value, except for a sheep walk or a rabbit warren, than the same land would be in a state of suitable enclosure. If they are disjointed and intermixed in a state of common field, or common meadow, their value may be reduced one third. If the common fields or meadows are what is termed Lammas land, and become common as soon as the crops are off, the depression of value may be set down at one half of what they would be worth, in well fenced enclosures, and unencumbered with that ancient custom. Again, the difference in value between lands which lie in a detached state, and those of the same quality that lie in a compact form, is considerable. The disadvantages of a scattered estate are similar to those of a scattered farm. Even the single point of a want of convenient access to detached fields and parcels is, on a farm, a serious evil. And it is on the value of farms that the value of an estate is to be calculated.

3429. *The state of the roads*, whether public or private, within an estate, and from it to the neighbouring markets, or places of delivery of produce, is an object of consideration to a purchaser.

3430. *The state of the watercourses*, or shores and ditches, within and below an estate, requires to be examined into; as the expense of improvement or reparation will be more or less, according to their existing state at the time of purchase; or, perhaps, by reason of natural causes, or through the obstinacy of a neighbour, and the defectiveness of the present laws of the country in this respect, the requisite improvement cannot be effected at any expense.

3431. *The state of drainage of lands* that lie out of the way of floods or collected water requires to be taken into consideration; for although the art of draining is now pretty well understood, it cannot be practised, on a large scale, without much cost.

3432. *The state of the lands, as to tillage and manure*, is entitled to more regard than is generally paid to it, in valuing them. But even to a purchaser, and still more to a tenant for a term, their state, in these respects, demands a share of attention. Lands that are in a high state of tillage and condition, so as to be able to throw out a succession of full crops, may be worth five pounds of purchase money an acre more than those of the same properties, which are exhausted by repeated crops, and lie in a useless state of foulness, from which they cannot be raised, but at a great expense of manure and tillage.

3433. *The state, as to grass or arable*, is better understood, and generally more attended to. Lands in a state of profitable herbage, and which have lain long so, are not only valuable, as bearing a high rent while they remain in that state; but after the herbage has begun to decline, will seldom fail to throw out a valuable succession of corn crops. Hence, the length of time which lands, under valuation, have lain in a state of herbage, especially if they have been kept in pasturage, is a matter of enquiry and estimation.

3434. *Lastly, the state of farm buildings and fences* is a thing of serious consideration. Buildings, yards, and enclosures, that are much let down, and gone to decay for want of timely reparation, incur a very great expense to raise them again to their proper state. And, when great accuracy of valuation is called for, as when the purchase value of an estate is left to reference, and when the tenants are not bound, or if bound are not able, to put them in the required state, it becomes requisite to estimate the expense which each farm, in that predicament, will require to put it in sufficient repair, so as to bring the whole into a suitable state of occupation. And the same principle of valuation holds good in ordinary purchases.

3435. *Deductions, encumbrances, and outgoing*s, are leases, tithes, taxes, fixed payments, repairs, and risks.

3436. *Leases*. In considering the nature of leasehold tenures, it appears that, by a long lease, the fee-simple value of an estate may be, in effect, annihilated. Even a lease for lives, with a mere conventional rent, may reduce it to nearly one third of its fee-simple value; and every other kind of lease, if the rent payable be not equal to the

fair rental value at the time of sale, is an encumbrance, even to a purchaser who has no other object in view than that of securing his property on land, and receiving interest, in rent, for the money laid out. If personal convenience be immediately wanted, or improvements required to be made, a lease, though the tenant pay a full rent, becomes an obstacle to the purchase.

3437. *Tithes.* If in valuing lands they are considered as tithe free, the tithe, or modus, if any, requires to be deducted as an encumbrance; and seeing the great variation in the values of tithes and moduses, according to customs and plans of occupation, it is the plainest way of proceeding, to value all lands as free of tithe, and afterward to make an allowance for whatever they may be estimated to be worth: an allowance which, in some cases, as on corn-land estates, forms a considerable portion of the fee-simple value of the lands; while on grass-land estates, especially such as are pastured by cattle, this encumbrance, so galling to the corn grower, is in great part avoided.

3438. *Taxes.* Although it may be called the custom of England for proprietors to pay the *land tax*, and the occupier all other taxes, yet this is not the universal practice. Nor is it, in valuing an estate on sale, and to be let at will, a matter to be enquired into. The annual amount of the payable taxes and other outgoings is the fact to be ascertained: for whosoever discharges them, they come as a burthen upon the gross value of the lands, out of which they are payable; for if a tenant pays them, his rent is, or ought to be, estimated and fixed accordingly. If, however, an estate on sale is already let under lease for a term to come, it is highly requisite to ascertain what parts of the annual outgoings and repairs are discharged by the tenants, and what the proprietor will be liable to, during the term to run. The land tax, where it still exists, is extremely uncertain as to its value, and the poor tax is equally variable in different situations. The church, highway, and county rates are, taking them on a par of years, less liable to local uncertainty, and are consequently less entitled to enquiry from a valuer.

3439. *Fixed payments, or rent charges,* such as chief rents, quit rents, annuities, endowments, schoolmasters' salaries, charitable donations, &c. to which an estate is liable; also

3440. *Repairs of public works,* buildings, roads, &c. incumbent on the estate on sale, are subjects of enquiry and estimation; as well as the ordinary repairs above noticed. And, moreover,

3441. *The hazard, or risk,* which naturally or fortuitously attends the lands under valuation, as that of their being liable to be inundated in summer, or to be torn away by floods at any season, is entitled to mature consideration: for, although these evils may generally be remedied by river breaks and embankments, the erecting of these is mostly attended with great expense; and the estimated value of this becomes, of course, a fair deduction.

3442. *Appurtenant to an expensive estate, there are generally other valuable considerations,* besides the purchase value of the lands. These are,

3443. *Minerals and fossils,* whether metals, fuels, calcareosities, or grosser earths.

3444. *Waters,* whether they are valuable for fisheries, decoys, mills, domestic purposes, or the irrigation of lands.

3445. *Timber,* of woods and hedgerows.

3446. *Buildings* that are not let with the farms, but which bear rent, independent of the lands; yet which, when scattered over an estate, may well be considered as belonging to landed property.

3447. *The estimated value of evident improvements.*

3448. *The abstract rights* which arise out of appropriated lands, or their appurtenances; as

3449. *The right of commonage,* which is generally of some value even when commons lie open, and may be of more when they shall be enclosed; provided the cost of enclosure do not turn out to be more than the extra value of the appropriated lands, above that of the common right in their open state.

3450. *The right of seigniority to fee-farm rents, or other chief rents,* payable to the possessor of the lands on sale, out of the lands of other proprietors. These rents, though small, are of certain value in themselves; and the idea of superiority which they convey to some men's minds may be worth more than the pecuniary value; which, indeed, where the sums are very small (as is often the case), is much lowered by the expense of collecting them: besides the trouble, vexation, private quarrels, and lawsuits they are liable to excite, when, through neglect, they are half forgotten, and the vassal is willing to catch at the circumstance, to try to get rid of the teasing and humiliating encumbrance. This, however, may serve to account for their having been handed down with reverential care, through a succession of ages; until, in many instances, even their origin, and much more the circumstances attending it, are difficult or impossible to trace. But, surely, a man of a liberal turn of mind, who has no interest in legal contests, and who prefers solid gold to a trinket, would not hesitate to collect these scattered wrecks of property, and to convert them to a more civilised, rational, and profitable purpose. On the other hand, any man of an independent spirit would pay more than a fair price — would pay liberally — to be exonerated from so base a burthen. If, however, a vassal's chains sit easy upon him, let him wear them. What is here meant to be intimated is, that he ought to have, in liberality, if not in law, a fair opportunity of throwing them off.

3451. *The rights of feudality, or manorial rights,* are at present, if not in their origin, very different from those last mentioned. In the day of their establishment, they appear to have been founded in wisdom and a degree of political necessity; and, by the correcting hand of time, they arrived at a high degree of

political perfection. The simple and easy mode of transferring property, which the feudal system established, was well adapted to the illiterate age in which it had its rise. Even in these lettered days, and among the ruins of feudal rights, the copy of a court-roll is considered as the clearest title a man can have to his possession! what a hint is this to modern legislators! The value of feudal rights is to be estimated by the quit rents, fines, heriots, escheats, and amerciaments, which long custom and a train of circumstances have attached to the given court; and besides what relates to the appropriated lands of the manor, the lord has a profit arising from the commonable lands (if any lie within it), as lord of the soil, which cannot be broken without his permission. Hence the fossils and minerals, which it covers, belong to him; as well as the timber which grows upon the waste, and the waters that are annexed to it. He is moreover, in ordinary cases, lord of the game which inhabits or strays upon this manor. This, however, being a right of pleasure, rather than of profit, has no fixed standard of estimation.

3452. *The right of tithe*, when attached to an estate, is the most desirable of abstract rights arising out of landed property: for, as far as the right extends (whether to a lay rectory, or a vicarial impropriety), the lands which it covers become, in effect, tithe free; as every judicious proprietor incorporates the rents of the tithe with those of the lands out of which it is payable, thus (if the right, as it generally is, be rectorial) freeing them wholly from the encumbrance of tithes, as a tax on improvements, and as an obstacle to the growth of corn. The value of tithes, as has been intimated, is so various, that nothing but local information can enable a valuer to estimate them with sufficient truth.

3453. *The right of advowson*, or the privilege of appointing a pastor to propagate religion and morality upon an estate, properly enough belongs to its possessor; as no other individual is so intimately concerned in the moral conduct of its inhabitants.

3454. *The right of representation or election*, or the appointment (in whole or in part) of a legislator to assist in promoting good order in the nation at large, equally belongs to the owner of territorial surface.

CHAP. III.

Purchase or Transfer of Landed Property.

3455. *In bargaining for an estate* there are two methods in use; the one by public bidding, and the other by private treaty. In either a certain degree of caution is requisite; and in both an accurate valuation is the best safeguard.

3456. *Among the preliminaries of purchase by private contract*, the particulars which may be required to be furnished by a seller are first to be enumerated. These are; the quantities of the several pieces of the lands on sale, together with the maps, or rough drafts, of the same: the tenure under which they are holden: some assurance as to the title of the seller, and his right of alienation: the tenancy under which the several farms are let; and, if on lives, the ages of the nominees; if for a term of years, the number unexpired; if at will, the notices (if any) which the tenants have had.

3457. *An abstract of the covenants under which they are let*; particularly of those which relate to taxes and repairs, to the expenditure of produce, to the ploughing of grass lands, &c.

3458. *The existing rents and profits receivable*; whether for tenanted lands, appurtenances, or abstract rights; with the estimated value of the demesne, and the woodlands in hand; together with the estimated value of the timber growing upon the estate on sale, as well as of the minerals and fossils which it may contain: the outgoing to which the estate is liable: the proposed time of the delivery of possession: the price, and the mode of payment expected.

3459. *The particulars of instruction to be given to a surveyor*, or other valuer, of an estate to be purchased, may next be particularised; it will be right, however, to premise, that much, in this respect, depends on the probability of purchasing, and on the time allowed for making the estimate.

3460. *In cases of sale by public auction*, where there can be no certainty as to purchase, and where the time for valuation is limited, a rough estimate of each farm, and a general idea of the value of the timber and other appurtenances, may be all that can be prudently ascertained.

3461. *But, in a sale by private contract*, where the refusal of an estate is granted, and time allowed for deliberate survey, a more minute investigation may be proper, especially when there is every reason to believe that a bargain will take place. For the same report will not only serve as a guide to the purchase, but will become a valuable foundation on which to ground the future management of the estate. For these, and other reasons, a purchase by private contract is most to be desired, by a gentleman who is not in the habit of personally attending public sales, and is unacquainted with the business of auction rooms.

3462. *The particulars to be required from a surveyor*, or surveyors, are principally these: the rental value of each field or parcel of land, with the state in which it lies, as to arable, meadow, pasture, or woodland; the value of the timber and other appur-

tenances; the characteristic, and the state of management, of each farm or tenement, with the eligibility of its occupier, together with the state of repair of buildings, gates, fences, watercourses, and roads; the amount of the encumbrances and outgoings; and, lastly, the probable value of the improvements of which the estate may appear to be capable, whether by ordinary or extraordinary means.

3463. *The subjects of treaty* after these particulars of information are procured are few. The two statements having been duly compared, so that no misunderstanding can take place between the parties, the price, with the times and mode of payment, are the principal matters of agreement. A clear understanding respecting the custody of title deeds, and the expenses of conveyance, require, however, to be enumerated among the preliminaries of purchase.

3464. *The business of negotiation* is best carried on by letters, which become vouchers of facts. Whatever is done by interview requires to be reduced to writing, and to be read by, or to, the parties, before they separate, that no possibility of misconception may arise; and, added to these precautions, it is proper, in large purchases, and when abstracts of intricate title deeds are to be made out and examined, that a legal contract, or memorandum of agreement, should be entered into, for the mutual satisfaction and surety of the parties.

3465. *This contract, and the deed of conveyance* (namely, the instrument which is legally to transfer the property from the seller to the purchaser), may be said to conclude and ratify the business of purchase; and in this part of it legal assistance is essentially necessary, to examine existing deeds, and see that the seller has a legal right and clear title to the land, and a legal power to dispose of it, as well as to draw up or examine the fresh deed of conveyance, and see that it is sufficient to transfer the property, legally and adequately, to the purchaser.

3466. *The preservation of titles* may be adverted to before dismissing this subject. In Scotland, deeds of conveyance and other deeds are registered in one magnificent building, whose internal economy is as admirably adapted to its design, as its outward form is beautiful: and, in England, there are two counties (Yorkshire and Middlesex) which are termed register counties; in which abstracts of deeds are preserved, and so arranged as to be readily referred to. Hence, in cases where the original deeds are destroyed or lost, these registered abstracts are sufficient evidences of their having existed, and capable of securing the titles of estates to their rightful owners; and are moreover valuable, in preventing fraudulent practices, particularly respecting mortgages. Nevertheless, the other counties of England remain, from reign to reign, destitute of these advantages.

BOOK II.

OF THE LAYING OUT, OR GENERAL ARRANGEMENT, OF LANDED ESTATES.

3467. *The laying out of an extensive landed estate* embraces a variety of subjects, and requires extensive information and enlarged views of political, agricultural, and even of moral improvement. In new countries, such as America, where an estate is laid out from a state of nature, this is more particularly the case; but the observation will also apply to many parts of the British Isles, where estates, long since appropriated, require re-arrangement and improvement.

3468. *Among the different objects of attention* in laying out or re-arranging a landed estate, one of the first is its consolidation, or the rounding off or simplifying the outline so that the whole may be brought into a compact form. This *envie de s'arrondir* seems to have existed, and the proximity and intermixture of property to have been felt as an evil by landed proprietors, in all ages. Ahab desired the field of Naboth, because it was near to his house; and Marvel, the attorney (*Massinger's New Way to pay Old Debts, &c.*) advised his client to "hedge in the manor of Master Frugal," because says he, "his land, lying in the midst of yours, is a foul blemish."

3469. *In consolidating property in Britain*, an equally desirable object is the appropriation of commonable lands; which, in England, can only be effected under the authority of a special act of the legislature, but is accomplished with less difficulty in Scotland, and is rarely necessary in Ireland. It is believed, indeed, that there are now no commons in Scotland, unless, perhaps, one or two belonging to the crown or the church, which cannot be divided by the general law, but must be done either by consent of parties or a special act of parliament. (C.)

3470. *The arrangement of the interior of an estate* naturally follows the determination of the ring-fence, and the complete possession of all that is within. Here the first thing

will probably be to determine the demesne lands, or site of the proprietor's residence, and the extent of territory he means to attach to it and retain in his own occupation. Then follows the intersection of the estate with roads, and probably a canal; the choice or determination of the sites for towns, villages, manufactories, and mines, mineral quarries, or fisheries, if such exist naturally. Lastly, the grounds to be planted being determined on, the remaining part of the property will consist of the lands to be let out for cultivation by farmers, or other tenants of the soil. In conformity with this view of the subject, we shall consider, in succession, the consolidating of estates, the appropriating of commonable lands, the choice of demesne, road-making, canal-making, the establishment of villages and manufactories, the working of mines and quarries, the establishment of fisheries, the formation of plantations, the planting of orchards, and the laying out of farms and farm-lands.

CHAP. I.

Consolidating detached Property.

3471. *The advantages of a compact estate over one whose lands lie scattered and intermixed with other men's properties are evident.* The management, whether of detached farms as parts of an estate, or scattered fields as parts of a farm, is conducted with inconvenience: beside the unpleasant altercations to which intermixed lands are liable to give rise. The different methods of compressing landed property into the required state are by exchange, by purchase, and by sale.

3472. *Where the lands of two proprietors lie intermixed with each other, an amicable exchange is the most eligible; and were it not for the childish piques and petty jealousies which so frequently take root between neighbouring proprietors (and are cherished perhaps by their officious friends), lands of this description could not long exist; the evil, in almost any case, being easily removed.* Each party having chosen one, or, in extensive concerns, two referees; and the two or four so chosen, having named a third or fifth, the required commission is formed; and bonds of arbitration being signed, the commissioners proceed, as under an act of appropriation of commonable lands, to assign each proprietor his rightful share, in the most profitable situation which the given circumstances will permit. This mode of proceeding might be adopted by the most distant parties, or the most inveterate enemies; and, doubtlessly, with advantage to the property and peace of mind of each.

3473. *Where an estate or a farm is disjointed by the intermediate lands of others, it is not only pleasurable to be possessed of them, but profitable to purchase them, even at a higher price than they are intrinsically worth; consequently at much more than their value, as detached lands, to their proprietor.* Yet such is often the waywardness and ill-judged policy of the holders of lands so situated, that they will rather continue to hold them with disadvantage, than sell them at a fair price. An equitable way of determining a matter of this sort is, to ascertain the value of the lands to the holder as detached lands, and likewise their value to the candidate as intermixed lands; and to let the mean between the two values be the selling price. By this method, both parties become actual and equal gainers. If the possessor of such lands should lie in wait for an exorbitant offer, the most efficient mode of proceeding is to offer a high number of years' purchase on their fair rental value, indifferently considered, in the situation in which they lie, and to propose to settle such rental value by arbitration. This is a sort of offer which every honest man can readily understand; and, if the holder has any character to lose in his neighbourhood, he cannot refuse it; if he has not, a calculation of the difference between the rent he is receiving and the interest of the money offered, consequently of the annual loss which he is sustaining by not accepting the offer, will, sooner or later, bring him to a sense, if not of his duty as a member of society, at least of his own interest.

3474. *It is, in general, right management to dispose of the detached parts of an estate, and to add to the main body.* The whole is then more easily superintended, and managed at less expense; while small properties, if suitable steps be taken, and proper seasons of disposal caught, will generally fetch more than larger parcels, of equal rental value, timely and judiciously purchased.

3475. *In selling, as in purchasing, estates, two methods present themselves.* They may be sold by auction or by private contract. To raise a sum of money expeditiously, the former may be the most eligible, though attended with more expense and more notoriety than the latter, which, for the purpose under view, and when expedition is not necessary, will generally, if properly conducted, be found preferable. To conduct a sale of detached lands with judgment and reputation, the first step is to have them deliberately

valued by at least two men of character and ability, and to divide them into parcels or lots, according to situation, and so as to render them of superior value to adjacent proprietors. Then fix upon each parcel such value as it is fairly worth to the owner of the lands with which it is naturally united; and give him the refusal of it. Such parcels as are not disposed of in this way, may either lie open to private contract, or be sold by public auction, the motive for selling being, in every case, openly declared. It is to be remarked, however, that for a sale by auction, a fresh arrangement of lots will be required, the principle of allotment being in this case the reverse of the former. At an auction, a certain degree of competition is requisite to raise the article on sale to its full value; and it is no more than common prudence in the seller to make up his lots in such a manner as will bring together the greatest number of competitors.

CHAP. II.

Appropriating Commonable Lands.

3476. *Commonable lands*, or such as lie intermixed, or are occupied in common by the inhabitants according to certain laws and customs, may be considered in regard to their *origin and kinds*, and their appropriation or *division*.

SECT. I. *Origin and different Kinds of Commonable Lands.*

3477. *A very few centuries ago, nearly the whole of the lands of Britain lay in an open, and more or less in a commonable, state.* (See Fitzherbert on the Statute *Ertenta Manorii.*) Each parish, or township (at least in the more central and northern districts), comprised different descriptions of lands; having been subjected, during successive ages, to specified modes of occupancy, under ancient and strict regulations, which time had converted to law. These parochial arrangements, however, varied somewhat in different districts; but, in the more central and greater part of the kingdom, not widely; and the following statement may serve to convey a general idea of the whole of what may be termed common-field townships, throughout England:—

3478. *Each parish, or township, was considered as one common farm; though the tenantry were numerous.* (See also *Blackstone's Commentaries*, art. *Tithing of Townsh.*) Round the village in which the tenants resided lay a few small enclosures, or grass yards, for rearing calves, and as baiting and nursery grounds for other farm stock. This was the common farmstead, or homestall, which was generally placed as near the centre of the more culturable lands of the parish or township as water and shelter would permit.

3479. *Round the homestall lay a suite of arable fields*, including the deepest and soundest of the lower grounds, situated out of water's way, for raising corn and pulse, as well as to produce fodder and litter for cattle and horses in the winter season; and, in the lowest situation, as in the water-formed base of a rivered valley, or in swampy dips, shooting up among the arable lands, lay an extent of meadow grounds, or ings, to afford a supply of hay, for cows and working stock, in the winter and spring months.

3480. *On the outskirts of the arable lands*, where the soil was adapted to the pasturage of cattle; or on the springy slope of hills less adapted to cultivation; or in the fenny bases of valleys which were too wet, or gravelly lands thrown up by water which were too dry, to produce an annual supply of hay with sufficient certainty; one or more stunted pastures, or hans, were laid out for milking cows, working cattle, or other stock which required superior pasturage in summer.

3481. *The bleakest, worst-soiled, and most distant lands of the township*, were left in their native wild state, for timber and fuel, and for a common pasture, or suite of pastures, for the more ordinary stock of the township, whether horses, rearing cattle, sheep, or swine, without any other stint or restriction than what the arable and meadow lands indirectly gave; every joint tenant or occupier of the township having the nominal privilege of keeping as much live stock on these common pastures, in summer, as the appropriated lands he occupied would maintain in winter.

3482. *The appropriated lands of each township* were laid out with equal good sense and propriety. That each occupier might have his proportionate share of lands of different qualities, and lying in different situations, the arable lands, more particularly, were divided into numerous parcels of sizes, doubtless, according to the size of the given township, and the number and rank of the occupiers.

3483. *The whole was subjected to the same plan of management*, and conducted as one common farm; for which purpose the arable lands were divided into compartments, or "fields," of nearly equal size, and generally three in number, to receive, in constant

rotation, the triennial succession of fallow, wheat (or rye), and spring crops (as barley, oats, beans, and peas): thus adopting and promoting a system of husbandry, which, howsoever improper it has become in these more enlightened days, was well adapted to the state of ignorance and vassalage of feudal times. When each parish or township had its sole proprietor, the occupiers being at once his tenants and his soldiers, or meaner vassals, the lands were, of course, liable to be more or less deserted by their occupiers, and left to the feebleness of the young, the aged, and the weaker sex: but the whole township being, in this manner, thrown into one system, the care and management of the live stock, at least, would be easier and better than they would have been under any other arrangement; and, at all times, the manager of the estate was better enabled to detect bad husbandry, and enforce that which was more profitable to the tenants and the estate, by having the whole spread under the eye at once, than he would have been had the lands been distributed in detached unenclosed farmlets, besides avoiding the expense of enclosure. Another advantage arose from this more social arrangement, in barbarous times; — the tenants, by being concentrated in villages, were not only best situated to defend each other from predatory attacks, but were called out by their lord, with greater readiness, in cases of emergency. Therefore, absurd as the common-field system is, in almost every particular, at this day, it was admirably suited to the circumstances of the times in which it originated; the plan having been conceived in wisdom, and executed with extraordinary accuracy, as appears in numberless instances, even at this distance of time.

3484. *Uninhabited tracts or forests.* In different parts of Britain there were, and still are, extensive tracts of land, some of them of a valuable quality, lying nearly in a state of wild nature, which were never inhabited unless by freebooters and homebred savages. These uninhabited tracts are styled forests; and, heretofore, many or most of them have been attached to the crown; and some of them are still under royal patronage. Whether they were originally set out for royal pastime merely; or whether the timber which stood on them was of peculiar value; or whether, at the time of laying out townships, those tracts were impenetrable woods inhabited by wild beasts, and, when these had been destroyed, or sufficiently overcome to render them objects of diversion, were taken under the protection of the crown; is not, perhaps, well ascertained. There were also tracts of that description in different parts of England, but which appear, evidently, to have been enclosed from a state of woodland or common pasture; though it is possible they may have been nominally attached to neighbouring parishes. Of this description, principally, are the Wealds of Kent and Sussex, and many other old enclosed lands, in different parts of the kingdom, whose fields or enclosures are of irregular shapes, and their fences crooked. These woodland districts are, like the forest lands, divided into manors, which have not an intimate connection or correspondence with parishes or townships; — a further evidence that they were in a wild state when the feudal organisation took place.

3485. *In the western extreme of the island, the common-field system has never, perhaps, been adopted;* it has certainly never been prevalent, as in the more central parts of England. There, a very different usage would seem to have been early established, and to have continued to the present time, when lords of manors have the privilege of letting off the lands of common pastures to be broken up for corn, the tenant being restricted to two crops, after which the land is thrown open again to pasturage; and it is at least probable, that the lands of that country have been cleared from wood, and brought into a state of cultivation, through similar means. At present, they are judiciously laid out, in farms of different sizes, with square straight-lined enclosures, and with detached farmsteads situated within their areas; the villages being generally small and mean — the mere residences of labourers. Circumstances these are, which strongly evince that the common-field system never took place in this part of the island, as it did in the more central parts of England. Ireland, also, has been enclosed (though not fenced) from time immemorial.

3486. *The feudal organisation, having lost its original basis, has itself been mouldering away, more particularly during the last century.* A great majority of the appropriated common-field lands and commons have been partially or wholly enclosed; either by *piecemeal*, each proprietor enclosing his own slip, — a very inconvenient mode of enclosure; or by *general consent*; the whole of the proprietors agreeing to commit their lands to the care and judgment of arbiters, or commissioners, who, restoring the fields to their original entirety, repareelled them out in a manner more convenient to the several proprietors, and laid each man's portion, which had consisted of numberless narrow slips, in one or more well shaped grounds.

3487. *In England this requires to be effected by a separate act of parliament for each enclosure.* In these acts commissioners are named, or directed to be chosen by the proprietors, who, according to certain instructions in the act or law, and the general principles of equity, divide the township among all who have an interest in it. It appears by the statute books, that from the year 1774 to the year 1813, no fewer than two thousand six hundred and thirty-two acts of enclosure have been passed; the average in the first twenty years being thirty-seven, and in the last twenty years ninety-four.

3488. *In Scotland* a general bill of enclosure was passed by the parliament in 1695, and in consequence of it the whole country has for nearly a century past been in distinct possessions. In Ireland, as we have already remarked, no enclosure act became necessary, and the country is considered as suffering from the long continued minute division of landed property.

3489. *As a contrast to the general eagerness for enclosing*, it may be useful to present the moderate, and in our opinion judicious, observations of Loch, to whom it appears very doubtful how far the indiscriminate enclosure of commons, arising out of the high nominal prices of grain, has been in every instance of advantage to the nation. Many of them, he says, certainly, could never pay the expense of obtaining the act, of the commissioners' fees, of the construction of the fences, and of bringing the land into cultivation. In this respect there has been a dead loss of capital to the country. It is conceived that it is not carrying this feeling too far, to regret the destruction of some of those beautiful and picturesque forests and chases which once surrounded London, and to hope that this may go no further. It may even be permitted, perhaps, to include within this regret as a national loss, the destruction of Windsor forest, the most appropriate accompaniment of the noblest royal residence in Europe. The preservation of some of these chases is as essential to the poorer classes of the metropolis as to the rich. To the former they afford health, exercise, and amusement; in the latter they produce and cherish that love of the country, and of rural sports, so important in a constitutional point of view. They nourish that feeling for, and knowledge of, the beauties of nature (freed from the love of gain as connected with the productions of the soil), which enlarge our understandings, and exalt every other better sentiment of the heart—encouraging the practice of the social virtues, and checking those more selfish habits which the general distribution of great wealth is too apt to engender. There cannot be a doubt, that not only for these reasons would the abstaining from some of these enclosures have been beneficial, but, in an economical point of view, it would have been most advantageous to the nation. In how many ways could not the capital, thus lost, have been beneficially applied both for the individual and the country! How much a richer man would the land-owner have been, if he had saved much of this expense, and permitted a more liberal importation of foreign corn! How much better would it have been for the country! In this, as in every other instance, it might be demonstrated, that that which would have been best for one, would have been so for all, and that the same system must always benefit equally the English landlord, tenant, merchant, manufacturer, and artisan. (*Marquess of Stafford's Improvements, &c.*)

SECT. II. *General Principles of appropriating and dividing Commonable Lands.*

3490. *There are few lands in Britain unappropriated, except in England*, and these may be classed as forest lands, and other extensive wastes, on which several manors, or adjacent townships, have a right of common pasturage; commonable lands of distinct townships or manors, whose appropriated lands are wholly enclosed, and in a state of mixed cultivation; commonable lands of townships, whose arable fields, &c. are partially enclosed; and commonable lands of townships, whose arable fields remain wholly open.

3491. *The principles on which the appropriation of those lands requires to be conducted* are thus laid down by Marshal. By an established principle of the general law or constitution of the country, immemorial custom establishes right. Hence the original rights and regulations respecting the lands under view are not now the proper subjects of investigation; nor are the changes that may have taken place during a succession of centuries, from the origin of forests and townships to the latest time which is no longer within memory, objects of enquiry; but, solely, the acquired rights which exist in a given case at the time of appropriation, and which would continue to exist were it not to take place. The possessor of a cottage which has enjoyed, from time immemorial and without interruption, the liberty of pasturage, though such cottage were originally an encroachment of a freebooter or an outlaw, has indisputably as legal a claim to a proportionate share of the commonable lands, as the possessor of the demesne lands of the manor has, merely as such, although they may have descended from father to son from the time of their severalty; for it is evidently on the estimated values of the respective rights which exist, and which can be rightfully exercised *in time to come*, and on these alone, that a just and equitable distribution can be effected.

3492. *But before the distribution of commonable lands* among the owners of common pasturage can take place, the more abstract rights which belong to commons require to be estimated, and the just claims of their possessors to be satisfied. These are principally manorial rights, and the rights of tithes.

3493. *Manorial claims* are to be regulated by the particular advantages which the lord of a given manor enjoys, and which he will continue to enjoy while the commons remain open and unappropriated; whether they arise from mines, quarries, water, timber, alien tenants, fuel, estover, pannage, or game. His claim as guardian of the soil that is productive of pasturage only is, in most cases, merely honorary; and it remains with parliament to fix the proportional share of the lands to be appropriated, which he shall be entitled to as an equivalent for such honorary claim.

3494. *But in the case of thriving timber standing on the property*, the claim of the lord of the manor in right of the soil is more substantial; for out of this he has in effect a real yearly income, equal to the annually increasing value of the timber;—a species of advantage which, if the commons remain open and unappropriated, he will of course continue to enjoy so long as the timber continues to increase in value. His claim, therefore, in this respect, depends on the quantity of timber and its state of growth, taken jointly. Young thriving timber not only affords an annual increase of value at present, but will continue its benefits for many years to come, if it be suffered to remain undisturbed on the soil; and its owner, doubtless, has a prospective claim on the soil which supports it during the estimated period of its future increase; whereas dotards and stunted trees,

which afford no increase of value, do not entitle their owner to any share of the soil they stand upon. All that the lord has a right to claim appears to be limited to the trees themselves or their intrinsic value.

3495. *The claims of tithe owners*, aggregately considered, are more complex and obscure. In cases where the great and small tithes are united, and in which the tithe of wool and lambs, and that of grain, roots, and herbage, belong to the same owner, it may seem to be reasonable that he should have the option of receiving land of equal value to the existing value of the tithes, or of taking the chance of their value, in the state of cultivation. But seeing the evil tendency of corn tithes, and the impropriety of laying on so harmful a burthen, as they are now become, upon lands that have never borne it, there can be little risk in saying that it would be at least politic in parliament to prevent it. Besides, it stands part of the statute law, that lands which have never been under tillage shall not pay tithes during the first seven years of their cultivation; during which time the incumbent's income might, by leaving the tithe to take its course, be materially abridged, and his circumstances thereby be rendered distressful. On the whole, therefore, it appears to be proper in this case, that the law to be enacted should instruct commissioners to set out lands equal to the existing value of the tithes at the time of appropriation; and where much corn land shall be appropriated, to set out a farther quantity equal to the estimated reversion of their extra value (if any arise in the estimate), seven years after the appropriation shall have taken place.

3496. *Again, in cases in which the tithe of lambs and wool, and the tithe of corn, &c. belong to separate owners*, the line of rectitude and strict justice to all parties appears to be still more difficult to be drawn. The former is clearly entitled to land, or a money payment equal to his loss of tithe; but the right of the latter is less obvious. To cut him off entirely from any share of the lands, and likewise from any share of tithes to arise from them after they shall have been appropriated, may seem unjust; he may be a lay rector, and may have lately purchased the tithes, or a clerical rector who has recently bought the advowson, under the expectation of an enclosure. On the other hand, it appears to be hard, that the proprietors of the parish should first give up land for the tithe of wool and lambs which will no longer exist, and then be liable to a corn tithe on the same lands, after they shall have bestowed on them great expense in clearing and cultivation. Indeed, the injustice of such a measure is evident. A middle way, therefore, requires to be sought; and it will be difficult, perhaps, to find one which has more justice in it than that which is proposed for the first case. Thus, after the value of the lamb and wool tithe, &c. has been ascertained, and land set out as a satisfaction for it, estimate the value of the corn tithe, &c. seven years after the time of appropriation; and set out a further quantity for the reversion of the extra value (if any) of the latter over the former, and thus free the lands entirely from this obstacle to their improvement.

3497. *If any other abstract claim on the lands to be appropriated be fairly made out, or any alien right* (as that of a non-parishioner, or extra-manorial occupier, who has acquired, by ancient grant or by prescription, the privilege of depasturing them) be fully proved, its value requires to be accurately estimated, and land to be assigned in its stead.

3498. *The remainder of the unstinted commons of a given township or manor belong to the owners of its common-right lands and houses; but in what proportion, it may be difficult to determine with mathematical precision.* Nevertheless, by adhering strictly to the general principle, on which alone an equitable appropriation can be conducted, — namely, that of determining each man's share by the benefit which he has a right to receive at the time of appropriation, and which he might continue to receive were it not to take place, — truth and justice may be sufficiently approached.

3499. *One of the first steps toward an equitable distribution of unstinted commons is to ascertain the common-right houses, and to distinguish them from those which have no right of commonage; and which, therefore, can have no claim to any share of the lands of the unstinted commons, further than in the right of the lands they stand upon.* By an ancient and pretty generally received, though somewhat vague, idea respecting the rights of commonage, the occupier of every common-right house has the privilege of depasturing as many cattle, sheep, or other live stock, on the common in summer (provided, it must be understood, that it is large enough to permit every occupier to exercise this right), as the grounds he occupies within the township or manor can properly maintain in winter; and no one can exceed that proportion; for the surplus of the pasturage, if any, belongs to the lord of the soil. (See *Fitzherbert and Blackstone.*)

3500. *Under this regulation, the appropriated lands of a common-field township, which are not occupied jointly with a common-right house, may be said to be deprived, during the time they are so occupied, of their right of commonage; and in some of the private bills of enclosure, which have been suffered to pass through parliament, the lands which happened to be in this state of occupancy, at the time of passing the bills, were deprived*

of their interest in the common lands for ever; notwithstanding, perhaps, they had a few years preceding this accidental circumstance an undoubted right to their portion of them, — a right which, a few weeks or a few days afterward, might have reverted to them, without the smallest taint by the temporary alienation. If any of the appropriated lands of a township or manor have been estranged from its commons, during time immemorial; have never been occupied jointly with a common-right house, or in any way enjoyed, of right, the common pasturage within memory; they may with some reason be said to have lost their right, and be excluded from a participation.

3501. *By this ancient and in a degree essential usage, common-right houses have a clear right to the lands of the commons, superior to that of the ground they stand upon; especially if they rightfully enjoy a privilege of partaking of the fuel and pannage (as acorns, masts, &c.) they afford, for these properly belong to the houses, not to the lands: and still more especially, if they are conveniently situated for enjoying the several benefits which the commons afford in their wild state. And whatever a common-right house is worth, merely as such; that is to say, whatever it will let or sell for, over and above a noncommon-right house of the same intrinsic value; it certainly ought to participate in the distribution, according to such extra value.*

3502. *The true proportionate shares of the common-right lands are to be ascertained on the same principle; for although the ancient regulation respecting common-rights may continue in force, while the commons remain open and unappropriated, it would be found troublesome or unmanageable as a rule to their just appropriation. There are few, if any, commons (of common-field townships at least) that now afford pasturage in summer for all the stock which the appropriated lands are capable of maintaining in winter; so that their several proportions only could be used: and these proportions may be calculated with much greater certainty and despatch on the respective rental values of the lands, than on the more vague and troublesome estimation of the quantities of stock they would winter, which, indeed, would be best calculated by the rental value of the land. Consequently, in adopting this as the basis of calculation, the ancient rule is, in effect, complied with. (Blackstone, book iii. c. xvi. sect. 2.)*

3503. *But although each common-right occupier has a right to stock in proportion to the productiveness or rental value of his appropriated lands, every one could not do this with equal profit, and of course could not receive equal benefit. Lands situated on the side of a common are much more beneficial in this respect, than lands which lie a mile or two from it, with bad roads between them; and it is the real advantage which an occupier can fairly receive, that is the true guide in the partition, which consequently ought to be conducted, not on the rental value of the land, abstractly considered, but on this and its situation with respect to the commonable lands jointly. In other words, it is the rental values of the common-right lands while the commons remain open, not what they will become after the commons are enclosed, which I conceive to be the proper groundwork of appropriation.*

3504. *In cases where commonable lands are wholly attached to manors, and not common to the parish or township in which they are situated, as in forests and woodland districts, the selfsame principle of distribution is applicable. The remainder of the commons (after the owners of abstract rights have been satisfied) belong to the common-right lands and houses; no matter whether such lands and houses belong to copyhold tenants exclusively, or to copyholders and freeholders jointly, provided the immemorial custom of the manor make no distinction in their respective rights; the well established customs of manors being in all cases rules of conduct, and unerring guides to commissioners. Here may be said to end the greater difficulties as to the principles of appropriation: the rest is merely technical; the works of admeasurement, estimate, and calculation, — operations that are familiar to professional men in every district, and want nothing but application and integrity to render them sufficiently complete.*

3505. *The technical routine of the business of conducting an enclosure is as follows: — The act being passed, and two or more commissioners named, these commissioners meet on a certain day at a certain place within the township or parish, having previously given public notice of their intention. The chief business of that day is the fixing of a land surveyor and an attorney to the commission. At a second meeting the commissioners, surveyor, attorney, and some of the principal proprietors or their agents, attend and make a general perambulation of the township, in order to point out to the surveyor the different properties, with their limits, &c. The surveyor now proceeds to make a correct map of the whole. This done, the commissioners, attended by the surveyor, proceed to value each separate lot or piece; and having done this, they next advertise different meetings for the purposes of hearing the rights of townsmen, &c. Next they set about dividing the lands according to these rights, reserving proper roads for footpaths, quarries, gravel-pits, wells, springs, &c. for public purposes. When this is done, and set out on the ground, contractors are next employed to carry the whole into execution, the expense of which and also of the commission is generally paid by the sale of a part of the lands.*

CHAP. III.

Choice of the Demesne or Site for the Proprietor's Residence.

3506. *The most desirable situation for the mansion of the owner of a landed estate will, in almost every case, be somewhere near its centre.* The advantage of being at an equal distance from every part of the boundaries; of having as much as possible on every side that which we can call our own; of not being overlooked by near neighbours; and of reposing as it were in the bosom of our own tenantry, cottagers, cattle, and woods; are obvious, and felt by every one. There may be instances where, from a public road passing through the centre of an estate, or of a town or village there situated, or mining works carried on, and similar circumstances, it may not be desirable to form a central residence; but such cases are not common, and, in laying out an estate newly appropriated, or re-arranging an old one, may always or very generally be avoided. It may happen, however, that an estate may be so extensive, or its surface so hilly or mountainous, that a central situation may be dispensed with for other advantages. When an estate is situated near an extensive lake, at the foot of high mountains, or includes an extent of sea-shore, it will generally be found preferable, in point of effect and enjoyment, to place the mansion near these interesting features. Proximity to the sea, though it be on the margin of our estate, can never be offensive; for if the ocean does not belong to us, neither does it belong to any one else: nearly the same thing may be said of an immense lake, which at least is for the greatest part devoid of visible appropriation, and the same thing may often be observed of rivers and mountains, especially if the latter are of a savage, or wooded character.

3507. *Various other circumstances* must also be taken into view, in fixing on the situation of a mansion and demesne; such as its healthfulness, prospects, exposure, water, the nature of the soil, and the extent of territory.

3508. *To be healthy,* a situation should in almost all cases be somewhat elevated above the adjoining surface; and though this cannot be the case with respect to the whole of the demesne lands, it should at least apply to the spot intended for the dwelling-house. Even a level situation is objectionable in point of health, because, when the usual plantations have grown up round the house, they tend to stagnate the air and generate moisture, and thus deteriorate the atmosphere to their own height, which generally equals or exceeds that of the house. Besides, a flat situation can never have views of much beauty, and can only be interesting from the plants or other objects immediately under the eye, and the elevated grounds or hills, if any, in the extreme distance. On an elevated situation, even though surrounded by trees higher than the house, the frequent and varying winds will always prevent the stagnation of the air, and sweep away the moisture accumulated from the evaporation of so many leaves.

3509. *The nature of the soil* requires to be attended to, even with a view to health. On a level, a gravelly or sandy soil is generally more apt to generate damp in the lower parts of a house, than a clayey soil; but on an eminence gravel has not this objection: in the former case, the water lodged in the stratum of gravel finds its way from all sides to the excavation made for the foundations of the house; in the latter, the declivity on every side carries it away. Clay not too adhesive, chalk, and rock, are the best surfaces to build on in a flat: on an elevated situation any soil will do; but chalk, rock, or gravel, is to be preferred.

3510. *The prospects* from the immediate site of the mansion, and from those parts of the adjoining grounds which will be laid out as pleasure-ground, or recreative walks, demand some consideration. Such prospects should consist of what painters call middle and third distances, bold, distinct, and interesting; the fore-ground, or first distance, being formed by the artificial scenery of the pleasure-ground. Noble features in prospects are, rivers, lakes, or mountains: interesting ones are, churches or their spires, bridges, aqueducts, ruins of ancient castles or abbeys, water-mills, distant towns or cities, distant canals, and sometimes roads, &c.: pleasing rural objects are, picturesque cottages, neat farmhouses, field barns, and sometimes distant windmills; for objects offensive, when near, often become valuable features at a distance. Something depends on the state of civilisation of the country, and its general character; the sight of a road, sea-port, canal, or even a neighbouring mansion, would be preferred to most others in many parts of Ireland, Russia, or America.

3511. *The exposure* with regard to the sun and the prevailing winds of a country, also requires attention. It was the custom of former times, in the choice of domestic situations, to let comfort and convenience prevail over every other consideration. Thus the ancient baronial castles were built on the summits of hills, in times when defence and security suggested the necessity of placing them there, and difficulty of access was a recommendation: but when this necessity no longer existed (as mankind are always apt to fly from one extreme to the other), houses were universally erected in the lowest situ-

ations, with a probable design to avoid those inconveniences to which lofty positions had been subject; hence the frequent sites of many large mansions, and particularly abbeys and monasteries, the residence of persons who were willing to sacrifice the beauty of prospect for the more solid and permanent advantages of habitable convenience; amongst which, shelter from wind, and a supply of water for store fishponds, were predominant considerations. (*Enquiry, &c. by Repton, p. 83.*) In hilly countries, or in any country where the surface is varied, the choice is neither made in the bottoms (*fig. 532. a*) nor on

the summits of hills (*c*), but generally on knolls, or on the south or south-east side of considerable eminences (*b*), upon an elevated platform, either natural or raised by art from the earth of the foundations; and the rising grounds behind (*d*) are planted both for effect and shelter.

3512. *The proximity of water* is essential to the comfort of every country residence. Where there are none in springs or surface streams, it may, indeed, be collected from the roofs of buildings and otherwise, and filtered, and preserved sweet and cool in tanks underground; but supplies obtained in this way are precarious and expensive, and the water is inferior to that obtained from the soil by contiguous wells, or from a distance by pipes or drains. Water is also extensively required in country residences for the use of gardeners, sometimes for fishponds; at a moderate distance, and on a lower level, it is always desirable in considerable quantity for the purpose of forming artificial lakes, or river-like reservoirs. Few home features are finer than where the house is situated on a knoll which slopes down on two or more sides to one encircling piece of water. (*fig. 533.*)

3513. *The nature of the soil* is a consideration inferior to the others, because all bad soils are susceptible of great improvement; but, still, it should be taken into consideration along with other objects. A soil retentive of surface water, such as some clayey and soft peaty soils, is the worst, as it is always unpleasant to walk on after rains, and easily poached by cattle and horses. Such soils also require more expense in drainage and roads, and are much less suitable for garden and farm culture, than firmer soils, and such as are naturally friable or dry.

3514. *The subsoil* is sometimes of more importance than the soil; for the former in general can only be improved by draining, and subsoils differ materially in their susceptibility of this improvement. A bad subsoil is an effectual barrier to the thriving of timber trees; and as these constitute the finest ornament of every country seat, the importance of choosing a subsoil either naturally congenial to them, or capable of being rendered so by art, is sufficiently obvious.

3515. *Where the surface-soil is dry and poor, but on a dry subsoil, and all other circumstances are favourable, it may often be desirable for a proprietor to fix on such a situation for his demesne; because such a surface is probably among the least valuable as farm lands, because land to be laid out as a park is not required to be rich, and because it will not be difficult to ameliorate all that part wanted as farm and garden ground.*

3516. *The extent that should be kept as a demesne is more easily determined than any of the foregoing points. The general wealth of the proprietor, and his style of living, are here the leading guides. The extent of the demesne may bear very different relations to the extent of the estate; because the proprietor may have other estates and other sources of wealth. He may have chosen a small estate, on which to fix his residence, from its local advantages; or he may prefer a small demesne on a large estate, from his style of life and the habits of his establishment.*

3517. *The park, in general, occupies much the largest part of the demesne lands. In a civilised and populous closely cultivated country, like Britain, nothing can be more noble than a large forest-like park surrounding the mansion. In partially cultivated countries, or open field countries, it is less imposing; and in countries scarcely appropriated and but thinly distributed with spots of culture, the park becomes a less noble feature, and less a mark of wealth and distinction than a well-hedged and regularly cropped farm.*

3518. *The apparent extent of a park depends much less on its contents in acres, than on the inequalities of its surface, the disposition of its woods and waters, and the concealment or unobtrusiveness of its boundaries. An extensive flat, surrounded by a belt, and interspersed with clumps, may be great, but can hardly be felt as grand or interesting by any but the owner: the acres it occupies will be guessed at by hundreds, and the estimate will generally be found to fall short of the reality. On the other hand, a hilly park, ingeniously wooded, with a piece or pieces of water, and probably rocks, bridges, and other objects, will appear to a stranger of much greater extent than it really is, and sets rational estimate at defiance: such a park is certainly much more grand and picturesque than one of mere "bulk without spirit vast."*

3519. *The home or demesne farm and farmery will be regulated in extent and style of cultivation by the wants and wishes of the proprietor. It is sometimes a determinate space in the least picturesque part of the demesne; and sometimes, the greater part of the park is brought in succession under the plough and the sickle.*

3520. *The kitchen-garden is the next and only remaining large feature in the demesne: it is generally placed near the house and stable offices, so as to have a convenient and unobtrusive communication with the kitchen court, and the livery-stable dung heap.*

3521. *The pleasure-ground, or lawn and shrubbery, often surrounds the house, offices, and kitchen-garden; and sometimes embraces them only on two or three sides.*

3522. *The details of all these and other parts of the demesne belong to landscape-gardening and architecture, and require no further notice in this work. (See *Encyc. of Gard.* part iii. book iv.)*

CHAP. IV.

Formation and Management of Roads.

3523. *The advantages of good roads are so obvious and so generally acknowledged, as to need no comment. Roads, canals, and navigable rivers, have been justly called the veins and arteries of a country, through which all improvements flow. The Romans, aware of their importance, both in a military and civil point of view, constructed them from Rome to the utmost extent of their empire. With the dismemberment of that empire, the roads became neglected, and continued so during the dark ages. In modern times attention was first paid to them on a large scale by the government of France, in the seventeenth century; and in England in the beginning of the century following. About the middle of the eighteenth century, considerable expense had been incurred in road-making, in several districts, and the expenses of toll-gates began to be felt as oppressive. This produced *An Enquiry into the State of the Public Roads*, by the Rev. H. Homer, &c. 1767, which may be considered as the origin of scientific research on the art of road-making in England.*

3524. *In Scotland, the first turnpike act, as we have seen (771.), was passed in 1750; since which period existing public roads have been improved, and many new ones formed: but the great impulse there was given, after the act for abolishing heritable jurisdictions, by the money advanced by government, and the able military engineers sent from England to conduct the roads in the Highlands. The appearance in Britain, about this time, of a new order of professional men, under the name of civil engineers, also contributed to the same effect.*

3525. *In Ireland*, very little attention was paid to the art of road-making before the establishment of the Dublin Society; but the subject was treated of in the early volumes of their *Transactions*, and some useful instructions there given, as it is generally understood, by R. L. Edgeworth; and the surface as well as substrata of that country being singularly favourable for road-making, the art soon began to make considerable progress. This was greatly owing to the exertions of Edgeworth, well known as a scientific engineer. and as the author of a tract on roads published in 1810.

3526. *The extraordinary increase of toll duties* in England, having been felt as a very heavy burthen by the landed interest during the last twenty years, has drawn the attention of various persons to the subject of roads, and given rise to important improvements, both in laying them out, and in forming and repairing them. By far the most useful of these may be considered the mode of forming practised since 1816, by L. M'Adam of Bristol; for which its author was rewarded by parliament. That mode is now, with more or less variation, adopted in a considerable number of districts in the three kingdoms, and, together with the attention and emulation it excites, promises to effect an entire revolution in the state of the public roads every where. At the same time it is but candid to state, with Paterson of Montrose, author of two tracts (1819 and 1822) on the subject, that in many districts a considerable improvement had taken place, previously to the time of M'Adam, in the state of the roads, simply from a greater attention being made to keep them dry by under-drainage, to break the stones small, and constantly to obliterate the ruts.

3527. But M'Adam's plan of making roads promises to be valuable as a substitute for pavement or causeways in towns; at the same time its value, as compared with the most improved methods of paving, cannot be considered as finally determined.

3528. *In the following view of the present state of knowledge as to roads* we shall avoid entirely that part of the subject which relates to national or parochial management, and confine ourselves to the kinds, the direction or line, the form, the materials, the execution, and the repairs.

SECT. I. *Different Kinds of Roads.*

3529. *Though all roads agree in being tracks of passage from one point to another*, yet they differ in their magnitude, construction, and other modes of adaptation for that purpose. Most good roads consist of two parts; one "metalled" or coated with stones for the use of carriages and horses

(fig. 534. a); another of common earth or soil, as a border to the metalled part (b), or for the use of

pedestrians; and probably a footpath for the latter (c). Several kinds of roads are distinguished by the relative proportions of these two parts; but some also are characterised by other circumstances.

3530. *National roads*, or highways, are such as communicate between the capital cities and sea-ports of a country, and are those of the greatest magnitude. In Britain, the metalled part of such roads, where they are most frequented, as within a few miles of large towns, is from 30 to 50 and even to 60 feet wide, with footways on each side of 12 feet wide or upwards, and in no case is the metalled part of the road narrower than 20 feet; that width being requisite to admit of one loaded waggon passing another. Many or most of these narrower national roads are without footpaths, and often want a sufficient bordering of earth road, or footpath.

3531. *Parochial roads* may be considered as secondary highways, deriving their name from the circumstance of being made and supported by the parish in which they are situated; whereas the others are the work of government, or of the counties in which they are situated, and are supported by tolls levied on carriages and animals passing over them.

3532. *Lanes* are parish or private roads, generally narrow, and often either not metalled at all, or very imperfectly so; sometimes they are called *drift-ways*, but that term is more properly applied to the green or unmetalled space which runs parallel to any made road, for the passage of flocks and herds.

3533. *Estate roads* are such as are made by landed proprietors on their own territory, for the purpose of intercommunication and connection with public roads.

3534. *A farm-road* is either one which leads to a farmery, from a public road, or which leads from the farmery to different parts of the farm. Such roads are never narrower than 16 feet, to admit of two carriages passing each other; but they are often only half metalled, presenting a turf road for summer, dry weather, and for empty carriages and foot passengers, and a metalled or winter road for winter and loaded carriages. In a road from a highway to a farmery, it may often be advisable to place the metalled road in the middle, and keep the earth road at each side, on account of admitting the sun and air more readily to the metalled road; but in roads within a farm, it is found a great convenience in carting out manure or bringing home produce, for the loaded carts to have

uninterrupted possession of the metalled road, and the others of the earth road. In many cases, farm roads of this description are only metalled in the horse tracks

(fig. 535. *a*) and wheel ruts (*b c*), which, on dry firm-bottomed land, and with careful preservation, is found to answer very well.

3535. *Open farm roads*, Beaton observes, should be, as much as possible, placed on the headlands of the fields; that is, the portion of land adjacent to the hedge, on which the plough is turned; and every opportunity should be taken of placing gates, so that either

side of a hedge may be used as a road (fig. 536.), to avoid driving over a field in tillage. This may be easily effected by a few gates being placed in the line of the headland or nearly so, and not too near each hedge or to each other, so that a waggon may easily drive through them on the right or left, as the crops may require; a few hurdles (*a*) may guard each field in grain alternately, and will furnish a useful fold or enclosure to detain sheep, colts, &c.

3536. *Horse roads* are paths for the transit of single horses with a rider, or a back load: they are commonly of earth, and from six to ten feet wide: the statute width is eight feet.

3537. *Footpaths* are tracks for pedestrians; sometimes metalled to the width of three or four feet; but often of the natural surface.

3538. *Paved roads* are of three kinds: those with small stones, or causeways, which are most common; those with large blocks of stone, or what is called ashlar pavement; and those with sections of timber

trees. The first, though almost peculiar to towns, yet form the whole of the metalled road in some cases of country roads; and in others a space of ten or twelve feet in the middle, or at each side, is causewayed for the use of the heavier carriages. Broad stones are sometimes used for covering part of a road, destined for the greatest part of the traffic, or for forming wheel tracks. In the latter case they are always squared or regularly jointed, but in the former the most irregular forms may be used. Timber causewaying is only used in entrance courts to town mansions, for the sake of avoiding the noise made by the wheels of carriages and horses' feet on stone; or on suspension bridges, for the sake of lightness. For these purposes timber paving is excellent, and lasts for a very long time. On the Continent, fir timber is used for this sort of paving; but oak or larch would, no doubt, last longer.

3539. *Street roads with stone tracks* (fig. 537.) have been proposed by Mr. Stevenson, a distinguished engineer. These tracks may either be laid in connection with common

or rubble causeway (*a*), or with common road metal (*b*). Mr. Stevenson proposes to lay these stone tracks upon a firm foundation, if not throughout the whole extent to

our principal roads, at least upon all their acclivities which exceed a greater rise than at the rate of 1 perpendicular to 26 horizontal feet; — an undulating line of road which obliges the carrier, in most instances, to modify his load to one half of what his horse can take along the more level parts. It is likewise proposed, that the leading streets of all towns and villages situate upon the principal highways should be laid with these stone tracks. The traveller would then glide smoothly along, instead of being accompanied with a thundering noise and jolting motion most unpleasant to himself and the inhabitants of the respective places through which he passes.

3540. *The advantages of stone tracks in roads* “cannot be better exemplified than by noticing an experiment made in presence of some of the Directors of the Forth and Clyde Canal Company, upon a set of cast-iron tracks, laid upon an acclivity rising at the rate of about 1 in 15 to Port Dundas, near Glasgow. Here one horse actually drew up a load of three tons on a cart weighing nine cwt. In this case, the horse proceeded up hill without much apparent difficulty till he reached the top, and was about to enter on the common causeway, when he could proceed no further, although the road had now become level. The carters frequenting this road agree that their horses had formerly greater difficulty in taking up twenty-four cwt. on the causeway, than was now experienced with three tons. How great, therefore, must be the beneficial effects of such an immense acquisition of power, as even the partial introduction of wheel-tracks is calculated to afford to the traffic of the country!”

3541. *Mr. Stuart Menzies of Closeburn* “has had single-horse waggons with four wheels applied to the ordinary purposes of his estate. These waggons are constructed upon the principle of those of Switzerland; they are ten cwt. on which a horse, weighing about eleven cwt., takes a load of thirty cwt. between Edinburgh and Closeburn, a distance of sixty-six miles. This gentleman, whose knowledge in such matters is extensive, estimates, that if wheel-tracks were laid upon the principal acclivities of the road, as above recommended, his horses could work with a load of about two tons.” (*Stevenson's Plan for Track Roads*. Edin. 4to. 1826, p. 4.)

3542. *Planked roads* are formed over morasses; or in particular cases by laying down a flooring of flanks, on which carriages pass for temporary purposes. A permanent kind of road of this description has been made by weaving (or wattling) an endless hurdle of the breadth of the road, and covering it with a coating of gravel or broken stones. The advantage of this mode is, that the road may be made on a bog before the substratum dries, and even if it is so soft as not to bear a man. By the time the hurdle rots, the base will be consolidated and fit to bear any thing.

3543. *Rail roads* are roads exclusively for the use of carriages, and are characterised by a rail, commonly of iron, but sometimes of wood or stone, laid along the track of each wheel, in order to produce the effect of a perfectly even surface. There is also a recent invention of this kind, named a suspension railway, which, under particular circumstances, promises very considerable advantages. In general the carriages for such roads have their wheels low, and of a particular construction to fit the rails; but in some cases the rails have grooves for the use of common narrow wheels. Such roads are almost exclusively in use at coal and other great mineral works; but it has lately been proposed to introduce them as side roads to the more public highways, for the purpose of locomotive steam-engines, and it seems highly probable that this may be done before long on several of our main roads. (See Sect. V.)

SECT. II. *Line of Direction, or laying out of Roads.*

3544. *Before carriages of burthen were in use*, little more was required than a path upon hard ground, that would bear horses. All marshy grounds were therefore shunned; the fords of rivers were resorted to, and the inequality or circuit of the road was of much less consequence, that when carriages, instead of pack-horses, began to be employed. When carriages were first employed, they probably were light and narrow, and did not require to have roads of any considerable breadth or firmness; and when roads had once been thus traced, indolence and habit prevented any great exertions to lay them out in better lines, or to repair them in any manner beyond what present convenience absolutely required. When heavier carriages and greater traffic made wider and stronger roads necessary, the ancient track was pursued: ignorance and want of concert in the proprietors of the ground, and, above all, the want of some general effective superintending power, continued this wretched practice. (*Edgeworth on Roads*, p. 3.) At length turnpikes were established, and laws passed investing magistrates with authority to alter established lines, so that now the chief obstacle to the improvement of the lines of public roads is the expense.

3545. *In laying out roads*, a variety of circumstances require to be taken into consideration; but the principal are evidently their line or direction, and its inclination to the horizon.

3546. *The most perfect line*, according to Marshal, is that which is straight and level. But this is to be drawn in a country only which is perfectly flat, and where no obstructions lie in the way; — joint circumstances that rarely happen. Where the face of the country, between two points or places to be connected by a road, is nearly but not quite level, by reason of gentle swells which rise between them, a straight line may be perfect, — may be the most eligible under these circumstances: but where the intervening country is broken into hill and dale, or if one ridge of hill only intervenes, a straight line of carriage road is seldom compatible with perfection. In this case, which is nearly general, the best skill of the surveyor lies in tracing the midway between the

straight and the level line. The line of perfection, for agricultural purposes, is to be calculated by the time and exertion, jointly considered, which are required to convey a given burthen, with a given power of draught, from station to station. On great public roads, where expedition is a principal object, time alone may be taken as a good criterion.

3547. *According to Stevenson*, "although in road-making the line of direction must always be subordinate to the line of draught, yet the former is notwithstanding of importance, both as it regards the safety of the traveller, and the trackage of the load. Independently of the numerous accidents which occur from the sudden collision of carriages travelling at speed upon a tortuous line of road, it were even better to go up a moderate acclivity, than to introduce numerous turns, which, to a certain extent, are not less detrimental to the effective power of the horse, than the uphill draught. Every turn in the road, which ultimately amounts to a right angle, does, in effect, suppose the carriage to have been brought from a state of motion to a state of rest, and from rest to motion again. Turns in a road, where they are unavoidable, ought to be formed on curves of as large a radius as the situation will admit. There ought, in laying out a road, to be a kind of compensating balance between the lines of direction and draught; and wherever weighty reasons occur for varying the direct line, such as an acclivity to be avoided, more proper soil to be obtained, the avoiding of valuable property, or the including of a village or town, — where such motives present themselves, the judgment of the engineer will, of course, be exercised in varying the line of direction." (*Ed. Enc. art. Roads.*)

3548. *A regular method of finding out the true line of road between two stations, where a blank is given, and where there is no other obstruction than what the surface of the ground to be got over presents, is to ascertain, and mark at proper distances, the straight line, which is the only certain guide to the surveyor. If the straight line be found to be ineligible, each mark becomes a rallying point, in searching on either side of it for a better. If two lines of equal facility, and nearly of equal distance from the straight line, present themselves, accurate measurements are to determine the choice. If one of the best two lines which the intervening country affords is found to be easier, the other shorter, the ascent and the distance are to be jointly considered; the exertion and the time required are to be duly weighed.*

3549. *The nature of the ground, the source of materials, and the comparative expense of forming the road, by two doubtful lines, as well as their comparative exposure, are also to be taken into consideration. Although, in some places, Paterson observes, it may be of little consequence, either to the traveller or to the public in general, which way the bendings are turned, provided the level is nearly obtained, yet a great deal may depend upon those turns or bendings for the real benefit and advantage of the road. In bending it one way, you may have no metals that will stand any fatigue, unless at a great distance and expense; while, in turning it the other way, you may have metals of the very best quality in the immediate vicinity. In the one way, too, you may be led over ground of a wet bottom, where, even with twelve or fourteen inches deep of metals, there would be difficulty in keeping a good road; while, in the other, you may have such a dry bottom, that the road would be much easier upheld with seven or eight inches of metals. So that the track that may appear most eligible to the eye, at first sight, may not always be the one that should be adopted. "A combination of all the requisites I have already mentioned should be studied, as far as possible; and where these cannot be found all to unite, the one possessing the most of these advantages, and subject to no other material objection, should, of course, be adopted." (*Treatise on Roads, p. 19.*)*

3550. *Roads*, Edgeworth observes, *should be laid out as nearly as may be in a straight line; but, to follow with this view the mathematical axiom, that a straight line is the shortest that can be drawn between two points, will not succeed in making the most commodious roads: hills must be avoided, towns must be resorted to, and the sudden bends of rivers must be shunned. All these circumstances must be attended to; therefore a perfectly straight road cannot often be found of any great length. It may, perhaps, appear surprising, that there is but little difference in the length between a road that has a gentle bend, and one that is in a perfectly straight line. A road ten miles long, and perfectly straight, can scarcely be found any where; but if such a road could be found, and if it were curved, so as to prevent the eye from seeing further than a quarter of a mile of it, in any one place, the whole road would not be lengthened more than one hundred and fifty yards. It is not proposed to make serpentine roads merely for the entertainment of travellers; but it is intended to point out, that a strict adherence to a straight line is of much less consequence than is usually supposed; and that it will be frequently advantageous to deviate from the direct line, to avoid inequalities of ground. It is obvious, that, where the are described by a road going over a hill, is greater than that which is described by going round it, the circuit is preferable; but it is not known to every overseer, that within certain limits it will be less laborious to go round the hill,*

though the circuit should be much greater than that which would be made in crossing the hill. Where a hill has an ascent of no more than one foot in thirty, the thirtieth part of the whole weight of the carriage, of the load, and of the horses, must be lifted up, whilst they advance thirty feet. In doing this, one thirtieth part of the whole load continually resists the horses' draught; and in drawing a waggon of six tons' weight, a resistance equal to the usual force of two horses must be exerted.

3551. *A perfectly level road is not always the best for every species of draught.* Slight and short alternations of rising and falling ground are serviceable to horses moving swiftly; the horses have time to rest their lungs, and different muscles: and of this experienced drivers know well how to take advantage. Marshal concurs in this opinion, and also Walker, Telford, and most engineers; and Paterson considers that it would not be proper to line a road upon a perfect level, even to the length of one mile together, although it could be quite easily obtained. It is a fact, he says, well known to most people, at least every driver of loaded carriages knows by experience, that where a horse, dragging a load over a long stretch of road, quite level, will be exhausted with fatigue, the same length of a road, having here a gentle acclivity, and there a declivity, will not fatigue the animal so much. This is easily accounted for. On a road quite level, the draught is always the same, without any relaxation: but on a gentle ascent, one of his powers is called into exercise; on the descent, another of his powers is called into action, and he rests from the exercise of the former. Thus are his different muscular powers moderately exercised, one after another; and this variety has not the same tendency to fatigue. A perfectly level road, both with respect to its direction and its breadth, is always dirty in wet weather; because the rain water can neither run off to the side of the road, nor along the ruts. Such roads, therefore, as are level in their line of direction, should always have a fall from the middle to the sides, and should be kept as much as possible free from ruts.

3552. *According to Stevenson, and we believe to all the most scientific road engineers, a level straight road is decidedly the best.* He says, "in an uphill draught, a carriage may be conceived as in the state of being continually lifted by increments proportional to its rise or progress upon the road. Every one knows that on a stage of twelve miles the post-boy generally saves, as it is termed, at least half an hour upon the level road, because on it he never requires to slacken his pace as in going uphill. Now, if he, or his company, would agree to take the same time to the level road that they are obliged to do upon the undulating one, the post-master would find no difficulty in determining which side of the argument was in favour of his cattle. With regard to the fatigues or ease of the horse, Mr. Stevenson upon one occasion submitted the subject to the consideration of a medical friend (Dr. John Barclay of Edinburgh, no less eminent for his knowledge, than successful as a teacher of the science of comparative anatomy), when the Doctor made the following answer:—"My acquaintance with the muscles by no means enables me to explain how a horse should be more fatigued by travelling on a road uniformly level, than by travelling over a like space upon one that crosses heights and hollows; but it is demonstrably a false idea, that muscles can alternately rest and come into motion in cases of this kind. The daily practice of ascending heights, it has been said, gives the animal wind, and enlarges his chest. It may also, with equal truth, be affirmed, that many horses lose their wind under this sort of training, and irrecoverably suffer from imprudent attempts to induce such a habit." In short, the Doctor ascribes "much to prejudice originating with the man, continually in quest of variety, rather than the horse, who, consulting only his own ease, seems quite unconscious of Hogarth's Line of Beauty." (*Report on the Edinburgh Railway.*)

3553. *A dry foundation, and clearing the road from water, are two important objects which, according to Walker (Minutes of Evidence before a Committee of the House of Commons, 1819.), ought to be kept in view in lining out roads.* "For obtaining the first of these objects, it is essential that the line for the road be taken so that the foundation can be kept dry, either by avoiding low ground, by raising the surface of the road above the level of the ground on each side of it, or by drawing off the water by means of side drains. The other object, viz. that of clearing the road of water, is best secured by selecting a course for the road which is not horizontally level, so that the surface of the road may, in its longitudinal section, form in some degree an inclined plane; and when this cannot be obtained, owing to the extreme flatness of the country, an artificial inclination may generally be made. When a road is so formed, every wheel-track that is made, being in the line of the inclination, becomes a channel for carrying off the water much more effectually than can be done by a curvature in the cross section or rise in the middle of the road, without the danger or other disadvantages which necessarily attend the rounding of a road much in the middle. I consider a fall of about one inch and a half in ten feet to be a minimum in this case, if it is attainable without a great deal of extra expense.

3554. *The ascent of hills, it is observed by Marshal, is the most difficult part of laying out roads.* According to theory, he says, an inclined plane of easy ascent is proper; but as the moving power on this plane is "neither purely mechanical, nor in a sufficient degree rational, but an irregular compound of these two qualities, the nature and habits of this power" require a varied inclined plane, or one not a uniform descent, but with levels or other proper places for rests. According to the road act, the ascent or descent should not exceed the rate or proportion of one foot in height to thirty-five feet of the length thereof, if the same be practicable, without causing a great increase of distance.

3555. As precedents for roads through hilly countries, Telford (*Minutes before the Committee of the House of Commons, &c.* 1819.), refers to those which he has lately made through the most difficult and precipitous districts of North Wales. "The longitudinal inclinations are in general less than one in thirty; in one instance for a considerable distance there was no avoiding one in twenty-two, and in another, for about two hundred yards, one in seventeen; but in these two cases, the surface of the road-way being made peculiarly smooth and hard, no inconvenience is experienced by wheeled carriages. On flat ground the breadth of the road-way is thirty-two feet; where there is side cutting not exceeding three feet, the breadth is twenty-eight; and along any steep ground and precipices it is twenty-two; all clear within the fences: the sides are protected by stone walls, breast and retaining walls and parapets; great pains have been bestowed on the cross drains, also the draining of the ground, and likewise in constructing firm and substantial foundations for the metalled part of the roadway."

3556. The road between *Capel Cerig* and *Lord Penrhyn's* slate quarries may also be adduced as an example of a very perfect enclosed plane in which the ascent is accurately divided on the whole space.

3557. Cutting through low hills to obtain a level is recommended by some, who, as Paterson observes, will argue, "that where the hill of ascent is not very long, it is better, in that case, to cut through it in a straight line, and embark over the hollow ground on each side, than to wind along the foot of it. This, however, should only be done where the cutting is very little indeed, and an embankment absolutely necessary. Few people, except those who are well acquainted with the subject, are aware of the great expense of cutting and embanking; and the more any one becomes acquainted with road-making, the more, it may be presumed, will he endeavour to avoid those levels on the straight line that are obtained only by cutting and embanking, and will either follow the level on the curved line round the hill, or, where this is impracticable, will ascend the hill, and go over it by various windings, avoiding always abrupt or sudden turnings." (*Treatise, &c.* p. 15.)

3558. All crossings, intersections, and abuttings of roads, should be made at right angles, for the obvious purpose of facilitating the turning from one road to the other, or the more speedily crossing. Where roads cross each other obliquely, or where one road abuts on another at an acute angle, turning in or crossing can only be conveniently performed in one direction.

3559. In laying out a road over a hill or mountain of angular figure and considerable height, much practical skill, as well as science, is requisite. In order to preserve a moderate inclination, or such a one as will admit of the descent of carriages without locking their wheels, a much longer line will be required than the arc of the mountain. In reaching the summit or highest part to be passed over, the line must be extended by winding or zig-zagging it along the sides, so as never to exceed the maximum degree of steepness. This may occasion a very awkward appearance in a ground plan, but it is unavoidable in immense works. If a hill, 50 feet in perpendicular height (*fig.* 538.),

has an arc (*a, b, c*), or would require 150 feet of road (*a, b, c*) to go over its summit in a straight line; then to pass over the same hill, on a road rising at the rate of two inches in six feet (the slope of the Simplon road), would require a length of 600 feet. If this length were extended in a straight line (*d, b, e*) on each side, it would require an enormous mound, and an immense expense; but by being conducted in a winding direction (*b*), up the hill on one side, and down the other, the same end is gained at a moderate cost. Such works show the wonderful power and ingenuity of man; and perhaps no example exists where this power is so strikingly displayed in road-making as in the case of the Simplon.

3560. In laying out a road towards a river, stream, ravine, or any place requiring a bridge or embankment, an obvious advantage results from approaching them at right angles; and the same will apply in regard to any part requiring tunnelling or crossing by an aqueduct, &c.

3561. In tracing out winding railroads, or such carriage roads as are only to be metalled in the horse track and paths of the wheels, some management is necessary in the case of quick bends. Where the line is straight, the horse path ought to be exactly in the middle between the wheel tracks; but, where the road winds, and most especially at a quick bend, the horse track ought ever to incline toward the outer side of the curve, by which the wheels will be uniformly kept on the middles of the supports prepared for them. Hence, it is advisable to dig the trench for the horse path (*fig.* 535. *a*) first; and to draw a carriage for which the road is intended, with the horses walking in this middle trench: thus marking out, by the impressions of the wheels, the precise middle lines of the outer trenches, in every part of the road, from end to end.

3562. The directions of roads through an extensive estate cannot be determined on without having in contemplation the other fundamental improvements, such as the situations of villages, farmeries, mills, or other objects; and these artificial improvements must be taken in connection with the natural surface, soil, materials, waters, &c., the probable system of agriculture that will be pursued, and the external intercourse. A hilly country under aration, will evidently require more roads than if chiefly under

pasture; and, indeed, other circumstances the same, a country abounding in hills and valleys requires many more roads than one of a more even surface. The roads in such a country are also more expensive, on account of the bridges, and extra work at their abutments. On an estate composed of gentle hills chiefly intended for arable or convertible husbandry, the best situation for the roads will generally be found about half way between the bottoms and highest surfaces. By this means the labour of carting up the produce from the fields below the road, and carting up the dung to the fields above it, is evidently much less than if the road were either entirely on the highest ground or the lowest. Bridges over the brooks or open ditches necessary for drainage in valleys, are also rendered less frequent.

3563. *Accurate sections* of the rises and falls of the natural surface on which a road is to be formed should always be taken before the line is finally determined on. As the figure of an exact section of this sort, on any ordinary scale, would convey no data sufficiently accurate for execution, it is usual to adopt one scale for the length, and another for the rises and falls of the road, and to mark the latter with the dimensions as taken on the survey.

SECT. III. *Form and Materials of Roads.*

3564. *On the structure and composition of roads*, men of science and practical road-makers are much more divided than on their laying out. The subject is of itself of greater importance in old countries, because it more frequently occurs that a road is to be enlarged or renewed, than that a new line is to be devised. We shall first lay down the fundamental principles of the formation, and wear of roads; and next treat of forming them, and of the different kinds of road materials.

SUBSECT. 1. *Formation of Roads, and of their Wear or Injury.*

3565. *A road may be defined a path of transit* on the earth's surface, for men, animals, and machines; of sufficient width for the given traffic; of sufficient strength and solidity for the given weight; of sufficient smoothness to offer no impediment; and of as great durability as possible.

3566. *The width* is obviously determinable by the nature and extent of the traffic: every road should be made sufficiently broad to admit two of the largest sized carriages which are in use in the country or district to pass each other; and highways, and roads near towns, should be made wider in proportion to their use. The maximum and minimum can only be determined by experience: sixty feet is the common and legal width of a turnpike-road in Britain, and this includes the footpath.

3567. *The strength of a road* depends on the nature of the material of which it is formed, and of the basis on which it is placed. A plate of iron or stone of the road's width placed on a compact dry soil would comprise every thing in point of strength; but as it is impracticable to employ plates of iron or stone of such a size to any extent, recourse is had to a stratum of small stones or gravel. The great art, therefore, is so to prepare this stratum, and place it on the basis of the road, as that the effect may come as near as possible to a solid plate of material. To accomplish this, the stones or gravel should be broken into small angular fragments, and after being laid down of such a thickness as experience has determined to be of sufficient strength and durability, the whole should be so powerfully compressed by a roller as to render it one compact body, capable of resisting the impression of the feet of animals and the wheels of carriages in a great degree, and impermeable by surface water. But the base of the road may not always be firm and compact; in this case it is to be rendered so by drainage, artificial pressure, and perhaps in some cases by other means.

3568. *In cases of a wet or soft foundation*, where from the nature of the soil and the pressure of the springs lying on a higher level, as on the great north road, near Highgate, draining has been found ineffectual in drying the foundation of the road; the same object has been attained by laying down, and joining by cement, blocks composed of coarse gravel and Roman cement. The water is thus prevented from oozing up, and a foundation formed, at once firm, durable, and dry. This invention, with many others in modern road-making, belongs to Mr. Telford. (*Newton's Journal*, vol. ii. p. 28.)

3569. *The durability of a road*, as far as it depends on the original formation, will be in proportion to the solidity of its basis, the hardness of the material of which the surface-stratum is formed, its thickness, and the size and form of the stones which compose it. The form and size of the stones which compose the surface-stratum have a powerful influence on a road's durability. If their form is roundish, it is evident they will not bind into a compact stratum; if they are large, whether the form be round or angular, the stratum cannot be solid; and if they are of mixed sizes and shapes, though a very strong and solid stratum may be formed at first, yet the wheels of carriages and the feet of animals operating with unequal effect on the small and large stones would soon derange the solidity of the stratum to a certain depth, and, consequently, by admitting rain and frost to penetrate into it, accelerate its decay. A constant state of moisture, even without any derangement of surface, contributes to the wearing of roads by friction: hence

one requisite to durability is a free exposure to the sun and air, by keeping low the side fences; and another is keeping a road clear of mud and dust — the first of which acts as a sponge in retaining water, and the second increases the draught of animals, and of course their action on the road. Both the strength and the durability of a road will be greater when the plate or surface-stratum of metals is flat or nearly so, than when it is rounded on the upper surface: first, because no animal can stand upright on such a road with a regular bearing on the soles of its feet; and, secondly, because no wheeled carriage can have a regular bearing, except on the middle or crown of the road. The consequence of both these states is the breaking of the surface of the plate into holes from the edges of horses' feet, or ruts from the plough-like effect of wheels on the lower side of the road, or the reiterated operation of those which pass along the centre.

3570. *The smoothness* of a road depends on the size of the stones, and on their compression either by original rolling or the continued pressure of wheels. The continued smoothness of a road during its wear depends on small stones being used in every part of the stratum; for if the lower part of it, as is generally the case in the old style of forming roads, consists of larger stones, as soon as it is penetrated by wheels or water from above, these stones will work up and produce a road full of holes and covered with loose stones.

3571. *The wear or decay of roads* takes place in consequence of the friction, leverage, pressure, grinding, and incision of animals and machines, and the various effects of water and the weather.

3572. *Friction* will in time wear down the most durable and smooth material. Its effects are more rapid when aided by water, which insinuates itself among the particles of the surfaces of earthy bodies, and, being then compressed by the weight of feet or wheels, ruptures or wears them. Even when not compressed by wheels or other weights, the action of frost, by expanding water, produces the same effect. This any one may prove, by soaking a soft brick in water and exposing it to a severe frost. A road in a state of perfect dryness is, under the action of wheels, as liable to be injured in its solidity, as when too wet; because it loses its elastic tenacity under the pressure, and becomes broken into a loose superstratum. This is the greatest advantage of watering roads, as proved by the experience of trustees, and shown in their annual accounts of expenses; besides the comfort to travellers, of laying the dust, for which alone watering was first thought necessary.

3573. *The leverage of the feet of animals* has a tendency to depress one part of the surface and raise up another. The line which forms the sole of every animal's foot may be considered as a lever of the second kind, in which the fulcrum is at the one extremity (*fig. 539. a*), the power at the other (*b*), and the weight between them (*c*). Hence the injury done to the road, even if formed on the best construction, will be as the pressure on the fulcrum: this amounts to from the half to the whole of the weight of bipeds and their loads, and from a fourth to a half of that of quadrupeds. But if the stones of the road are large, that is, if they are more than two inches in breadth, the horse's foot acts as a compound lever, and, by depressing one end of the stones and raising the other, deranges the surface of the stratum, and renders it a receptacle for water, mud, or dust.

3574. *The leverage of wheels* is of a nature to be less injurious to roads than that of the feet of animals, because the fulcrum (*fig. 540. a*), is continually changing its position: but if the stones of the road are large, then the wheel acts as a compound lever, raising up the one end (*b*), and depressing the other (*a*), of every stone it passes over; and in this case becomes more injurious on a bad road than the feet of loaded animals. The reiterated operation of this effect, by wheels following in the same track, soon destroys badly constructed roads.

3575. *Such being the effect of leverage, and especially of compound leverage, in wearing roads*, it becomes of the first importance to ascertain that size and shape of stone on which its effects will be least; that is to say, how short a compound lever may be made use of consistently with other advantages. This must in general be a matter of experience, and chiefly depends on the hardness of the stone. The size must always be sufficiently large, and the shape sufficiently angular, to form, when embedded, a compact, hard, and

immovable stratum ; and the smaller the size the better, provided that object be obtained. One inch in diameter may be considered the medium size.

3576. *The mere pressure of bodies* on a smooth road does little mischief ; and hence the advantage of perfectly cylindrical wheels, and a road as nearly level as practicable. But if the surface of the road is rough, the pressure both of cylindrical wheels and the feet of animals may do mischief, by forcing down a loose stone among others of different sizes, and thus loosening the latter and raising the largest to the surface. Where a road, however, is composed of materials of small size, and the surface is clean and dry, the advantage derived from the pressure of cylindrical wheels acting as rollers will, it is probable, always be greater than the injury sustained from their friction.

3577. *Grinding* is produced by the twisting motion of the feet of horses or other animals when pulling hard or carrying a heavy weight, and by the twisting, dragging, or sliding of wheels from whatever cause. The grinding of wheels, Fry observes, " may in every case be defined to be the effect produced on any substance interposed between two bodies, one of which has a sliding motion, yet so firmly confined or pressed between them, that the moving body cannot slide over the interposed substance ; but, in consequence of the pressure, the interposed substance, adhering firmly both to the fixed and to the moving body, is necessarily lacerated or torn asunder, and reduced to atoms. This is the process in corn-mills, in drug-mills, and in every other mill, properly so called. I remember," he adds, " frequently when a boy, to have trodden with one heel on a piece of soft brick, or of dry old mortar, which was firm enough to bear the weight of my body, uninjured ; but, on giving my body a swing round with my other foot, I have instantly reduced it to powder. The action in this case is very obvious : the weight of my body confined the piece of brick firmly to the ground ; my heel was also pressed by the same weight firmly upon the brick ; one part of the brick therefore remaining confined to the ground, and the other part being carried round by my heel, the brick of course was torn asunder and reduced to powder. This I conceive is a simple elucidation of the difference between pressing and grinding ; and this is the difference of the effects on the materials of our roads, produced by the use of upright cylindrical wheels, which act only by *pressure* ; by the use of conical wheels, which, by their constant twist, act also by *grinding* ; and by very convex roads, by which means the wheels of all carriages, except such as occupy the crown of the road, whether cylindrical or otherwise, act in the same twisting, sliding, and grinding manner." (*Obs. on Roads*, &c. 1819.)

3578. *By the incision of objects passing along roads*, we allude to the dividing operation of wheels, which, independently of their effect as moving levers, act also as moving wedges, or perhaps, more properly, as endless saws, in forming ruts or deepening such as are already made. Flat roads, so as to produce less temptation to follow in the middle track, watchful repair, and broad wheels, are the mitigators of this description of wear.

3579. *Water* is one of the most serious causes of the wear of roads. As we have already observed (3572.), it acts, aided by pressure, like gunpowder, in rending the surface of bodies. Frozen, it acts exactly in the same manner ; and when it has penetrated deeply into a stratum of materials, a thaw produces their entire derangement. Mud is formed in consequence of the presence of water and dust or earth, and acts as a sponge to retain it, and perpetuate its bad effects. A well composed and thoroughly compressed substratum will not imbibe water, unless it rests in ruts or other hollows. To form such a stratum, therefore, and obliterate all hollows as soon as they appear, and to remove mud and dust, are the palliatives of this mode of wear. On such a road heavy showers may do good, by washing away the earthy particles, dung, and other injurious earthy or vegetable matters.

3580. *Wind* is mostly a favourable agent to roads, by drying them and blowing off the lighter dust ; but in some cases, in very exposed situations, it has been known to blow the dust into heaps, and sometimes to carry off larger particles than could be spared. The last evil is fortunately rare ; the other only requires the removal of the accumulated heaps of dust.

SUBSECT. 2. *M'Adam's Theory and Practice of Road-making.*

3581. *M'Adam* agrees with other engineers, that a good road may be considered as an artificial flooring, forming a strong, solid, smooth-surfaced stratum, sufficiently flat to admit of carriages standing upright on any part of it, capable of carrying a great weight, and presenting no impediment to the animals or machines which pass along it. In forming this flooring, *M'Adam* has gone one step beyond his predecessors, in breaking the stone to a smaller size than was before practised, and in forming the entire stratum of this small-sized stone. By the former practice a basement of large stones is first laid ; then stones a degree smaller ; and, lastly, the least size on the surface. It is in this point of making use of one small size of stones throughout the stratum, that the originality of *M'Adam's* plan consists, unless we add also his assertion, " that all the roads in

the kingdom may be made smooth and solid in an equal degree, and to continue so at all seasons of the year." It is doubted by some, whether this would be the case in the northern districts at the breaking up of frosts, and especially in the case of roads not much in use, and consequently consisting of a stratum less consolidated, and more penetrable by water. M'Adam, probably, has much frequented public roads in view. "The durability of these," he says, "will, of course, depend on the strength of the materials of which they may be composed; but they will all be good while they last, and the only question that can arise respecting the kind of materials is one of duration and expense, but never of the immediate condition of the roads." (*Remarks on Roads*, §c. p. 11.) The following observation of Marshal is worthy of remark, as tending to confirm, to a certain extent, the doctrine of M'Adam:—"It may seem needless to repeat, that the surface of a road which is formed of well broken stones, binding gravel, or other firmly cohesive materials, and which is much used, presently becomes repellant of the water which falls upon it; no matter as to the basis on which they are deposited, provided it is sound and firm enough to support them."

3582. *M'Adam's theory of road-making* may be comprised in the following quotation from his *Report to the Board of Agriculture* (vol. vi. p. 46.):—"Roads can never be rendered perfectly secure until the following principles be fully understood, admitted, and acted upon: namely, that it is the native soil which really supports the weight of traffic; that while it is preserved in a dry state it will carry any weight without sinking, and that it does, in fact, carry the road and the carriages also; that this native soil must previously be made quite dry, and a covering impenetrable to rain must then be placed over it to preserve it in that dry state; that the thickness of a road should only be regulated by the quantity of material necessary to form such impervious covering, and never by any reference to its own power of carrying weight. There are some exceptions to this rule; a road of good naturally binding gravel may be laid on a sub-bed of bog earth, which, from its tenacity, will carry all kinds of carriages for many years."

3583. *The erroneous opinion so long acted upon, and so tenaciously adhered to*, that by placing a large quantity of stone under the roads, a remedy will be found for the sinking into wet clay or other soft soils; or, in other words, that a road may be made sufficiently strong, *artificially*, to carry heavy carriages, though the subsoil be in a wet state, and by such means to avert the inconveniences of the natural soil receiving water from rain or other causes; has produced most of the defects of the roads of Great Britain. At one time M'Adam had formed the opinion that this practice was only a useless expense; but experience has convinced him that it is likewise positively injurious.

3584. *If strata of stone of various sizes* be placed as a road, it is well known to every skilful and observant road-maker, that the largest stones will constantly work up by the shaking and pressure of the traffic; and that the only mode of keeping the stones of a road from motion is, to use materials of a uniform size from the bottom. In roads made upon large stones as a foundation, the perpetual motion, or change of the position of the materials, keeps open many apertures, through which the water passes.

3585. *Roads placed upon a hard bottom*, it has also been found, wear away more quickly than those which are placed upon a soft soil. This has been apparent upon roads where motives of economy or other causes have prevented the road being lifted to the bottom at once; the wear has always been found to diminish, as soon as it was possible to remove the hard foundation. It is a known fact, that a road lasts much longer over a morass than when made over rock. The evidence produced before the committee of the House of Commons showed the comparison on the road between Bristol and Bridgewater to be as five to seven in favour of the wearing on the morass, where the road is laid on the naked surface of the soil, against a part of the same road made over rocky ground.

3586. *The common practice, on the formation of a new road*, is, to dig a trench below the surface of the ground adjoining, and in this trench to deposit a quantity of large stones; after this, a second quantity of stone, broken smaller, generally to about seven or eight pounds' weight: these previous beds of stone are called the bottoming of the road, and are of various thickness, according to the caprice of the maker, and generally in proportion to the sum of money placed at his disposal. On some new roads, made in Scotland in the summer of 1819, the thickness exceeded three feet. That which is properly called the road is then placed on the bottoming, by putting large quantities of broken stone or gravel, generally a foot or eighteen inches thick, at once upon it. Were the materials of which the road itself is composed properly selected, prepared, and laid, some of the inconveniences of this system might be avoided; but in the careless way in which this service is generally performed, the road is as open as a sieve to receive water, which, penetrating through the whole mass, is received and retained in the trench, whence the road is liable to give way in all changes of weather. A road formed on such principles has never effectually answered the purpose which the road-maker should constantly have in view; namely, to make a secure level flooring, over which carriages may pass with safety and equal expedition at all seasons of the year.

3587. *An artificial road in Britain* is only required to obviate the inconvenience of a very unsettled climate. Water, with alternate frost and thaw, are the evils to be guarded against; consequently, nothing can be more erroneous than providing a reservoir for water under the road, and giving facility to the water to pass through the road into this trench, where it is acted upon by frost to the destruction of the road. As no artificial road can ever be made so good and so useful as the natural soil in a *dry state*, it is only necessary to procure and preserve this dry state of so much ground as is intended to be occupied by a road.

3588. *The first operation in making a road* should be the reverse of digging a trench. The road should not be sunk below, but rather raised above, the ordinary level of the adjacent ground; care should at any rate be taken, that there be a sufficient fall to take off the water, so that it should always be some inches below the level of the ground upon which the road is intended to be placed: this must be done, either by making drains to lower ground; or if that be not practicable, from the nature of the country, then the soil upon which the road is proposed to be laid must be raised by addition, so as to be some inches above the level of the water.

3589. *Having secured the soil from under-water*, the road-maker is next to secure it from rain water, by a solid road made of clean dry stone or flint, so selected, prepared, and laid, as to be perfectly impervious to water; and this cannot be effected unless the greatest care be taken that no earth, clay, chalk, or other matter, that will hold or conduct water, be mixed with the broken stone; which must be so prepared and laid, as to unite with its own angles into a firm, compact, impenetrable body.

3590. *The thickness of such road* is immaterial, as to its strength for carrying weight; this object is already obtained by providing a dry surface, over which the road is to be placed as a covering or roof, to preserve it in that state; experience having shown, that if water passes through a road, and fills the native soil, the road, whatever may be its thickness, loses its support, and goes to pieces. In consequence of an alteration in the line of the turnpike road, near Rownham Ferry, in the parish of Ashton, near Bristol, it has been necessary to remove the old road. This road was lifted and re-laid very skilfully in 1806; since which time it has been in contemplation to change the line, and consequently it has been suffered to wear very thin. At present it is not above three inches thick in most places, and in none more than four: yet on removing the road, it was found that no water had penetrated, nor had the frost affected it during the winter preceding, and the natural earth beneath the road was found perfectly dry.

3591. *Several new roads* have been constructed on this principle within the last three years. Part of the great north road from London, by Hoddesdon, in Hertfordshire; two pieces of road on Durdham Down, and at Rownham Ferry, near Bristol; with several private roads in the eastern part of Sussex. None of these roads exceed six inches in thickness; and although that on the great north road is subjected to a very heavy traffic (being only fifteen miles distant from London), it has not given way, nor was it affected by the late severe winter (1819-20), when the roads between that and London became impassable, by breaking up to the bottom, and the mail and other coaches were obliged to reach London by circuitous routes. It is worthy of observation, that these bad roads cost more money per mile for their annual repair, than the original making of this useful new road.

3592. *Improvement of roads*, continues M'Adam, "upon the principle I have endeavoured to explain, has been rapidly extended during the last four years. It has been carried into effect on various roads, and with every variety of material, in seventeen different counties. These roads being so constructed as to exclude water, consequently none of them broke up during the late severe winter (1819-20); there was no interruption to travelling, nor any additional expense by the post-office in conveying the mails over them, to the extent of upwards of one thousand miles of road."

3593. *On M'Adam's theory* the only practical road-maker who has published his opinion is Paterson of Montrose. He says (*Letters and Communications*, &c. 1822.), "These certainly ought to be considered as the grand first principles of road-making." He commends M'Adam's reasoning on these principles; but objects, as we think with reason, to his drainage of three or four inches, as being insufficient. He adds, however, that though he considers M'Adam's system as erroneous and defective in draining and preparing the road for the materials, yet, in regard to the materials themselves, the method of preparing and putting them on, and keeping the road free from ruts by constant attention, has his entire approbation. These principles, however, he adds, "are not new; but have been acted upon before. In regard to small breaking, he certainly has had the merit of carrying that mode to greater extent than any other individual that I have heard of; and the beneficial effects arising from it have consequently been more extensively seen and experienced." (*Letters on Road-making*, p. 49.)

SUBJECT. 3. *Road-making, as treated of and practised by various eminent Engineers and Surveyors.*

3594. *The subject of forming a road* may be considered as to breadth, drainage, fences, base of the hard materials or artificial stratum, upper line of the stratum, composition of the stratum, size of the materials, laying, and compressing.

3595. *With respect to breadth*, the site of every public road, according to Marshal, ought to be sufficiently ample to admit of its division into three travelable lines; namely, 1. A middle road of hard materials, for carriages and horses in winter and wet seasons; 2. A soft road, formed with the natural materials of the site, to be used in dry weather, to save the unnecessary wear of the hard road, and to favour the feet of travelling animals, as well as for the safety, ease, and pleasantness of travelling in the summer season; and 3. A commodious path, for the use of foot passengers, at all seasons. There are few roads, even in the environs of populous towns, so public as to require a hard road of more than two statute poles (thirty-three feet) in breadth; and every public road ought, under ordinary circumstances, to have a line which is travelable at any season, and of ample width to permit two carriages to pass each other with freedom and safety. This ample width let us set down at one statute pole. In deep clayey districts, where hard materials are difficult to be procured, a single road, of half a pole in breadth, with dilations at proper distances, to let carriages pass each other, may, in many reclusive situations, be advisable.

3596. *Seventy feet in width* seems to be considered by Farey, Walker, Telford, and most engineers, as sufficient near the largest towns; and in the case of the metropolis and some others, they consider that ten or twenty feet in width may be paved. The London Commercial road, executed under the direction of Walker, is seventy feet wide; ten feet on each side are occupied as footpaths, twenty feet in the centre are paved for heavy carriages, and there are fifteen feet of gravel road at each side for light carriages and saddle horses. This road has been executed for sixteen years, and has given the greatest satisfaction; but Walker thinks that considerable improvement would be found from paving the sides of a road, upon which the heavy traffic is great in both directions, and leaving the middle for light carriages. The carmen or drivers, walking upon the footpaths or sides of the road, would then be close to their horses, without interrupting or being in danger of accidents from light carriages, which is the case when they are driving upon the middle of the road; and the unpaved part being in the middle or highest part of the road, would be more easily kept in good repair. But unless the heavy traffic in both directions is great, one width, say ten or twelve feet, if very well paved, will be found sufficient; and in this case, the paving ought to be in the middle of the road. The width of many of the present roads is, besides, such, that ten or twelve feet can be spared for paving, while twice that width would leave too little for the gravelled part. Although the first cost of paving is so great, he does not think that any other plan can be adopted so good and so cheap in those places where the materials got in the neighbourhood are not sufficient for supporting the roads. A coating of whinstone is, for instance, more durable than the gravel with which the roads round London are made and repaired, but much less so than paving; although the freight and carriage of the whinstone, and of the paving stones, which form the principal items of the expense, are nearly the same.

3597. *Roads ought to be wide and strong*, Edgeworth observes, in proportion to their vicinity to great towns, mines, or manufactories. As they approach the capital, they should be wider and stronger than elsewhere. When a number of roads leading to a great city combine and fall into one, the road from that junction should be proportionably solid and capacious. Near the capital, the width of roads is however often restricted by buildings, that cannot with propriety be suddenly removed; but every opportunity for removing these buildings, and for widening the road, should be attended to, and no future buildings or encroachments should be allowed. And, though in some cases it appears reasonable to permit the erection of new buildings, and the making new plantations, nearer than thirty feet from the centre of a road, upon condition that security should be given to the public for the constant preservation of the road that is thus injured; it is, however, far safer to prohibit what is injurious to public convenience, than to compromise with individuals: cases of private hardship may and must occur, but it is part of the true glory of Britain that there exists no exemption in our laws in favour of the rich.

3598. *Proportioning the breadth of roads to the traffic* for which they may be employed is not sufficiently attended to. In remote places, where there is but little traffic, the waste of ground, occasioned by superfluous width of roads, is an error of considerable magnitude. There are many places where roads of twenty feet in breadth would suit the public convenience, as well as if they were twice as broad. Now it is clear, that if a road is one pole or perch wider than is necessary, there is a waste of 320 perches in a

mile, equal to two acres of ground, which, at the rate of three pounds per acre, would, if the road had been once well made, keep half a mile of such road as is here alluded to in good repair.

3599. *The breadth of the road and the width of the metals*, according to Paterson, should depend on circumstances different from the former. For a few miles in the vicinity of such cities as London or Edinburgh, the most proper breadth at which a road should be formed, is properly from sixty to seventy feet, and the metals from twenty-five to thirty-five feet. While in the neighbourhood of such towns as Newcastle or Perth, it will be sufficient that it be formed forty feet broad, and that the width of the metals be about eighteen or twenty feet. These are the breadths presumed to be the most eligible in such situations. But rules cannot be given to suit every situation: the breadth ought to be regulated according to the extent of the run of commerce, or traffic, upon the road. As a general rule, however, for public roads over the different counties of Great Britain, he "should suppose the following might, in most cases, be adopted. Take, for instance, the road betwixt Edinburgh and Glasgow, or betwixt Edinburgh and Aberdeen by the way of Dundee. These roads are formed in general from thirty-five to forty feet wide; and the breadth of the metals is from fourteen to sixteen feet, for the most part. Such roads as these would be found to answer very well, in general, over the kingdom." A breadth sufficient for the general purposes of country travelling, according to M'Adam, is sixteen feet of solid materials, with six feet on each side formed of slighter materials. The Bristol roads, he says, are made with stone about the width of sixteen feet.

3600. *The increased breadth which is now given to our public roads*, according to Stevenson, independently of the safety and convenience of the traffic, is favourable to the more speedy drying of the road by evaporation, and is calculated to render less injurious the rising growth of the hedgerows, and the ultimate erection of buildings along the line. "The highways or great lines of road should, in no instance, be formed of a less breadth than forty feet, and the metal bed not less than eighteen feet broad, with at least one footpath of five feet in breadth along the side; especially within a few miles of all towns and villages. It would be difficult to give any scale of breadths for public roads, the local circumstances of which vary so much. But, without presuming to be fastidious, we notice, that, within six or eight miles of all large cities or towns, the approaches should not be formed at less than sixty feet between the fences. In such situations the whole breadth should be metalled, or laid with broken stones. In the vicinity of towns of about 50,000 inhabitants, the breadth should be at least fifty feet between the fences, and be in like manner metalled from side to side. Where the population does not exceed 30,000, the statutory breadth of forty feet may be adopted, the metalling being still continued of the whole breadth, with paved side-drains. At intermediate distances, where it is not thought advisable to have the metal of a greater breadth than eighteen feet, the compartments between the metal bed and the side-drains may be laid with gravel or chips of stone to the depth of not less than half the thickness of the central part of the road. In the vicinity of London, and the capitals of Dublin and Edinburgh, and other great towns, as Glasgow, Manchester, Liverpool, &c. it would be desirable that the principal approaches were at least seventy feet in breadth, fully metalled between the side-drains, which ought to be neatly formed, and paved, and the roads provided with a footpath on each side." (*Ed. Encyc. art. Roads.*)

3601. *Narrow roads*, it is judiciously observed by Fry, are almost always in bad condition, which is to be accounted for from the circumstance of every carriage being obliged to go in the same ruts; and as each rut is generally only six inches wide, *one foot* of the road only is worn by the wheels instead of the whole breadth of it; which would be the case if the road were of a proper width, and if it were well constructed. If a road be laid out, from twenty to thirty feet wide, so flat as that a carriage may stand nearly upright on every part of it, and if moderate care be taken by the surveyor to prevent the first formation of ruts, such a road will be worn by the wheels nearly alike on every part of it: provided also that the ground on each side, for at least four or five feet, be moderately flat, so as not to excite fear in the drivers of carriages; but if there be deep ditches close to the sides of the road, or if the circumjacent land fall off very abruptly to the depth of two or three feet, whereby fear of approaching the edges would operate on the minds of the drivers, every driver will instinctively avoid the danger on either hand; and a road so circumstanced will, in spite of any care of the surveyor, inevitably be worn into ruts in the middle. There is a remarkable instance of this kind in a piece of road on Durdham Down, near Bristol. This road is a causeway over a piece of soft ground; and although it is from twenty to twenty-five feet wide, yet, as the ground falls away abruptly on both sides of it, it has been found impossible, for more than twenty years past, to his knowledge, to prevent deep ruts being formed along the middle of it; notwithstanding the Down itself consists of hard limestone, and the other roads upon

consolidated as to form a solid body, and to be impervious to water. Bushes, however, the Down are as fine and even as any roads in England. Were this piece of road widened out on each side, in an easy slope of about five feet, by rubbish of any kind, and by the scrapings of the road itself, whereby the instinctive operation of fear of approaching the sides of the present road would be obviated, that piece of road would be found to wear as fairly as the other roads on the same Down.

3602. *In regard to the drainage of roads*, Marshal directs to examine the site in every part, to ascertain whether offensive waters lodge beneath it, or quicksands, and land springs, which break out in a wet season. If defects of this kind be found, effectual drains are to be run up to them, from the ditches or outer side drains of the site.

3603. *When roads run through marshy ground*, Edgeworth observes, "the substratum must be laid dry by proper drainage; and where the road is liable, from the flatness of the country, to be at times under water, the expense of raising it above the water must be submitted to in the first instance. All drains for carrying off water should be under the road, or at the field-side of the fences, and these drains should be kept open by constant attention, and should be made wide at the outlet."

3604. *The method of draining which Paterson has found the most effective* is thus described:—"Before the materials are put on, run a drain along the middle of the road, all the way, from two to three feet deep; then fill it with stones up to the surface, making those at bottom of a pretty good size, and those at the top fully as small as the road materials. And, in order that the quantity of stones used for the said drain may be as little as possible, and every way to save expense, it may be made as narrow as it can possibly be dug. From this leading drain make a branch here and there, to convey off the water to the canals on the sides of the road." This mode of draining he has found, from experience, to be so beneficial, that a road so drained would be better and more durable with eight inches, than it would otherwise be with twelve inches of materials; and not only so, but that on such a road there would be a saving on the incidental repairs, ever afterwards, of about one half of the labour, and at least one third of the material.

3605. *All moisture from under the road materials* must be carried off by such drains. Then, if the materials are properly broken, they will become so firm and solid that little or no water will get through them; and if it should, this drain would carry it away. So that, under any view of it, the utility of these drains must be very apparent; but when we consider that, to have the ground under the road materials perfectly dry is to insure a good road, these drains become indispensably necessary, and the expense is a mere trifle. There are two miles of road, which were made on this plan under Paterson's directions, which have stood all the winter rains without injury, and which promise to make one of the finest roads in the kingdom. There is another road of ten miles, that he has lately planned, for the greater part of which he has specified *two* such drains, running parallel to each other, and five feet apart; and he would even recommend three or four parallel drains where there is a great breadth of metals, except where the road is formed over dry sand or open gravel. Although the effect of such drains will be at all times beneficial to the road; in time of a thaw, after there have been a few weeks of frost, it will be peculiarly so. In frost, the surface of the road, though wet before, becomes dry, the water being absorbed by the road, or otherwise condensed by the frost; but no sooner is this succeeded by a thaw, than the absorbed or condensed water again makes its appearance all over the surface of the road. This is the time that these drains are so peculiarly beneficial.

3606. *Where such drains are wanting*, the road, on the return of a thaw, throws up to the surface all the water it had imbibed; and in many places, the materials, swelling up, become quite loose and open. This is a natural consequence, where the material is not thick, and where the soil under the road is not perfectly dry; but where a road is dried in the way described, it will be uniformly seen, that the water, instead of spewing out on the return of a thaw, is sucked in by the drains, so leaving the surface of the road quite dry. It may be observed, that at such times, the places of the road where a few rods of such drain had been introduced, presented to the eye, at a quarter of a mile distant, quite a contrast to the other parts of the road: the one opaque and dry, from the moisture being sucked in; the other all wet and glistening, *from its being thrown out to the surface.* (*Paterson's Letters, &c.* 44. 48. 84.)

3607. *Thorough drainage*, Stevenson observes, "should pervade the whole system of the formation of roads. The smaller drains, connected immediately with the road, must vary in their number, direction, and description, according to the judgment of the engineer. They consist of what are technically termed *box* and *rumbling* drains; the former of which are built, and the latter consist of a stratum of rubble stones, simply thrown into an excavation made for their reception, through which the moisture is allowed to percolate. Where the road is to be made through a boggy or marshy soil, which is generally pretty level, the opportunities for drainage are less obvious; nor

is this so material, as ground of this description is capable of containing a great quantity of water without endangering the flooding of the road. In such situations it also fortunately happens that land is seldom of much value, and therefore, in making a road through a morass, a much greater breadth should be included between the lateral drains than where the ground has an undulating surface. Attention should also be paid to cut the ditches of a moderate depth, as the tenacity of such soils depends upon their being kept in a somewhat moist state. If a section of such ground be exposed to the sun and air, by deep side cutting, it soon pulverises, and loses its elasticity, when the level of the road falls, and its surface gets into disorder. The drainage of a road should rather be made across than in a lateral direction, as being less apt to be injured by the traffic upon it." (*Ed. Encyc. art. Roads.*)

3608. *The side drains* Telford and Walker recommend to be, in every instance, on the field side of the fence. In cases, Telford observes, where a road is made upon ground where there are many springs, it is absolutely necessary to make a number of under and cross drains to collect the water and conduct it into the side drains, which should always be made on the field side of the fences. The orifices of these cross drains should be neatly and substantially finished in masonry.

3609. *The surface-drains, or water-tables*, should be made a few inches lower than the side of the road, and of the common width of a spade at the bottom, and they should have frequent cross drains under the path and fence, back into the outer side drain.

3610. *Water-tables across the road* become requisite in some cases, as in flat roads on a steep slope. These should always be made at right angles to the road, with their sides gently sloping, to occasion as little obstruction to carriages as possible. In some few cases, where roads are liable to floods, or are deficient in drainage, these surface-tables may require to be made of a considerable breadth, and paved; in this case Greig (*App. to Structures on Road Police*, p. 219.) directs to lay six feet at the bottom of it flat, and twelve feet on each side to rise at the rate of one inch in the foot, which will make the depth one foot; and from the size, no carriage will feel any jerk or shake in passing it. The pavement should be made of hammered stones, of nearly equal depth, each stone from nine to twelve inches long on the surface, and four to eight inches broad, and nine inches to a foot deep; the under-side to be flat in the under-face, and not of an irregular or angular under-surface, as in that case it would not be solid.

3611. *Bridges and embankments, of different degrees of magnitude*, are required in all lines of road of any length or variety of surface. The subject of large bridges we leave to the engineers, no department of their art having attained higher perfection; of which the wonderful erections by Telford, in almost every mountainous district in Britain, may be referred to as proofs. We confine ourselves entirely to such stone arches as may be designed by road-surveyors, and built by country masons. In many cases, cast-iron might be substituted for stone with economy and advantage as to waterway; but though the principle of constructing both cast and wrought iron bridges is perfectly simple, the execution, and especially the putting up, requires more skill, and are attended with much more risk than the erection of either stone or timber bridges.

3612. *One low arch* is in general the most desirable description of common road-bridge. But most of the country bridges, as Clarke observes, consist of several small, high, semicircular arches: where there is a single arch, the stream passes without interruption; if there are two or three in the same situation, the space through which the water is to pass is necessarily contracted by the width of the piers. Ice, and large bodies carried down by floods, frequently stop up the small arches, and the accumulated water carries away the bridge; but if such accidents should not happen, the constant currents rushing against those piers wash out the mortar, loosen the stones, and very soon undermine the work, if not extremely well put together, which is seldom the case. Unless the river or stream is narrow, or the banks very high, a semicircle is an inconvenient shape for an arch; it has been adopted on account of the insufficiency of the abutments, and because the pressure is more perpendicular; but scientific engineers, in all countries, now construct their bridges with wide openings, and make the arches either semi-ellipses, or segments of large circles—so that the space above the highest floods is comparatively little, and the ascent over the bridge inconsiderable. In country bridges in Ireland, Clarke continues, the foundations are invariably, and often intentionally, defective: the mason considers himself an honest man, if his bridge lasts *seven years*; whereas, from the durability of materials in that country, it ought to endure for ages. Whatever is under water is out of sight, and is generally composed of loose stones, thrown promiscuously together, on which the masonry is erected, and all the pains and expense are bestowed on the *cut-waters* and *wings*, when the heaviest stones, and those accurately jointed, ought to be laid in the foundations. The greatest attention should be paid to the quality of the materials: the stones should be large, and laid in level courses, in the best mortar, composed of sharp sand, free from loam, and quicklime, accurately mixed together; the coping of the parapet is generally so slight, that it is

broken down as soon as built, and the entire parapet quickly follows; — it ought to be of large heavy stones, roughly hammered, and there should be substantial quoins at the ends of the parapets with an immovable stone over them.

3613. *Arches not exceeding eight feet span* may be semicircular; tunnels not exceeding eighteen inches wide may be covered with strong flags, and either flagged or paved under, and there ought to be across either end a deep long stone, sunk below the surface of the current, and under the walls, to prevent the water from undermining the work; if the stones are square and heavy, those small conduits may be built without mortar, except at the ends.

3614. *In building tunnels* or arches across a road in a flow-bog, great pains must be taken with the foundation, or the whole structure will inevitably sink: the building of those should be deferred as long as possible, till the peat has subsided, and has obtained a tolerable consistence; then make an opening equal to the whole work, and sink it eighteen inches below the intended bottom of the arch or gullet; collect a quantity of black-thorn bushes, and tie them in faggots of the same size; place these in regular courses in the direction of the road, and lay across them a platform of strong plank three inches thick, the whole length and width of the intended mason work; on this build your arch, and make an allowance in the height of the abutments for sinking. Wherever walls are necessary to support banks, and prevent their crumbling down upon the road, if large even stones can be procured, they will not require any mortar; when mortar is used, there ought to be a great many apertures in the work to give vent to the water, otherwise the pent-up moisture from behind will push out the wall. In many cases, where embankments can be made of earth and sods, they are to be preferred to masonry, which is extremely expensive at the commencement, and very perishable; for mortar soon loses its cementing quality, when exposed alternately to frost and damp.

3615. *Draining the site of a road on a flow-bog*, according to Clarke, is a tedious operation, and often requires some years. A single drain at each side will not be sufficient, as the water from the adjacent moss would fill it up as fast as it was made. Lay out the road here sixty feet wide, which will allow for the banks when the whole shall be finished; make a drain at each side six feet wide, and at a distance of fifteen or twenty feet more, parallel drains of the same width. If the interval between the parallel drains be afterwards cut away regularly for fuel, it will tend still to the condensation of the moss.

3616. *Open drains, in the case of ground liable to sink* or to moulder down by frost, ought to be made very much sloped on the sides, especially the side next the road, otherwise, after repeated scouring out, the road will be found to have sunk at the sides; — a very common case, and highly injurious in the case of narrow roads. Whenever this tendency to sink is observed, it should be made up by the scrapings of the road, or by other materials. Roads made over bogs and artificial mounds are particularly liable to sink at the sides, which should be immediately counteracted to prevent the bad consequences.

3617. *Fences* along the sides of roads are essential in all enclosed countries; and all engineers and road-makers agree that they should never be allowed to rise of a greater height than what is necessary for a fence. To give free admission to the sun and air by keeping the fences low, Marshal considers as providing an unexpensive, yet most accurate, method of cleaning roads. — incomparably more so than washing or scraping. The legislature, Edgeworth observes, has limited, in several instances, the height of hedges to five feet; but this limitation is neglected or evaded. Even were it strictly adhered to, it would not be sufficient for narrow roads: the hedges would be still too high; for it is the sweeping power of the wind which carries off dust in dry weather, and which takes up moisture in wet. In fact, roads become dry by evaporation; and when they are exposed to the sun and wind, the effect of heat and ventilation is more powerful than any surface drainage that could be accomplished.

3618. *Walker observes, that the advantage of having the hedge next the road* consists in its greater safety to the traveller, particularly if a ditch of any considerable depth is necessary, and in the hedge being supported in its growth from the ground under the road, without drawing upon the farmer's side of the ditch.

3619. *The fences*, Telford observes, form a very material and important subject, with regard to the perfection of roads; they should in no instance be more than five feet in height above the centre of the road, and all trees which stand within twenty yards from the centre of it ought to be removed. I am sure that twenty per cent. of the expense of improving and repairing roads is incurred by the improper state of the fences and trees along the sides of it, on the sunny side more particularly: this must be evident to any person who will notice the state of a road which is much shaded by high fences and trees, compared to the other parts of the road which are exposed to the sun and air. My observations with regard to fences and trees apply when the road is on the same level as the adjacent fields: but in many cases, on the most frequented roads of England, more stuff has been removed from time to time than was put on; the surface of the road is consequently sunk into a trough or channel from three to six feet below the surface of

the fields on each side: here all attempts at drainage, or even common repairs, seem to be quite out of the question, and by much the most judicious and economical mode will be to remove the whole road into the field which is on the sunny side of it. (*Exam. before the House of Commons, &c.*)

3620. *In the junction of roads*, whether of a by-road with a principal road, or of two by or principal roads, their respective levels ought, if possible, to be the same, and the materials ought to be rather broader than usual at the point of turning. In like manner the communication of fields by gates ought to be carefully managed, so as not to injure the public road, the footpath, the water-table, or the inner drain. All gates should open inwards to the fields, and not to the road.

3621. *That plantations of trees* should not be made close to roads, all are agreed. What the distance ought to be must depend on the elevation of the country, the soil and subsoil, the breadth of the road, its direction, whether the plantation is to be made on the north or south side of the road, its thickness, kind of tree, &c. An elevated situation is always more exposed to the wind than a level or hollow; and a dry soil and subsoil will always, other circumstances being the same, have a favourable effect on the roads which pass over them. A broad road, and a road winding in its direction, have chances of the direct influence of the sun and wind, according to the width of the former and obliquity of the latter; a road running north and south, though planted closely on both sides, will enjoy the sun during a part of every day in the year; one running east and west, planted on the south side with trees forty feet high, will enjoy no sun but through the interstices of the branches during the three winter months. Supposing the average height of the sun from ten to two o'clock during these three months to be 20 degrees, then a tree forty feet high will throw a shadow every day during that period, upwards of 100 feet long, which may show that no plantation should be made nearer the south sides of roads than 80 or 100 feet. On the north-east and north-west sides, they may be nearer, according to the elevation and natural tendency to dryness of the site, and also taking into consideration whether the trees are evergreens, and with or without underwood. The least injurious trees are single rows trained to high stems, properly pruned in, or foreshortened.

3622. *The preparation of the base of a road*, for the reception of the metals or hard materials, is a matter of primary importance. Marshal, Edgeworth, and some other writers, with almost all practical men, seem to have entertained much less enlightened notions on this subject than M'Adam.

3623. *Marshal's preparation* consists in striking off the protuberances, and filling up the hollow parts; the footpath and the higher side of the soft road being raised with the earth which is required to be taken off the bed of the hard road, whose base or foundation ought to be formed with peculiar care. Every part is required to be firm and sound, dry earth, or hard materials, being rammed into every hollow and yielding part. In a dry situation, as across a gravelly or stony height, little more, he says, is required, than to remove the surface mould, and lay bare the rock or bed of gravel beneath it; and then to give the indurate base a round or a shelving form, as the lying of the ground may require. In this way, a travelable road may be made, and kept up, at one tenth of the expense incurred by the ordinary practice in this case; which is to gather up the surface-soil into a ridge, and, on this soft spongy bed, to lay, coat after coat, some hard materials, fetched perhaps from a distance.

3624. *A soft bed* is now found by far the best; and M'Adam has proved, in the case of part of the road between Bridgewater and Cross, that a stratum of hard materials covering a morass will last longer than a similar stratum laid on rock: indeed, it may be questioned whether a properly made road on a bog, which yields by its elasticity, will not last longer than one on a firm surface. We have been told by a gentleman of some experience in road-making, that in Ireland this is actually found to be the case. "Precisely," as Fry observes, "for the same cause that a stone placed upon a woolpack would bear a greater pressure before it would be broken, than it would if placed on an anvil." (*Essay on Wheel Carriages, &c. App. 129.*)

3625. *Covering the base of an unsound road with faggots*, branches, furze, or heath, is recommended by Edgeworth. Flat stones, he adds, if they can be had, should then be laid over the faggots, and upon them stones of six or seven pounds' weight, and, lastly, a coat of eight or ten inches of pounded stone. If the practicability of consolidating a mass of stones each of six or eight ounces' weight and under, so as to act as one plate or flooring, be admitted, then the faggots and flat stones must at least be useless, and the stones of six or seven pounds' weight injurious; because, whenever the upper stratum had worn down a few inches, some of these stones, and eventually the greater number, would be worked up to the surface, and the road destroyed, or put in a state to require lifting, breaking, and relaying.

3626. *A basement of trees, bawns, or bushes*, is made use of by Walker when the ground is very soft. They carry off the water previously to the materials of the road being so

should not be used, unless they are so low as always to be completely moist. When they are dry and excluded from the air they decay in a very few years, and produce a sinking in place of preserving the road: a thickness of hard chalk has been recommended for the same purpose; the chalk, mixing with the gravel or stones, becomes concreted, and presents a larger surface to the pressure. It is alleged on the other hand, that chalk is one of the worst materials for roads, as it absorbs water, which, when frozen, never fails to break up the road.

3627. *The base of the road is constructed by Telford and Stevenson of an elliptical form; if it is upon clay or other elastic substance which would retain water, Telford would recommend to cover the whole bottom of the road with surface soil; in cases where the natural shape of the ground admits, he would not remove the original surface; and, where there are inequalities, he would fill them up with surface soil, so as to cut off all connection with clay.*

3628. *In forming the basis of a road on a flow-bog, Clarke directs to strip the heathy sods (tussocks) off the whole surface of the side-drains, and place them with the heath uppermost on the space intended for the road; or if a sufficiency of brushwood or furze can be procured, it will answer still better. Proceed to let off the water at the lowest ends of the drains, leaving an open channel in the middle of each. After the water has run off for some time, throw off another spit; and repeat this operation month after month, till the space for the road becomes compact and dry; and be sure to keep it in that state by cleaning the drains frequently. There should be eight or ten inches of tough clay laid over the tussocks or brushwood, which will be greatly the better of being consolidated by rollers. This part of the road may be left rather higher in the centre than the other parts, to allow for settling. There is no situation where it is more difficult to make a good road than through a flow-bog; but, if once made well, it is the most permanent of all roads, and, from its elasticity, the most easy to horses.*

3629. *In forming the basis of a road on thin moor, the whole of the peat should be removed from the space on which the road is to be made; for, if allowed to remain between the hard subsoil and the small stones, the weight of carriages would press down the latter, force up the black peat through them, and totally spoil the road: this happens only where there is a thin, soft, peaty stratum between two hard bodies; for in deep bog, the elasticity of the foundation yields to the superficial pressure, and contributes to the durability of the materials: after this has been so removed, the surface, when formed and drained, will be ready for the road materials.*

3630. *In forming the base or metal-bed, Paterson observes, "it is common to cut it to the exact breadth and depth of the metals, and to make it quite flat in the bottom, or level from the one side of the metals to the other. Supposing this metal-bed to be formed fourteen feet broad, and nine inches deep, on a breadth of fourteen feet, the metals would require to be about three inches higher in the middle than on the sides. In this case, then, they would be nine inches deep on the sides, and twelve on the middle; and as it is evident that the middle of the road, where the metals are deepest, is not subjected to so much waste from the tread of the horses' feet, as that nearer the sides is from the grinding of the wheels, this is, therefore, a waste of metals on the middle of the road. But this is not the greatest evil of which I complain: the metal-bed being cut into the solid ground, and flat in the middle, and having the earth on each side about nine inches higher than it, — this, upon any other ground than that of dry sand or gravel, forms a bed for retaining the water, as well as for holding the metals, which often deluges the middle of the road with mud or gutters, when it might be prevented. I would therefore propose, that a metal-bed of fourteen feet broad should, instead of being level, have a rise in the middle of at least four inches, which will make a declivity from the middle to each side of nearly two inches in the yard. Then, supposing the surface of the metals to have the same shape as mentioned above, viz. three inches higher on the middle than on the edges, the metals on the sides will be the same depth as formerly mentioned, namely, nine inches; but instead of twelve inches on the middle, they will then only be seven inches deep, which makes a saving of five inches. This saving of five inches on the middle, or two inches and a half on the whole breadth of the metals, is very considerable; but this is not the only benefit arising from this mode of procedure. The metal-bed, having a slope from the middle to each side of the road, so far from retaining the water, runs it off from the middle; and this will be of more service in keeping the road in good order ever afterwards, than if you were to put three or four inches more of additional depth to the metals on the common plan. This appears to me to carry so much of common sense on the face of it, that I am surprised it has not long ere this time been generally adopted." Here Paterson seems to infer that water may, or rather does, penetrate the stratum of metal to the base, which, in properly made roads, will at least not often be the case. The argument of a saving in materials is quite sufficient to justify him and Telford in adopting the elliptical form for a basis.*

3631. *A soft base is always preferred by M'Adam, who drains effectually, and puts no*

intervening material between the metals and the earth, even if it were a bog, "provided it admitted a man to walk over it." (*Examination, &c.* 1819.) The Somersetshire morass is so extremely soft, he says, "that when you ride in a carriage along the road, you see the water tremble in the ditches on each side; and after there has been a slight frost, the vibration of the water from the carriage on the road will be so great as to break the young ice. I never use large stones on the bottom of a road; I would not put a large stone in any part of it, nor faggots, nor any material larger than will weigh six ounces. If a road be made smooth and solid, it will be one mass, and the effect of the substratum, whether clay or sand, can never be felt in effect by carriages going over the road; because a road well made unites itself in a body like a piece of timber or a board."

3632. *An instructive proof of the preference given by M'Adam to a soft base* is derived from a case which occurred near Montrose. This case was sent to him by Paterson in the following report:—"This road," says the reporter, "for about a mile, goes over a bank of sea-beach, many feet in depth, and all round stones from two to five or six inches in diameter. Always as the stones above three inches work up, and make their appearance on the surface, they are taken off to the side of the road, and broken to the ordinary size. This has been done several times every year for many years back, but the road always continues loose and open as ever." The answer of M'Adam was,—"The road you have sent me a report of is novel in its situation, but very far from hopeless. The sea-beach, of which it is wholly composed, should be picked; that is to say, the large-sized pebbles should be carefully removed from the surface, and carried to the side of the road, and there broken, not to what your surveyor calls my size, which is six ounces, but smaller, say to three or four ounces. And I must also warn you, that any round stone, when broken in half so as to form a hemisphere, is nearly as unmanageable, and as little likely to consolidate in a road, as one left quite round; therefore, with regard to weight, your stones must be taken so as to form as many angles as possible. No large pebble must be left in sight upon the bottom of the road, otherwise they will work up through the broken stones of which your road will be composed; but having prepared a surface upon which to place your road, by removing the large-sized pebbles (I mean all above six ounces), and evenly covering the surface with sand soil or other soft matter, lay on your properly broken stones." Paterson entirely concurs with M'Adam in regard to the advantage of a soft base, adding, in his last publication (*Letters, &c.* 1822.), "although the ground under the materials can never be too dry, the materials never unite so firmly when placed upon a hard rock or upon gravel, as they do upon earth, moss, or sand. There should always, therefore, be a few inches of the one or the other of these put under the road, as a bed for the materials, where it is on a rocky or gravelly bottom."

3633. *When the basis consists partly of firm, and partly of loose, materials, or moved earth*, some nicety is required to determine the allowance for the sinking of the latter; and, indeed, roads, under such circumstances, cannot often be finished out of hand. Some judicious directions on this subject are given by Paterson. "When a road," he observes, "is formed along the side of a hill or sloping bank, the earth that is produced from the side-cutting makes up a part of the breadth of the road; so that the road is formed, partly on the solid ground, and partly on the embankment. All new-made-up earths or embankments subside a little, whatever be the nature or quality of the stuff of which they are composed: for which reason, that part of the breadth of the road, that is formed upon the embankment, should be raised a little higher than the solid ground. No precise rule can be given to ascertain exactly how much the different kinds of earths, clays, gravel, &c. will subside; but the following has been found so near to the truth, in most cases, that it may with safety be admitted as a general rule. At all places where there are embankments, whether over hollow ground, or along the side of a sloping bank, for every foot that these embankments or mounds are raised in height, one inch may be allowed for subsiding. So that if an embankment, or the outer edge of a road formed from the side-cutting, requires, for instance, six feet deep of forced earth to bring it to the level required, in that case it should be made six inches higher; namely, six feet six inches upon the newly made up ground; and it will be found, in general, to be about six months, from the time that the embankment has been made, until it has become properly consolidated."

3634. *Where the bottom is naturally wet and spongy*, Stevenson observes, it is well to ram it with chips of stone, or with rubbish somewhat freed from earthy particles. It is extremely desirable, in every situation, that the road-metal should be broken to a uniform size, so as to form a compact body throughout. But, as the preparation of the small metal suitable for the surface of a road is expensive, it will, in many situations, be found advisable to lay a stratum or course of *hand-laid* stones, of from five to seven inches in depth, with their broadest ends placed downwards, and the whole built compactly together, upon the prepared bed or soil.

3635. *The materials of the road* may be considered in regard to their nature or kind, the proper size and weight, the outline of their upper surface, and the mode of laying them on and consolidating them.

3636. *Stone* is universally allowed to be the best kind of material for roads; and granite, trap, or flint, the best species of stone; next in order are some sorts of limestone, and hard sandstone. Soft claystone is the worst. Limestone is the principal material in Wiltshire, Somersetshire, Gloucestershire, and Ireland; granite and trap in the north of England and Scotland; slatestone in North Wales; sandstone pebbles in Shropshire and Staffordshire; flint in Essex, Sussex, and part of Kent; and gravel in Middlesex and Surrey. "The stones used for the metals of any road," Paterson observes, "should always be the hardest and most durable that the place or neighbourhood can afford. But this durability will be found in a great measure to depend on the dryness of the road. Freestone, of a moderate hardness, such as mineralogists would term No. 6., 'that would with difficulty yield to the knife,' will make a very good road on a dry sloping bank, exposed to the sun and air, or even on a level surface that has a dry gravelly bottom. Nay, even seven or eight inches deep of such metals, on such situations, will make a better road than twelve inches of the best metals where the bottom is constantly damp, and will actually surpass them in point of durability. This, however, is not meant to give a preference to those metals, but merely to show the great difference there is betwixt a wet and a dry bottom; and that such metals will answer very well in the situations above described. Still it must be held as a general rule, to take the best and hardest metals the neighbourhood can afford, as formerly mentioned."

3637. *But the hardest metals will not always be found the most durable*; and here it may be remarked, as another general rule, with some exceptions, that the harder they are to break, the greater their durability. Some stones, for instance, as hard as No. 9. of mineralogists, "such as would give a few feeble sparks with steel," are so free that they will fly under the stroke of a hammer like so many pieces of glass. These, although very hard, being of a quality so free and brittle, will grind down by the wheels rather easily, and in time of rains will be formed into mud; while, on the other hand, there are stones not harder than No. 7. that are so tough, that there is great difficulty in breaking them. Yet these latter, although two degrees softer, will absolutely last longer than the former, on any road whatever.

3638. *Flints* reduced to a small size, and mixed with chalk, make an excellent road in dry weather; but chalk being very absorbent of water, they become slippery and soft in moist weather, and are much affected by frost.

3639. *Whinstone*, M^cAdam and all road engineers agree in considering the most durable of all materials; and, wherever it is well and judiciously applied, the roads are comparatively good and cheap. Fry, however, has uniformly observed, in various parts of England, that where limestone is used, the roads are the best; and this superiority is not in his opinion owing merely to the hardness of this substance, but also to its *adhesive* or cementing property: how otherwise, he says, are we to account for the firmness and solidity of the roads around Bristol, that are made of white limestone. Fall mentions dewstone, which abounds in Nottinghamshire and other counties of the North, as equally durable with whinstone. (*Every Man his own Road-maker*, p. 8.)

3640. *Gravel* is of two kinds; that obtained from pits, and that from the beds of rivers. Gravel is generally silicious and hard; otherwise, indeed, it would have been worn down to sand, in undergoing the operation with has rendered it gravel. This material is chiefly used on the roads round London: it is often found, Paterson observes, "to answer very well in point of durability. But such kind of gravel, being composed chiefly of hard sand, and smooth, little, round stones, does not so easily bind together, and seldom makes a very firm road. On the other hand, stones that are broken have so many sides that they readily lock into one another; whereas the small round gravel keeps rolling and shifting about by every motion of the wheels. All road metals, therefore, should be of stones as large as to require breaking before they are used. The roads on which gravel will be found to answer best, are those which are neither too wet nor too dry. I have seen a road made with such materials, not only easily rutted in time of the winter rains, but the same road, in the drought of summer, became as loose as ashes, and was then, also, very easily rutted; while betwixt these extremes it answered exceedingly well. Upon the whole, it would be improper to use gravel for any turnpike or public road, where stones can be got that require to come under the hammer." (*Treatise*, &c. p. 31.)

3641. *The gravel of which roads are usually formed* is mixed with a large portion of clay; and the component parts of gravel are round, and want the angular points of contact by which broken stone unites and forms a solid body: the loose state of the roads near London is a consequence of this quality in the material, and of the entire neglect or ignorance of the method of amending it.

3642. *Gravel is the worst material for making roads subject to great traffic.* Telford, on being asked his opinion of it by the road committee, replied, "I am of opinion that the materials in the whole valley or plain round London being entirely silicious, or flints, and easily ground to dust, are very improper. This must be evident to every person who travels near London in any direction." In this opinion M^cAdam concurs.

3643. *Artificial materials* for roads are sometimes had recourse to, when stone or gravel is not to be procured, and sometimes used because unfit for any thing else. They are chiefly the scoria of founderies, dross, cinders, &c., to which may be added burnt clay; the last a very perishable material. It is burned in clamps like bricks, and differs from them in being in irregular masses, and in not having been previously worked.

3644. *Chambers's substitute for road metals*, or for gravel in gardening, is nothing more than vitrified clay, loam, marl, or any other earth that will not fall to powder or burn to lime. The material is intended to be burnt in a temporary kiln, to be erected by the side of the road about to be made or repaired; the earth may be taken from the side drains. The kilns are to be of about six yards in width, and of any length: a stratum of dried earth is to be laid about two feet in thickness, between two layers of combustibles, so as to turn to a vitrified state the greater portion of the earth so enclosed. The principal part of the contents of the kiln will then be in lumps, which are to be separated from the dust or powder; and such vegetable matter as produces alkali may be burnt with the other materials, to assist the vitrification: salt, barilla, potash, or soap-ashes also, if they can be procured at a small expense, may be employed for the same purpose. The dust unavoidably produced, or remaining from the above described burning of clay, &c having been separated from the vitrified matter, is first employed to damp or extinguish the fire, and afterwards, though not applicable to road-making, becomes a valuable material, and may be appropriated for dressing land. (*Newton's Journal*, vol. i. p. 354.)

3645. *The preparation of materials* relates chiefly to their proper size or weight, and cleaning from earthy matters.

3646. *Breaking the materials evenly* is a point, Marshal observes, on which very much depends; for by doing this, the wear of the road becomes regular. Where the heads of large stones rise above the general surface, they become obstacles to carriages, and stumbling-blocks to horses: beside their tending, by the jolting motion which they give to carriages, to indent the surface on either side of them; and thus to increase the roughness, and hasten the decay of the road.

3647. *The proper size of road stones* requires much latitude. Not only the intended use of the road, but the nature of the material, is to be considered. A road for broad-wheeled carriages of burthen only, may be made of larger stones than one for narrow wheels; and hard stones require to be broken smaller than those which more readily wear down and form a travelable surface. For when once the surface of the materials becomes united and cemented together, and its rock-like texture established, the stones that are crushed, and the smaller fragments which are splintered off, in wear, serve to encrust and bind together the stratum of stones which lie next in succession beneath: especially if proper attention be paid to the irregularities of wear, and to bring back the surface, wherever it is requisite, to its original evenness of convexity; so that it may, in every part, act as an arch, and may be able to resist, with the greatest firmness, the weight with which it may be impressed.

3648. *In forming and repairing roads with stones of large size*, a considerable share of the expense arises from the labour of reducing the materials; and, in consequence, the smaller they are broken, the greater becomes the expense. This, on ordinary occasions, is a serious consideration. Hence, in constructing and repairing common roads, it is advisable,—instead of reducing the surface stones to small fragments, with the hammer, at a great cost,—to cover them with materials that are already reduced; as the rubbish of stone quarries, soft stones or gravel, or the scrapings of the road to be repaired. Such cementing materials being washed and worked down, by rains, and the action of carriages and the feet of travelling animals, among the surface stones, assist much in binding and fixing them in a firm crust, and in making the road immediately passable by horses and light carriages; most particularly, if the whole be compressed and united together, by a heavy roller (suitable to the purpose) repeatedly passed over the surface. Such is Marshal's opinion; how much it differs from M^r Adam's and Paterson's cannot but be remarked by the reader.

3649. *The size of stones preferred by Edgeworth* is not specifically mentioned; but on bogs he would lay stones of six or seven pounds' weight: he elsewhere observes that no stones larger than an inch and a half in diameter should be left on the surface of the road.

3650. *The size which Walker approves of* he has not given in very definite terms; and his observation as to the foundation acting by an arch is, in our opinion, erroneous. He says, "Where whin or other stone is to be used, the size of the pieces into which it is broken should decrease as we approach the surface—the superficial coating not exceeding a cube from one inch to one inch and a half. If the foundation is bad, breaking the bottom stone into small pieces is expensive and injurious, upon the principle I have above described, and also for the same reason that an arch formed of whole bricks, or of deep stones, is to be preferred to one of the same materials broken into smaller pieces; for in some counties the materials will admit of the foundation of the road being considered as of the nature of a flat arch, as well as of being supported by the strata directly under it."

3651. *The size of metals, according to Paterson*, should be different for the upper and under surfaces of roads; and both should be regulated according to the situation of the road, and the nature of the ground over which it is formed. "Such small broken

metals as are most proper for a road formed on a sloping bank, or on a very dry bottom, would be quite improper for a road that is perfectly level, and is much subjected to dampness. In the former case, even six or eight inches deep of such metals will make a good road; but in the latter case, twelve or fourteen inches will be found inadequate. In the former case, too, the metals should be of such a size as may fill and pass through a ring from two to two inches and a half in diameter; and in the latter case, they should not be under three inches; as under that size I have never found them to make a durable road in such situations. Every road that has more than eight inches deep of metals, should have the half of these in the bottom broken considerably larger than those on the top. If the road, however, has a dry hard bottom, there is not so much need for this; but if the bottom is soft and wet, it is of the greatest service in making a firm road, and preventing the metals from sinking: and the softer the bottom, the larger, of course, they should be." But it is to be remarked, that the same author in his *Letters, &c.* published three years afterwards, says, "In my former treatise I proposed, where the bottom was soft, to have the under course of stones a little larger than those at top. This I have seen of service, in several cases: but my mode of draining, which should never be neglected, supersedes this entirely.

3652. *The criterion of size adopted by M^r. Adam* is six ounces, or under, for every part of the stratum.

3653. *The size approved of by Clarke* is not defined, but it should, he says, be small. "The common practice is to lay a stratum of stones nearly the size of a man's head, as a foundation, and to cover them with two or three inches of smaller ones; but, from experience and observation, I am decidedly of opinion, that all the stones should be small, and as nearly as possible of the same size: for, though a road made as above described may be very good at first, the wheels of carriages will grind the small stones to powder, the large ones will then rise to the surface, and the road will become intolerably rough, and though frequently repaired with new materials, the same cause will produce a similar effect; whereas, if all the stones are small, and nearly of the same size, they will soon be cemented into one solid mass, and will be worn evenly to the last, so that no repairs will ever be necessary, but the addition of a few broken stones occasionally." (*Obs. on Roads*, p. 11.)

3654. *In fixing upon the size of the top metal*, Stevenson observes, "the more hard and tough its nature is, the smaller it may be broken; it being an object of main importance to have the metal 'well assembled,' as the road-makers express it, or broken of a uniform size. In almost every county there is a variation in the quality of the rock, and also in the size to which it is broken. Roads have latterly been made under a specification as to the weight of the pieces, varying from six to eight ounces. Formerly it was not uncommon to have them specified, of the size of a 'hen's egg,' or even of a 'man's fist.' By reference to weight, the road-maker's operations became more precise; but regard should also be had to the specific gravity of the materials, which differs considerably. For example, granite may be taken at twelve cubic feet in the ton, and whinstone (the greenstone, basalt, and clinkstone of mineralogists) is often met with of similar weight. Compact limestone and flint are about fourteen, and quartz sandstone about fifteen feet to the ton. Perhaps the most convenient and uniform test for the size of road metal is a ring measuring two inches and a half diameter in the void. When the metal is thus broken, and the road carefully treated, its surface soon becomes smooth and compact, without requiring the addition of blinding, or filling up the interstices with gravel, which, if used, should be free of earthy particles. But this addition is hardly necessary, where there is much traffic, as the rough and angular sides of the metal soon lock into each other, and form a smooth surface." (*Ed. Encyc. art. Roads.*)

3655. *The mode of preparing gravel* is nearly the same by all the best road engineers, who agree with Telford, that it ought to be completely cleansed of every particle of clay or earthy substance, and its different sizes ought to be selected and arranged by means of riddling or washing. In the use of the ridder, the particles of earth or clay adhere so much to the stones, that it frequently requires to be exposed to the sun, air, and frost, for several months, and then riddled over again. In this gravel, the stones are of different sizes and different shapes; all those that are round ought to be broken with a small hammer. Some attempt to attain the same end sooner by washing; but this is both a more expensive and less effectual mode than that of taking advantage of the weather.

3656. *The mode of breaking stones* recommended by Edgeworth, is by persons sitting, and using small hammers. A hard stone should be used as an anvil, and the stone to be broken may be advantageously held in a forked stick. Attempts were made some years ago to break limestone for roads, by the force of horses, wind, and water. Stampers, shod with iron, and raised by proper mill-work, were employed; they were let fall upon blocks of whinstone. These mills were found profitable for breaking limestone to powder, as a manure, where fuel was scarce, but they crushed the stone to dust rather than to fragments; if lighter stampers were employed, they frequently failed to break

the stone. Feeding the mill was also found difficult and dangerous. This unsuccessful attempt should not discourage mechanists from further trials. Stones previously broken to the size of five or six inches, might be thrown upon a strong circular horizontal grating, made of cast iron. The stones might be forced downwards through this grating by an iron rammer or a sledge; they would thus be broken to fragments that could not exceed a certain size, and that would not be reduced to powder.

3657. *The manner of breaking, according to Telford, is of great importance.* More depends, he says, on the weight, shape, and manner of using hammers, than any one can conceive who has not had much experience in road-making; the difference in managing this operation being not less than ten per cent.; and is, besides, of equal importance towards the perfection of the road. The size and weight of the hammer he would apportion to the size and weight of the stones; and the stones should be broken upon the heap, not on the ground. It must be evident that using round stones, instead of broken ones, will be the means of deranging the position of those near them, and of grinding them to pieces.

3658. *According to M'Adam, the only method of breaking stones, both for effect and economy, is by persons sitting:* the stones are to be placed in small heaps; and women, boys, or old men past hard labour, must sit down with small hammers and break them, so as none shall exceed six ounces in weight.

3659. *In Nottinghamshire, and part of Yorkshire, a very convenient portable machine is employed for the breaking of small land and waterworn stones.*

The diameter of the stones to be broken according to the mode in question should not exceed five or six inches: they are placed on a table of a triangular shape (fig. 541.), boarded on three sides like a dressing-table, but open at the narrow end, which is placed next and in front of the operator, who sits on a stool (b) or stands as he may

choose, and has a block between him and the point of the table (a), the top of which is about six inches lower than the top of the table. By means of an iron ring fixed into a handle of wood (fig. 542.), he draws from the table as many of the stones as the ring will enclose on the block, and then breaks them while still enclosed in the ring, which is held by his left hand. When this is done, then, with another motion of his left hand, he draws them in the ring off the block till they form a heap at one side, or he at once drops them into the hand-barrow measure (fig. 543.) To prevent any fragments from getting to his face, he puts on a wire guard or veil (fig. 544.), which may be tied by a ribbon round his head, or

suspended from his hat. The same hand-barrow, which serves as a cubic yard measure, serves to carry the stones to any distance. The price paid is so much a yard. In some places, the breaking apparatus consists of three separate parts, the table, the block, and the stool: in others, the whole is combined in one machine, furnished with a wheel (fig. 541. c), which serves as one foot when the machine is stationary, and handles (d); and which admits of moving it from place to place, as easy as a common wheelbarrow. All that is wanted to render this apparatus complete, is a portable shelter or shed, which might be formed entirely of plate-iron, to move on three wheels; or a slight iron frame on three wheels, to be covered with reed frames or straw matting. The shelter should be formed so as not only to protect from perpendicular rain or sun, but from side winds and drifting snows or rains. (*Gard. Mag.* vol. v.)

3660. *Boulder stones, according to Fall, "are broken with a hammer upon a block made of cast iron.* The hammer should weigh about three pounds and a half or four pounds, with two flat faces of about an inch and a quarter in diameter, and a handle similar to a blacksmith's hammer. The cast-iron block must be six or seven inches square, and three inches and a half in thickness, and let into a piece of coarse solid wood, about thirteen or fourteen inches square, and seven or eight inches thick. The block, when used, is to be placed firmly upon the ground, with a kind of trough so fixed that the

pebbles may, with ease, be brought on the block with a ring. The ring should be about five or six inches in diameter, an inch and a half in breadth, and a little thicker than hoop-iron, with a short handle to it: this instrument is used for confining the stones on the block, while going through their operation. The trough has four feet to support it, two of which (those nearest to the breakers) are no longer than what is necessary to allow the stones to come upon the block: the other two are placed at a little distance from the block, and should be somewhat longer, in order that the far end of the trough may be higher, say four or five inches; by which means the person who breaks the stones will, with ease, pull them up on the block; and, as he must always be in a sitting posture, it is requisite that he should get all the advantage over them he can. The trough is, in form, like a washing tub, except that the end next the block is much narrower than the other, and left open; at the bottom of it—the end next the block—should be fixed a grate, to let through the dirt or sand which is shovelled up with them when put into the trough. It will sometimes be of great advantage to gravel, when clay, earth, or other matter, adheres to it; for, by constantly removing it about, and being frequently exposed to frost, wet and dry weather, the dirt becomes tender and moulders into pieces, which the grate will readily separate, without any hinderance to the breaker or waste in the stone. A blacksmith's anvil is the best block; and a box or trough, made as just described, must be framed so as to agree with it." (*Fall's Surveyor's Guide.*)

3661. *Breaking by machinery.* On a new line of road, between Bury and Bolton, in Lancashire, a rotatory steam-engine is attached to a machine similar to a stone-mill, but considerably stronger, which breaks the stones to cover the road at the astonishing rate of seventy or eighty tons in ten hours. The engine is movable on wheels, so that it can be removed to any part of the road without being taken to pieces. (*London Journal of the Arts, &c.* Sept. 1822.)

3662. *M'Adam's criterion for size* is weight. On being asked by the road commissioners to mention the dimensions, he stated, that there was very little difference in the weight of the stones used in road-making. "I did imagine," he says, "that a difference existed; but having weighed six ounces of different substances, I am confident there is little difference in appearance, and none in effect: I think that none ought to exceed six ounces; I hold six ounces to be the maximum size. If you made the road of all six-ounce stones, it would be a rough road; but it is impossible but that the greater part of the stones must be made under that size."—"Do you find a measure or ring through which the stones will pass, a good method of regulating their size?"—"That is a very good way; but I always make my surveyors carry a pair of scales and a six-ounce weight in their pocket, and when they come to a heap of stones, they weigh one or two of the largest, and if they are reasonably about the weight, they will do; it is impossible to make them come exactly to it."

3663. *With respect to the size of stones*, Paterson disapproves of six ounces being made the maximum, as proposed by M'Adam. "I find," says he, "there are many under the weight that are yet of a very improper shape and size; even from three to four inches between the extreme points. Besides, scales for weighing are not so portable nor convenient as gauging-rings for the size. The ring I generally use is two inches and a half in diameter; and the stones should be broken so that the largest may pass, in any direction, through it. On this plan you have the materials smaller, more equal, and more square in shape, than on his plan. An inexperienced person, on the first view of it, may think otherwise; but it is a fact, that taking my ring as a gauge, you will not have five stones in a thousand that will exceed four ounces in weight, and none of improper shape or dimensions: while on Mr. M'Adam's plan you will have more than twenty in a thousand that will not pass longitudinally, even through a three-inch ring. It is now nearly three years since I first heard of his standard weight. During that time I have had people both working to it, and also to my ring-gauge; but I have uniformly found that mine are so much smaller, that they cost about a fifth more in breaking than his. Upon the whole, then, I would recommend the ring as every way preferable to the scales: and I have no doubt that it would be an improvement even to reduce the ring a little, where the ground under the road is completely dried by the method I have described."

3664. *With respect to the depth of metals*, Marshal mentions twelve inches; but Edgeworth considers an average of nine inches as sufficient for any road on a good basis; and two thirds of the quantity, he says, will make an excellent road at a distance from any great town.

3665. *The depth of materials, according to Walker*, depends so much upon the soil and the nature of the materials themselves, that it is impossible to lay down any general rules for them. The thickness ought to be such that the greatest weight will not affect more than the surface of the shell; and it is for this purpose chiefly, that thickness is required, in order to spread the weight which comes upon a small part only of the road over a large portion of the foundation.

3666. *The depth of solid materials recommended by Mr. Adam is one of ten inches, which he thinks equal to carry any thing when well consolidated, and whether on a soft or hard substratum; he should prefer a soft one. (Examinations, &c. 1819.)*

3667. *The depth of metals, according to Paterson, should be regulated according to their quality, the situation of the road, and the nature of its basis. On the generality of turnpike roads it should be made from ten to twelve inches; and upheld afterwards at the depth of nine or ten inches. Yet, in some situations, even six or eight inches will make a much better road than twelve or fourteen in other situations.*

3668. *The depth, according to Stevenson, must depend a good deal on the quality of the rock, but it should seldom be less than eight inches in all those parts of the road on which carriage wheels may be supposed to pass. Towards the verge, it may be less. (Ed. Encyc. art. Roads.)*

3669. *With respect to the shape of the surface of the metals, almost all road-makers agree that it should be convex, but they differ a little in the degree of convexity. It is also allowed by most of them that on roads up ascents, the surface of the metals may be flat, bevelled, or somewhat inclined to one side. Concave roads are not here taken into account, as they require a different general plan, and may be considered as not resorted to in preference, but from accidental circumstances.*

— 3670. *Concave roads (fig. 545.) were recommended, and to a certain extent adopted, by the celebrated Bakewell of Dishley. Practically considered, such a road is in effect nothing more than a flat road with a gutter in the middle, instead of a gutter at each side.*

3671. *The proper convexity of a wet-weather road, according to Marshal, is to be regulated by a variety of circumstances; as, first, by the materials of which it is to be formed: soft materials are most liable to be worn into ruts and hollows, and require to be laid up with a quicker descent for rain-water than hard materials, which require less elevation or rotundity of surface; and least of all a firm even pavement. Secondly, a convex road in the face of a steep is to be laid up higher, with a given material, than one on more level ground, on which rain-water has no other tendency than to the sides: whereas, in the face of a steep, it may have an equal or greater tendency along the line of the road, and is liable to be caught by the slightest impressions of wheels; and thus to wear channels, as may too often be seen, from the top to the bottom of the hill. Even where the surface of the road is perfectly smooth, it may have twice the distance to run, before it reaches the outer margin, that it has on a level. And, thirdly, the degree of convexity is to be determined, in part, by the width of the road; the materials and descent being equal. A wide road requires to be formed with a greater side-ways descent than a narrower one; which more readily frees itself from rain-water, inasmuch as the distance is shorter from the crown to the outskirts of the road. Nor is freeing a road from rain-water the only object to be kept in view, with regard to its convexity. The ease and safety of carriages, and particularly those of burthen, whose loads, being of light materials, are laid up high, require to be consulted. A carriage moves most freely, and with the least exertion of draught, when the load lies evenly upon the wheels on each side. In proportion as the weight is thrown on one side, or the other, the resistance is increased; especially on a road which is liable to impression. Hence an inconvenience of a highly convex road in the face of a steep, and hence the utility of breaks in long ascents.*

3672. *It is evident that every part of a road should be equally and duly convex, — should be equally safe and easy for carriages of every description, — otherwise it becomes more partially worn; the more level parts only are used, the steeper being in a degree useless. Hence a road of even and due convexity is not only easy and safe, but may be formed of a narrower width, than one whose steep sides are neither easy nor safe to be travelled, and whose crown only is in use. On measuring different passages of roads which appeared to lie in the most desirable form, Marshal found that their convexity, or the elevation of the crown or middle of the road above the base line, in roads of twenty feet in width, was about ten inches; namely, one inch in every foot on each side: and he is of opinion that this result may be taken as a general guide in forming roads; this middle degree of convexity being liable to be altered, according to the width of the road, the nature of the materials, and other circumstances.*

3673. *A whole barrel or convex road cannot easily be kept up in a narrow site, as in the case of narrow lanes. If raised, it presently wears into a middle track and two wheel-ruts, with four drains on each side of them, and becomes, in wet weather, a dirty trough, which is unfit for either carriages or horses; and in which a foot passenger has not where to set his foot. But if such a lane be thrown into a shelving form, resembling*

half a barrelled or convex road, a greater width of travelable road for carriages and horses will be obtained; ruts will not be so liable to be formed; the whole of the water of rains will be thrown to one side, while the other will afford a comfortable walking path, at all seasons. It is to be remarked, that when water in a wet season is apt to ooze out of the banks on the upper side of the lane, a narrow channel is to be cut, to prevent its overflowing the road; or, in forming the bed of the road, the inclination may in some cases be reversed, so as to throw the drain on that side of the lane whence the spring water issues: thus the same drain will serve for the spring and the rain waters.

3674. *Semi-convex roads* are applicable not only to narrow lanes, but to the sides of hills, where the road, as it generally ought, is conducted sidelong (not directly) up the slope. By this form of the road, the whole of the water which falls upon it will be got rid of without inconvenience or expense; and the bed of the road for this purpose may be made narrower than for a full convex road,—a circumstance which in some cases may become a saving of much expense. The upper side of a road in this form being nearly level, and firm to the foot of the steep, would be chosen by ascending carriages, while the lower side would acquire a looseness of surface, and be used by laden carriages going downward; while a raised footpath on the lower margin would be a secure guard, and a relief to the apprehensions of timorous travellers.

3675. *The convexity of a road, according to Edgeworth*, need be no more than what will prevent it from being worn hollow before it can be conveniently repaired; and he very judiciously assigns as a reason, that no lateral inclination of the ground, consistent with the safety of carriages, would empty a rut of three inches deep. So far from this being the case, whoever attends to the fact will find, that, even down a moderate slope, where any dirt remains upon the road, the water will be obstructed. Even if there are no ruts on a road, the mud and sludge will not run down a slope even of two degrees, which is the utmost inclination that should be permitted on a mail-coach road.

3676. *The degree of convexity preferred by Benjamin and John Farey* is one of twelve inches in a road fifty-five feet wide; but to attain this shape when the road is worn down, in first forming there should be a rise in the centre of sixteen or eighteen inches.

3677. *The convexity preferred by Telford* is no more than is just sufficient to permit the water to pass from the centre towards the sides of the road; the declivity may increase towards the sides, and the general section form a very flat ellipsis, so that the side should (upon a road of about thirty feet in width) be nine inches below the surface in the middle.

3678. *The degree of convexity proposed by Clarke*, a young Irish road-surveyor, is still less than that of Telford. Were it not absolutely necessary, he says, to let the rain-water run off quickly, the best shape for a road would be a flat surface, and, therefore, the nearer we can approach to that form the better; for, if the road is much elevated in the centre, wheel carriages will all run in the middle, and, of course, very soon wear that part into deep ruts; and if they are then forced to go upon the sides, almost the whole weight will press upon the lower wheel, which will, of course, sink deeper, and occasion a distressing resistance to the shoulder of the horse at that side: therefore, as before observed, the flatter a road can be made, consistently with a moderate fall for the rain-water to escape, the more convenient and durable it will be; for a road should be as hard and as smooth as possible. An idea of a perfect road may be formed from a frozen canal, where flatness, smoothness, and hardness, are combined: in imitation of such a surface railways were invented, and fully illustrate the principles assumed. Roads cannot be made so as fully to attain those perfections: but we should always have them in our view; for the nearer we approach to such a standard, the less will be the friction, and the greater the facility of draught. On a site of sixty-three feet he forms a metalled road of thirty-four feet, with a rise of nine inches in the middle; a six-foot path at one side; and a ditch and bank at each side, occupying ten feet six inches. (*fig. 546.*)

3679. *The degree of convexity preferred by Walker* is just a sufficient rise towards the middle, to incline the water to the sides; and in place of making the whole width the section of one curve, to form it by two straight lines, forming inclined planes, and joined by a curve towards the middle. "I have seen," he says, "ridges formed in what I

thought well-farmed land, much after what I would recommend for the form of a road. The object of forming the land into ridges, raised a little in the middle, is the same as that of raising the middle of a road, to prevent the water from settling upon it; and what is sufficient for the ploughed land, is certainly enough for a road. If the road is of good stone, four to five inches rise in ten feet is sufficient; gravel and other inferior material will allow a little more. This shape not only assists the water to pass from the centre towards the sides, but greatly contributes to the drying of the road, by allowing the action of the sun and air to produce a great degree of evaporation. Surveyors ought to use a level in giving roads a proper shape, in order that the surface may be of one uniform curvature, without the smallest deviation, in any one spot, from the prescribed line of the cross section."

3680. *The degree of convexity preferred by M'Adam is less than that approved of by any of the road-engineers mentioned, unless perhaps Edgeworth.* "I consider," he says, "that a road should be as flat as possible, without regard to allowing the water to run off at all, because a carriage ought to stand upright in travelling as much as possible. I have generally made roads three inches higher in the centre than I have at the sides, when they are eighteen feet wide; if the road be smooth and well made, the water will run off very easily in such a slope. When a road is made flat, people will not follow the middle of it as they do when it is made extremely convex, which is the only place where a carriage can run upright, by which means three furrows are made by the horses and the wheels, and the water continually stands there: and I think that more water actually stands upon a very convex road, than one which is reasonably flat."

3681. *If a road be high and convex in the middle,* Fry observes, no care of the surveyor can prevent the formation of a pair of ruts along the ridge of the road: from an instinctive operation of fear every driver will take this track, as being the only part of the road where his carriage can stand upright; and even if it be not so convex as to excite fear, yet the inconvenience of travelling on a sloping road will always produce the same effect.

3682. *The convexity recommended by Paterson on the level ground, where the bottom is dry, should be from one inch to one inch and a half in the yard.* From this, the declivity may increase even to three inches in the yard, just in proportion as the ground increases in wetness; but beyond that declivity it would probably be improper to carry it in any instance. If the bottom, however, is dry sand or gravel, the convexity should be very little indeed. But in all cases, whether wet or dry, a road formed on *sloping ground*, should be very nearly level from side to side. The reasons are obvious. In the first place, it is well known that carriages running quickly over a hill, are more easily overturned than on level ground; it would therefore be dangerous, in this respect alone, were the road to have much slope on the sides. In the next place, as the great end in giving it the convex shape is to run off the water and prevent it from lodging, this is not so necessary on a road formed upon sloping ground, as there the water will not lodge so as to injure it. In his second work (*Letters, &c.*) Paterson observes of the above directions, "In my treatise respecting the *form* of the road, I proposed the slope from the edges of the materials, to the side ditches, to be from an inch to an inch and a half in the yard, where dry; and to increase the slope a little, where wet. But by adopting those drains under the road, no greater slope will be required, in any situation, than an inch to the yard.

3683. *The convexity recommended by Stevenson is, where the road passes through a level track of country, an ellipsis, "falling from the centre to the verges on either side, at a rate not exceeding an inch and a half perpendicular to a yard horizontal.* (*fig. 547.*) But

547

when an acclivity in the line of draught occurs, where carriages are in the greatest danger of being upset, the surface of the road should be kept flat, or with a fall not exceeding three quarters of an inch to the yard, to take the water gently off toward the sides, and prevent it, during heavy rains, from rutting the road in a lateral direction." (*Ed. Encyc. art. Roads.*)

3684. *With respect to the order and mode of laying out the materials, there is some difference of opinion.* Some begin with the largest, and finish with the very smallest, or with gravel; some lay on the whole at once, and others in two or more strata, and so on. That such a mode of depositing materials could never make a good road is evident, for the reasons given by M'Adam and Clarke: the larger stones would soon rise to the surface, and roll about loose on it; the strata, being thus broken up, would admit and

retain water, which, by the traffic of the road, would render the substratum, in all such places, a mass of mud; and the whole would become bad in proportion to the traffic, the subsoil, and the climate. Marshal is equally wrong in his directions for forming farm-roads, by filling the wheel-tracks with hard materials. In depositing these, he says, the largest and roughest are to be thrown to the bottoms of the wheel-trenches, as foundations for the hardest, which ought to receive the immediate pressure of the wheels, the softest and finest being disposed of in the horse-track. It is evident the continual action of the wheels in the same rut, aided by the water which must infallibly lodge there, would soon work up the larger and rougher stones, and render the traction more oppressive than if no metals had ever been laid there.

3685. *Telford's mode of disposing of the materials of roads* is as follows: — Where a road has no solid and dry foundation, it must be constructed anew. Upon the eighteen centre feet of it stones must be put, forming a layer seven inches deep. Soft stones will answer, or cinders, particularly where sand is prevalent. These bottoming stones must be carefully set by hand, with the broadest end down, in the form of a close neat pavement; the cavities should be filled with stone chips, to make all level and firm, and no stone should be more than five inches broad on its face. Over its bottoming of stones or cinders, six inches of stones, of a proper quality, broken of a size that will, in their largest dimensions, pass through a ring of two and a half inches' diameter, must be laid. The six feet of the road, on each side of the eighteen centre feet (making thirty feet), when formed of a proper shape, may be covered with six inches of good clean gravel, or small stone chips.

3686. *No covering or mixture of any sort is added to the material by Edgeworth*, except clean angular gravel, that may insert itself between the interstices of the stones; but no more should be used than what will thus sink to a level with the surface. If the whole were covered with gravel, it would be impossible to discover the defects of the road, till it might be too late. No stones larger than an inch and a half in diameter should be suffered to remain on the road; where much inaccuracy in this respect is suspected, an iron ring may be employed as a gauge. In all cases, after the road has been covered with stones, it should be carefully examined, and every stone that is too large should be picked off to be broken smaller.

3687. *The preference generally given to gravel*, Paterson considers to be greater than it deserves, and that the earth obtained from the sides of the road, free of expense, will not only barely answer the purpose, but in most cases equally well; and that on a perfectly dry bottom, it is questionable whether it should not even be preferred to gravel. It is in winter only, and on wet ground, that I consider gravel entitled to any preference whatever. (*Treatise, &c.* p. 43.)

3688. *The mode of laying on gravel, according to Walker*, "is to lay it on as it comes from the pit, except the upper foot, or eighteen inches or so, which is screened: but in all cases, whether the material is gravel or hard stone, the interstices between the pieces should be filled up solid with smaller pieces, and the finishing made by a thin covering of very small pieces, or road-sand or rubbish; for those interstices must be filled up before the road becomes solid, either in this way or by a portion of the materials of the road being ground down, which last mode occasions a waste of the material, and keeps the road unnecessarily heavy and loose. In the original making or effectually repairing of a road, it is, I think, best that the whole of the proposed thickness be laid on at once, for the sake of the road as well as of the traveller; the materials of the road then form a more solid compact mass than when they are laid in thin strata at different times, for the same reason that a deep arch of uniform materials is preferable to a number of separate rings." Laying on a stratum of unsifted gravel, under a sifted stratum, is rather at variance with the doctrine of "a deep arch of uniform materials;" and it seems to us, that when a stratum of properly broken stones are to be powerfully rolled, the previous filling up of their interstices with very small matters might counteract the effect of rolling, in squeezing the angular stones into the angular interstices.

3689. *The mode of laying on gravel by M^r Adam* is that of scattering with a shovel, and never emptying down cart or barrow-loads on the middle of the roadway, as is generally practised. He completes the stratum by three separate layers; leaving the first to be consolidated by wheels, and in some cases a heavy roller, before he lays on the second; and the second, in like manner, before he lays on the last.

3690. *A covering from four to five inches thick*, according to Fry, forms a bed or mass, which is proof against the severe crush of heavy wheels; while in the case of a very thin covering, the stones lying bare upon a hard road, and receiving in this unprotected state the stroke of every wheel that passes over them, like the thin covering on a mill-bed, they are quickly reduced to powder, and disappear. Stones in a thick bed are protected from the immediate destructive grind; while stones that are thinly laid on are instantly reduced to powder, either by pressure or grinding.

3691. *Telford*, in filling broken stones, and also in scattering them on the road, makes

use of a pronged shovel, fourteen inches square, which may be universally recommended for this purpose (*fig. 548. d*). His large hammer (*a*), small one (*b*), and gauge for the size of the broken stone (*c*), are in very general use, as well as the pronged shovel. Hammers may be made of cast iron, where the stones to be broken are about their own weight; the best shape is a narrow oval: the advantage of using cast iron is its cheapness. (*Farm. Mag. xxii. 159.*)

3692. *Telford's level*, for adjusting the declivity of roads from the middle to the sides (*fig. 549.*), is also a very complete implement of the kind.

3693. *The mode of depositing materials by Paterson* is as follows: — “Bottom metals should be broken on the road. When they are thus broken, they are, by the force of the hammer, firmly bedded into the bottom, and are so closely and compactly beaten together, that they become like pavement. In this state they are not only less liable to sink, but they form a much better bed for the top metals than when they are thrown loosely on. And besides this, when they are put on in a loose manner, as is frequently done, the mud more readily works up through the metals in time of rains, and makes a disagreeable road: the top metals also are easily beaten down, by the horses' feet and the carriages, through the bottom stones, when loose and open; so that the small metals frequently get undermost, and the large ones make their appearance at the surface, very much to the injury of the road. Taking all these circumstances, therefore, into consideration, it is of the greatest importance that the bottom metals should not only be much larger in size, but that they also be broken on the road.” This may be considered as at variance with several parts of *Paterson's* second publication, *Letters, &c.* The road being drained and prepared for the materials, he then directs (*p. 80.*) to put them on in the following manner: — “*M'Adam's* mode of putting them on, in coats of three or four inches, though good in particular instances, will not do as a universal rule. If the bottom is wet, and the weather rainy, the earth will poach and work up through the materials, in spite of all the attention and care that can be bestowed. I would, therefore, recommend in such cases to put on the first course from five to six inches thick. But then to leave these materials to consolidate, or rather to move and shift about by the wheels; and then to be levelled by the rakes, alternately, according to *M'Adam's* plan, wears away the corners of the stones, by which means they do not unite together and make such a firm road. There were upwards of two miles of road made under my directions lately, on which I caused a course of about six inches to be put. But before opening it to the public, I got a heavy stone roller to ply upon it for four days. This beat and firmed the materials so much, that the wheels of the carriages made little impression upon it. Of course the materials retained their angular points more than in rolling and shifting by every carriage-wheel that passed; and there was less labour in raking and levelling the road. This plan, which carries reason on the face of it, I would strongly recommend. As to *M'Adam's* plan of putting on the materials in shovelfuls, it is certainly good. I used to prohibit putting them on with carts (as in that case you never have the small and the great properly mixed together), and generally put them on with wheelbarrows: but even this does not mix them quite so well as scattering them with the shovel; and as it is of considerable importance to have them well mixed, I would by all means recommend the mode best calculated for that purpose.”

3694. *Rolling newly laid on metals* is generally approved of. The roller used should not be less than four or five feet in diameter; a smaller size, especially in the use of gravel, being apt to drag and force the loose materials before it. Some have attempted to keep roads in order by occasionally harrowing and then rolling them; but the best

judges are of opinion with John Farey (*Evidence, &c.* 1819.), that a roller cannot be beneficially used upon a road at any other times but after new coating it with materials, or after a frost, or when the sticking of materials to the wheels may have loosened up the stratum.

3695. *Beaton's new theory of roads*, as given in vol. i. of the *Communications to the Board of Agriculture*, is as follows: — Water percolates through porous strata, and is retained by compact strata. Whatever may be the form of the surface, therefore, if there is a porous stratum underneath, the surface will be generally dry. When a new road is to be formed, reduce the natural surface so as the lines of a section of it may meet in an angle or ridge in the middle of the road (*fig. 550. a*), having a slope from thence of

550

about an inch in a foot. The road being thus formed, must be allowed to harden and settle for some time, and then covered to a level, by a stratum (*b b*) sufficiently porous to admit water to pass through it; small drains (*c c*) being formed at the sides, to lead the water from the gutters (*d d*), into the open ditches (*e e*). Over this is to be laid the coat of hard materials (*f*), which need not be more than 6 or 7 inches in thickness, of stones broken very small, or of the best gravel: it is then to be rolled with a roller, which admits of being loaded, so as to render the surface harder and harder by degrees. The advantages of this construction, Mr. Beaton tells us, are, every part of the road being equally commodious for carriages, and very little repair required. These advantages, however, are by no means obvious.

SECT. IV. *Paved Roads.*

3696. *Causeways and pavements* are chiefly made use of in towns, and may therefore be considered as belonging more to architecture than to agriculture. But as it is the opinion of some of the first engineers, that pavements might be introduced with advantage on the public roads for some distance from the larger towns, we shall shortly consider this subject with reference to that object. Paving, as applied to roads, is therefore to be considered as a substitute for a part or the whole of the metalled part of the road, and not as occupying every part of its width or site, as in the case of streets.

3697. *For roads near capital or great commercial towns*, paving, according to Edgeworth, is the only certain method yet known that gives sufficient hardness, smoothness, and permanency. B. and J. Farey are of the same opinion, and the latter considers it would be proper to pave the sides of all the principal entrances into London. Walker, who was the engineer of the Commercial Road, ten feet of the centre of which is paved with granite, and has given great satisfaction for upwards of 16 years, is a great advocate for paving. "The advantage," he says, "of paving part of a road where the traffic is great, and the materials for making roads bad or expensive, is not confined to improving the conveyance for heavy goods and reducing the horses' labour; but as the paving is always preferred for heavy carriages, the sides of a road are left for light carriages, and are kept in much better repair than otherwise they could possibly be. It is not overstating the advantage of the paving, but rather otherwise, to say, that, taking the year through, two horses will do more work, with the same labour to themselves, upon a paved road, than three upon a good gravelled road; if the traffic upon the gravel road is at all considerable, and if the effect of this, in point of expense, is brought into figures, the saving of the expense of carriage will be found to be very great when compared with the cost of the paving. If the annual tonnage upon the Commercial Road is taken at 250,000 tons, and at the rate of only 3s. per ton from the docks, it could not upon a gravelled road be done under 4s. 6d., say however 4s., or 1s. per ton difference, making a saving of 12,500l., or nearly the whole expense of the paving in one year. The introduction of paving, therefore, would, in many cases, be productive of great advantage, by improving the gravel road, reducing the expense of repairs, and causing a saving of horses' labour much beyond what there is any idea of."

3698. *Telford* considers that it would be of advantage to pave a part of the centre of great public roads; and in conformity with this principle, when forming a gravel road, he lays eight or ten feet of it in the centre with stones.

3699. *The parts of the road most desirable to be paved*, according to B. Farey, are the sides. "If the centre were paved," he says, "the light carriages would be much an-

noyed ; when the gravel road was good on the sides, the heavy carriages would go there, and the light carriages would be driven on the stones from the sides again : if the centre were paved, the carters would be obliged to walk on that road to manage their horses, and would be considerably annoyed by carriages, horsemen, &c. passing ; but if the sides of that road were paved, the carters would be enabled to walk on the footpath, and to manage their horses without annoyance."

3700. *Paving the sides* is also preferred by J. Farey, " but not the middle, as has been done on the Commercial Road, the Borough Road and others. My reasons for preferring the sides being paved are, that it is next to impossible to compel the carters to keep upon the pavement in the middle of the road ; in too many instances, the fear of damage, from the swift going carriages, occasions them either to draw their carts close to the sides, and walk upon the footpaths, or, what is worse, to leave their horses in the middle, beyond a train of carriages. The sides being paved would enable one of those trains of carriages to enter London on one side of the road, and go out of it on the other, without many occasions to turn out of their tracks : which circumstance of keeping nearly to the same tracks, upon a well-paved road, would not be prejudicial ; but on a road formed of gravel is entirely ruinous."

3701. *Walker also prefers paving the sides*, though in the case of the Commercial Road he paved the centre, as already described (3699.).

3702. *Stevenson*, as we have seen (3539.), is an advocate for wheel-tracks of stone, as greatly lessening the draught of heavy carriages in the country, and especially in acclivities, and avoiding the irksome noise and jolting motion of causeways in town. Specimens of these tracts have been laid down in Glasgow, and they may be seen in various towns in Italy. " The stones of the tracks recommended by Mr. Stevenson, are of a cubical form (fig. 551.), measuring only from 6 to 8 inches in the lengthway of the track, and 12 to 14 inches in depth, 18 inches in breadth at the base, and twelve inches on the top or wheel-track. The stones are therefore proportionate in all their dimensions ; for, unless they contain a mass of matter corresponding to their length, they will be found to want strength and stability. It would hardly be possible to keep slender stone rails in their places, and hence the chief benefit of a connected railway would be lost. On the other hand, very large materials are difficult to be got, and

are also more expensive in carriage and in workmanship than stones of a smaller size. The Italian wheel-tracks are composed of stones 2 feet in breadth, and of various lengths. To lessen the risk of horses falling, these broad stones are kept in a rough state, by occasionally cutting grooves with a pick-axe upon their upper surface." (*Edin. Encyc. art. Roads.*)

3703. *Mathews* also has proposed a plan for a stone railway ; he proposes that the stones should be in pieces measuring 4 feet 2 inches in length, 11 inches in breadth at the top, 14 inches at the base, and 10 inches in depth. He has various modes of connecting these stones : by a mortice and tenon joint (fig. 552.), bevelled so as to prevent the joint from sinking ; by a bevelled joint in which the ends of the two rails are made to rest on a centre or intervening block (fig. 553.) ; and with bevelled and grooved joints, so as to prevent lateral derangement, as well as sinking. (fig. 554.) The manner of placing stones on these different methods together, of securing them by a row of rubble causeway stones on each side, and preserving the horsepath between, may be easily conceived. (fig. 555.) Mr. Mathews intended these railways for all the principal highways in the kingdom ; but the expense of the plan was one of its chief

objections. It has been alleged also, that unless the cubic contents of these blocks bore a greater proportion to their length, they would be deranged by the pressure of very heavy carriages. (*Ed. Encyc. art. Roads.*)

3704. *Paving the whole or any part of a road is entirely disapproved of by M'Adam.* " The measure," he says, " of substituting pavements, for convenient and useful roads, is a kind of desperate remedy, to which ignorance has had recourse." The badness or scarcity of materials cannot be considered a reasonable excuse, because the same quantity of stone required for paving is fully sufficient to make any excellent road any where ;

are also more expensive in carriage and in workmanship than stones of a smaller size. The Italian wheel-tracks are composed of stones 2 feet in breadth, and of various lengths. To lessen the risk of horses falling, these broad stones are kept in a rough state, by occasionally cutting grooves with a pick-axe upon their upper surface." (*Edin. Encyc. art. Roads.*)

3703. *Mathews* also has proposed a plan for a stone railway ; he proposes that the stones should be in pieces measuring 4 feet 2 inches in length, 11 inches in breadth at the top, 14 inches at the base, and 10 inches in depth. He has various modes of connecting these stones : by a mortice and tenon joint (fig. 552.), bevelled so as to prevent the joint from sinking ; by a bevelled joint in which the ends of the two rails are made to rest on a centre or intervening block (fig. 553.) ; and with bevelled and grooved joints, so as to prevent lateral derangement, as well as sinking. (fig. 554.) The manner of placing stones on these different methods together, of securing them by a row of rubble causeway stones on each side, and preserving the horsepath between, may be easily conceived. (fig. 555.) Mr. Mathews intended these railways for all the principal highways in the kingdom ; but the expense of the plan was one of its chief

objections. It has been alleged also, that unless the cubic contents of these blocks bore a greater proportion to their length, they would be deranged by the pressure of very heavy carriages. (*Ed. Encyc. art. Roads.*)

3704. *Paving the whole or any part of a road is entirely disapproved of by M'Adam.* " The measure," he says, " of substituting pavements, for convenient and useful roads, is a kind of desperate remedy, to which ignorance has had recourse." The badness or scarcity of materials cannot be considered a reasonable excuse, because the same quantity of stone required for paving is fully sufficient to make any excellent road any where ;

objections. It has been alleged also, that unless the cubic contents of these blocks bore a greater proportion to their length, they would be deranged by the pressure of very heavy carriages. (*Ed. Encyc. art. Roads.*)

3704. *Paving the whole or any part of a road is entirely disapproved of by M'Adam.* " The measure," he says, " of substituting pavements, for convenient and useful roads, is a kind of desperate remedy, to which ignorance has had recourse." The badness or scarcity of materials cannot be considered a reasonable excuse, because the same quantity of stone required for paving is fully sufficient to make any excellent road any where ;

555

and it must be evident that road materials of the best quality may be procured at less cost than paving stone. The very bad quality of the gravel round London, combined with want of skill and exertion, either to obviate its defects, or to procure a better material, has induced several of the small trusts, leading from that city, to have recourse to the plan of paving their roads, as far as their means will admit. Instead of applying their ample funds to obtain good materials for the roads, they have imported stone from Scotland, and have paved their roads, at an expense ten times greater than that of the excellent roads lately made on some of the adjoining trusts. Very few of these pavements have been so laid as to keep in good order for any length of time, so that a very heavy expense has been incurred without any beneficial result; and it is to be lamented that this wasteful and ineffectual mode is upon the increase in the neighbourhood of London.

3705. *The practice of paving roads* has also been adopted in places where the same motive cannot be adduced: in Lancashire, almost all the roads are paved at an enormous cost, and are, in consequence, proverbially bad. At Edinburgh, where they have the best and cheapest materials in the kingdom, the want of science to construct good roads has led the trustees to adopt the expedient of paving to a considerable extent; and at an expense hardly credible, when compared with what would have been the cost of roads on the best principles.

3706. *The advantages of good roads, when compared with pavements, are universally acknowledged*; the extension of pavement is therefore to be deprecated as an actual evil, besides the greatness of the expense. Pavements are particularly inconvenient and dangerous on steep ascents, such as the ascent to bridges, &c. A very striking example of this may be observed on the London end of Blackfriars bridge, where heavy loads are drawn up with great difficulty, and where more horses fall and receive injury than in any other place in the kingdom. The pavement in such places should be lifted, and converted into a good road, which may be done with the same stone at an expense not exceeding 10*d.* per square yard. This road would be more lasting than the pavement, and, when out of order, may be repaired at less than one tenth of the expense which relaying the pavement would require. This measure has been adopted with great success, and considerable saving of expense, in the suburbs of Bristol, where the pavements were taken up, and converted into good roads, about three years ago. The same thing has lately been successfully adopted on Westminster and Blackfriars bridges.

3707. *In preparing for laying down pavements, the first thing to be attended to, Edgeworth observes, is the foundation.* This must be made of strong and uniform materials, well rammed together, and accurately formed to correspond with the figure of the superincumbent pavement. This has no where been more effectually accomplished, than in some late pavement in Dublin. Major Taylor, who is at the head of the Paving Board, before he began to pave a street, first made it a good gravel-road, and left it to be beaten down by carriages for several months; it then became a fit foundation for a good pavement. The Romans, in preparing for pavement, laid a substratum of masonry, in some cases two or more feet thick, and never less than a foot or eighteen inches. This mode is adopted in one or two cases near St. Petersburg, and might be advantageously used in this country, were not the expense an objection. Planking, broad stones, iron plates, slates, tiles, and brickwork, have also been proposed in this country; but a consolidated stratum of broken stone of ten inches in thickness is perhaps the simplest and best preparation, especially for the sides of roads. A substratum of sand is sure to be deranged after the first rains.

3708. *The kinds of stone used in paving* are chiefly granite, whinstone or trap,

Guernsey or other pebbles, or water-worn granitic or trapstones. Walker prefers the granite of Guernsey to that of Aberdeen.

3709. *The size of the stones used in road pavements* is commonly from five to seven inches long, from four to six inches broad, and from six to eight inches deep. Walker prefers stones nine inches deep; and Telford is of opinion that the general shape of the stones at present used for paving, and the mode of distributing them, are very imperfect; the lower part of the stones being of a triangular wedge-like shape, which, instead of enabling them to resist the weights which come upon them, easily penetrate into the substratum: the stones are also broken of an unequal size. The remedies for these defects are obvious: they should be as nearly as possible of a cubical form, the lower bed having an equal surface with the upper face; they should be selected as nearly as possible of an equal size, and they should never be of unequal length on the face. In quarrying and preparing the stones there would certainly be an additional expense in the preparation, because there would be more work required in the dressing, and many stones must be rejected which are now used; but the additional expense would be very well bestowed.

3710. *In laying down the stones*, each stone, according to Edgeworth, should bear broadly and firmly on its base; and the whole should be rammed repeatedly, to make the joints close; the upper and lower sides of the stones should be as near each other as possible, but they should not touch each other laterally, except near the top and bottom, leaving a hollow in the middle of their depth, to receive gravel, which will serve to hold them together. This method of paving may be easily executed by common workmen, who may throw in gravel between the stones as they are laid down. It may be easily conceived, that if a grain of gravel inserts into holes that are in stones opposite to each other, it will *dowel* them together. It will be useful to cover a newly made pavement with gravel, which will preserve the fresh pavement for some time from the irregular pressure of wheels, till the whole is consolidated. The stones should be of equal hardness, or the soft ones will be worn down into hollows. In every species of paving, no stones should be left higher or lower than the rest; for a wheel descending from a higher stone will, by repeated blows, sink or break the lower stone upon which it falls.

3711. *The requisites for laying down the stones and forming a good pavement* are, according to Walker, to have the stones properly squared and shaped, not as wedges, but merely as rectangular prisms; to sort them into classes according to their sizes, so as to prevent unequal sinking, which is always the effect of stones, or rows of stones, of unequal sizes being mixed together; to have a foundation properly consolidated before the road is begun to be paved; to have the stones laid with a close joint, the courses being kept at right angles from the direction of the sides, and in perfectly straight lines; the joints carefully broken, that is, so that the joint between two stones in any one course shall not be in a line with or opposite to a joint in any of the two courses adjoining. After the stones are laid they are to be well rammed, and such of the stones as appear to be rammed loose should be taken out and replaced by others; after this the joints are to be filled with fine gravel, and, if it can be done conveniently, the stability of the work will be increased by well watering at night the part that has been done during the day, and ramming it over again next morning. The surface of the pavement is then to be covered with an inch or so of fine gravel, that the joints may be always kept full, and that the wheels may not come in contact with the stones while they are at all loose in their places. Attention to these points will very much increase both the smoothness and the durability of the paving. He has found great advantage from filling up, or, as it is called, *grouting* the joints with lime water, which finds its way into the gravel between and under the stones, and forms the whole into a solid concreted mass. The purpose served by the lime might also be effectually answered by mixing a little of the borings or chippings of iron, or small scraps of iron hoop, with the gravel used in filling up the joints of the paving. The water would very soon create an oxide of iron, and form the gravel into a species of rock. He has seen a piece of rusty hoop taken from under water, to which the gravel had so connected itself, for four or five inches round the hoop, as not to be separated without a smart blow of a hammer; and the cast-iron pipes which are laid in moist gravel soon exhibit the same tendency.

3712. *As substitutes for paving stones*, plates of cast iron moulded into the form of the surface of a pavement of different sizes (*fig. 558. c, d, e*) have been tried; but on the whole they are not considered as likely to succeed. They are very hot in summer, and more slippery than stone in winter; but what is most against them is, that the water finds its way beneath them and softens the substratum. This, at any time of the year, tends directly to produce holes by the leverage of wheels and the feet of animals (3573.); but after a severe frost the effects are ruinous. At all events, this description of pavement does not appear so well adapted for the sides or middle of public roads as that of granite stones prepared in Telford's manner (3709.).

3713. *Various improvements in laying pavements* have recently been devised, such as laying the stones dry on clay; using square stones, or stones equally wide at bottom as at top; using stones alternately wider at bottom and top, and joining them with cement (*fig. 556.*); paving on plates of iron, wood, or stone, or on a mass of masonry, &c. If pavements in towns did not require to be frequently lifted on account of sewers, and water and gas pipes, paving in this manner on a solid foundation would certainly be the best mode; but as things are, and even probably if pavements did not require to be frequently lifted, M'Adam's roads are found greatly preferable for all broad streets, and where care is taken to keep them clean and in complete repair. In Britain, at least, they will probably soon supersede all common pavements, and all other descriptions of common roads.

556

3714. *Large blocks of granite* (*fig. 557.*) have been substituted for common-sized paving stones; each block is two or more feet square, nine inches deep, and channelled on the surface in imitation of common-sized paving stones. These are found to answer much better than the cast-iron plates; but they are liable to the same objection as to leverage; are difficult to replace properly; and as the raised pannels between the grooves will in time wear down to the level of the grooves, they cannot be considered so durable as common square stones, which, after all, appear the best for general purposes, and, at all events, for paving the middle or sides of highways.

557

3715. *Blocks of stone, and also of timber*, have been proposed to be laid in iron boxes; but the effect of the granite blocks laid down in Fleet-street does not warrant the expectation of any advantage from either of these modes. Where nothing but light carriages pass over a road, no material is more agreeable than blocks of wood set endways, as is done in many parts of Russia and Germany; and this mode of paving may, therefore, be considered very suitable for private court-yards, or stable-yards in country residences. (*Newton's Journal*, vol. vii. p. 197.)

3716. *The defects of common pavement, and the theory of its wear*, are thus given by Edgeworth. "Stones, in a common pavement, are usually somewhat oval, from five to seven inches long, and from four to six inches broad. They are laid in parallel rows on the road (*fig. 558. c, d.*), or alternately (*a, b.*) as bricks are laid in a wall. On the first sort of pavement, wheels slip from the round tops of the stones into the joints between, and soon wear away the edges of the stones, and their own iron tire. By degrees, channels are thus formed between some of the stones, and in time the pavement is ruined.

3717. *On the second sort of pavement* (*a, b.*) where the stones are placed alternately, to prevent the injury to which the former method is liable, the wheel (*f.*) sliding sideways, makes a channel between two stones, and is then obliged to mount from the groove which it has made, to the top of the stone opposite to it; when it has attained this situation, the wheel may slide sideways, or may go forwards over the top of the stone, till it drops into the interstice between the two next stones. By continual wearing, these ruts become so wide and deep, that the wheel does not touch the stones on either side, nor does it reach the ground between them, but it bounds from one stone to the other, thus jolting the carriage in every direction. This method is not at present in use.

3718. *In the pavements last described*, the stones are but of a small size; but if flat stones of twelve or fourteen inches long (*e.*) are well laid, wheels are not liable to slide into the joints; and if such stones are laid with their longest sides crossing the road, they are less liable to injury; but still narrow wheels sometimes fall into the joints between the largest stones, and having in time worn away their own edges, and those of the stones, they will act like wedges, and will displace the stones. No pavement, of the best stone that could be procured, can long resist this action of a narrow wheel. And the only effectual means of preserving pavements is, to increase the breadth of all wheels to at least three inches. Were no wheels narrower, a cheap and durable pavement might be made of flat stones, not more than three inches square, provided they were eight or nine inches deep, to give them reciprocally lateral support; for the tire of such broad wheels could never sink between the joints of the stones." (*Edgeworth.*)

3719. *Various improved methods of paving* have been lately brought into notice. About 1811 or 1812, we suggested the idea of placing the stones on a foundation

559

of flag-stones or cast-iron plates on a bed of mortar. (*fig. 559.*) When this mode is adopted in the streets of cities, the gas and water pipes (*a*) may be placed in drains, covered with large blocks of granite (*b*), channelled on the surface to prevent horses from slipping. Access to the pipes might be had by simply lifting these stones, without disturbing any other part of the pavement. (*Gard. Mag.* vol. v. p. 79.)

3720. *George Knight* has suggested the idea of placing the paving stones with the broadest surface undermost, on a Macadamized foundation; and some streets in the metropolis have been so paved. The improvement has been found considerable; but as the rain-water sinks to the Macadamized stratum, and cannot run off through it for want of drains, the mud still works up to the surface. With adequate under-drainage, or with the stones so compact as that the surface-water would run off instead of running through, this plan would be one of the most perfect which has been suggested.

3721. *Colonel Macirone* recommends pressure, "which may be applied in three different stages of the work: first, to harden the ground previously to laying the stones; secondly, to fix and depress them when laid; thirdly, to equalise and perfect a pavement after it has been some time in use, by applying the pressure only on the protuberant parts. The machine he proposes for the above purpose is similar to a pile-driver of the smaller kind; the weight being drawn up by a rope passing over a single pulley-wheel at the top of the slide shafts, and terminating on the other side in a cluster of smaller ropes or cords, one for each of the six, eight, or ten men employed to work the machine." (*Hints to Paviours*, 8vo. 1826.)

3722. *Lieutenant Brown* suggests "that, after the foundation has been formed in the necessary shape, and the surface rolled or rammed hard, the paving stones, dressed so as to fit close together, should be laid or set in a thick coat of good mortar, and the joints grouted with cement; the whole mass would thus become a solid body, and the rain would be effectually prevented from penetrating to the foundation, which would remain dry and firm in the position in which it was originally placed. By bedding the stone in mortar, properly placed in the situation in which it is to remain, then grouting the joint, and allowing it to set hard, without afterwards ramming or disturbing it, the pavement will remain immovable and water-tight, until fairly worn out, and save all the expense of an artificial foundation of Macadamized stones or other matter. A grand objection to a Macadamized pavement, in this and every cold climate is, that a severe frost setting in after wet, does incalculable injury, owing to its porous state; now, as no water can penetrate beneath the surface of this pavement, if properly made, this serious fault is obviated." (*Quar. Jour. Science*, Jan. 1850.)

SECT. V. Milestones, Guide-posts, and Toll-gates.

3723. *Milestones* of the most improved kind are generally formed of durable stone, or cast iron. They ought to have two faces (*fig. 560.*); one to contain the distance from the metropolis of the country to the stone, and the distance from that stone to the next market town, and village or place; and the other the distance from the extremity of the road to the stone, and from the stone to the next market town, and village or place, in proceeding to the metropolis. On a face on the apex of the stone may be the name of the county and hundred, and on the base, the name of the township, parish, and hamlet or village. In some countries of the Continent, as in Wirtemberg and Bavaria, a small open area of 10 or 12 feet in diameter is preserved round the milestones; a bench of stone or turf forms a semicircle, in the radius of which is the milestone, and immediately beyond the bench a row of ornamental trees or shrubs. In several places, every milestone is formed in three steps, the lowest 2 feet 6 inches, the next 3 feet 6 inches, and the last or top of the milestone 4 feet 6 inches. The use of these steps is, to enable people of different heights, travelling alone, and carrying burthens on their backs or heads, to set down these burthens, rest themselves on the benches, and resume the burthens without assistance. In England such an arrangement is unnecessary; but various plans have been suggested for rendering milestones interesting: names of benefactors to mankind who lived near; dates of remarkable events; monuments, tombs, statues, small burial places, cottages, alehouses, &c. &c. (See *Gard. Mag.* vol. v.) We should prefer a cottage or a burial place at every milestone, because, as the majority of travellers are on horses or in carriages, they can have little time to peruse milestones; but the cottage might afford protection to the foot traveller, and a glance at the burial

560

place would afford matter of reflection to all. " It has been suggested to us that milestones might be made larger, in the form of an obelisk or sarcophagus, on the model of an ancient classical or other building, or in other forms ; and that there might be inscribed on them the names and dates of events which took place, or of great men who lived, in the neighbourhood ; and that, in addition to these, there might be inscribed on each milestone, or structure serving the same end, maxims of conduct, or funda-

mental principles of science. Thus, on some roads, the milestones might exhibit sculptured reliefs, representing a historical series, either of events in the history of that part of the country, in the life of some eminent character who had lived there, in the progress of discovery in some art or science of the human mind generally, or in general history. If all the proprietors on a line of road were agreed, a group of exotic trees and shrubs might be planted as a back ground to a small area, which might contain the milestone ; and by limiting every group to one genus of timber tree, and one or two fruit trees,

considerable variety would be produced, and the botanical interest of the road kept up for many miles. Small burial-grounds round milestones would, we think, be unobjectionable ; and, indeed, we do not think they could be better placed : and tombstones there, or any where along the road-side, would attain their end more effectually than in churchyards, and, at any rate, would be what is called classical ; which is an excellence to be aimed at, and which is beneficial in a certain stage of progress, but too often, in architecture and in sculpture for example, an impediment to improvement, by being considered the highest degree of excellence. Some one has proposed to build cottages as milestones, and to that plan and to various others we have no objection, to a certain extent ; the danger being the production of sameness, by adopting the same plan every where." (*Gard. Mag.* vol. v. p. 117.)

3724. *Guide-posts.* Wherever one road branches from another there ought to be a guide-post ; and it is not a little remarkable that in this improving age, when every street and lane in towns is so carefully named, that so little has been done in the streets and lanes of the country. The posts which bear the names ought, where the expense is not an insuperable object, to be of iron, on account of its durability. Swaine proposes to have the posts hollow cylinders of cast iron, and the letters to be also of iron, with the space between them open, " so that the light may be seen through them ; by which means the characters of this hand-post will be legible at night, by viewing them against the sky, unless it should be exceedingly dark. The direction of the road is denoted by the manner of disposing the letters : thus, in a guide-post between London and Windsor (*fig.* 561. *a*), the letters of the word London are reversed, to denote that the direction of London is to the left hand ; the word Windsor in the line beneath is not reversed,

as that town must be understood to lie to the right hand: the number of miles to each place is shown by figures placed beneath each word. The same object may also be effected in the more obvious manner in general use (fig. 561. b).

561

3725. Toll-gates and gate-houses have also partaken of the improvement of the age. The form and hanging of the gates have been scientifically treated of by Parker, who may be considered as having arrived at a high degree of practical excellence. For his general principles, and the details of his compensation hinge for turnpike-gates, see § 3081, 3082.), and his valuable *Essay on Hanging Gates, &c.*, ed. 3., 1826.

3726. Gate or toll-houses have been materially improved, both in point of internal comfort, and as objects of taste. Some of those in the neighbourhood of London are elegant objects. As an example we shall select that at Edgeware. (fig. 562.) On

562

the summit of the cupola of this house there was originally a lamp with three burners and three separate reflectors. Two of the reflectors directed the light along the road in opposite directions, to show what might be coming or departing on either hand; the third reflector threw the light directly across the road, and down on the gate, for the purposes

of the gate-keeper and those passing through. After this light had remained between two and three years, it was taken down, as being too brilliant and as having frightened some horses; but it might surely have been softened, so as to be retained. Where there are two gates, as in various examples, a lamp post is very properly placed between them, which thus answers all the purposes of the cupola and triple lamp at Edgeware.

SECT. VI. *Preservation and Repair of Roads.*

3727. *The preservation of a road* depends in a great measure on the description of machines and animals which pass over it, and on keeping it dry and free from dust and mud. The repair of a road should commence immediately after it is finished, and consists in obliterating ruts the moment they appear, filling up any hollows, breaking any loose stones, and correcting any other defect. After cleaning and this sort of repair have gone on hand in hand for a longer or shorter period, according to the nature of the materials and traffic on the road, a thorough repair or surface-renewal, by a coating of metal of three or more inches in thickness over the whole of the road, may be required.

3728. *To preserve a road, by improving the wheel carriages* which pass over it, all agree that the wheels should be made broader than they usually are, and cylindrical; that carts with two horses abreast are less injurious than such as are drawn by two horses in a line; and that it would be an advantage to have the axletrees of different lengths.

3729. *Edgeworth*, upon a careful examination, concludes that the system of rolling roads by very broad wheels should be abandoned; and that such a breadth only should be insisted upon, and such restrictions made as to loading, as will prevent the materials of the road from being ground to powder, or from being cut into ruts. With this view the wheels of carriages of burthen should have felles six inches broad, and no more than one ton should be carried upon each wheel.

3730. *Farey* is of opinion, that six-inch cylindrical wheels, or under, are the most practicable and useful, provided the projecting nails are most rigidly prohibited, which can never be done but by a penalty per nail upon the wheelers who put in those nails, and upon the drivers of the carriages who use such roughly-nailed wheels.

3731. *Telford* thinks that no waggon or cart wheel ought to be of less breadth than four inches, and that in general no carriage ought to be allowed to carry more than at the rate of one ton per wheel: "when it exceeds that weight," he says, "the best materials for road-making must be deranged and ground to pieces."

3732. *Paterson* is a warm advocate for broad wheels. "If the wheels were used double the breadth that they are at present," he says, "they would act as rollers upon the materials, binding them together; and consequently the surface would remain always smooth and free from ruts, and the waste or decay would, of course, be exceedingly little." All broad wheels, however, should be constructed differently from those that are in

common use (*fig. 563. a*). Those in common use, whether broad or narrow, are generally *dished* (as it is called) on the outside, and the ends of the axletree bent a little downwards. This causes the wheels to run wider above than below; and the reason, I believe, for adopting this plan was to allow people to increase the breadth of their carriages, and yet the wheels to run in the same track.

Upon this plan, the edges of the wheel, to run flat upon the road, must be of a *conical* shape, the outer edge being of a less diameter than the inner one. Any bad effect arising from this is, indeed, very little felt from the narrow wheels; but as they increase in breadth, the evil increases in the same proportion. "A conical wheel," says Edgeworth, "if moved forwards by the axletree, must partly roll and partly slide on the ground, for the smaller circumference could not advance in one revolution as far as the larger. Suppose," says he, "the larger revolution sixteen feet, and the smaller thirteen feet, the outer part must slide three feet, while the carriage advances sixteen, *i. e.* it must slide nearly one fifth of the space through which the carriage advances, — thus, if loaded with ten tons, the horses would have two tons to drag, as if that part of the weight were placed on a sledge." The same thing has been ably and beautifully demonstrated by Cumming (*Essay on the Principles of Wheels and Wheel Carriages, &c.*), and is very easily illustrated: take, for instance, the *frustum* of a cone, or a sugar loaf from which you have broken off a little bit at the point; then set this a rolling upon a table, and instead of going straight forwards it will describe a circle; and if you will put a pin or axletree right through the centre of it, and upon that axle cause it to move straight forwards, the smaller diameter must slide instead of rolling. It is evident, therefore, that the rims of the wheels ought to be of a *cylindrical* form (*b*). Edgeworth states, in relation to this, that, from the testimony given to the committee of parliament, cylindrical wheels and straight axletrees have been unequivocally preferred by every person of science and judgment.

3733. *Farey* finds the Whitechapel road more injured by broad wheels than any other, owing to these wheels being barrelled and conical, and not running flat, and the middle tier projecting above the others, with rough nails.

3734. *Cumming* has proved experimentally before the committee of 1808, that when the rim of a wheel is made truly cylindrical, so as to have an equal bearing on its whole breadth, the resistance to its progress on a smooth road is not increased by increasing its breadth. With regard to the immense saving that would accrue to the nation, *Jessop*, in his report, says, "I may venture to assert, that by the exclusive adoption of cylindrical broad wheels and flat roads, there would be a saving of one horse in four, of seventy-five per cent. in repairs of roads, fifty per cent. in the wear of tire; and that the wheels with spokes alternately inclined would be equally strong with conical ones, and wear twice as long as wheels do now on the present roads." But, over and above the preference due to such wheels, in respect of public roads, they are no less preferable when applied to purposes of husbandry. Besides the great resistance to the draught occasioned by the sinking of the narrow wheels on soft land, every farmer knows what injury is frequently done to subsequent crops by such poaching and cutting up of the land. But this is not all. Many a field of beautiful pasture, when subjected to the destroying operation of the narrow wheels, is very much injured, both in respect of the appearance and of the crop, which would be entirely prevented by using broad wheels. Thus it has been stated, with regard to the introduction of the use of broad wheels, that the saving on the incidental repairs of the road would be immense; that the roads would uniformly retain a smooth and even surface, which would greatly contribute to the comfort of the traveller and the ease of the draught; that in husbandry also the advantages would be great; in short, that, in every point of view, the benefits which would be derived in consequence would be paramount to every thing that could be urged in favour of the narrow wheels.

3735. *M^r Adam* thinks a waggon wheel of six inches in breadth, if standing fairly on the road with any weight whatever, would do very little material injury to a road well made, and perfectly smooth. The injury done to roads is by these immense weights striking against materials; and, in the present mode of shaping the wheels, they drive the materials before them, instead of passing over them. If a carriage passes fairly over a smooth surface, he says, it cannot hurt the road, but must rather be an advantage to it, upon the principle of the roller. On being asked, "Are you not of opinion that the immense weights carried by the broad-wheeled waggons, even by their perpendicular pressure, do injury by crushing the materials?" he answered, "On a new-made road the crush would do mischief, but on a consolidated old road the mere perpendicular pressure does not do any. But there is a great deal of injury done by the conical form of the broad wheels, which operate like sledging instead of turning fairly. There is a sixteen-inch wheel waggon, which comes out of Bristol, that does more injury to our roads, than all the travelling of the day besides."

3736. *With regard to regulating the weight to be carried on wheels*, *Farey* judiciously observes, that though it is not easy to state any one scale which would be generally applicable for each breadth of wheels below six inches, there should be a rate fixed, which would apply to ordinary or gate tolls; and at the weighing machines additional or what may be called machine tolls should be levied upon all carriages which exceeded the weight, to be regulated in an increasing scale for each breadth of wheel, so as very greatly to discourage, but not ruinously to prohibit the occasional carrying of large weights upon any wheels.

3737. *Axletrees of different lengths* have been proposed by some engineers with a view to preserving the roads. On this subject *Paterson* observes, "At present the axles of all kinds of carriages are made to one length, so that their wheels all run at the same width, and in the same track, than which nothing could be more fitly devised for the destruction of the roads. I would, therefore, propose, that the length of the axletrees should be so varied, that the wheels of the lighter description of carriages should run two inches narrower than the present track; and that the axles for the more weighty carriages should be increased in length, so that their wheels should run from one to four inches beyond the present track. I would also propose, that mails, and other heavy coaches, should be so constructed, that the hind wheels should follow, either two inches within, or two inches outside, the track of the fore wheels, as might be considered most proper. Were the axletrees of all kinds of carriages to be of various lengths, as here proposed, we should have no rutted roads. The stones now displaced by the wheels of one carriage, would be replaced again by the next carriage that came up, having its axle of a different length; and in the same manner would the hind wheels repair the injury done by the fore wheels of a carriage. If this plan were to be acted upon all over the kingdom, it is evident that it would have a very beneficial effect on the roads; and if it should be found thus to contribute to keeping the roads smooth and even, it is also evident that it must contribute, in the same proportion, to the comfort of travellers of every description, and also to the ease of the beast of draught."

3738. *J. Farey* is of opinion that varying the length of axles, so as to prevent their running in the same track, would be very beneficial. This he particularly stated to the Board of Agriculture, with an example of the tolls over a new road in Derbyshire, which are regulated according to the length of the axle.

3739. *The division of weight* has been proposed by Fry as a means of preserving roads: that is to say, the division of the power, which any carriage may possess, to crush or destroy the materials of the roads; and the division of the power, which any carriage may possess, to resist the power of the horses drawing such carriage. "A man can break an ordinary stick, an inch in diameter, across his knee; but if he tied ten of these sticks together, he could not break them if he tried ten times, nor if he tried a thousand times; although, by these thousand efforts, he might have broken a thousand such sticks separately. A stone might be of such a size and texture that a strong man with a large hammer might break it into pieces at one blow; while a boy with a small hammer, striking it with one tenth part of the force, might strike it a thousand times, applying in the whole one hundred times the power upon it that the man would have done, without producing the same effect. So it is with the pressure of wheels on the materials of the roads. Suppose a stone, the size of a man's fist, to be detached on a firm part of the road, and a waggon-wheel, pressing with the weight of two tons, were to pass over it, the consequence would be that it would crush it to powder. But suppose these two tons to be distributed into forty wheelbarrows, of one hundred weight each, and they were to pass over over it succession, the only effect likely to be produced would be a trifling rounding of its corners; nor would probably five hundred such wheelbarrows, of twenty-five tons, crush the stone so completely as the single waggon-wheel. Nor do I think that five hundred gig or one-horse chaise wheels, of four hundred weight each, in all one hundred tons, would so completely destroy the cohesion of the stone, as the single crush of the heavy wheel. Conceiving, therefore, that the destructive effect of pressure on the roads increases, from the lowest weights to the highest, in a very rapidly increasing ratio, I think that all reasonable ingenuity should be exercised, so to construct our carriages, as for each wheel to press the road with the least possible weight that the public convenience will allow."

3740. *A great weight in one rolling mass* (*fig. 564.*), Fry continues, "has a tendency

564

to disturb the entire bed of the road, whether it be on a six-inch wheel or on one of sixteen inches, and whether on conical (*fig. 563. a*) or on cylindrical wheels (*fig. 563. b*). Under all these considerations, I am satisfied that the only grand desideratum, on behalf both of the roads and the horses, is light pressure; and therefore any dependence on breadth of wheels, as a security against the destructive effects of pressure, is in my opinion fallacious. I wish here to be understood as applying these remarks upon a supposition that wheels were made upon the most philosophical construction; that is to say, perfectly cylindrical (*fig. 563. b*); and that they stood perfectly upright or vertical. The present system of broad wheels I consider a system of mere mockery."

3741. *Fry proposes to attain his principle of the division of power* by the adoption of light one-horse waggons with six or eight wheels; which in our opinion are of very questionable advantage, all things considered, compared to one-horse carts, to carry one ton, and four-wheel waggons to carry four tons. "One-horse waggons," he says, "fully embrace the principle; and the labour of the horses would be much more efficiently applied than at present. If light one-horse waggons were constructed, to weigh eight hundred weight each, and these were charged with a load of sixteen hundred weight each, a good ordinary cart-horse would travel England over with such a load; drawing just as much net weight as the ten horses in a heavy waggon take each in gross weight; and the roads would never have a pressure, on one point, exceeding six hundred weight. The only objection to such carriages that I see is, that each must be attended by a man. [There is no reason for this; in Scotland one man always drives two single-horse carts.] But, were they adopted, roads would last, I will not say ten times as long, I think they would last a hundred times as long, as they now do. Carriages so constructed ought therefore to pass at the lowest possible rate of toll. The next mode is by the use of carriages with six or eight wheels. About twenty years ago there were several stage-coaches constructed in this manner. Two eight-wheel coaches plied some years between Bath and Bristol; and they were so constructed that each wheel supported its share of the load, carrying its proportion, and no more, over every obstruction: the consequence was, that when a wheel passed over a stone two inches high, the middle part of the carriage rising only an eighth part of two inches, or one quarter of an inch, they were perhaps the easiest coaches to passengers that ever were sat in. They had, however, one defect in their construction; which was, that the two hinder axles being fixed, whenever the coach varied from a straight line on the road, the hindermost pair of wheels must have been dragged sideways. How the six-wheel coaches were circumstanced in this respect, I had no opportunity of observing."

3742. *Double shafts* have been proposed by Edgeworth, Morton, and some others, as likely to divide the traction of draught cattle. B. Farcy considers single shafts in waggons very injurious; the horses follow in one track, in the centre of the carriage; and the wheels also follow each other in their tracks, and cut ruts. If there were double shafts, they would naturally avoid former wheel tracks, which would be less injurious to the road.

3743. *J. Farcy* concurs in opinion with his brother, and thinks that some abatement of tolls might be made to those carriages which now generally use single shafts, like the farmers' carts and waggons, on their adopting double shafts, so that all their horses may draw in pairs; this being applicable even to three-horse carts, as far as the two foremost are concerned. Stage-coaches, for the reasons here alluded to, as they all draw in pairs, and very seldom follow in any previous and deep rut, do far less damage to the roads than otherwise would happen; their springs also, and swiftness of motion, contributing, very materially, to lessening their wear of the road.

3744. *Roads are generally repaired by manual labour*; but various machines have been contrived for this purpose. The snow-plough is a well known implement, consisting simply of two boards placed on edge in the form of two sides of a triangle, and drawn by a hook attached to the apex. The common harrow, followed by the common roller, has been used for levelling roads broken up by ruts, and a studded roller has also been lately invented for this purpose.

565

3745. *Harriott's road harrow* (fig. 565.) has been used in some places, for dragging over roads when much out of repair, to replace the stones or gravel disturbed by wheel carriages. "A man, a boy, and two horses, will do three miles in length in one day; completely harrowing down the quarters, and drawing the stones together, which, by means of the mould-boards, are dropped into the ruts far better than a man can stub them in."

3746. *To prevent the formation of ruts in roads, and for use in lanes and unmetalled farm roads,*

566

Beaton suggests the idea of placing a roller between the other wheels (fig. 566.), and so strongly secured to the axle tree, as to be able to support the whole weight in the cart when necessary. This roller he proposes to call a protector, and he thinks it will be much more easily drawn than two wheels running in deep ruts. (*Com. to B. of Ag. vol. i. p. 154.*)

3747. *The cleaning of roads* is effected by scraping, sweeping, watering, and washing.

3748. *Scraping* is an operation universally necessary to keep roads clean, by the removal of mud in wet weather, dust in a very dry season, and snow in winter. It has been performed by machinery; and on a well made road,

this mode might be attended with a considerable saving of labour. Were the scraping board edged with a brush of wires, or even of birch spray, the work, even on a road somewhat irregular, might be done to great perfection. Both in scraping and sweeping, care should be taken as soon as possible to dispose of the mud or dust, either in making or keeping up the sides of the road or fence mounds, or in such other way as circumstances may direct. Hand scrapers are commonly made with iron plates; but a piece of board is considered less likely to raise the surface of the road.

567

3749. *The scraping machine* (fig. 567.) is the invention of John Boase, Esq., and consists of an oblong frame of iron, supported on three wheels, two of which are common carriage-wheels, about three feet in diameter, working on an axle fixed to the frame; the third is a small cast-iron one, placed under the centre of the front bar of the frame. Below the frame, and obliquely to it, is placed the flexible scraper,

consisting of a number of plates of sheet-iron, arranged in a line, and connected to each other by small bolts. On the back of each plate is bolted a piece of iron, in the shape of the letter T inverted: the stem of this iron is continued to the upper end of the plate, and then bent forward in a horizontal direction to a shaft (secured to the frame) parallel to the scraper, at the distance of about eighteen inches from it, to which it is joined. By this arrangement, when the machine is moved forward, the shaft draws after it the series of plates forming the scraper, which being attached to each other by joints, or bolts acting as such, each plate has sufficient freedom of action to adapt itself to the inequalities of the surface. Springs, equal in number to the plates, are fixed to the shaft, by which any degree of pressure required can be given to the scraper. As the machine proceeds, a portion of road, equal in width to the quadrilateral figure of which the scraper forms the diagonal, is cleared; and the mud or dirt, as fast as it collects, is slid off by the oblique surface of the scraper, and finally left in a line on the off-side of the machine. This process is commenced near the centre of the road; and the machine, having gone a convenient distance in a straight line, is turned and brought back on the other side of the centre, removing the dirt in an opposite direction. For the next course the machine is brought to the side where it first acted, and removes the dirt from a like portion of ground, and with it the line formed by the preceding course. This is continued until the scrapings are brought to the side of the road. The manager is enabled to lift the scraper, by turning a wooden roller fixed above it, and attached to each plate by a corresponding chain. This is done in order to pass over parts of roads recently repaired; and, when going to work or returning, the plates are kept in this elevated position by a ratchet and catch at the end of the roller. A curved scraper is attached to the back part of the frame at the off-corner, to be used only during the last course of the machine, for the purpose of collecting the scrapings into heaps ready for removal. This machine, drawn by two horses, and attended by one man, will clean five miles of road, twenty-four feet wide, in eight hours. Two additional men will be required to throw the scrapings off the road, and clear the water-courses. The same work would require twenty-five men *per diem*, with scrapers, according to the present method. (*Gard. Mag.* vol. v.)

3750. *Sweeping*, as a mode of cleaning roads, is chiefly applicable to pavements, to side railways, whether of stone or iron, and to footpaths. On country roads, sweeping might be required to keep the paved or rail-laid parts, where such existed, free from small stones or gravel, which the feet of cattle, &c. might scatter over it from the metallated part.

3751. *The sweeping machine* (fig. 568.), also the invention of Mr. Boase, has a frame similar to that of the scraper, supported in front by two common wheels about four feet in diameter, and behind by two

small iron wheels with vertical axles, one under each corner. Within the frame, and diagonal to it, is the cylinder of brooms, consisting of five rows of heath, each row secured between two boards by screws, and attached to an axle by radiating arms of cast-iron. This receives a rotatory motion from the carriage wheels, by means of a bevelled tooth wheel fixed on their axletree, working in another half its size on the axle of the brooms. When the machine is drawn forward, the brooms are thus made to revolve twice to each revolution of the carriage wheels, and in an opposite direction to them. The brooms are regulated so as to bear more or less on the ground, according to the state of the dirt; and, as the heath wears shorter, they can readily be drawn out from the centre, in order to preserve a proper bearing. The dirt is removed from the space over which the brooms pass to the right or off-side of the machine. Like the scraper, the work is commenced near the centre of the road or street, and carried on in a similar manner. When this machine is wanted to proceed without sweeping, the larger bevelled tooth wheel is drawn out of gear by a lever for that purpose. The brooms are covered and the frame enclosed by oil-cloth, to prevent any splashing or dirt from escaping beyond the machine. This machine, with the same power and attendants as the scraping machine, is capable of cleaning three miles, twenty feet wide, daily. (*Gard. Mag.* vol. v.)

3752. *Watering*, where applied to roads, is more for the sake of laying the dust than of cleaning or preserving them. Some consider it injurious. B. Farey considers that watering the Whitechapel-road in summer, and especially before May and after August, is very injurious, by separating the stones, owing to the softening of the loam, and so making the road spongy and loose. In winter, however, he waters, and for the following reasons: — "After the most careful sifting of the gravel, a small quantity of loamy dirt will unavoidably still adhere to the stones; and this loam, together with a glutinous matter which accumulates in the summer from the dung and urine of the cattle (which accumulation the summer watering has a tendency to increase), occasions the wheels to stick to the materials, in certain states of the road, in spring and autumn, when it

is between wet and dry, particularly in heavy foggy weather, and after a frost; by which sticking of the wheels, the Whitechapel-road is often, in a short time, dreadfully torn and loosened up; and it is for remedying this evil that I have, for more than eight years past, occasionally watered the road in winter. As soon as the sticking and tearing up of the materials is observed to have commenced, several water-carts are employed upon these parts of the road, to wet the loamy and glutinous matters so much, that they will no longer adhere to the tire of the wheels, and to allow the wheels and feet of the horses force down and again fasten the gravel-stones: the traffic, in the course of four to twenty-four hours after watering, forms such a sludge on the surface, as can be easily raked off by wooden scrapers, which is performed as quickly as possible; after which the road is hard and smooth. The advantages of this practice of occasional winter watering have been great; and it might, I am of opinion, be adopted with like advantages on the other entrances into London, or wherever else the traffic is great, and the gravel-stones are at times observed to be torn up by the sticking of the wheels.

3753. *One of the best constructed watering barrels (fig. 569.) is that used on the Uxbridge-road, in which the water is delivered with the greatest regularity from a cast-*

iron trough (a), so as to cover a space of nine feet in width. The water is turned off and on by a lever at the fore-end of the barrel (b) in the usual manner.

3754. *Washing or flooding roads, with a view to cleaning them, has been proposed by Jessop and some other engineers; but it is evidently a mode that can only be adopted in particular situations, and the advantages which it would have over clean scraping does not appear.*

3755. *Rolling, as a mode of preserving roads, is recommended by various writers on the subject; and appears to be useful on some roads after being loosened by frost. In general, however, it is chiefly applicable after repairs, such as filling in ruts or laying on a coat of new materials. Rolling has also been employed to consolidate snow on roads: it is said to indurate the snow so much, that it becomes a smooth hard body on which the wheels of carriages make but little impression, and the materials of the road are preserved. When a thaw happens, the whole of the snow is scraped off by snow-ploughs or scrapers, and not being allowed to melt on the metals, they are said to remain unloosened. This plan is said to be general in America, and appears to have been tried, in one instance, in the north of Scotland, with success.*

3756. *A road roller should be of large diameter, perhaps not less than five feet: to facilitate its turning, it may be made in three lengths; and the only material is cast iron, with a large wooden box over.*

3757. *Biddle's machine for repairing roads (fig. 570.) consists of three cylindrical rollers, mounted upon axles, in a frame, to be drawn by one or more horses. The rollers are placed obliquely, side by side, but running in parallel positions; their axes receding a little behind each other: these rollers are intended to pass over the surface of the road, for the purpose of pressing the broken stones, gravel, and other materials, close together, so as to produce a solid or compact road with a smooth surface. In the front of the rollers a long scraper is placed, crossing the frame obliquely, for the purpose of collecting up and conducting away the mud, and the slush, to the side of the road; and at the back part of the apparatus, there is a perforated cylinder, intended to take up the softer, or muddy parts of the road, and deposit*

it in a swinging box within. *Fig. 570.* is a view of the machine, or apparatus, as seen on the top; *a a a*

are the three cylinders for pressing the loose stones of the road together. As the apparatus is drawn along, these cylinders revolve upon their axles, which are mounted in the frame *b b b*. There is a small guide roller, or wheel in front of the frame to which the shafts are attached, and by which the apparatus may be turned round, or guided in a curved course; *d d* is a thin plate of iron placed obliquely across the machine, in front of the rollers; it is attached to the framing by rods and

screws, and is thereby made adjustable to any height, so as to scrape the surface of the road evenly. The foremost end of the scraper is curved, for the purpose of preventing the escape of the mud, which, being collected as the machine advances, runs along the inclined surface of the scraper, and is conducted to the side of the road. Thus the mud is proposed to be scraped off the surface as the apparatus advances, and the materials of the road compressed and hardened by the traversing of the rollers. It may be added, that in order to increase the pressure of the rollers, a box, to be affixed to the framework, is proposed to be placed over the rollers, which may carry stones, or other heavy materials, that might be used in making or repairing of the road. Under some circumstances, the patentee proposes to adapt to the apparatus the auxiliary cylinder *c*, which is made to revolve upon its axle as it rolls along the road, and is attached to the former by a frame *f f*: this cylinder (*c*) is perforated all over its surface with holes, or slots; and when it passes along the road, the mud, which is conducted to it by the scraper *g g*, presses through these holes, or slots, to the interior. *Fig. 571.* is a side view of this cylindrical roller (*c*) attached to the frame *f f*: within this cylindrical roller the box *h* is suspended, swinging upon pivots; and as the roller goes round, the brush *i* removes the mud from the cylinder, and causes it to fall into the box below. When the box is filled with mud, it may be discharged through the door *k*. (*Newton's Journal*, vol. xiii. p. 27.)

3758. *Marshal*, on the subject of repairing roads, observes, that the best service of the surveyor is to keep their surfaces smooth and even, so that rain-water may find a free and ready passage to its proper drain. Ruts and hollow parts are to be filled up, level or even with the general surface, as often as they are formed. This attention is more especially requisite to a new-made road, whose bed and foundation are not yet fully confirmed. But in every case, and at all times, a solicitous regard is due to this most important, yet most neglected, part of road-surveying. Much expense of materials and labour may thereby be saved, and the great end of road-making be fully obtained; namely, that of rendering the road, in all seasons, easy, safe, and pleasant to the traveller.

3759. *To keep a road in repair*, Edgeworth observes, it will for some time require the attention of the maker: ruts will be continually formed in the loose materials; these must be sedulously filled up, and a small sprinkling of river gravel should be added. All stones larger than the rest should be removed and broken smaller, and no pains should be spared to render the whole as compact and smooth as possible. At a moderate distance from the capital, if no wheels of a smaller breadth than six inches, and if no greater load than one ton on each wheel, be permitted to pass on it, a road will last a long time, and may be kept in constant repair at a moderate yearly expense.

3760. *The repair of a road* which has been well made, or after it has been put into a good state of repair, Paterson observes, requires attention more than expense. "No more metals ought to be used for the incidental repair of that road ever afterwards, than are just equivalent to the decay of the road. And in order that the decay of the old, and of course the supply of new, metals may be as little as possible, it is of the greatest consequence that the road never be allowed to get rutted; for, besides the unpleasantness of such a road to the traveller, it is a fact not generally thought upon, that the lateral rubbing of the wheels into the ruts will wear and grind down more than double the metals that would be destroyed on a smooth road, where the only friction of the wheels is that of rolling over the metals. Besides, when a road is much rutted, it not only retains the water, and consumes a greater quantity of metals (as has been noticed); but the rubbing and jolting of the wheels into the ruts wears down the iron of the wheels, fatigues the beast of draught, and also wears harness, &c., much sooner than when the road is smooth. All these, and much more, are the bad effects of a rutted road. Having premised thus much, I shall next advert to the method to be adopted in order to keep the road free from ruts, at as little expense and labour, and with as few metals, as possible."

3761. *In order to prevent any road from getting rutted*, it is indispensable that it be kept free from water by under-drainage. No road, Paterson continues, "that has any tendency to rut, should be, for many days together, from under the eye of one who has a general charge, and who is ready to withdraw a workman to this or that part, as need may require."

3762. *So soon as newly put on metals begin to shift by the wheels*, or form into ruts, they should be immediately replaced, every little ridge broken down, and every rut, hole, or inequality, filled up; and the road kept in proper shape until the metals become bound and consolidated together. When the road is attended to in this manner, it has the effect, too, of subjecting the whole of the metals to an equal fatigue. Every time that a little new metal is put on to fill up any hollow parts of the road, those parts being then, from the new metals, a little rougher than the rest of the road, the horses naturally avoid travelling on them for a while at first, until they have become a little smoother, or until the other parts begin to get rutted. This shifting upon the road wears down the metals equally, and prevents those regular tracks of the horse and of the wheels which would otherwise be the consequence. By adopting this method, it will be found that less labour and fewer metals will be required in the course of the year, and the road will always be in good order. But, on the other hand, to allow the road to get rutted, and then to fill these ruts with new metals every time they get into this state, as is frequently done, raises the track of the wheels, leaving hollow the track of the horse, and so gives the road a concave, instead of a convex, shape in the middle: this retains the water, and injures the road very much. The same thing occurs again, and the same process is repeated; and in this way the most extravagant quantity of metals may be put on, and yet the road never be in good order."

3763. *For the repair of an old road*, the following directions are given by M^r Adam, in his *Report of the Committee, &c. of 1811*, corrected however to 1819:—

3764. "No addition of materials is to be brought upon a road, unless in any part it be found that there is not a quantity of clean stone equal to ten inches in thickness."

3765. *The stone already on the road is to be loosened up and broken*, so as no piece shall exceed six inches in weight. The road is then to be laid as flat as possible; a rise of three inches from the centre to the side is sufficient for a road thirty feet wide. The stones, when loosened in the road, are to be gathered off by means of a strong heavy rake, with teeth two and a half inches in length, to the side of the road, and there broken; and on no account are stones to be broken on the road.

3766. *When the great stones have been removed*, and none left in the road exceeding six ounces, the road is to be put in shape, and a rake employed to smooth the surface, which will at the same time bring to the surface the remaining stone, and will allow the dirt to go down.

3767. *When the road is so prepared*, the stone that has been broken by the side of the road is then to be carefully spread on it: this is rather a nice operation, and the future quality of the road will greatly depend on the manner in which it is performed. The stone must not be laid on in shovelfuls, but scattered over the surface, one shovelful following another, and spreading over a considerable space.

3768. *Only a small space of road should be lifted at once*; five men in a gang should be set to lift it all across; two men should continue to pick up and rake off the large stones, and to form the road for receiving the broken stone; the other three should break stones; the broken stone to be laid on as soon as the piece of road is prepared to receive it, and another piece to be broken up; two or three yards at one lift are enough. The proportioning of the work among the five men must of course be regulated by the nature of the road; when there are many very large stones, the three breakers may not be able to keep pace with the two men employed in lifting and forming, and when there are few large stones the contrary may be the case; of all this the surveyor must judge and direct. But to lift and relay a road, even if the materials should have been originally too large, would in many cases be highly unprofitable. The road between Cirencester and Bath is made of stone too large in size, but it is of so friable a nature that in lifting it becomes sand; in this case I recommended cutting down the high places, keeping the surface smooth, and gradually wearing out the materials now in the road, and then replacing them with some stone of a better quality properly prepared. A part of the road in the Bath district is in like manner made of freestone, which it would be unprofitable to lift.

3769. *At Egham in Surrey* it was necessary to remove the whole road, to separate the small portion of valuable materials from the mass of soft matter of which it was principally composed, which was removed at considerable expense, before a road could be again made upon the site.

3770. *Other cases of several kinds have occurred*, where a different method must be adopted, but which it is impossible to specify, and which must be met by the practical skill of the officer whose duty it may be to superintend the repair of a road, and who must constantly recur to general principles. These principles are uniform, however much circumstances may differ, and they must form the guide by which his judgment must be always directed. When additional stone is wanted on a road that has consolidated by use, the old hardened surface of the road is to be loosened with a pick, in order to make the fresh materials unite with the old.

3771. *Ruts*. Carriages, whatever be the construction of their wheels, will make ruts in a new-made road until it consolidates, however well the materials may be prepared, or however judiciously applied; therefore a careful person must attend for some time after the road is opened for use, to rake in the tracks made by wheels.

3772. *The tools to be used are*, strong picks, but short from the handle to the point, for lifting the road; small hammers of about one pound weight in the head, the face the size of a new shilling, well steeld, with a short handle; rakes with wooden heads, ten inches in length, and iron teeth about two inches and a half in length, very strong, for raking out the large stones where the road is broken up, and for keeping the road smooth after being relaid, and while it is consolidating; very light broad-mouthed shovels, to spread the broken stone and to form the road.

3773. *Every road is to be made of broken stone, without mixture of earth, clay, chalk, or any other matter* that will imbibe water and be affected with frost: nothing is to be laid on the clean stone on pretence of binding; broken stone will combine by its acute angles into a smooth solid surface that cannot be affected by vicissitudes of weather, or displaced by the action of wheels, which will pass over it without a jolt, and consequently without injury."

3774. *Telford's directions for repairing roads* differ little from his instructions for forming roads, already quoted.

3775. *Where a road has no solid and dry foundation*, he breaks it up, lays bare the soil, drains it, and bottoms with soft stones or cinders,—the former set by hand with the broadest end down, in the form of a neat pavement (*fig. 572.*); over this foundation he, as usual, lays on six inches of stones broken so as to pass through a ring two inches and a half in diameter, &c.

572

sufficient to give it a proper shape, and to make it solid and hard.

3777. *Where a road already has a good foundation*, and also a good shape, no materials should be laid upon it, but for the purpose of filling ruts and hollow places, in thin layers, as soon as they appear. Stones

3776. *Where a road has some foundation*, but an imperfect one, or is hollow in the middle, all the large stones appearing on the surface of it must be raised and broken; the eighteen centre feet of it must be so treated, and then covered with a coating of broken stones, suf-

broken small, as above described, being angular, will fasten together. In this way a road, when once well made may be preserved in constant repair at a small expense.

3778. *Partial metalling.* Where the breadth of that part of a road, which alone has been formed of hard materials, and over which the carriages commonly pass, is less than eighteen feet, it must be widened with layers of broken stones to that breadth, first digging away the earth, and forming a bed for them with pavement and broken stones at least ten inches deep. Near large towns the whole breadth of the roadway should be covered with broken stones.

3779. *All labour by day wages* ought, as far as possible, to be discontinued in repairing roads. The surveyors should make out specifications of the work of every kind that is to be performed in a given time. This should be let to contractors; and the surveyors should take care to see it completed according to the specifications, before it is paid for. Attention to this rule is most essential, as in many cases not less than two thirds of the money usually expended in day labour is wasted.

3780. *The best seasons for repairing roads* are generally considered to be autumn and spring, when the weather is moist rather than otherwise.

3781. *B. Farey prefers laying on gravel when the road is in a moist state*, immediately after the road has had a scraping, in consequence of there being upon the surface of the road a small quantity of dirty matter and broken gravel, which then form a sort of cement for the gravel to fix in.

3782. *Walker considers the best season for repairing roads* to be the spring or very early in the summer, when the weather is likely neither to be very wet nor dry; for both of these extremes prevent the materials from consolidating, and therefore cause waste, and at the same time either a heavy or a dusty road: but if done at the time he has recommended, the roads are left in good state for the summer, and become consolidated and hard to resist the work of the ensuing winter.

3783. *The seasons for repairing preferred by Paterson* are also spring and autumn. "Although it is proper," he says, "at all times of the year, to put on a little metals whenever any hole makes its appearance, yet in the drought of summer this will seldom be necessary. In summer, the roads are less liable to cut; but if, at some places, a little fresh metals may be necessary, no more should be put on than are barely sufficient to bring those holes to the level of the rest of the road. Metals that are put on in the drought of summer do not soon bind together. Until such time as there is rain sufficient to cause them to bind, they will keep shifting and rolling about, and make a very unpleasant road to travel on. The most proper times of the year to put on any quantity of metals are about the months of October and April, as they always bind best when the road is neither too wet nor too dry. When they are put on about the month of October, they become firm before winter; and with a little constant attention, the road will be easily kept in good order until the spring: and if it has been the case that the road has not been sufficiently attended to during the winter, and that it has got into a bad state towards the spring, by putting on fresh metals about the month of April, sufficient to bring it into smooth surface order, it will be very easily kept in this good state throughout the summer."

3784. *M'Adam*, on being asked, "Would you prefer repairing old roads in dry weather or in wet weather?" answers: "In wet weather always; I always prefer mending a road in weather not very dry."

SECT. VII. Railroads.

3785. *Railways or tramroads* are not intended to be considered here as connected with mines, canals, or other works which come directly under the province of the higher branches of engineering; but merely as substitutes for the whole or a part of the metallated surface of common roads. The necessity of an expeditious and cheap mode of conveying coals from the pits to the ships had, as early as the year 1676, introduced the use of wooden railways for the waggons to move upon between the Tyne river and some of the principal pits; and these by degrees became extended to a great number of other coal-works. They were first solely employed for transporting coals to a moderate distance from the pits, to the places where they could be shipped, being universally made of wood. By degrees they were, however, carried to a farther extent; and the scarcity of wood, and the expense of their repairs, suggested the idea of employing iron for the purposes of improving these roads. At the first, flat roads of bar iron were nailed upon the original wooden rails, or, as they were technically called, *sleepers*; and this, though an expensive process, was found to be a great improvement. But the wood on which these rested being liable to rot and give way, some imperfect attempts were made to make them of cast iron; but these were found to be liable to many objections, until the business was taken in hand by Ontram, an engineer at Butterly Hall, Derbyshire, who contrived, at the same time, so far to diminish the expense, and improve the strength of the road, as to bring them to a degree of perfection that no one who has not seen them can easily conceive could have been done. This having been carried into execution in a few cases, and found to answer, has been improved upon and simplified by practice, till it is now brought to such a state of perfection as to have given proofs that it admits of being carried much beyond the limits of what was for many years conceived to be possible, and to afford demonstrative evidence that it may be in future employed to a wider extent still, to which no limits can be at present assigned or foreseen.

3786. *Railways are of three kinds*; flat, edged, and suspension railways. The flat railway is composed of pieces of timber, four or five inches square, called rails; or of pieces of cast iron, of about four inches in breadth, and one or more inches in thickness, according to the weight they are to carry. The edge rail is formed of pieces of cast or wrought iron (the latter is now generally preferred), with a ledge or flanch rising at right angles in the inner side of the rail. The flat rails are generally laid on pieces of timber called sleepers, and the edge rails on solid blocks of stone, from nine to twelve inches in thickness. The suspension rail consists of a line of vertical edge, elevated on posts; across this line the load is placed, like the panniers on the back of a horse, by a suitable contrivance for diminishing friction, and adjusting the weight so as it may be

equally balanced on both sides. As we have before observed, this subject belongs more properly to engineering than to agriculture, and therefore we shall confine ourselves to railroads, as substitutes for, or as connected with, common country roads. (*Trans. Highl. Soc.* vol. vi.)

3787. In countries, the surfaces of which are rugged, or where it is difficult to obtain water for lockage, where the weight of the articles of the produce is great in comparison with their bulk, and where they are mostly to be conveyed from a higher to a lower level—in these cases, Telford observes, iron railways are, in general, preferable to canal navigation.

3788. On a railway well constructed, and laid with a declivity of fifty-five feet in a mile, it is supposed that one horse will readily take down waggons containing from twelve to fifteen tons, and bring back the same waggons with four tons in them. This declivity, therefore, suits well, when the imports are only one fourth part of what is to be exported. If the empty waggons only are to be brought back, the declivity may be made greater; or an additional horse applied on the returning journey will balance the increase of declivity. If the length of the railway were to be considered, it may, it is supposed, without much inconvenience, be varied from being level to a declivity of one inch in a yard; and by dividing the whole distance into separate stages, and providing the number of horses suitable for each portion of railway, according to the distance and degree of declivity, the whole operation may be carried on with regularity and despatch.

3789. Railways may be laid out so as to suit the surface of very irregular countries, at a comparatively moderate expense. A railway may be constructed in a much more expeditious manner than a navigable canal; it may be introduced into many districts where canals are wholly inapplicable; and in case of any change in the working of mines, pits, or manufactories, the rails may be taken up, and laid down again in new situations, at no very great expense or trouble.

3790. The whole load to be drawn by one horse upon railways was at first put into one waggon; but now, when the load is so much augmented, it has been found eligible to divide it into many parts, so that no one waggon shall carry more than one or two tons; by this method the weight is so divided, that the pressure is never so great upon one

573

point as to be in danger of too much crushing the road; the carriages can be made much more limber and light in all their parts (*fig. 573.*), and they are much more easily moved, and more manageable in all respects, than they otherwise would have been. And another advantage of this arrangement, which deserves to be particularly adverted to, is, that it admits

of shifting the carriages, so as to leave a load, as it were, in parcels at different places where they may be required, without trouble or expense. This, when it comes to be fully understood and carried into practice, will be a convenience of inestimable value; a thing that has been always wanted, and never yet has been found, though it has been diligently sought for.

3791. Of the advantage of railways a striking proof is given by Anderson (*Recreations, &c.*), in the case of one formed by Wilkes near Loughborough. Its extent was about five miles, and it led from a coal-mine to a market. He found it so fully to answer his expectations after it was finished, that he communicated to the Society of Arts an account of some trials he had made of it, requesting that such of the members of that respectable institution as were desirous of information on that head would do him the honour to witness some experiments that he wished to make upon it for the information of the public. A committee of the members was accordingly deputed for that purpose, and before them he showed that a moderate-sized horse, of about twenty pounds value, could draw upon it with ease down hill (the descent being one foot in a hundred) thirty-two tons, and without much difficulty forty-three, and seven tons up hill, independent of the carriages. The doctor concludes from these facts, that upon a perfect level a horse could draw with ease from ten to twenty tons. It is observed that Wilkes's railway, on which the experiments were made, was, from local circumstances, laid upon wooden sleepers, and is not so perfect as those done upon stone. But, it is added, that twenty tons constitute the load which such a horse could draw with ease, travelling at the usual waggon rate, in boats upon a canal; so that the number of horses required in this way will not be much, if at all, greater than on a canal. Certain advantages attach to this mode of conveyance, which do not so well apply to a canal, and *vice versa*; but it is not his intention to draw a parallel between these two modes of conveyance. Nobody can entertain any doubt, he thinks, about the utility of canals where they are easily practicable. He only wishes to point out this as an eligible mode of conveyance, where canals cannot be conveniently adopted.

3792. *In forming and constructing railways*, the best line the country affords should be traced out, having regard to the direction of the carriage of articles, or trade to be expected; and if such trade be both ways in nearly equal quantities, a line as nearly horizontally level as possible should be chosen. If the trade is all in one direction, as is generally the case between mines and navigation, then the most desirable line is one with a gentle gradual descent, such as shall make it not greater labour for the horses employed to draw the loaded waggons down, than the empty ones back; and this will be found to be the case on a railway descending about one foot vertical in one hundred feet horizontal: or, if the railway and carriages are of the very best construction, the descent vertical may be to the length horizontal as 1 to 50, where there is little or no upgate loading. In cases between mines and navigations, the descents will often be found greater than could be wished. On a railway on the improved plan, where the descent is more than as 1 to 50, six or eight waggons, loaded with thirty or forty hundred weight each, will have such a tendency to run downwards, as would require great labour of one horse to check and regulate, unless that tendency were checked by sledging some of the wheels. On such, and steeper roads, iron slippers are applied, one or more to a gang of waggons, as occasion may require. Each slipper being chained to the side of one of the waggons, and, being put under the wheel, forms a sledge. Where the descent is very great, steep inclined planes, with machinery, may be adopted so as to render the other parts of the railway easy. On such inclined planes the descending loaded waggons being applied to raise the ascending empty, or partly loaded ones, the necessity of sledging the wheels is avoided, and the labour of the horse greatly reduced and lessened. (*Fulton.*)

3793. *In order to obtain the desired levels*, gentle descents, or steep inclined planes, and to avoid sharp turns and circuitous tracks, it will often be found prudent to cross valleys by bridges and embankments, and to cut through ridges of land; and, in very rugged countries, short tunnels may sometimes be necessary. The line of railway being fixed, and the plans and sections by which the same is to be executed being settled, the ground for the whole must be formed and effectually drained. The breadth of the bed for a single railway should be, in general, four yards; and for a double one six yards, exclusive of the fences, side drains, and ramparts.

3794. *The bed of road being thus formed* to the proper inclination, and the embankments and works thereof made firm, the surface must be covered with a bed of stones broken small, or good gravel, six inches in thickness or depth. On this bed must be laid the sleepers, or blocks, to fasten the rails upon. These should be of stone, in all places where it can be obtained in blocks of sufficient size. They should be not less than eight, nor more than twelve, inches in thickness; and of such breadth (circular, square, or triangular) as shall make them 150 lbs. or 200 lbs. weight each. Their shape is not material, so as they have a flat bottom to rest upon, and a small portion of their upper surface level, to form a firm bed for the end of the rails. In the centre of each block should be drilled a hole, an inch and a half in diameter, and six inches in depth, to receive an octagonal plug of dry oak five inches in length: for it should not reach the bottom of the hole; nor should it be larger than so as to put in easily, and without much driving; for if too tight fitted, it might, when wet, burst the stone. These plugs are each to receive an iron spike, or large nail, with a flat point and long head, adapted to fit the counter-sunk notches in the ends of two rails, and thereby to fasten them down in the proper position or situation in which they are to lie.

3795. *With regard to the rails*, they should be of the stoutest cast-iron, one yard in length each, formed with a flanch on the inner edge, about two inches and a half high at the ends, and three and a half in the centre; and shaped in the best manner to give strength to the rails, and keep the wheels in their track. The soles of the rails, for general purposes, should not, he thinks, be less than four inches broad; and the thickness proportioned to the work they are intended for. On railways for heavy burthens, great use, and long duration, the rails should be very stout, weighing 40 lbs., or in some cases nearly half a hundred weight, each. For railways of less consequence, less weight of metal will do; but it will not be prudent to use them of less than 30 lbs. weight each, in any situation exposed to breakage above ground. But it is observed that in mines, and other works under ground, where very small carriages only can be employed, very light rails are used, forming what are called tramroads, on a system introduced by Carr; and these kinds of light railways have been much used above ground in Shropshire, and other counties where coals and other minerals are obtained.

3796. *In fixing the blocks and rails*, great attention is required to make them firm. No earth or soft materials should be used between the blocks and the bed of small stones or gravel, on which the rails must all be fixed by an iron gauge, to keep the sides at a regular distance, or parallel to each other. The best width of road, for general purposes, is four feet two inches between the flanches of the rails; the wheels of the carriages running in tracks about four feet six inches asunder. Rails of particular forms are necessary, where roads branch out from or intersect each other, and where

carriage roads cross the railways; and, at turnings of the railways, great care is required to make them perfectly easy. The rails of the side forming the inner part of the curve should be fixed a little lower than the other; and the rails should be set a little under the gauge, so as to bring the sides nearer together than in the straight parts: these deviations in level and width to be in proportion to the sharpness of the curve. The blocks and rails being fixed and spiked fast, nothing more remains to be done than to fill the horse-path, or space between the blocks, with good gravel, or other proper materials; a little of which must also be put on the outside of the blocks, to keep them in their proper places. This gravel should always be kept below the surface of the rails on which the wheels are to run, to keep the tracks of the wheels free from dirt and obstructions. The form of the rails must be such as will free them from dirt if the gravelling is kept below their level.

3797. *The formation of edge railways, on the middle or sides of public roads, has been recommended by Dr. Anderson, Fulton, Edgeworth, Middleton, Stevenson, Mathews, Baird, and others.* A flat railway, with the rail ten or twelve inches broad, we conceive, might be laid down along the sides of a road with advantage. It would require a rib below of sufficient strength to bear waggons of any weight. This strength would be communicated partly by the mass of material, but chiefly by the rib (*fig. 574. a, a*), resting on a bed of bricks or masonry below (*b*). Such a railroad might be used by any description of carriage,

574

light or heavy. But the best description of railroad for the sides of a highway is probably some of those formed of blocks of stone, already described. Stone railways of this sort appear to have been suggested by Le Large (*Machines Approuvées*, vol. iii.) in France; and afterwards by Mathews (*Committee Examinations*, May 1808.) in England, but they have never been fairly tried. The best specimen we have seen is in a street in Milan, where it is not so necessary, the whole breadth being very well paved.

CHAP. V.

Formation of Canals.

3798. *Though the subject of canals is not included in that of agriculture, yet it is so intimately connected with territorial improvement, that it would be improper in a work of this description to pass it over.* Canals of any extent are never the work of an individual; they are always formed by public bodies, constituted and empowered by public acts: but it is of importance to individuals to know the sort of effect which a canal passing through their property may have, both on its appearance and value; not merely as a medium of conveyance, but as a source of population, of water for irrigation or mills, or the use of stock, and even as an object of ornament. For this purpose we shall submit some remarks on the utility of canals, the choice of lines, the powers granted to canal companies, and the mode of execution.

SECT. I. Utility and Rise of Navigable Canals.

3799. *Good roads, canals, and navigable rivers, Dr. Smith observes (Wealth of Nations, i. 229.), by diminishing the expense of carriage, put the remote parts of the country more nearly upon a level with those in the neighbourhood of large towns; and on that account they are the greatest of all improvements.* They encourage the cultivation of the remote parts, which must always be the most extensive circle of the country. They are advantageous to towns, by breaking down the monopoly of the country in its neighbourhood; and they are advantageous to all parts of the country, for though they introduce some rival commodities into the old markets, they open many new markets to its produce. "All canals," says an intelligent writer on this subject (See *Phillips's General History of Inland Navigation*, Introd.), "may be considered as so many roads of a certain kind, on which one horse will draw as much as thirty horses on ordinary turnpike roads, or on which one man alone will transport as many goods as three men and eighteen horses usually do on common roads. The public would be great gainers were they to lay out upon the making of every mile of a canal twenty times as much as they expend upon a mile of turnpike road; but a mile of canal is often made at a less expense than

the mile of turnpike; consequently there is a great inducement to multiply the number of canals."

3800. *General arguments in favour of canals* are superseded by the rapidly improving and thriving state of the several cities, towns, and villages, and of the agriculture also, near to most of the canals of the kingdom; the immense number of mines of coal, iron, limestone, &c., and great works of every kind, to which they have been conducted, and to which a large portion of them owe their rise, are their best recommendation. In short, it may be concluded, that no canal can be completed and brought into use, but the inhabitants and the agriculture of the district will shortly feel great benefit from it, whatever may be the result to the proprietors.

3801. *The great advantages of canals as means of transport* result from the weight which may be moved along by a small power. The velocity with which boats can be drawn along a canal is confined within very narrow limits, owing, as Edgeworth has observed, to the nature of the resistance to which they are exposed; this resistance increasing in a geometrical proportion, as the squares of the velocity with which the moving body is impelled: whereas, on roads or railways, an increase of velocity requires only an arithmetical increase of power. Or, in other words, to draw a boat with ten times a given velocity, would require a hundred times as much power as was requisite to draw it with that given velocity; whereas, to draw a carriage on a road or railway with ten times a given velocity, would require only ten times the given power. For this reason, however advantageous canals may have been found, for transporting heavy loads, they will be found upon trial inferior to roads in promoting expedition.

3802. *Canals appear to have been first made in Egypt.* Though less attended to by the Romans than roads, yet they formed some in this country near Lincoln and Peterborough.

3803. *China is remarkable for its canals*, and there are said to be many in Hindostan, though we believe they are principally for the purpose of irrigation. In Russia there are some, and several in Sweden; one or two in Denmark; some in Germany; and a great many in Holland. The canal of Burgundy in France was commenced under Henry IV.; and that of Languedoc finished by Riquet, the Brindley of France, under Louis XIV. Some attempts have been made to form canals in the hilly country of Spain; and a great many excellent ones are executed in Aincira.

3804. *Navigable canals in Britain* took their rise between 1755 and 1760, by the Sankey Brook Company in Lancashire; but the great impulse was given by the duke of Bridgewater about 1757, when he first commenced, under the direction of Brindley, the canal between his coal-works at Worsley and Salford. The duke of Bridgewater has, in consequence, not improperly been called the father of canals in England; while his engineer, Brindley, by his masterly performances on the duke of Bridgewater's canal, altered and extended as the scheme thereof was by the three subsequent acts of parliament, has secured to himself, and will, it should seem, (from a comparison of the great features and minutiae of execution in this the first canal, with most others in this country, even of the latest construction,) long continue to hold that rank among the English engineers, to which Riquet seems entitled among foreigners.

3805. *Since the duke of Bridgewater's time*, the extension of canals in the British Isles has been rapid. A number of scientific engineers have arisen, of whom we need only mention Smeaton, Reunin, and Telford, and point to the Caledonian canal.

SECT. II. *Of discovering the most eligible Route for a Line of Canal.*

3806. *The first object, when the idea of a canal is determined on* by a few landed proprietors, is the choice of a skilful and experienced engineer. Such an artist should undoubtedly possess a considerable degree of mathematical knowledge. Calculations, of which some are of the most abstruse and laborious kind, will frequently occur; and he should, therefore, be well acquainted with the principles on which all calculations are founded, and by which they are to be rightly applied in practice. An engineer should also have studied the elements of most or all of the sciences immediately connected with his profession; and he should particularly excel in an acquaintance with the various branches of mechanics, both theoretical and practical. His knowledge should comprehend whatever has been written or done by other engineers; and he should have information in every department of his business, from an accurate examination of the most considerable works that have been executed, under all the various circumstances that are likely to occur. It is necessary that he should be a ready and correct, if not a finished, draughtsman. He should also be conversant with the general principles of trade and commerce; with the various operations and improvements in agriculture; with the interests and connection of the different owners and occupiers of land, houses, mills, &c.; and with all the general laws and decisions of courts pertaining to the objects connected with his profession. By an extensive acquaintance with the disposition, inclination, and thickness of the various strata which compose the soil or land of the British Islands, he will be able to avoid many errors incident to those who are destitute of this knowledge. As the last, though not the least, of these qualifications of an engineer, which we shall enumerate, he should be a man of strict integrity.

3807. *A proper engineer being fixed upon*, the adventurers should not tie him down too closely by restrictions as to time; but allow him leisure to consider, digest, and revise, again and again, the different projects and ways, which will, in most instances, naturally present themselves to him in an extensive and thorough investigation. The engineer should be allowed to choose and employ the most competent assistants, and to call in and occasionally to consult the opinions of eminent or practical men, as land-surveyors, agents of the neighbouring landed property, the principal and most expert commercial men of the district who are best acquainted with its trade and wants, any eminent miners, &c. &c.; and such men the engineer should be authorised liberally, and at once, to remunerate for their services and intelligence. Previously to the beginning of any minute survey or system of levelling, the engineer ought to visit all the objects within the district under consideration, and endeavour to make a just estimate and preserve memorandums of them; as of the trade and importance of all the towns likely to be affected by the undertaking; of all mines of coal, iron, &c., quarries of limestone, freestone, slate, &c., or the situation where such can be found; of all the manufactories of heavy and cumbersome goods, and other extensive works; and generally of every thing likely to furnish tonnage for a canal. The most eligible route for a canal being settled in the engineer's mind, he will then proceed to make a rough calculation of the quantity of goods of each kind which may be expected to pass upon the line in a given time; he will also

examine all the canals and rivers with which the proposed canal is to connect, and ascertain the widths and depths thereof, the sizes of their locks, and of the vessels usually navigating them.

3808. *The dimensions, number, and kind of locks or inclined planes, length of levels, &c., may now be determined on, and how far railways or branch canals or roads may be connected with the main line.* Many engineers, and especially Fulton, have warmly advocated the formation of small canals. On this subject Chapman, a most judicious artist, observes, "that the system of small canals is particularly eligible in all countries where limestone, coal, iron ore, lead, and other ponderous articles, not liable to damage from being wet, or not likely to be stolen, are the objects chiefly to be attended to; and where the declivity of the country runs transversely to the course of the canal, which will generally be the case along the sides of mountains, at an elevation above the regular ground at their feet." In those situations, the great falls or inclined planes may be made at the forks of rivers, so that the upper levels may branch up both the vales, and thus give the most extended communication. A situation suited for those canals will often be found in countries that are not absolutely mountainous, but where the ground regularly declines towards the vales or large rivers."

3809. *A rough section of the proposed line will enable the engineer to see the places of the heights, and breadths of the various summits, or ranges of high land, that are to be passed, and whether any two or more adjacent ones can be connected by a long summit level, without deserting any considerable town or point of trade, which will diminish the difficulties of supplying the canal with water; as every such junction of summits preserves the water of two lockages, besides presenting so many more points at which the canal can be supplied with water from springs and rivulets above its level, or where, in less favourable situations, the same can be collected in a lower level, to be pumped up.* From one end of the proposed summit level it will be right now to proceed with the survey, tracing the level accurately, and marking the same by pegs or stakes, that will last for some time, and be known by the surveyor, who is to follow and make a plan of the line; the levels being frequently transferred to what are called bench marks, upon the trunk of a tree, a large post, or a building, the same being noted so particularly in the field or survey book, that they may be readily found for years afterwards. We suppose the engineers, by this time, to have settled the rise that each lock should have, according to the dimensions adopted for the canal, the probable supply of water on the summit, and other circumstances; the summit level will be traced as above, till the proper place occurs for making a fall of two or more locks, at about 100 yards, or a little more from each other; and the places of these falls being marked, the level is again to be pursued and traced from the bottom of them, and marked out as before, till the opportunity occurs for another pair or more of locks, or till some obstacle, as a gentleman's park, houses, gardens, orchards, mills, roads, &c. present themselves at a distance; when it will be proper, after transferring the level arrived at to a proper and permanent mark, to proceed forwards, and to examine and well consider the different ways and levels, if more than one present themselves, by which the obstacle can be passed. From the most confined part of the course for the canal, owing to the obstacle, it will be right to level back, till the former work is met, and to determine the most eligible mode of bringing the two levels together, upon the principles before stated; if they can be applied, either by adding another lock, or taking one from any of the sets which had been before marked out, as occasion may require, and marking out the new levels thereby occasioned: the line between the summit and the first obstacle, or confined part of the course, being thus adjusted, a new point of departure is to be taken from such obstacle, and the level pursued as before, till the fall for a pair or more locks can be gained, at the proper distance from each other. In this way, the patience, perseverance, and abilities of the engineer must be exercised, until a practicable line of some length is obtained, and staked out; when the assistant land-surveyor must follow, and make a correct and particular plan of the line of the several proposed locks, embankments, tunnels, &c. upon the same, and of the several fields, or pieces of land through which it passes, or that come within 100 or 150 yards of it in any part: it will likewise be the business of the surveyor to ascertain, with the utmost care, the boundary of every parish and township; what county each is in; the proper names of the owners and occupiers of every piece of land in each, however small, upon or within that distance of the line, with reference to the same upon his plan; and to describe correctly all public and private roads and paths that cross or intersect the line, and to and from what places they lead; the course of all brooks or streams of water, and particularly such as lead to, and contribute to the supply of, any mill: the situation of the houses and towns upon the line, or within some miles of it, should also be determined; the nearer they are the greater accuracy will be necessary. A complete plan of the line, and all the projected collateral cuts, feeders, reservoirs, &c. being finished, the engineer will enter on a most careful revival of the whole scheme, with this plan in his hand; or which all the places where culverts or drains will be required are to be marked, as also the proper places for the bridges, and the necessary alterations of the roads and paths, which will be cut off by the canal, so that the public may not be inconvenienced and turned long distances round about, and still, that as few bridges as possible, and those in the least expensive places, may be erected. In some instances new channels will require to be cut for brooks and water-courses, to a considerable extent, in order to save culverts, or bring them to the most desirable spots. For proper security against accidental errors, the whole of the levelling should now be gone over again, and the several bench marks compared, and renewed with the utmost care by the engineer's assistants, while he is proceeding with the necessary enquiries and calculations for an estimate of the whole expense of the undertaking.

3810. *The supplying of a canal with water, in a great number of instances, occasions no inconsiderable share of the whole expense, either in the first cost of mills or streams of water; in land for, and labour in constructing, reservoirs, engines to pump water, &c.; or annually, ever afterwards, in the fuel for, and repairing of, engines; hire of water from mills in dry seasons, &c.:* this subject should, therefore, employ the most sedulous attention of the engineer, to make the most economical use of what streams he finds, to procure other supplies of water at the least expense, and above all, to secure abundance. The dimensions and heights of the locks, and breadth of the canal, being settled, an accurate calculation should be made of the quantity of water required to fill a lock; and, with the largest probable number of boats that will pass in a day, of the quantity required daily in every part of the canal: this, with a due allowance for the evaporation, from the surface of the whole canal and its reservoirs, and for the soakage that will take place into the banks, however well they are constructed, will show the number of locks full of water that will be required, from the different sources.

3811. *In estimating the expense of all such works, it will be necessary to have the lengths and solid contents of the several embankments, and the distance from which the stuff or soil must be fetched for the same; the lengths and dimensions of all the deep cuttings, and the distance to which the stuff must be removed; the lengths of the tunnels, and number and depths of the several shafts or tunnel pits; the lengths or headings of soughs that will be wanted to drain the tunnelling work: these, and all the great variety of other works, some of which we have already mentioned and others we shall have occasion to mention in the sequel, being particularly stated, and prices affixed to each species of work and kind of material (which prices ought not to be below the current prices of the best articles at the time, and due allowance should also be made for the advance of prices which will take place during the progress of the work); the total probable expense, with a due allowance for contingencies, will be thus obtained, on which*

the engineer will prepare his general report and estimate, to be laid, with the plan, before a meeting of the adventurers or proposed proprietors.

SECT. III. Powers granted to Canal Companies by Government.

3812. As a canal must pass through a great variety of private property, and necessarily affect different individuals in very opposite ways, considerable powers are requisite to carry it into execution. The first steps to attain these are the appointment of a solicitor, and an application to parliament for an act of incorporation and regulation.

3813. A canal bill contains numerous clauses; but the following may be considered the most general heads:—

Regulations as to raising money by shares or otherwise.

Election of committees, and general meetings of proprietors.

Enactments relative to purchasing lands, &c.

Powers for erecting wharfs, and enforcing certain equitable rates of wharfage.

Tolls, or rates of tonnage, with exemptions, if any.

Fixing mile-stones, for regulating distances and tonnage.

Removing the surface-soil, and clamping it, for the purpose of being again laid on the surface of the exterior banks of the canal; or for other purposes.

Forming watering places for cattle or irrigation.

Regulations as to mills, &c.

Power to make by-laws.

Form of conveying land to the canal company.

Regulations as to depositing plans of the canal, and making variations from them, &c.

3814. The act of parliament for a canal being passed, and therein the time and place for the first meeting of the subscribers or proprietors thereof being fixed; the first business of such meeting will be the election of a general committee of management, consisting of the most independent, respectable, and generally informed persons among the proprietors. The committee of management will then proceed to elect a chairman and subordinate officers; to fix upon their place of meeting, and to arrange the order of their business.

3815. A resident engineer and land-surveyor and valuer should now be fixed on, and probably also a local or select committee: auditors of accounts will be appointed, and salaries determined. The chief engineer will now revise the line, and divide it into different parts, assigning names to each for convenient reference. Of these distinct parts, or divisions, a separate account of the expenses should be strictly kept by the resident engineer; the overseers, or counters, as they are generally called, that the engineer is to recommend or employ upon the works; and by the office clerks, in a ledger, with proper heads for each length of canal, set of locks, tunnel, embankment, deep cutting, reservoir, aqueduct, or other great work, that may form a separate division: such particular and divided accounts of the works will prove of the most essential service to the committee, and to all others concerned, in informing and maturing their judgment on the actual or probable expense of every different kind of work; and will enable the committee to explain to the proprietors how great, and sometimes unavoidable, as well as unexpected, expenses may be incurred.

3816. Such lands as are wanted should now be treated for by the land-surveyor, and the purchase and conveyance concluded with the approbation of the committee, and the aid of the solicitor, with or without the aid of the sheriff and a jury, as the case may require. In general, the ground for reservoirs and locks ought to be the first purchased, to permit the embankments and masonry to be proceeded with.

SECT. IV. Execution of the Works.

3817. The first operation of execution is the setting out of the work by the resident engineer and surveyor. He will accurately trace and indicate the levels of each pound or level reach of the canal, marking them with stakes, and comparing his work with the bench marks; he will also make two or more of the men who assist him perfectly acquainted with the position of the stakes, to provide against their derangement by cattle or from other causes.

3818. The calculations for excavation form the next part of execution. The great desideratum in canal-digging is, that the stuff dug from one part of the work shall, with the least labour of moving, exactly supply or form the banks that are to be raised in another, so that, on the completion of the work, no spoil banks, or banks of useless soil, shall remain, nor any ground be unnecessarily rendered useless by excavations or pits.

3819. Six different cases will be found frequently to occur in the cutting or forming of a canal. In each case the towing-bank (fig. 575. a) is wider than the off-bank (b);

and, in all, the sides slope one foot and a half for one foot in depth, that being found the least slope which can be given.

3820. Where there is deep cutting on one side (*c*), or both (*d, e*), a bench or berm (*d, e*) is provided to retain and prevent the loose earth that may moulder down from the upper bank from falling into the canal. The banks are usually made one foot higher than the water is intended to stand in them.

3821. In level cutting (fig. 575. *a, b*), the height of the canal should be so contrived, that in any cross section the sum of the areas of the made banks (*a, b*) should just equal that of the area of the section of excavation (*d*).

3822. In side-lying ground (fig. 575. *c*, and fig. 576. *f*), the same object may be attained with a little extra calculation; and in all other cases (*g, h*), the engineer will show the perfection of his skill in so conducting

576

the line, that every embankment shall have deep cutting at both, or at least at one of its ends, to furnish the extra stuff with least expense in moving it; in like manner, every deep cutting (*d, e*) should have embankments at one or both of its ends, to receive the extra stuff.

3823. Before cutting out the lock-spit, or small trench between the several slope holes, as a guide to the men who are to dig, the engineer ought to cause holes to be dug in the line of the canal, near every second or third level peg, or oftener, if the soil be variable, in order to prove the soil to a greater depth, by two or three feet, than the cutting of the canal is to extend; and each of these the engineer ought carefully to inspect, in order to determine what puddling or lining will be necessary; and what will be the difficulties of digging, owing to the hardness of the stuff, or to water that must be pumped out, &c.; all which circumstances, as well as the extra distance that any part of the stuff may require to be moved, must be well considered before the work can be let to the contractors.

3824. The puddling or lining of the canal, to make it hold water, is a matter of the greatest importance, and we shall consider five cases that are likely to occur or present themselves in the search into the soil that is to be dug, by sinking holes as above mentioned. The first case we suppose to be that in which the whole is clay, loam, or other water-tight stuff; all soils that will hold water, and not let it soak or percolate freely through them, are called water-tight. Our second case is that in which the whole cutting will be in sand, gravel, loose or open rock, or any other matters that will let water easily through them, and such are called porous soils or stuffs. The third case, we suppose to have a thin stratum of water-tight stuff on the surface, and to have porous stuff for a considerable depth below. The fourth case may have porous stuff near the surface, and water-tight stuff at the bottom of the canal. The fifth case is that where water-tight stuff appears on the surface; and below this a stratum of porous stuff, but having again water-tight stuff at no great distance below the intended bottom of the canal. The new-raised banks are always to be considered as porous stuff, as, indeed, they will always prove at first, and in a great portion of soils they would ever remain so, unless either puddling or lining were applied; all ground that has been dug or disturbed, must also be considered as porous. It should also be remarked, that any kind of soil which is perforated much by worms or other insects, should, in canal-digging, be considered as porous stuff.

3825. Puddle is not, as some have attempted to describe it, a kind of thin earth mortar, spread on places intended to be secured, and sufficed to be quite dry before another coat of it is applied; but it is a mass of earth reduced to a semifluid state by working and chopping it about with a spade, while water, just in the proper quantity, is applied until the mass is rendered homogeneous, and so much condensed that water afterwards cannot pass through it, or but very slowly.

3826. The best puddling stuff is rather a lightish loam, with a mixture of coarse sand or fine gravel in it; very strong clay is unfit for it, on account of the great quantity of water which it will hold, and its disposition to shrink and crack as this escapes; vegetable mould, or top soil, is very improper, on account of the roots and other matters liable to decay, and leave cavities in it; but more on account of the temptation that these afford to worms and moles to work into it, in search of their food. Where puddling stuff is not to be met with, containing a due mixture of sharp sand, or rough small gravel stones, it is not unusual to procure such to mix with the loam, to prevent moles and rats from working in it; but no stones larger than about the size of musket bullets ought to be admitted.

3827. That the principal operation of puddling consists in consolidating the mass, is evident from the great condensation that takes place; it is not an uncommon case, where a ditch is dug, apparently in firm soil, that though great quantities of water are added during the operation, yet the soil which has been dug out will not, when properly worked as puddle, fill up more than two thirds of the ditch. It should seem, also, that puddle is rendered by that operation capable of holding a certain proportion of water with great obstinacy, and that it is more fit to hold than transmit water. It is so far from true, that puddle ought to be suffered to get quite dry, that it entirely spoils water when by exposure to the air it is too much dried; and many canals which have remained unfilled with water during a summer, after their puddling or lining has been done, have thereby become very leaky, owing to the cracks in the puddle-ditches or lining. One of the first cares of an engineer, when beginning to cut a canal, is to discover whether good puddling stuff is plentiful; and, if it is not, it must be diligently sought for, and carefully wheeled out or reserved wherever any is found in the digging; or, perhaps, it must be procured at considerable distances from the line, and brought to it in carts. It has happened in some stone brash or loose rocky soils, that all puddling stuff for several miles of the line required to be brought to it; but even this expense, serious as it may be, ought not to induce the imitating of those, who have left miles of such banks without puddling, and have made a winter canal, but one which no stream of water that is to be procured can keep full in the summer months. It is usual in canal acts to insert a clause, for the security of the landowners, to require the company to cause all the banks that need it to be secured by puddling, to prevent damage to the land below by leakage; and it would have been well for all parties, in many instances, if this clause had been enforced.

3828. *If we compare our first, fourth, and fifth cases (3824),* we shall find in all of them a water-tight stratum, as the basis; and the practice in these cases is to make a wall of puddle, called a puddle-ditch, or puddle-gutter, within the bank of the canal; these puddle-gutters are usually about three feet wide, and should enter about a foot into the water-tight stuff, on which they are always to be begun; and they should be carried up as the work proceeds, to the height of the top water-line, or a few inches higher. Our second and third cases (3824) evidently will not admit of the above mode, because we have no water-tight stratum on which to begin a puddle-gutter, as a bottom; in these cases, therefore, it is usual to apply a lining of puddle to the sides and bottom of the canal.

3829. *History of puddling.* It appears that the Dutch have been in the habit of making mud ditches to secure the banks of their canals and embankments, from time immemorial; and that operations similar to our puddling have been long known on the Continent, but it is not clear at what period it was introduced into this country. We think that the fens in Cambridgeshire and Lincolnshire, in which so many works have at different times been executed by Dutchmen, are the most likely places in which to search for early evidence of its use. We cannot think that Brindley was the first who ever used it in this country, although we might admit that the Bridgewater canal was the first in which it was systematically employed as at the present day.

3830. *Adjustment of materials.* Canals set out with the care that we have recommended, will always have the proper quantity of stuff to allow for the settlement of the banks; since the united sections of the loose banks will always equal the section of excavation in the same settled or consolidated state in which it was before the digging commenced. The slopes of made banks, it is to be observed, on account of their settling, should be steeper in the first instance than they are ultimately required to be.

3831. *The letting of the cutting of certain lengths of the canal to contractors,* who will employ a number of navigators under them, in digging and puddling the canal, is the next business.

3832. *It is usual to let the work at a certain price per cubic yard of digging,* and to pay for the puddling or lining either at a certain price per cubic yard or per yard run of the canal. The engineer ought to inform himself thoroughly of the difficulties and facilities which attend the work he is about to let, and to draw up a short but explicit contract to be signed by the contractor. The prices allowed ought to be fair and liberal, according to the circumstances, so that the contractor may have no pretence, on account of low prices, to slight his work, particularly the puddling; and they ought in every instance to be strictly looked after, and made to undo and renew immediately any work that may be found improperly performed. We recommend it to the engineer to keep a strict account, by means of his overseers or counters, of the time of all the men employed upon the works; distinguishing particularly the number upon each work, and whether employed under the company by the day, or upon the work let to contractors. These particulars are most essential towards knowing what money ought to be advanced to the contractor during the progress of his job, and towards informing and maturing the judgment of the engineer, with regard to the length of time that a certain number of men will be in performing any future work he may have to direct. A calculation should also be made of the day-work in every instance, and compared with the contract price, by which alone a correct judgment can be formed of the proper prices at which work ought afterwards to be let, so that the labourers may receive wages proportionate to their exertions, and the contractor be amply paid for his time, skill, and superintendance; and yet economy, and the interest of the company, be duly consulted.

3833. *Barrows and wheeling planks, horsing-blocks,* and other implements, are generally found by the company; and it is usual to consider twenty to twenty-five yards a stage of wheeling, and to fix a price per cubic yard according to the number of stages that the soil is to be moved. Where this distance exceeds 100 yards, it will rarely be eligible to perform it by wheel-barrows; therefore runs of plank with an easy descent, if the same is practicable, should be laid, for large two-wheeled barrows or trucks to be used thereon.

3834. *Where the line of a canal is to cross an extensive stratum of valuable brick earth,* or one of good gravel for making roads, it will often be advisable, especially if the line can be thereby rendered more direct, when setting out the canal, to cut pretty deep into such materials, and even quite through the gravel, if the same is practicable; for although considerable expense will in the first instance be incurred in digging and in damage done for spoil banks, yet such materials as good brick earth and gravel will, in almost every instance, find a market as soon as the canal is opened. Such a situation may prove of essential service to the trade of the canal, by enabling the adjoining proprietors to work the whole thickness of their brick earth, gravel, or other useful matters, with but little detriment to the surface of the ground, and without being annoyed by water; this the canal, instead of losing water by preserving a high level through porous stuff, would, it is probable, catch in very considerable quantities. In districts where stone and gravel for making and repairing roads are scarce, it will be proper to pay the labourers certain rates per cubic yard for all the stones or gravel that may be collected by them during the work, and stacked in proper places. These will form resources for making the towing-path, and for making good the landing or ascent to the several bridges, and the several pieces of new road that the engineer will have to form near to the canal bridges. The lock banks, and all wharfs and landing places, should also be covered with good gravel, to render them safe and convenient for use. If good gravel can in places be intersected in deep cuttings, much of the above expense, as well as that of cartage, may be saved, by an early use of dirt boats in the bottom of the canal.

3835. *How important and various the duties of the resident engineers are,* must have struck every reader; but it would be much more apparent, could we enter into the subject of reservoirs, feeders, aqueducts, embankments, culverts, safety gates, weirs, tunnels, deep cuttings, locks, substitutes for locks, inclined planes, railways, bridges, towing-paths, fences, drains, boats, towing or moving boats and trams, cranes and implements; but these, as less important for our purpose, we must leave the reader to study in the works of Philips, Fulton, Chapman, Plymley, Badeslade, Kindersly, Anderson, Telford, and from the article Canal, in the three principal Encyclopædias.

CHAP. VI.

Improvement of Estates by the Establishment of Mills, Manufactories, Villages, Markets, &c.

3836. *Connected with the laying out of roads and canals, is the establishment of different scenes of manufactorial industry.* The forced introduction of these will be attended with little benefit; but where the natural and political circumstances are favourable, the improvement is of the greatest consequence, by retaining on the same estate, as it were, the profits of the grower, the manufacturer, and to a certain extent of the consumer.

3837. *The establishment of mills and manufactories to be impelled by water, necessarily depends on the abundance and situation of that material; and it should be well considered beforehand, whether the water might not be as well employed in irrigation, or how far irrigation will be hindered by the establishment of a mill.* In the state of society in which water corn-mills were first erected, they were doubtlessly considered as blessings to the country. There were then no flour manufactories: and it was more convenient for the inhabitants to carry their corn to a neighbouring mill, than to grind it less effectually, by hand, at home. Hence, the privileges and immunities of manorial mills. To secure so great a comfort, every tenant of a manor would willingly agree to send his corn to be ground at the lord's mill; and, perhaps, was further obliged to stipulate to pay toll for the whole of his growth; though it were sent out of the manor unground.

3838. *In Scotland,* this impolitic, and now absurd, custom was only lately given up: till when no farmer dared to send his corn to market, until he had delivered a proportional quantity to the proprietor or the occupier of the mill to which he was thirled, or had previously stipulated to pay him thirlage for what he might send away; this arbitrary regulation operating, like tithes, to decrease the growth of corn.

3839. *In England and Ireland,* however, no restriction of this sort at present exists: but, in the remote parts of the north of England, there are mills which claim (or lately claimed) the exclusive right of grinding the whole of the corn which the inhabitants of the respective parishes or manors required to be ground for their own use, suffering none to be sent out of the parish for the purpose of grinding. In the more western counties, where grist mills are still the schools of parochial scandal, something of this sort remains, and is piously preserved in modern leases: but, in the kingdom at large, grist mills are now going fast into disuse. Even working people purchase flour, instead of corn; and, whether in a private or a public light, this is an eligible practice. They can purchase a sort which is suited to their circumstances, and they know the quality and the quantity of what they carry home; whereas, in the proverbial rascality of grist millers, they have no certainty as to either: besides, in a flour mill there is no waste; every particle may be said to be converted to its proper use.

3840. *A valuable property belonging to modern flour manufactories,* is their not requiring every brook and rivulet of the kingdom to work them. In Norfolk, a great share of the wheat grown in that corn country is manufactured into flour by the means of windmills; and such are modern inventions, that neither wind nor water is any longer necessary to the due manufacture of flour; the steam engine affording, if not the most eligible, at least the most constant and equable power.

3841. *The most eligible kinds of water-mills* are, the tide-mill and the current mill: the former placed in creeks, inlets, bays, estuaries, or tide rivers; and the latter in the current of a river. There are many situations, Marshal observes, in which these species of mills may be erected with profit to proprietors, and the community; and without any injury to the landed property, or the agricultural produce of the country. He is of opinion that numerous river mills existing in different parts of the country are unnecessary to the present state of society.

3842. *Grist mills* may be still required in some remote situations: but, seeing the number of flour mills which are now dispersed over almost every part of the kingdom, seeing also the present facility of carriage by land and water, and seeing, at the same time, the serious injuries which river mills entail on agriculture, Marshal recommends land proprietors to reduce their number, as fast as local circumstances will allow.

3843. *The inducement to establish manufactories* depends on a variety of circumstances, as well as on a supply of water. Among these may be mentioned the price of labour, convenience for carriage, export or import, existence of the raw material at or near the spot, as in the case of iron works, potteries, &c. In England, while the poor laws exist, the establishment of any concern that brings together a large mass of population will always be attended with a considerable risk to land-owners; though it is a certain mode, in the first instance, of raising the price of land, and giving a general stimulus to every description of industry.

3844. *A populous manufactory,* even while it flourishes, according to Marshal, operates mischievously in an agricultural district by propagating habits of extravagance and immorality among the lower order of tenantry, as well as by rendering farm labourers and servants dissatisfied with their condition in life; and the more it flourishes, and the higher wages it pays, the more mischievous it becomes in this respect. Lands bear a rental value in proportion to the rate of living in the district in which they lie; so that while a temporary advantage is reaped, by an increased price of market produce, the foundation of a permanent disadvantage is laid; and, whenever the manufactory declines, the lands of its neighbourhood have not only its vices and extravagances entailed upon them, but have the vicious, extravagant, helpless manufacturers themselves to maintain. This accumulation of evils, however, belongs particularly to that description of manufacture which draws numbers together in one place; where diseases of the body and the mind are jointly propagated; and where no other means of support is taught than that of some particular branch or branchlet of manufacture. But all these evils, belonging to the first introduction of manufactures on a great scale, will be cured with the progress of education and refinement among the operative manufacturers: it is already improved in comparison with what it was in Marshal's time.

3845. *Cottages.* Wherever cottages for any class of men are built, whether singly or congregated, they ought never to be without an eighth or a fourth of an acre of garden ground. It is observed in the *The Code of Agriculture*, that "where a labourer or country tradesman has only a cottage to protect him from the inclemency of the weather, he cannot have the same attachment to his dwelling, as if he had some land annexed to it; nor is such a state of the labourer so beneficial to the community. When a labourer has a garden, his children learn to dig and weed, and in that manner some of their

time is employed in useful industry. If he is possessed of a cow, they are taught early in life the necessity of taking care of cattle, and acquire some knowledge of their treatment. But where there is neither a garden to cultivate, nor any cows kept, they are not likely to acquire either industrious or honest habits. So strongly were these ideas formerly prevalent, that, by the 43d of Elizabeth, no cottage could be built on any waste without having four acres attached to it. This is in general too much. If the quantity were reduced to half an acre for a garden, and if no person could gain a settlement who was not a native, or, if a stranger, who did not fairly rent in the same parish a house and land worth twenty, instead of ten pounds per annum, both the poor and the public would thence derive very essential benefit."

3846. *The most advantageous system for keeping a cottage cow* is that adopted in grazing districts, where a cottager has a sufficient quantity of enclosed land in grass, to enable him to keep one or two cows both summer and winter, grazing the one half, and mowing the other, alternately. Nothing tends more materially to teach the poor honesty, than allowing them to have property. Feeling how intensely they would depreciate all infringement upon it, they are less likely to make depredations upon that of others; and this will produce more honesty among them than the best delivered precepts can instil. By the cultivation of a small spot of land, a cottager not only acquires ideas of property, but is enabled to supply himself with that variety of food, as fresh vegetables in summer and roots in winter, which comfort and health require. If he should fortunately be able to keep bees in his garden, and if its surplus produce should also enable him to rear, and still more to fatten, a hog, his situation would be much ameliorated. But if, in addition to all these advantages, he can keep a cow, the industrious cottager cannot be placed in a more comfortable situation. Goats have recently been recommended (*British Farmer's Magazine*, vol. iii.) as a substitute for a cow, as being more easily kept, costing less at first, and producing milk the greater part of the year. The chief difficulty of introducing them is the want of sufficient enclosures, as no animal is more inimical to shrubby vegetation of any kind. Some useful hints on the subject of cottagers, and the means by which they may be enabled to keep a cow, will be found in Cobbett's *Cottage Economy*, though his statements are in many cases highly exaggerated.

3847. *Cottages and villages* necessarily result from manufactories, as well as from extensive mines, quarries, or harbours. A few cottages will necessarily be scattered over every estate, to supply day labourers and some description of country tradesmen. Villages are seldom, in modern times, created by an agricultural population; it being found so much more convenient for every farm to have a certain number of cottages attached to it.

3848. *A village* may be created any where, by giving extraordinary encouragement to the first settlers; but unless there be a local demand for their labour, or they can engage in some manufacture, the want of comfortable subsistence will soon throw the whole into a state of decay. Fishing villages, and such as are established at coal and lime works, are perhaps the most thriving and permanent in the kingdom. Some fine example of fishing villages, recently established, occur on the Marquess of Stafford's estates in Sutherland.

3849. *In forming the plan of a town or village*, the first thing, if there is a river or other means of communication by water, is to fix on a proper situation for a quay or harbour; and next, at no great distance from it, on an open space as a market. Round the latter ought to be arranged the public buildings, as the post-office, excise or custom-house, police-office, the principal inn and the principal shops. Near the harbour ought to be placed the warehouses and other depositories for goods; in a retired part of the town the school; and out of town on an eminence (if convenient) the church and the cemetery of garden of burial. There ought to be a field or open space, as a public recreation ground for children, volunteers or troops exercising, races, washing and drying clothes on certain days, &c. Public shambles ought to be formed in a retired and concealed spot, so should public necessaries. Proper pipes, wells, or other sources of good water, with the requisite sewers and drainage should also be provided. Buckets, to be used in case of fire, ought to be kept at the market-house.

3850. *The village of Bridekirk on the Annan, in Dumfriesshire (fig. 577.), was begun in 1800, by Gen. Dirom, and is thus described by him in the survey of the county:—* "It is situated at a part of the river which affords falls and power capable of turning any weight of machinery; and I have had it in view to give encouragement to manufacturers, to whom such a situation is an important object. A woollen manufactory (a) upon a large scale, and the most approved plan, has been established there for ten years, and is gradually increasing its machinery. In this village there are already, in the course of that time, about two hundred and fifty industrious inhabitants, and it has every appearance of a further rapid increase. On the opposite side of the river a situation is fixed on for corn-mills (b), where a complete set has been built upon the best construction, including wheat and barley mills. Half of the water there is reserved for any other works, and is likely to be let for a mill for dressing and for spinning flax, and for machinery required in bleaching, there being at the foot of the mill-race a holme of six acres (c), well calculated for a bleach field; and I propose to let part of it for such a manufactory.

3851. "The lots for building and gardens in the village, each consisting of from nine to ten falls of ground, are granted in perpetuity at the rate of six pounds the English acre, either upon leases for 999 years, or feu-rights; as the settlers choose; the former being generally preferred, as being the holding or title attended with least expense. This rent would of itself be no object when the waste of ground in streets and enclosures is considered; but the great advantage to be derived from such an establishment is, the increased value that lands acquire from having a number of industrious people settled in the heart of an estate. Each person who fees a house-stead is obliged to build with stone and lime, according to a regular plan; and a common entry is left between every two lots for access to their offices, which are built immediately behind their houses; and the whole of the buildings are covered with slate. The feuers are also bound to make a common sewer through their property when required; to pave ten feet in front of their houses, between them and the street; and to pay at the rate of a penny per fall yearly, according to the extent of their lots, to form a fund for keeping the streets and roads in repair, and for making small improvements. No person is allowed to sell liquor of any kind without my permission; nor can any shop or chandlery, tannery, or other work, that might be considered as a nuisance, be set up or built, unless in places allotted for these purposes; and to prevent all interference on the part of the feuers, I reserve to myself full liberty to make such alterations as may appear to me or my successors to be proper in the plan of the village. These regulations are the best security against having vagabonds in such a place, as none but industrious people can afford to build or rent such houses."

3852. *A new village sea-port in Devonshire was formed by Sir Lawrence Palk, in the northernmost part of Torbay. A new pier, projected south-westwardly from the eastern cliff, affords complete protection to shipping from the south-east winds. The regularity of the buildings lately raised for the accommodation of company resorting hither for the convenience of sea-bathing, adds neatness and beauty to the wild and picturesque scenery of its natural situation; and, from the size of the vessels the harbour is now capable of protecting whilst they receive and discharge their cargoes, there are well-grounded expectations that this place will become of some maritime consequence on a future day. A plan of this sea-port (fig. 578.)*

578

is given in the *Devon Survey*, and is described as containing a pier (1), quay (2), harbour (3), warehouses (4), inn and garden (5), stables (6), strand (7), cove for building ships and timber yard (8), beacon (9), cove for bathing machines (10), new carriage-way to the park (11), terrace (12), the park (13), plantation (14), road to Torwood (15), road from Newton, &c. (16), meadows (17), circus in the park (18).

CHAP. VII.

Of Mines, Quarries, Pits, and Metalliferous Bodies.

3853. *Against mines, as a species of property, considerable prejudice has long existed, from the variation of their produce, and the uncertainty of their extent and duration. Modern discoveries in geology, however, have thrown great light on the subject of mining, and introduced into the art a degree of certainty not before contemplated. In proof of*

this, we may instance coal and limestone: of these minerals, tradition asserts the existence in various parts of the island, where from the strata on the surface the modern geologist well knows it is impossible.

3854. *Among the various mineral substances found in quantity in Britain*, the chief are coal, lime, building and other stone, gravel, clay, fuller's earth, marl, &c. among the earths; salt, among saline substances; and lead, copper, and tin, among the metals. Cobalt, manganese, and some other metals and earths, are found in some places, but in small quantities. No saline or metalliferous bodies ought to be sought for, or attempted to be worked, but with the advice and assistance of an experienced and skilful mineral surveyor; nothing being more common than for proprietors to be induced by local reports or traditions to fancy their lands contain coal, lead, or some other valuable subterraneous product, and to incur great expense in making abortive trials. To ascertain the nature and value of the minerals of an estate of any magnitude, or of one of small size but of peculiar exterior organisation, it will always be worth while for the proprietor to have a mineral survey, map, and description, made out by a professional man.

3855. *Coal* is at present perhaps the most valuable British mineral; because, among other reasons, it does not appear to be worked in any other country in such quantity as to lessen by importation the home produce. There are three species of coal, the brown, the black, and the unflammable. To the first belongs the Bovey coal or bituminised wood, found chiefly at Bovey, near Exeter; to the second the slate coal, which includes the pit and sea-coal, and all the kinds in common use, and also the canal coal, which occurs only occasionally in the coal pits of Newcastle, Ayrshire, and Wigan in Lancashire; to the third belong the Kilkenny coal, and Welsh culm, or stone coal, which burn to ashes without flaming.

3856. *The indications of coal are different in different coal districts.* In general the surface is argillaceous or slaty, and limestone commonly forms an accompanying stratum. In some collieries near Newcastle, however, limestone is wanting; but whinstone, sandstone, and others of secondary formation, are present in a great variety of forms.

3857. *The discovery of coal is made by boring*, and that operation is generally performed in coal districts as a guide for sinking new shafts. By this means the owners procure most essential data on which to proceed, being informed beforehand of the nature of the earth, minerals, and waters, through which they have to pass; and knowing, to an inch or so, how deep the coal lies, as well as the quality and thickness of the stratum bored. It is confessedly of the first importance, either to the inhabitants of a district in general, or to the owners of the soil in particular, to be able to detect and work such veins of coal as may exist under their soil; and hence we find, on enquiry in the neighbourhood, that almost every common, moor, heath, or piece of bad land, in parts where coals are scarce, have at one time or other been reported by ignorant coal-finders to contain coal. How many times, for instance, have our grandmothers, and nurses, repeating their stories, told us, that plenty of coals might be dug at such and such a place, if government had not prohibited their being dug, for encouraging the nursery for seamen, &c.? Farley's enquiries, and those of Smith, have brought to light hundreds of instances, where borings and sinkings for coals have been undertaken on advice in situations in the southern and eastern parts of England; attended with heavy and sometimes almost ruinous expenses to the parties, though a source of profit to the pretended coal-finders. These attempts a very slight degree of geological knowledge would have shown to be vain.

3858. *The coal fields of Britain* will be found scientifically described in *Outlines of Geology*, by Conybeare and Phillips, and also in *Bakewell's Geology*.

3859. *Limestone, chalk, and building or other stone*, are found in strata either on or near the surface. At a great depth it is seldom found worth while to work them. When stones of any kind are procured by uncovering the earth and then working them out, they are said to be quarried; but when a pit or shaft is sunk, and the materials are procured by working under ground, they are said to be mined.

3860. *Gravel, chalk, clay, marl, and other loose matters*, when worked from the surface, are said to be worked from a pit, and hence the terms stone, quarry, gravel, clay, or marl pit. Little knowledge of geology is in general required for the discovery of gravel or marl; but, still, even a little would be found of the greatest advantage.

3861. *The working of quarries* is a simple operation, and one depending more on strength than skill. In quarrying sandstone, consisting of regular layers, the work is performed chiefly by means of the pick, the wedge, the hammer, and the pinch or lever; recourse being seldom had to the more violent and irregular effects of gunpowder. But for many kinds of limestone, and for greenstone and basalt, blasting with gunpowder is always resorted to; and some of the rocks called primitive, such as granitic, gneiss, and sienite, could scarcely be torn asunder by any other means.

3862. *The burning of lime* may be considered as belonging to the subject of quarrying. This operation is performed in what are called draw kilns, or perpetual kilns. These should always be close to or near the quarry, and either situated at a bank, or furnished with a ramp or inclined plane of earth for carting up the coal and lime to the top of the kiln. Lime-kilns may be built either of stone or brick; but the latter, as being better adapted to stand excessive degrees of heat, is considered preferable. The external form of such kilns is sometimes cylindrical, but more generally square. The inside should be formed in the shape of a hoghead, or of an egg opened a little at both ends and set on the smallest; being small in circumference at the bottom, gradually wider towards the middle, and then contracting again towards the top. In kilns constructed in this way, it is observed, fewer coals are necessary, in consequence of the great degree of reverberation which is created, above that which takes place in kilns formed in the shape of a sugar-loaf reversed. Near the bottom, in large kilns, two or more apertures are made; these are small at the inside of the kiln, but are sloped wider, both at the sides and the top, as they extend towards the outside of the building. The uses of these apertures are for admitting the air necessary for supplying the fire, and also for permitting the labourers to approach with a drag and shovel to draw out the calcined lime. From the bottom of the kiln within, in some cases, a small building called a horse is raised in the form of a wedge, and so constructed as to accelerate the operation of drawing out the burned limestone, by forcing it to fall into the apertures which have been mentioned above. In other kilns of this kind, in place of this building there is an iron gate near the bottom, which comes close to the inside wall, except at the apertures where the lime is drawn out. When the kiln is to be filled, a parcel of furze or faggots is laid at the bottom, over this a layer of coals, then a layer of limestone (which is previously broken into pieces, about the size of a man's fist), and so on alternately, ending with a layer of coals, which is some-

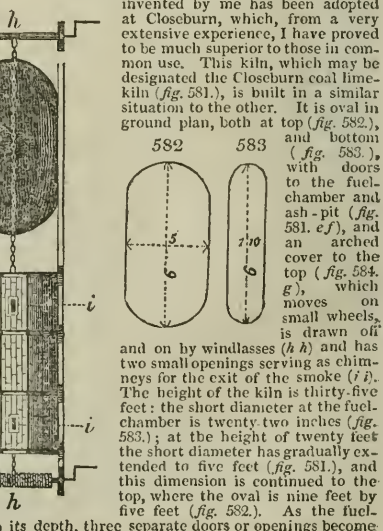

times, though seldom, covered with sods or turf, in order to keep the heat as intense as possible. The fire is then lighted in the apertures; and when the limestone towards the bottom is completely calcined, the fuel being considerably exhausted, the limestone at the top subsides. The labourers then put in an addition of limestone and coal at the top, and draw out at bottom as much as they find thoroughly burned; and thus go on, till any quantity required be calcined. When limestone is burned with coals, from two bushels are produced for every bushel of coal used. Lime will, in all cases, be most economically burned by fuel which produces little or no smoke; because the necessary mixture of the fuel with the broken limestone renders it impossible to bring it in contact with a red heat, which may ignite the smoke. Dry fuel must also, in all cases, be more advantageous than moist fuel, because in the latter case a certain quantity of heat is lost in expelling the moisture in the form of vapour or smoke.

3863. *Booker's lime-kiln* (fig. 579.) is the best of all forms that have hitherto been brought into notice for burning lime with coke or other dry smokeless fuel. The kiln of this description at Closeburn is built on the side of a bank; it is circular within, thirty-two feet high from the furnace, three feet in diameter at top and bottom, and seven feet in diameter at eighteen feet from the bottom; it has cast-iron doors to the fuel-chamber (fig. 580. a) and ash-pit (b), and a cast-iron cap or cover (fig. 579. c, d), which turns on a pivot, and rests on a curb-ring fixed on the top of the masonry of the kiln (d). The use of this cover is to prevent the escape of more heat than is necessary to keep the fuel burning, for which last purpose the cover has only an opening at top (d), twelve inches in diameter. The principal advantage of this construction is, that very little heat is lost, and that lime may be burned with almost as little fuel in winter as in summer. Another advantage, and one of considerable importance in a country sale, where a kiln is not worked sometimes for two or three days together, is, that by closing the orifice (d) at top, and the furnace doors (fig. 580. a b) below, the fire may be kept alive for four or five days. In the ordinary descriptions of kilns without covers, the fire is usually extinguished in twenty-four hours, especially in the winter season. In Booker's kiln, one measure of coke will burn four measures of limestone. The fuel for the lime-kilns at Closeburn is brought from a distance of twenty-five miles, and it is found that one third of the expense of carriage is saved by coking it at the coal-pits. A measure of this coke burns as much lime as the same measure of coal; as when coal is used in the lime-kiln it may be said to be coked before it has much effect on the limestone. One of Booker's kilns, when coke is used, yields nearly three fourths of its contents of well burned lime every day.

3864. *Menteath or Closeburn coal lime-kiln.* When lime is to be burned with coal or smoky fuel, a form invented by me has been adopted at Closeburn, which, from a very extensive experience, I have proved to be much superior to those in common use. This kiln, which may be designated the Closeburn coal lime-kiln (fig. 581.), is built in a similar situation to the other. It is oval in ground plan, both at top (fig. 582.), and bottom (fig. 583.), with doors to the fuel-chamber and ash-pit (fig. 581. c, f), and an arched cover to the top (fig. 584. g), which moves on small wheels, is drawn off and on by windlasses (h h) and has two small openings serving as chimneys for the exit of the smoke (i i). The height of the kiln is thirty-five feet: the short diameter at the fuel-chamber is twenty-two inches (fig. 583.); at the height of twenty feet the short diameter has gradually extended to five feet (fig. 581.), and this dimension is continued to the top, where the oval is nine feet by five feet (fig. 582.). As the fuel-chamber to this kiln is very broad in proportion to its depth, three separate doors or openings become

3863. *Booker's lime-kiln* (fig. 579.) is the best of all forms that have hitherto been brought into notice for burning lime with coke or other dry smokeless fuel. The kiln of this description at Closeburn is built on the side of a bank; it is circular within, thirty-two feet high from the furnace, three feet in diameter at top and bottom, and seven feet in diameter at eighteen feet from the bottom; it has cast-iron doors to the fuel-chamber (fig. 580. a) and ash-pit (b), and a cast-iron cap or cover (fig. 579. c, d), which turns on a pivot, and rests on a curb-ring fixed on the top of the masonry of the kiln (d). The use of this cover is to prevent the escape of more heat than is necessary to keep the fuel burning, for which last purpose the cover has only an opening at top (d), twelve inches in diameter. The principal advantage of this construction is, that very little heat is lost, and that lime may be burned with almost as little fuel in winter as in summer. Another advantage, and one of considerable importance in a country sale, where a kiln is not worked sometimes for two or three days together, is, that by closing the orifice (d) at top, and the furnace doors (fig. 580. a b) below, the fire may be kept alive for four or five days. In the ordinary descriptions of kilns without covers, the fire is usually extinguished in twenty-four hours, especially in the winter season. In Booker's kiln, one measure of coke will burn four measures of limestone. The fuel for the lime-kilns at Closeburn is brought from a distance of twenty-five miles, and it is found that one third of the expense of carriage is saved by coking it at the coal-pits. A measure of this coke burns as much lime as the same measure of coal; as when coal is used in the lime-kiln it may be said to be coked before it has much effect on the limestone. One of Booker's kilns, when coke is used, yields nearly three fourths of its contents of well burned lime every day.

chamber to this kiln is very broad in proportion to its depth, three separate doors or openings become

585

when a greater quantity of lime is required in a certain time, than usual, as it is well known to lime-burners that the process of burning is done most economically when the kiln is in full action, so as

586

almost constantly to have a column of fire from the bottom to the top of the kiln, with as short intervals as possible in working the kiln. Having found that limestone is apt to be vitrified during the process of calcination, during stormy weather, from the increased circulation of air through the kiln, which adds much to the heat derived from the fuel employed, and which experienced lime-burners would have diminished, could they be aware at all times of an occurrence of this kind. From having experience of the bad effects of too great a circulation without properly providing against it, I have reason to believe, that having a power to throw in at pleasure an additional quantity of air into the bottom of a lime-kiln, that a considerable saving of fuel necessary for the calcination of lime would take place, and another object would be gained, that of cooling the limestone in the bottom of the kiln, which frequently retards the drawing out of the burnt limestone for some hours, or until the limestone is so cold as not to burn the wooden structure of carts.

3866. In working a kiln with narrow circular mouths, the stone and coal should be carefully measured, so that the workmen can proportion the fuel employed to the quantity of stones; and it is obvious, that the quantity of coal to be used must depend upon its relative quality, and the hardness of the stone to be burnt. If this measure were adopted in kilns of any construction, the lime shells would be found better burnt.

3867. Two furnace doors are employed at the bottom of the kilns; the upper one for letting through the burnt shells [or stones], which allows at all times through ingress of air into the bottom of the kiln, and facilitates the drawing out of the lime, as it takes off the pressure of the stone from top to bottom of the kiln. The lower door is for drawing out the lime ashes, which is a clear gain to the lime-burner. In the long oval kiln, which admits of being made of any length, the eyes or fire-places are opposite to each other, upon the two sides, which admits of a kiln being made ten or twelve feet wide at bottom, and enables the lime-burner to supply a very great demand from the kiln daily. (C. G. Stuart Mentcash.)

necessary (fig. 585.) as well as advantageous, for more speedily and easily drawing out the lime. In some cases, instead of a movable cover, a permanent roof of masonry (fig. 586.) may be adopted. This roof should have proper openings to admit the supply of lime and fuel, and those may be closed by sliding shutters or hinged doors; while, in the roof, there should be a chimney for the escape of the smoke. It will readily be understood, that the use of a cover, whether fixed or movable, is chiefly to retain the heat; but where the cover is a fixed structure, and sufficiently large, something will be gained by placing the fuel and limestones there, to be dried and heated before they are thrown into the kiln. Three fifths of the contents of the Close-burn oval kiln may be drawn out every day, and when it is closed at top and bottom, the fire will not go out for five or six days.

3865. Subsequent improvements by Mr. Mentcash are thus detailed in a letter to us from that gentleman, dated Feb. 28. 1830. — I now employ kilns of an egg shape, and also oval; the oval-shaped kilns are divided by arches across the kiln, descending four feet from the top; the object of the arches across the kilns is to prevent the sides of the kiln falling in or contracting, and also to enable you to form circular openings for feeding in the stone and coal at the mouth of the kiln. Upon this plan, a kiln of any length might be constructed with numerous round mouths. In the model of the kiln lately sent to the Highland Society, Booker's conical cover may be seen revolving upon an iron ring placed upon the circular mouth, and having placed a lid to the cover, I am enabled to prevent the escape of heat at the top, and by cast-iron doors at the bottom the air is prevented from passing through the kiln; so that by these precautions the lime-burner can regulate the heat and prevent its escape for several days, when the fire would be extinguished at this season in the course of 24 hours. This is an object of great importance, as it enables you to burn lime as well, and with as small a quantity of fuel, in the winter as the summer season, and to supply the farmer with as well burned lime, at any time of the year, which cannot be done in the common construction of kilns, open both at top and bottom. When coke is employed for burning lime during the day, small coal should be used in the evening, in order to prevent as much as possible the escape or waste of heat during the night, from the rapid circulation of air through the limestone in the kiln where coke is the fuel made use of for its calcination: a kiln in which coke is the fuel employed will yield near a third more burnt lime in a given time than when coal is the fuel, so that coke may be used occasionally,

3868. *Heathorn's combination of a lime-kiln and coke oven* (fig. 587.) has for its object to prepare quick-

lime and coke in the same kiln by a single operation; and the arrangements to effect it are at once so simple and so complete, as seemingly to preclude the capability of any material improvement. The economy of the process is likewise carried to the greatest possible degree; for that portion of the coal which is separated from it to form coke is, by its combustion, rendered subservient to the burning of the limestone; and the coke, owing to its increased bulk, being nearly, if not quite, as valuable as coal in the market, the expense of burning is very much reduced. This kiln and oven are raised on a flat surface, the lime being raised by means of a jib and crane, though, like other kilns, it might be placed on the side of a bank for supply in the usual manner. The kiln is now, and has for some time past been, in full operation, at the patentee's lime-works at Maidstone. In districts where coal is dear, this will probably be found a valuable improvement; but with some descriptions of coal it is impracticable, and in all cases the labour will be considerably increased. The side walls of this kiln (*a a*) are four feet thick; the iron bars at the bottom (*b b*) are drawn out when the kiln is to be emptied. The limestone is raised in a box (*d*), by means of a jib and crane (*e*); when raised, the jib is swung round, and the lime-box tilted, by which the whole contents are thrown down the shaft. The coke ovens (*f f*) may be two, or a greater or less number, according to the magnitude of the works. They are supplied with coal through iron doors, which doors have a long and narrow horizontal opening in the upper part of them, to admit sufficient atmospheric air to produce combustion in the inflammable part of the coal; the flames thus produced pass into the lime shaft, and the flues (*g g*) are prevented from interfering with each other by a partition wall (*h*). When the kiln is charged, the openings in front and beneath the iron bars (*i i*) are closed, as are certain openings made in the shaft (*h*), and in the coke ovens (*l*), at convenient distances, for the purpose of introducing iron bars as pokers, to accelerate the process. When the coal is reduced to coke, it is taken out by a long-handled iron hoe. (*Reg. of Arts and Sci.* vol. iv. p. 290.)

3869. *A Yorkshire lime-kiln*, (said to be a very good one), for burning lime with coal or coke, is thus described in the *Mechanics' Magazine* 1—4 "Bottom part, where the lime is drawn out, a circle of about eighteen inches diameter, and widening gradually upwards (in the shape of an inverted cone, with the apex cut off) to about one half or one third of the whole depth, and then the remainder carried up perfectly cylindrical to the top; the diameter of the cylinder being about one third of the whole depth. In fixing on a place to build such a kiln, the side of a hill, near the rock to be erected, of sufficient dimensions to bury the back part of it in the ground. In building up the kiln, there are two walls carried up; the space betwixt them is filled with small rubble, to keep in the heat, and next to the inner wall the kiln has a lining, about a foot or half a yard in width, of a slaty gritstone that will stand heat well. When the lining wants repairs or renewing, the wall behind it keeps the rest of the materials from falling in. (*Gard. Mag.* vol. ii. p. 402.)

3870. *Burning lime in heaps.* Where fuel is abundant, lime may be burned in heaps, as in charring wood, or in clumps like bricks. The fuel is intermixed, and the whole covered with turf or mud, in which a few holes are pierced to admit the passage of the smoke.

3871. *Machines for pounding limestone* have been erected, but the effect of the powder so obtained, both as a manure and for cement, is so much inferior to that of burnt lime, that they have long since been generally laid aside.

3872. *Salt* is procured from rocks, springs, and from the sea. In Chester, particularly in the neighbourhood of Northwich, the salt works are very extensive. Great quantities are got in the solid form, but not sufficiently pure for use. In this state it is conveyed from the mines to the Cheshire side of the river, nearly opposite to Liverpool. It is at this place dissolved in the sea-water, from which it is afterwards separated by evaporation and crystallisation. There are also in the same district salt works, at which the salt called Cheshire salt is extracted from brine. These works are described very intelligibly by Dr. Holland, in *The Report of Agriculture for the County of Cheshire*.

Considerable salt-works are carried on in Scotland, and in the northern counties of England on the sea-coast, by the *evaporation of sea water*. At Lynnington, in Hampshire, the sea-water is evaporated to one sixth of the whole by the action of the sun and air. The works in which the sea water is heightened into brine are called sun-works, or out-works. These are constructed on a flat down or oozy beach, within a mole, which is raised, if necessary, to keep out the sea; there is a large reservoir, or feeding pond, communicating with the sea by a sluice, and adjoining to this reservoir a long trench, parallel to which there are several square ponds, called brine pots, in which the water is evaporated to a strong brine, and afterwards it undergoes an artificial evaporation and purification in boilers.

3873. *The metalliferous ores or stones* should never be sought after, but in consequence of the best advice and most mature consideration. "Few," Marshal observes, "have made fortunes by mines, and many have been ruined by them." Should a man of large landed property discover a productive mine on his estate, he offers him "two words of advice. The first is, not to work it himself. A gentleman among miners is a pigeon to be plucked. Rather let the man who finds himself involved in such a predicament adopt the Cornish practice, and stipulate to take a proportional part of the ore which may be raised: according to the productiveness of the mine, and the expense of working it, jointly calculated. The other is, not to break in upon the *principal*, or gross sum, which arises from a mine. If the estate is encumbered, remove the encumbrance: if not, increase its size, or, in any other prudent way, secure the *interest* of the gross produce of the mine, and thus defy the evil effects of its failure; for no mine is inexhaustible."

CHAP. VIII.

Establishment of Fisheries.

3874. *Fisheries* may be arranged as marine, river, lake, and pond fisheries; the first being of the greatest importance to this and every country.

SECT. I. *Marine Fisheries.*

3875. *The importance of improving the marine fisheries* to an insular country, like Britain, is sufficiently obvious. By their augmenting the quantity of food, there would necessarily result a reduction in the prices of all the necessaries of life; the condition of the labouring poor, the artificers, and tradespeople, would as necessarily be improved: they would not only be the means of rearing and supporting a bold and hardy race of men for the defence of the sea-coast, but also of creating a nursery of excellent seamen for the navy in time of war, and of giving them employment when peace may render their further services unnecessary. If the fisheries flourished to that extent of which they appear to be capable, every seaport town and little village on the coasts, or on the banks of the creeks and inlets, would become a nursery of seamen. It was thus in Holland, where the national and natural advantages were very inferior to those of Great Britain; for it is well observed, in the report of the Downs Society, that Holland does not produce timber, iron, or salt, all of which are essential to fisheries, and all the natural produce of Great Britain; that Holland has no herrings on her own coast, while the coasts of our island abound with them and other fish, at different and at all seasons of the year, so that there are few, if any, months in which shoals of this fish in particular are not found on some part of our shores; and that her population is under 3,000,000, while ours amounts to about 18,000,000, giving to our fishermen six times the consumption of a home market that the Dutch have. With all the impediments to an extended use of fish in the home market, and notwithstanding the established character which the Dutch fish have always borne among foreign nations, it is consoling to find that the British fisheries are generally in a progressive state of improvement, and more particularly that the most important of all their branches, the herring fishery.

3876. *The rapid progress of the herring fishery* shows that there is no art or mystery in the catching and curing of herrings that the English cannot accomplish as well as the Dutch, which is further proved by the successful experiment made by the Downs Society of fishermen; in the report of whose proceedings it is stated, that herrings had been taken within the Cinque Ports of a quality so nearly resembling the deep sea fish, that they were cured and sold as the best Dutch herrings. The progressive increase of the herring fishery is confined to Scotland; the quantity brought under the inspection of the officers in England amounts not to one twenty-second part of the whole, while the flourishing little town of Wick alone furnishes nearly one fifth. But the most extraordinary increase is that which has taken place in the neighbouring county of Sutherland. Till a few years past, the people of this county were contented to hire themselves as fishermen to the adventurers of Wick. In 1814, they attempted, with the aid and encouragement of the Marquis of Stafford, a fishery on their own account, and the mouth of the Helmsdale was fixed upon as the station. A storehouse and curinghouse were here erected; the boats were manned by the people brought from the mountains and the interior of the country. Every thing

was new to them in the employment in which they were about to engage. The fishing commenced on the 20th of July, and ended on the 3rd of September, 1814; and the four boats won respectively 105*l.* 3*s.*, 83*l.* 8*s.*, 96*l.* 8*s.*, and 148*l.* 3*s.* They were manned by four men each, so that they made, on an average, rather more than 27*l.* a man. In 1815, the number of boats employed amounted to fifty, almost entirely manned by Sutherland men; and the number of barrels caught and repacked exceeded 4,000, chiefly gutted. In 1817, this fishery gave employment to about 3,000 tenants, 17 coopers, and 130 women. In 1818, 70 coopers, 520 women, 700 men, 140 boats; and, in the present year (1819), the quantity caught and cured at Helmsdale amounts to no less than 22,876 barrels, besides upwards of 100,000 cod and ling. While the herring fishery is making these rapid strides in the Highlands of Scotland, the ancient town of North Yarmouth, which owes its existence to the herring fishery, and in the time of Edward III. had an act usually called "The statute of herrings," passed in its favour, for the regulation of its herring fait, now exhibits only the small number of 1039 barrels.—See an Essay on the Migration and Food of the Herring, by J. F. Denovan, Esq., in the *Farmer's Magazine* (vol. xxvi. p. 135.) See also art. *Salmon*, in Part III. Book VII.

3877. *The cod or white fishery*, including haddocks, whittings, ling, skate, halibut, flounders, &c. may be reckoned next in importance to the herring fishery. The whole extent of sea, from the neighbourhood of the Orkney and Shetland islands to Iceland on the one hand, and to the coast of Norway on the other, and along the eastern and western shores of Scotland to the Flemish banks on the east, and the coast of Ireland on the west, may be considered as one great fishing domain, over which the different species of the cod genus are most plentifully dispersed; as are also turbot, skates, soles, haddocks, and whittings. These fish, which constitute collectively what is usually called the white fishery, surround, as it were, the whole of North Britain, and give to that portion of the united kingdom advantages which its southern neighbours cannot boast of.

3878. *The turbot fishery* is, perhaps, that alone in which neither the Scotch nor the English are as successful as the Dutch. The turbot fishery begins about the end of March, when the Dutch fishermen assemble a few leagues to the south of Scheveling. As the warm weather approaches, the fish gradually advance to the northward, and during the months of April and May, are found in great shoals on the bank called the Broad Fourteens. Early in June, they have proceeded to the banks which surround the small island of Heligoland, off the mouth of the Elbe, where the fishery continues to the middle of August, when it terminates for the year. The mode of taking turbot is as follows:—At the beginning of the season, the drag net is used, which, being drawn along the banks, brings up various kinds of flat fish, as soles, plaice, thornbacks, and turbots; but, when the weather has driven the fish into deeper water, and upon banks of a rougher surface, where the drag net is no longer practicable, the fishermen have then recourse to the hook and line. Each line extends from one to nearly three miles in length, and is armed with six, seven, or eight hundred hooks, fixed to at a distance of several yards from each other. To keep these long lines properly stretched, and prevent their being carried away by the tide, heavy masses of lead in some places, and small anchors in others, are attached to them. The hooks are baited with the common smelt, and a small fish resembling the eel, called the gore bill. Though very considerable quantities of this fish are now taken in various parts of our own coasts, from the Orkneys to the Land's End, yet a preference is given, in the London market, to those caught by the Dutch, who are supposed to have drawn not less than 80,000*l.* a year for the supply of this market alone; and the Danes from 12,000*l.* to 15,000*l.* a year, for sauce to this luxury of the table, extracted from about one million of lobsters, taken on the rocky shores of Norway; though our own shores are, in many parts, plentifully supplied with this marine insect, equal in goodness to those in Norway.

3879. *The mackerel fishery* is chiefly carried on off the coast of Suffolk and other southern counties; the season generally lasts about six weeks in May and June, and during which time fish to the value of 10,000*l.* or upwards, are caught off Suffolk alone. (*County Report*.)

3880. *Soles, gurnets, John dories, the red mullet, and other species*, are also caught off the southern coasts; and when the catch is greater than can be disposed of, they are salted and dried.

3881. *The stickleback* is caught in immense quantities in the Lynn river about once in seven years, and is purchased for manure at the rate of 6*d.* or 8*d.* a bushel.

3882. *The pilchard fishery* is carried on extensively on the coast of Cornwall. Enormous multitudes of these fish are taken on the coast of Devonshire as well as Cornwall, between the months of July and September inclusive, when the whole line of coast presents a scene of bustle and activity. The fish for foreign export and winter consumption are laid upon shore in large stacks or piles, with layers of salt between each row; here they are suffered to lie for twenty or thirty days, during which time a vast discharge of pickle mixed with blood and oil takes place, all of which is carefully caught in jits and preserved for manure, which is eagerly purchased by the farmer and carried away in casks. It is said that every pilchard will dress and richly manure one square foot of ground. The fish are then carefully washed with sea water, dried, and packed in hogsheads, in which state they are sent abroad. The average value of pilchards taken in one year in Cornwall is supposed to be from 50,000*l.* to 60,000*l.*

3883. *Lobsters, crabs, crawfish, shrimps, prawns, &c.* are caught generally on the south and east coast, but especially on the south and in the Channel. The Scilly Islands and the Land's End abound in lobsters, and crabs are to be found on most parts of the British shores.

3884. *The oyster* is to be found on most of the rocky shallows on the east and south coasts of Britain and Ireland. The most remarkable circumstance attending this fishery is the feeding or nursing of the oysters, which is almost exclusively practised in Essex. It has been tried, it is said, in the mouths of the Seine and some other rivers of France, without success. The oysters are brought from the coast of Hampshire, Dorset, and other maritime counties, even as far as Scotland, and laid in the beds or layings in the creeks adjoining those rivers. The number of vessels immediately employed in the dredging for oysters are about 200, from twelve to forty or fifty tons burden each, employing from 400 to 500 men and boys. The quantity of oysters bred and taken in Essex, and consumed annually, mostly in London, is supposed to amount to 14,000 or 15,000 bushels.

SECT. II. River Lake, and other Inland Fisheries.

3885. *The only inland fishery of any importance* is that of the salmon. Salmon fisheries, Marshal observes, are "copious and constant sources of human food; they rank next to agriculture. They have, indeed, one advantage over every other internal produce: their increase does not lessen other articles of human sustenance. The salmon does not prey on the produce of the soil, nor does it owe its size and nutritive qualities to the destruction of its compatriot tribes. It leaves its native river at an early state of growth; and, going even naturalists knew not where, returns of ample size, and rich in human nourishment; exposing itself in the narrowest streams, as if nature intended it as a special boon to man. In every stage of savageness and civilisation, the salmon must have been considered as a valuable benefaction to this country." This fish being rarely caught, except in estuaries or rivers, may be considered, in a great degree, as private property; and it may therefore be presumed that the fishery is conducted to the greatest possible extent and advantage. From the extremity of the Highlands, and from the

Orkney and Shetland Islands, these fish are sent up to the London market in ice; and when the season is at its height, and the catch more than can be taken off hand fresh, they are then salted, pickled, or dried, for winter consumption at home, and for the foreign markets. Perhaps the fishery of the Tweed is the first in point of the quantity caught, which is sometimes quite astonishing, several hundreds being taken at a single draught of the net.

3886. *The salmon as they are caught are packed in ice*, and sent away in vessels well known under the name of Berwick smacks. Formerly it was all pickled and kitted, after being boiled, and sent to London under the name of Newcastle salmon; but the present mode has so raised the value of the fish, as nearly to have banished this article of food from the inhabitants in the environs of the fishery, except as an expensive luxury. Within memory, salted salmon formed a material article of economy in all the farm-houses of the vale of Tweed, insomuch that in-door servants often bargained that they should not be obliged to take more than two weekly meals of salmon. It could then be bought at 2s. the stone, of nineteen pounds' weight; it is now never below 12s., often 36s., and sometimes two guineas.

3887. *With respect to the improvement of salmon fisheries*, admitting that the individual fish which are bred in any river instinctively return to the same from the sea, the most obvious means of increase in any particular river is that of suffering a sufficient number of grown salmon to go up to the spawning grounds; protecting them while there, and guarding the infant shoals in their passage thence to the ocean. Even admitting that those which are bred within the British Islands, and escape the perils that await them, return to these islands, it is surely a matter of some importance, viewed in a public light, to increase and protect the breed. It is a well ascertained fact, that salmon pass up toward the spawning grounds of different rivers at different seasons or times of the year; consequently, no one day in the year can be properly fixed by law to give them free passage up rivers in general. Perhaps every river of the island should have its particular day of liberation, which ought to be some weeks before the known close of the spawning season in a given river.

3888. *In a dry season, and for want of flood water* to assist them in their extraordinary efforts to gain the higher branchlets of a river, the salmon will spawn in its lower deeper parts. But here, it is probable, few of their progeny escape the voracity of fish of prey, which inhabit deep waters. While, in the shallow pebbly streams, at the heads of which they delight to lay their spawn, the infant shoal is free from danger; and it is for this security, no doubt, that the instinct of the parents leads them to the greatest attainable height, at the peril of their own lives. Thus far, as to the protection of the parents, and their infant spawnlings; it now remains to guard these from their native streamlets to the sea.

3889. *The enemies of young salmon* are fish of prey, as the pike, and trout of size; both of which ought to be considered as vermin, in rivers down which samlets are wont to pass.

3890. *The heron* is another destructive enemy of young salmon, especially in the higher branches of rivers; yet we see these common destroyers nursed up in heronries. But more wisely might the cormorant be propagated and protected. The heron is tenfold more destructive of fresh-water fish, than is the cormorant.

3891. *The otter* is a well known enemy to fish, but more so to grown salmon than to their young.

3892. *The angler* is a species of vermin which is much more injurious than the otter to young salmon; during minor floods, when the young "fry" are attempting to make their escape downward to the sea, the angler counts his victims by the score; and might boast of carrying home, in his wicker basket, a boat load of salmon. The net fisher is still more mischievous. But most of all the miller, who takes them in his mill traps, by the bushel, or the sack, at once.

3893. *The porpoise*, the most audacious marine animal of prey in northern latitudes, is said to be a great devourer of salmon and other fish on the sea-coast, and in narrow seas and estuaries. It is asserted by those who have had opportunities of ascertaining the fact, that they not only destroy salmon in the narrow seas, and open estuaries, but that they have been seen guarding the mouth of a river, in the salmon season, and destroying them in numbers, as they attempted to enter. If these are facts, it might be worth while for the proprietors of fisheries, or perhaps government, to offer rewards for catching this animal, and thus lessen their number, on the same principles as wolves were extirpated. The author of *The British Naturalist* affirms, from his own experience, that the seal is very easily rendered as docile and affectionate as the dog, and that it might be rendered as useful to man in fishing, as the dog is in shooting and hunting.

3894. *If by wise regulations, formed into a law*, the present supply of salmon could be doubled, the advantage to the community would be of some importance. When we see the great disparity of the supply, between the rivers of the north, and those of the south, of this island, it might not be extravagant to imagine, that the supply from the rivers of England might be made five or ten times what it is at present. One of the first steps towards regulations of this nature is to endeavour to ascertain the causes of this disparity, and to profit by such as can be subjected to human foresight and control. Accurate examinations of the Tay, the Tweed, the Trent, and the Thames, would, perhaps, be found adequate to this purpose.

3895. *There are various modes of taking salmon*, some of which may be mentioned; though it is foreign from our plan to enter into the art of fishing, which is practised by a distinct class of men, created, as it may be said, more by circumstances than regular apprenticeship or study. The situations in which salmon first attract the particular attention of fishermen, are narrow seas, estuaries, or mouths of rivers; in which they remain some time, more or less, probably, according to their states of forwardness with respect to spawning; and in which various devices are practised to take them.

3896. *In the wide estuary of Solway Frith*, which separates Cumberland and Dumfriesshire, several ingenious methods are practised, two of which are entitled to particular notice here. Besides the open channels worn by the Esk, the Eden, and other rivers and brooks that empty themselves into this common estuary, the sands, which compose its base and are left dry at low water, are formed into ridges and valleys, by the tides and tempestuous weather. The lower ends of these valleys, or false channels, are wide and deep, opening downward towards the sea; their upper ends grow narrower and shallower, terminating in points, at the tops of the sand-banks. As the tide flows upward, the salmon, either in search of food, or the channel of the river to which they are destined, enter these valleys or "lakes;" but finding, on the turn of the tide, that their passage farther upward is stopped, they naturally return with it into deep water; where they remain until the next tide. The manorial proprietors of these sand-banks having discovered this fact have, from time immemorial, run lines of nets, during the fishing season, across the lower ends of these lakes or valleys, half a mile, or more, perhaps, in width; the nets being

suspended in such a manner, that they are lifted from the ground by the current of the tide in flowing upward; so that the fish find no difficulty in passing beneath them into the lake: but, on the tide's turning, their lower edges fall down close to the sand, and effectually prevent the salmon from retreating. They are, in consequence, left dry, or in shallow water, and are easily to be taken, by hundreds, perhaps, at once.

5897. *The other remarkable method*, which is practised in the Frith of Solway, is founded on a well-known habit of salmon, when they first make the land, and enter into narrow seas and estuaries, to keep much along the shore: no matter whether to hit, with greater certainty, their native rivers; to rub off the vermin with which, in general, they are more or less infested, when they return from the ocean; or to seek for food. This method of taking salmon, if not a modern invention, has recently been raised to its present degree of perfection, by an enterprising salmon fisher and farmer in the neighbourhood of Annan; who has turned it to great profit. At a short distance below the mouth of the river Annan, he has run out a long line of tall net-fence, several hundred yards in length, and somewhat obliquely from the line of the shore, with which it makes an acute angle, and closes in with it, at the upper end: thus forming, in effect, an artificial lake; one side of which is the beach, the other the net fence. The lower end is ingeniously guarded, with nets of a more trap-like construction than those which are in use for natural lakes: in which fish are found to lie more quietly, until the turn of the tide. In this immense trap, great quantities, not of salmon only, but of cod, ling, soles, and other white fish are taken. Marshal knows no place in the island where sea fishing, for salmon, can be studied with so much profit as on the shores of Annandale.

5898. *River fishing for salmon* is chiefly done with the seine, or long draught net, the construction and use of which are universally known. In rivers liable to frequent and great changes of depth and strength of current, by reason of tides and floods, it is desirable to have nets of different textures, as well as of different depths: as, one of the construction best adapted to the ordinary state of the water, and to the size of the fish that frequent it (salmon peels, trouts, mullets, and other small-sized fish are, in some rivers, commonly taken with salmon); and another with more depth, and wider meshes, to be used during high water and strong currents, when the larger salmon do not fail to hasten upward: and the same strength of hands which is able to draw a close net on it, can work a deeper one with wider meshes. In wide rivers, with flat shores, a variety of nets are required of different lengths as well as depths, to suit every height and width of the water.

5899. *In rivers, traps are set for salmon*. The most common device of this kind is the weir, or salmon leap; namely, a tall dam run across the river, with a sluice at one end of it, through which the principal part, or the whole, of the river at low water, is suffered to pass with a strong current; and in this sluice the trap is set.

5900. *The construction of salmon weirs*, Marshal conceives to be, in all cases, dangerous, and in many highly injurious to the propagation of salmon: and although it would be altogether improper to demolish those which long custom has sanctioned, yet he is of opinion that it would be equally improper to suffer more to be erected; at least, until some judicious regulations are made respecting them; regulations which cannot be delayed without injury to the public.

3901. *It now only remains to speak of poaching, or the illegal taking of grown salmon*. There are already severe penalties inflicted for this crime; which, compared with that of destroying young salmon, might, in a public light, be deemed venial, the latter deserving tenfold punishment: for the grown salmon taken in season by poachers becomes so much wholesome food; there is no waste of human sustenance by the practice. Nevertheless, as theft, the crime is great, and ought to be punishable as such. As an improvement of the present law, Marshal proposes to make the receiver, in this as in other cases of theft, equally punishable with the thief. If poachers were not encouraged by purchasers of stolen salmon, the practice would not be followed.

3902. *Lake fisheries* are of small extent, and are chiefly confined to one or two mountainous districts; and, even there, unless where char or trout abound, as in Keswick and Lochlomond, their value is small, and their improvements few. The Lochfine fishery is to be considered as marine, it being in fact an inlet of the sea.

3903. *Pool-fishing* is, in most parts, peculiar to the seats of men of fortune, and the country residences of minor gentlemen. Surrey and Berkshire are, perhaps, the only districts in which fish-pools are viewed as an object of rural economy. On every side of the metropolis, something of this kind is observable. But it is on the south side, in adjoining parts of Surrey and Sussex, where the practice of fish-breeding may be said to be established. There fish-pools have been, and still are, formed with the view of letting them to dealers in carp and other pond fish; or of stocking them and disposing of the produce as an article of farm stock. In a general view of the kingdom, fish-pools can scarcely be considered as an object worthy of consideration, in the improvement of landed estates: yet there are situations in which they may be formed with profit; as in the dips and hollows of extremely bad ground; especially if waters which are genial to any of the species of pond-fish happen to pass through them, or can be profitably led to them. Even where the water which can be commanded is of an inferior quality, a profitable breeding-pool may be formed to stock ponds of a more fattening nature. Feeding and fattening fish for market is commonly practised in China, and no doubt might be practised in England, with the same ease as fattening pigs. In China, boiled rice, mixed up with the blood of animals, kitchen wash, or any greasy rich fluid of animal offal, is the food with which they are fed once or twice a day: they fatten quickly and profitably.

3904. *The crawfish*, though most delicious eating, and a native of England, neither abounds in sufficient quantities to be brought to market nor is reared by individuals. It requires warm rich marshy lands, and a calcareous soil.

3905. *The leech* is an amphibious animal of the Mollusca order, common about some of the lakes in the north of England, as Keswick. Formerly considerable quantities used to be packed up and sent to London, and other places; but the market is now chiefly supplied from the Continent.

CHAP. IX.

Plantations and Woodlands.

3906. *Without trees*, a landed estate may be very profitable, on account of its mines, waters, and farm lands; but it will be without the noblest characteristic of territorial surface. It may possess the beauty of utility in a high degree, and especially to the owner; but it will not be much admired by the public, nor contribute greatly to the ornament of the country—for what is a landscape without wood? It is not meant, however, that plantations of trees should be made on estates for the sake of ornament; on the contrary, none need ever be made which shall not be at the same time useful, either from the products of the trees individually, or their collective influence on surrounding objects.

3907. *Trees have been planted and cherished in all countries, and from the earliest ages*; but the formation of artificial plantations chiefly with a view to profit appears to have been first practised in Britain, about the end of the sixteenth century, when the insufficiency of the natural forests, which had hitherto supplied civilised society in England with timber and fuel, rendered planting a matter of necessity and profit. In the century succeeding, the improved practice of agriculture created a demand for hedges, and strips for shelter; and the fashion of removing from castles in towns and villages to isolated dwellings surrounded by verdant scenery, led to the extensive employment of trees both as objects of distinction and value. For these combined purposes, planting is now universally practised on most descriptions of territorial surface, for objects principally relating to utility; and, in all parks and grounds surrounding country residences, for the joint purposes of utility and beauty. It has often been suggested, that an agreement might be made between landlord and tenant, under which it would be the tenant's interest to plant trees upon suitable parts of his farm, of little value for other purposes, and to protect them when planted. This would not only promote the interests of both, but add much to the ornament of the country. We cannot but regret that some such plan is not devised and generally adopted.

3908. *Woodlands* are lands covered with wood by nature, and exist more or less on most extensive estates. Sometimes it is found desirable partially or wholly to remove them, and employ the soil in the growth of grass or corn; at other times, their character is changed by art, from coppice or fuel woods, consisting of growths cut down periodically, to trees left to attain maturity for timber.

3909. *In our view of the subject of trees*, we shall include some remarks on improving and managing woodlands, which might have been referred to the two following books; but, for the sake of unity, we prefer treating of every part of the subject together. The ornamental part of planting we consider as wholly belonging to gardening, and indeed the subject of timber trees may be considered as equally one of gardening and of agriculture, being the link by which they are inseparably connected. For a mere extended view of the subject, therefore, we refer to our *Encyclopædia of Gardening*, and *Encyclopædia of Plants*: in the former will be found all that relates to the culture of trees collectively; in the latter, all that relates to their botanical character, history, uses, height, native country, and other subjects, with their individual propagation, soil, and culture. We shall here confine ourselves to the soils and situations proper for planting, the trees suitable for particular soils and situations, the operations of forming and managing artificial plantations, and the management of natural woods.

SECT. I. *Soils and Situations which may be most profitably employed in Timber Plantation.*

3910. *As a general principle of guidance in planting*, it may be laid down, that lands fit for the purposes of aration should not be covered with wood. Where particular purposes are to be obtained, as shelter, fencing, connection, concealment, or some other object, portions of such lands may require to be wooded; but, in regard to profit, these portions will generally be less productive than if they were kept under grass or corn. The profits of planting do not depend on the absolute quantity of timber produced, but on that quantity relatively to the value of the soil for agricultural purposes. Suppose a piece of ground to let at 20s. per acre, for pasture or aration, to be planted at an expense of only 10l. per acre; then, in order to return the rent, and 5l. per cent. for the money expended, it ought to yield 30s. a year; but as the returns are not yearly, but say at the end of every fifteen years, when the whole may be cut down as a copse, then, the amount of 30s. per annum, at 5l. per cent. compound interest, being 32l. 8s., every fall of copse made at the interval of fifteen years ought to produce that sum per acre clear of all expenses. Hence, with a view to profit from the fall of timber, or copse wood, no situation capable of much agricultural improvement should be planted.

3911. *The fittest situations for planting extensively* are hilly, mountainous, and rocky surfaces; where both climate and surface preclude the hope of ever introducing the plough; and where the shelter afforded by a breadth of wood will improve the adjoining farm lands, and the appearance of the country. Extensive moors and gravelly or sandy soils may often also be more profitably occupied by timber trees than by any other crop, especially near a seaport, collieries, mines, or any other source of local demand.

3912. *On all hilly and irregular surfaces* various situations will be indicated by the lines of fences, roads, the situations of buildings, ponds, streams, &c., where a few trees, or a strip, or mass, or row, may be put in with advantage. We would not, however, advise the uniform mode of planting recommended by Pitt in his *Survey of Staffordshire*, and in *The Code of Agriculture*; that of always having a round clump in the point of intersection of the fences of fields. This we conceive to be one of the most certain modes ever suggested of deforming the surface of a country by planting; the natural character of the surface would be counteracted by it, and neither variety nor grandeur substituted; but a monotony of appearance almost as dull and appalling as a total want of wood.

3913. *Near all buildings* a few trees may in general be introduced; carefully however avoiding gardens and rick-yards, or shading low buildings. In general fewest trees should be planted on the south-east side of cottages; and most on their north-west side; farms and farm buildings in very exposed situations (*fig. 588.*), and also lines of cottages, may be surrounded or planted on the exposed side by considerable masses.

588

3914. *Wherever shelter or shade is required*, plantations are of the first consequence, whether as masses, strips, rows, groups, or scattered trees; all these modes may occasionally be resorted to with advantage even in farm lands.

3915. *Wherever a soil cannot by any ordinary process be rendered fit for corn or grass, and will bear trees*, it may be planted, as the only, or perhaps the best, mode of turning it to profit. There are some tracts of thin stony or gravelly surfaces covered with moss, or very scantily with heath, and a few coarse grasses, which will pay for no improvement whatever, except sowing with the seeds of trees and bushes. These growing up will, after a series of years, form a vegetable soil on the surface. The larch, Scotch pine, birch, and a species of rough moorland willow (*Salix*) are the only woody plants fit for such soils. Those who have subjected to the plough old woodland, Sir Henry Stewart remarks, well know how "inconceivably even the poorest soils are meliorated by the droppings of trees, and particularly of the larch, for any considerable length of time, and the rich coat of vegetable mould which is thereby accumulated on the original surface." It would appear indeed, that on certain surfaces the growth and decay of forests are the means adopted by nature for preparing the soil for the culture of corn; as on certain other soils, a stock of nutritive matter is created by peat moss, or marsh, as on the barest rocks, the rudiments of a soil are formed by the growth and decay of lichens.

3916. *Wherever trees will pay better than any other crop*, they will of course be planted. This does not occur often, but occasionally in the case of willows for baskets and hoops, which are often the most profitable crop on moist deep rich lands; and ash for hoops and crate ware, on drier, but at the same time deep and good, soils.

SECT. II. *Trees suitable for different Soils, Situations, and Climates.*

3917. *Every species of tree will grow in any soil*, provided it be rendered sufficiently dry; but every tree, to bring its timber to the highest degree of perfection, requires to be planted in a particular description of soil, situation, and climate. The effects of soils on trees are very different, according to the kind of tree and the situation. A rich soil and low situation will cause some trees, as the larch and common pine, to grow so fast that their timber will be fit for little else than fuel; and the oak, elm, &c., planted in a very elevated situation, whatever be the nature of the soil, will never attain a timber size. In general, as to soils, it may be observed that such as promote rapid growth, render the timber produced less durable, and the contrary; that such soils as are of the same quality for a considerable depth are best adapted, other circumstances being alike, for ramose-rooted trees, as the oak, chestnut, elm, ash, and most hard-wooded trees; and that such soils as are thin, are only fit for spreading or horizontal-rooted trees, as the pine and fir tribe.

3918. *A natural succession in the kind of tree* has been found to take place where natural forests have been destroyed. Evelyn noticed that, at Wooton, where goodly oaks grew and were cut down by his grandfather 100 years before, beech succeeded, and that, when his brother had extirpated the beech, birch rose up. (*Gard. Mag.* vol. iii. p. 351.) In Dwight's *Travels in New England*, a number of instances are given, in some of which the pine and fir tribe were succeeded by deciduous trees, and in others the reverse. Soulange-Bodin also, and some other French and German writers, have observed the same thing to take place on the continent of Europe, and use the fact as an argument for the introduction of exotic trees to succeed the natives.

3919. *A table of soils and the trees suitable to them*, which may be of some use, is given in *The Agricultural Survey of Kent*. It indicates the trees which grow naturally on a variety of soils and subsoils; and, next, the sorts which yield most profit on such soils.

Surface Soil.	Subsoil.	Common Growth.	Planted Growth.	Uses of.
Heavy and gravelly loams.	Heavy loam with chalk.	Birch, hornbeam, oak, ash, hazel, beech, &c.	Oak, ash, chestnut, willow, lime, walnut.	Timber, hop-poles, cordwood, hurdles, bavons for bakers, and lime-works. Ditto.
Sandy loams.	Heavy loam.	Ditto.	Elm, beech, Weymouth pine, common spruce.	
Flinty strong loam.	Heavy loam.	Ditto.	Willow and chestnut.	Timber, fencing-poles, and as above.
Gravelly and sandy loams.	Gravelly loam.	Ash, beech, oak, hazel, &c.	Chestnut, ash.	Hop-poles, fencing-poles, and all as above.
Gravelly, sandy, and flinty loams.	Heavy, gravelly, flinty loam.	Ash, beech, hornbeam, and oak.	Ash, beech, larch, &c.	Timber, - fencing, hop-poles, cordwood for charcoal, bavons, &c.
Flinty, dry, poor gravelly loams.	Chalk at two feet depth with gravelly loam.	Beech, oak, &c.	Beech, larch, &c.	Cordwood, bavons, and hop-poles.
Flinty and gravelly loams.	Chalk 4 feet with deep gravelly loam.	Ash, oak, hazel, &c.	Ash, larch, &c.	Cordwood, hop-poles, bavons, stakes, ethers, &c.
Ditto.	With a few flints, but nearly as above.	Oak, hazel, beech, and ash.	Chestnut, ash, and willow.	Hop-poles, fencing-poles, stakes, cordwood, &c.
Lightish black loam.	Dry sandy gravel.	Birch, elm, ash.	Ash, elm, &c.	Various uses in husbandry.
Flinty gravelly loams.	Strong loam with flints.	Oak, ash, beech, &c.	Ash, &c.	Poles, bavons, cordwood, &c.
Chalky, flinty, gravelly loam.	Chalk, with some gravelly loam.	Ditto.	Ditto.	Ditto.
Gravelly loam.	Heavy flinty and poor loam.	Oak, ash, hazel, and beech.	Ash, oak, &c.	Common produce a few poles, cordwood, bavons, &c. plantation many poles, and the above.
Gravelly and chalky loams.	Gravelly loam with chalk.	Oak, ash, &c.	Ash and chestnut.	Poles, cordwood, &c.
Gravelly loam. Ditto.	Ditto. Gravelly loam and heavy loam.	Ash, oak, & beech. Ditto.	Oak, larch. Scotch pine.	Ditto. The same.
Sandy gravel.	Gravelly and sandy loam.	Ditto, Scotch pine.	Larch, chestnut, &c.	Poles, stakes, ethers, &c. &c.
Stone, shatter, and gravelly loam.	Strong loam with ragstone.	Oak, hazel, birch, &c.	Birch, oak, &c.	Oaken tillers, small timber poles, &c.
Stone, shatter, and gravelly loam.	Gravelly loam with some stone.	Oak, birch, aspen, hazel, and ash.	Ash, chestnut, and willow.	Fencing-poles, hop-poles, cordwood, &c.
Gravelly loam.	Gravelly loam with some stones.	Oak.	Chestnut.	Hop-poles, fence poles, &c.
Sandy loam.	Gravelly loam.	Birch, oak, hornbeam, &c.	Chestnut, &c.	Fence poles, hop-poles, &c.
Sandy loam and stone shatter.	Gravelly loam with ragstone.	Oak, beech, birch, hazel, ash.	Ditto.	Ditto.
Gravelly loam and stone shatter. Ditto.	Deep loam, heavy clay and gravel. Gravelly loam.	Ditto.	Ditto.	Ditto.
Gravelly and sandy loam.	Strong clay and loam.	Oak, and ditto.	Ditto. Ash, larch, &c.	Ditto. Poles, fire-wood, &c. as above.
Gravelly loam flinty.	Gravel with clay and some flint.	Scrubby oak, hazel, &c.	Oak, ash.	Timber and ditto.
Wet spongy land.	Moist and boggy earth.	Alder, willow.	Alder, osier, willow, &c.	Hurdles, hop-poles, &c.
Drier ditto.	Ditto more dry.	Poplar.	White poplar, willow.	Hop-poles, &c.
Light sandy loam.	Dry gravelly earth.	Mountain ash, ash.	Scotch pine, silver fir.	Hop-poles.
Light gravelly loam.	With dry gravel.	Ash.	Sycamore.	Timber-turnery, &c.

5920. *With respect to climate*, the trees which grow nearest the regions of perpetual snow are the birch, common pine, white beam, larch, mountain ash, and elder. A warmer zone is required for the sycamore and hornbeam; and still more for the beech, ash, elm, and maple. The exotic pines and firs prefer dry sheltered dingles and ravines, not far up the sides of hills; and the oak, chestnut, lime, poplars, tree willows, and a variety of American trees, will not thrive at any great elevation above the sea. The hardiest shore trees are the sycamore, beech, and elder; but on sheltered shores, or such as are little subject to the sea-breeze, pines, firs, and most sorts of trees will thrive.

5921. *The sort of product desired from planting*, as whether shelter, effect, or timber, copse, bark, fuel, &c. and what kinds of each, must be, in most cases, more attended to than the soil, and in many cases even than the situation. The thriving of trees and plants of every kind, indeed, depends much more on the quantity of available soil, and its state in respect to water and climate, than on its constituent principles. Moderately sheltered and on a dry subsoil, it signifies little, as far as growth is concerned, whether the surface strata be a clayey, sandy, or calcareous loam: all the principal trees will thrive nearly equally well in any of these, so circumstanced; but no tree whatever in these or in any soil saturated with water, and in a bleak exposed site. The durability of the timber of different trees, produced under such circumstances, will also be very different. For durability, as already observed, it seems essential that every species of tree should be planted in its natural soil, situation, and climate. For hedge-row timber, those kinds which grow with lofty stems, which draw their nourishment from the subsoil, and do least injury by their shade, are to be preferred. These, according to Blaikie, are oaks, narrow-leaved elm, and black Italian poplar; beech, ash, pines, and firs, he says, are ruinous to fences, and otherwise injurious to farmers. (*On Hedges and Hedgerow Timber*, p. 10.)

SECT. III. Forming Plantations.

5922. *The formation of plantations* includes the enclosing, the preparation of the soil, and the mode of planting or sowing.

5923. *The enclosing of plantations* is too essential a part of their formation to require enlarging on. In all those of small extent, as hedges and strips, it is the principal part of the expense; but to plant in these forms, or in any other, without enclosing, would be merely a waste of labour and property. The sole object of fencing being to exclude the domestic quadrupeds, it is obvious, that whatever in the given situation is calculated to effect this at the least expense, the first cost and future repairs or management being taken into consideration, must be the best. Where stones abound on the spot, a wall is the best and cheapest of all fences as such; but, in the great majority of cases, recourse is obliged to be had to a verdant fence of some sort, and generally to one of hawthorn. This being itself a plantation, requires to be defended by some temporary barrier, till it arrives at maturity; and here the remark just made will again apply, that whatever temporary barrier is found cheapest in the given situation will be the best. Hedge fences are in general accompanied by an open drain, which, besides acting in its proper capacity, furnishes at its formation a quantity of soil to increase the nutriment of the hedge plants; an excavation (*fig. 589. a*), and an elevation (*f*), to aid in the formation of a temporary fence.

A hedge enclosing a plantation requires only to be guarded on the exterior side; and of the various ways in which this is done, the following may be reckoned among the best and most generally applicable: — an open drain and paling, or line of posts and rails; the plants inserted in a facing of stone, backed by the earth of the drain (*b*), an excellent mode, as the plants generally thrive, and almost never require cleaning from weeds; an open drain and paling, and the hedge on the top of the elevation (*c*); no open drain, but, the soil being a loam, the surface-turves formed into a narrow ridge, to serve as a paling, a temporary hedge of furze sown on its summit, and the permanent hedge of thorn or holly within (*d*); and an open drain, but on the inside, the exterior being protected by a steep bank sown with furze (*e*). The first of these modes is the most general, the second the best, and the fourth the cheapest, where timber is not abundant. Separation fences are commonly formed in the first, second, or third manner, but with a paling on both sides. (See *Fences*, Part II. Book IV.)

5924. *In the preparation of the soil* for planting, draining is the first operation. Whatever may be the nature of the soil, if the plants are intended to thrive, the subsoil ought to be rendered dry. Large open drains may be used, where the ground is not to undergo much preparation; but where it is to be fallowed or trenched, under-drains become requisite. It is true they will in time be choked up by the roots of the trees; but by that period, as no more culture will be required, they may be opened and left open. Many situations, as steep sides of hills and rocky irregular surfaces, do not admit of preparing the soil by comminution previously to planting; but wherever that can be done, either by trenching, digging, or a year's subjection to the plough, it will be found amply to repay

the trouble. This is more especially requisite for strips for shelter, or hedge-rows, as the quick growth of the plants in these cases is a matter of the utmost consequence. The general mode of planting hedges by the side of an open drain renders preparation for them, in many cases, less necessary; but for strips of trees, wherever it is practicable, and there is at the same time no danger of the soil being washed away by rains or thaws, as in some chalky hilly districts, or blown about by the wind, as in some parts of Norfolk and other sandy tracts, preparation by a year's fallow, or by trenching two spits deep, cannot be omitted without real loss, by retarding the attainment of the object desired. Mr. Withers of Norfolk not only prepares poor light land by paring, and burning, and trenching, but even spreads on it marl and farmyard dung, as for a common agricultural crop; and at the same time keeps the surface perfectly free from weeds by hoeing till the young trees have completely covered the ground. The progress that they make under this treatment is so extremely rapid, as apparently to justify, in an economical point of view, the extraordinary expenses that attend it. In three years, even oaks and other usually slow-growing forest trees have covered the land, making shoots of three feet in a season, and throwing out roots well qualified, by their number and length, to derive from the subsoil abundant nourishment, in proportion as the surface becomes exhausted. (*Trans. Soc. for Encour. Arts*, vol. xlv.) Cobbett (*The Woodlands*, 8vo. 1825.) recommends trenching the ground two feet deep at the least, keeping the old soil still at the top, unless there is plenty of manure, when, he says, the top soil may be laid in the bottom of the trench. There are instances stated, of promising oak plantations, from acorns dibbed into soil altogether unimproved, and of plantations of Scotch pine raised by merely scattering the seeds, without covering, on a heath or common, and excluding cattle (*General Report of Scotland*, ii. 269.); but these are rare cases, and the time required, and the instances of failure, are not mentioned. The practice is obviously too rude to be recommended as one of art. The best situations for planting, without any other culture but inserting the seeds or plants, are surfaces partially covered with low woody growths, as broom, furze, &c. "The ground which is covered, or rather half covered, with juniper and heath," says Buffon, "is already a wood half made." Gordon, Emmerich, Hayes, Speechly, Marshall, Cruikshank, and others, have shown that the most effectual method of raising oak plantations is by sowing patches of 3 or 4 acorns on dug spots, as far distant from one another as is to be the distance of the trees when half grown. The intermediate spaces, if not covered with furze, broom, or native copse, are to be planted with birch, larch, spruce, or Scotch pine. (See § 3923.)

3925. *A controversy on the subject of the preparation of the soil previously to planting*, has lately arisen between Sir Henry Steuart, Sir Walter Scott, Mr. Withers, Mr. Billington, and others, which it might be deemed improper to pass over here without notice. Scott contends, that preparing the soil accelerates the growth of the tree for a few years only, and, in as far as it has that effect, renders the timber of a less durable quality. Stuart admits the rapidity of the growth of timber on soils which have been prepared, but seems to allow, with Scott, that the timber will be less durable. Withers and Billington assert, that the preparation of the soil accelerates the growth of timber without impairing its durability; and the former has cited some experiments to show that oak, which has grown on good soils and rapidly, has proved stronger than oak which had grown on worse soils slowly. The result of general experience, or what may be called the common sense of gardeners and foresters on this subject, seems to be this:—Preparation of the soil greatly increases the rapidity of the growth of trees, and it has not been found to lessen the strength of the timber produced; on the contrary, oak, ash, willow, and poplar, when freely, or rapidly rather than slowly grown, seem to produce stronger timber, than when slowly and stintedly grown on poor soils. But strength and durability are properties that depend on different qualities of organisation, and it is generally considered that slowly-grown timber is the most durable. We have, ourselves, no doubt of the fact, and more especially in the case of the resinous timbers. We have seen both larch and Scotch pine of a timber size, which had been rapidly grown in rich soil, and which, when cut down, had begun to decay in the heart. We would not, however, on that account cease to prepare the soil for resinous trees, as much as for the other kinds, where practicable; but we would take care to plant resinous trees only on poor soils. We have reason to believe that these opinions on the preparation of the soil for trees, and the durability and strength of timber, are those of the practical men of the present day of greatest science and experience; such, for example, as Sang, Gorrie, Main, Billington, and Cruikshank; and therefore we consider them as more especially entitled to attention in a work like the present.

3926. *Whether extensive plantations should be sown or planted* is a question about which planters are at variance. Miller says, transplanted oaks will never arrive at the size of those raised where they are to remain from the acorn. (*Dict. Quercus*.) Marshal prefers sowing where the ground can be cultivated with the plough. (*Plant. and Rur. Orn.* i. 123.) Evelyn, Emmerich, and Speechly, are of the same opinion; Pontey and Nicol

practise planting, but offer no arguments against sowing where circumstances are suitable. Sang says, "It is an opinion very generally entertained, that planted timber can never, in any case, be equal in durability and value to that which is sown. We certainly feel ourselves inclined to support this opinion, although we readily admit that the matter has not been so fully established, from experiment, as to amount to positive proof. But although we have not met with decided evidence, to enable us to determine on the comparative excellence of timber raised from seeds, without being replanted, over such as has been raised from replanted trees, we are left in no doubt as to the preference, in respect of growth, of those trees which are sown, over such as are planted." (*Plant. Kal.* 43.) He particularly prefers this mode for raising extensive tracts of the Scotch pine and larch (p. 430.), and is decidedly of opinion, "that every kind of forest tree will succeed better by being reared from seeds in the place where it is to grow to maturity, than by being raised in any nursery whatever, and thence transplanted into the forest." (p. 344.) Dr. Yule (*Caled. Hort. Mem.* ii.), in a long paper on trees, strongly recommends sowing where the trees are finally to remain. "It is," says he, "a well ascertained fact, that seedlings allowed to remain in their original station, will, in a few seasons, far overtop the common nursed plants several years older."

3927. *The opinion of Dr. Yule seems to be founded on the idea that the tap-root is of great importance to grown up trees, and that when this is once cut off by transplanting, the plant has not a power of renewing it. That the tap-root is of the utmost consequence for the first three or four years, perhaps for a longer period, is obvious, from the economy of nature at that age of the plant; but that it can be of no great consequence to full-grown trees, appears highly probable from the fact, that when such trees are cut down, the tap-root is seldom to be distinguished from the others. The opinion that young plants have not the power of renewing their tap-root, will, we believe, be found inconsistent with fact; and we may appeal to nurserymen, who raise the oak and horse-chestnut from seed. It is customary when these are sown in drills, to cut off their tap-roots without removing the plants at the end of the second year's growth, and when, at the end of the third or fourth year, they are taken up, they will be found to have acquired other tap-roots, not indeed so strong as the first would have been had they remained, but sufficient to establish the fact of the power of renewal. We may also refer to the experiment recorded by Forsyth, which at once proves that trees have a power of renewing their tap-roots, and the great advantages from cutting down trees after two or three years' planting. Forsyth "transplanted a bed of oak-plants, cutting the tap roots near to some of the side-roots or fibres springing from them. In the second year after, he headed one half of the plants down, and left the other half to nature. In the first season, those headed down made shoots six feet long and upwards, and completely covered the head of the old stem, leaving only a faint cicatrix, and produced new tap-roots upwards of two feet and a half long. That half of the plants that were not headed, were not one fourth the size of the others. One of the former is now eighteen feet high, and fifteen inches in circumference, at six inches from the ground: one of the largest of the latter measures only five feet and a half in height, and three inches and three quarters in circumference, at six inches from the ground." (*Tr. on Fruit Trees*, 4to. edit. 144.) The pine and fir tribes receive most check by transplanting; and when removed at the age of four or five years, they seldom arrive at trees afterwards; those we should, on most occasions, prefer to sow, especially upon mountainous tracts. But for all trees which stole, and in tolerable soils and situations, planting strong plants, and cutting them down two or three years afterwards, will, we think, all circumstances considered, be found preferable to sowing. If we made an exception, it would be for the oak in poor soils, which we would raise from the acorn in Cruikshank's manner. Sir Henry Stuart (*Planter's Guide*, 2d edit. p. 423.) concurs in this opinion, with respect to deciduous trees, and considers that as the pine and fir tribes receive "the greatest check from transplanting; and as, when planted at four and five years old, they do not readily grow to timber, it is clear that they should always be sowed, or at least planted, very young, in high and cold regions."*

3928. *On the subject of disposing the plants in plantations, there are different opinions; some advising rows, others quincunx, but the greater number planting irregularly. According to Marshal, "the preference to be given to the row, or the random culture, rests in some measure upon the nature and situation of the land to be stocked with plants. Against steep hangs, where the plough cannot be conveniently used in cleaning and cultivating the interspaces, during the infancy of the wood, either method may be adopted; and if plants are to be put in, the quincunx manner will be found preferable to any. In more level situations, we cannot allow any liberty of choice: the drill or row manner is undoubtedly the most eligible." (*Plant. and Rur. Orn.* p. 123.) Pontey considers it of much less consequence than most people imagine, whether trees are planted regularly or irregularly, as in either case the whole of the soil will be occupied by the roots and the surface by the shoots. Sang and Nicol only plant in rows where culture with the horse-hoe is to be adopted. In sowing for woods and copses, the former places the patches six feet asunder and in the quincunx order. "It has been demonstrated (*Farmer's Mag.* vol. vii. p. 409.), that the closest order in which it is possible to place a number of points upon a plain surface, not nearer than a given distance from each other, is in the angles of hexagons with a plant in the centre of each hexagon." Hence it is argued, that this order of trees is the most economical; as the same quantity of ground will contain a greater quantity of trees, by 15 per cent. when planted in this form than in any other. (*Gen. Rep.* ii. 287.) It is almost needless to observe, that hedge plants should be placed at regular distances in the lines, and also the trees, when those are introduced in hedges. Osier plantations, and all such as like them require the soil to be dug every year, or every two years, during their existence, should also be planted in regular rows.*

3929. *The distances at which the plants are placed must depend on different circumstances, but chiefly on the situation and soil.*

3930. *Planting thick, according to Nicol*, is the safer side to err on, because a number of plants will fail, and the superfluous ones can be easily removed by thinning. For bleak situations, he observes, from thirty to forty inches is a good medium, varying the distance according to circumstances. For less exposed situations, and where the soil is above six inches in depth, he recommends a distance of from four to five feet. For belts, clumps, and strips of a diameter of about one hundred feet; the margin to be planted about the distance of two feet, and the interior at three feet. In sheltered situations of a deep good soil, he recommends a distance of six feet and no more. (*Pract. Plant.*)

3931. *According to Sang*, "the distances at which hard-timber trees ought to be planted are from six to ten feet, according to the quality of the soil, and the exposed or sheltered situation. When the first four oaks are planted, supposing them at right angles, and at nine feet apart, the interstices will fall to be filled up with five nurses, the whole standing at four feet and a half asunder. When sixteen oaks are planted, there will necessarily be thirty-three nurses planted; and when thirty-six oaks are planted, eighty-five nurses; but when a hundred principal trees are planted in this manner, in a square of ten on the side, there will be two hundred and sixty-one nurse-plants required. The English acre would require five hundred and thirty-six oaks, and one thousand six hundred and ten nurses." (*Plant. Kal.* 163.) Pontey says, "in general cases, a distance of four feet is certainly close enough; as at that space the trees may all remain till they become saleable as rails, spars," &c.

3932. *The number of plants which may be planted on a statute acre = 160 rods, or poles, = 4840 yards = 43560 feet, is as follows: —*

Feet apart.	No. of Plants.	Feet apart.	No. of Plants.	Feet apart.	No. of Plants.
1	43,560	6	1,210	15	193
1½	19,360	7	889	16	170
2	10,890	8	650	17	150
2½	6,969	9	537	18	134
3	4,840	10	435	19	120
3½	3,556	11	360	20	108
4	2,792	12	302	25	69
4½	2,151	13	257	30	48
5	1,742	14	222		

3933. *The size of the plants depends jointly on the site and the kind of tree; it is universally allowed that none of the resinous tribe succeed well when removed at more than two years' growth; but if the soil is of tolerable quality, prepared by digging or summer pitting, and the site not bleak, plants of such hard woods as stole may be used whose stems are an inch or more in diameter.*

3934. *Nicol is of opinion*, "That, generally, trees three, or at most four, years old from the seed, and which are from twelve to twenty-four inches high, will, in any situation or soil, outgrow those of any size under eight or ten feet, within the seventh year." (*Pract. Plant.* 130.)

3935. *Sang observes*, "the size of plants for exclusive plantations must, in some measure, depend on their kinds; but it may be said, generally, that the plants being transplanted, they should be from a foot to eighteen inches in height, stiff in the stem and well rooted. Plants for this purpose should seldom be more than three years from the seed; indeed never, if they have been raised in good soil. Many of them may be sufficiently large at two years from the seed; and, if so, are to be preferred to those of a greater age, as they will consequently be more vigorous and healthy. The larch, if properly treated, will be very fit for planting out at two years of age. A healthy seedling being removed from the seed-bed at the end of the first year, into good ground, will, by the end of the second, be a fitter plant for the forest, than one nursed a second year. The next best plant for the purpose is that which has stood two years in the seed-bed, and has been transplanted for one season. This is supposing it to have risen a weakly plant; for, if the larch rise strong from the seed the first season, it should never stand a second in the seed-bed. The ash, the elm, and the sycamore, one year from the seed, nursed in good soil for a second season, will often prove sufficiently strong plants. If they be weakly, they may stand two years in the seed-bed; and then, being nursed one season in good soil, will be very fit for planting out in the forest. The oak, the beech, and the chestnut, if raised in rich soil, and well furnished with roots at the end of the first year, and having been nursed in rows for two years, will be very fit to be planted out: but if they be allowed to stand two years in the seed-bed, and be planted one year in good ground, they will be still better, and the roots will be found well feathered with fine small fibres. The silver fir and common spruce should stand two years in the seed-bed. If transplanted into very good soil, they may be fit for being planted out at the end of the first year; but, more generally, they require two years in the lines. The Scots pine should also stand for two years in the seed-bed, and should be nursed in good ground for one year; at the end of which they will be much fitter for being planted, than if they were allowed to stand a second year in the lines. They are very generally taken at once from the seed-bed; and, in land bare of heath or herbage, they succeed pretty well; nevertheless, we would prefer them one year nursed. The above are the hardy and most useful forest trees; and from the observations made, whatever respects the age or size of other kinds may easily be inferred." (*Plant. Kal.* 158.)

3936. *According to Pontey*, "the best general rule is, to proportion the size of the plants to the goodness of the soil; the best of the latter requiring the largest of the former. Still, on bleak exposures, this rule will not hold good, as there the plants should never be large, for otherwise the greater part would fail from the circumstance of wind-waving, and, of those that succeeded, few, if any, would make much progress for several years; pines and firs of a foot, and deciduous trees of eighteen inches, are large enough for such places. As in extensive planting, soils which are good and well sheltered but seldom occur, the most useful sizes of plants, for general purposes, will be pines and firs of a foot, and deciduous trees of eighteen inches, both transplanted. None but good-rooted plants will succeed on a bad soil, while on a good one, sheltered, none but very bad-rooted plants will fail. A large plant never has so good a root, in proportion to its size, as a small one; and hence we see the propriety of using such on good soils only. Small plants lose but few of their roots in removal; therefore, though planted in very moderate-sized holes of pulverised earth, they soon find the means of making roots, in proportion to their heads. It should never be forgotten, that, in being removed, a plant of two feet loses a greater proportion of its roots than a tree of one, and one of three feet a greater proportion than one of two, and so on, in proportion to its former strength and height; and thus, the larger the plants, so much greater is the degree of languor or weakness into which they are thrown by the operation of transplanting." (*Prof. Plant.* 161.)

3937. *The seasons for planting are autumn and spring: the former, when the soil and situation are moderately good, and the plants large; and the latter, for bleak situations. Necessity, however, is more frequently the guide here than choice, and in extensive designs the operation is generally performed in all moderately dry open weather from October to April inclusive. "In an extensive plantation," Sang observes, "it will hardly happen but there will be a variety of soil, some parts moist and heavy, and others dry and light. The lightest parts may be planted in December or January; and the*

more moist, or damp parts, in February or March. It must be observed, however, that if the ground be not in a proper case for planting, the operation had better be delayed. The plants will be injured, either by being committed to the ground when it is in a sour and wet, or in a dry parched, state. At a time when the soil is neither wet nor dry, the operation of planting is most successfully performed. The mould does not then adhere to the spade, nor does it run in; it divides well, and is made to intermingle with the fibres of the plants with little trouble; and in treading and setting the plant upright, the soil is not worked into mortar, which it necessarily must be, if in a wet state, evidently to the great detriment of the plants. It is therefore improper to plant on a retentive soil in the time of rain, or even perhaps for some days afterwards, or after a fall of snow, until it has for some days disappeared. Whereas, in a dry absorbent soil, it may be proper to plant in the time of gentle showers, immediately after heavy rains, or as soon as the snow is dissolved." (*Plant. Kal.* 157.)

3938. *Pontey* is a decided advocate for autumn preparation of the soil, and spring planting. "Autumn planting," he says, "is advisable only in few cases, while spring planting may properly apply to all."

3939. According to *Sang*, the proper time for planting the pine and fir tribes, and all evergreens, is April, or even the first fortnight in May. "Attention should be paid, that no greater number of plants be lifted from the nursery than can be conveniently planted on the same day. Damp weather is the best. When very dry, and the plants rise destitute of earth at their roots, their roots should be dipped in mud (puddle) so as to be coated over by it. In all cases, care should be taken not to shake off any adhering earth from plants at the time of planting." (*Plant. Kal.* 341.)

3940. A puddle for trees is made by mixing water with any soil rather tenacious, so intimately as to form a complete puddle, so thick that when the plants are dipped into it, enough may remain upon the roots to cover them. The process of puddling is certainly simple, and its expense too trifling to deserve notice: its effects, however, in retaining, if not attracting, moisture are such that, by means of it, late planting is rendered abundantly more safe than it otherwise would be. It is an old invention, and hence it is truly astonishing that it is not more frequently practised. If people were to adopt it generally in spring planting, *Pontey* believes the prejudice in favour of autumn practice would soon be done away. (*Prof. Plant.* 167.)

3941. *Cobbett* prefers spring planting. "It is a great error," he says, "to suppose that you gain time by autumnal or winter planting. You do, indeed, see the buds come out a little more early in the spring; but it is the effect at the end, and not at the beginning, of the summer, at which you ought to look. If you plant in the autumn or winter, the plants get blown about for several months, and, in very wet weather, their stems work a sort of hole round themselves; and thus the root itself is shaken; and if left thus, they will, by March, be generally leaning on one side, with the hole open on the other side; and when the harsh winds of March come upon the long-time battered ground, it will present a surface nearly as hard as a road. In such a case, the ground ought to be dug or spaded up between the trees in March or in April; for nothing can thrive well in ground thus baked, however good the ground may be in its nature." (*The Woodlands*, 44.)

3942. *Pruning previously to planting.* If the plants have been brought from a distance, and the fibrous roots are dried up, they should all be cut off, because, like the leaves of a tree which has been taken up in the growing state and become withered, they have lost their vitality. The larger fibres, which are only dead at the points, should be shortened. The tap-root, also, should be shortened, perhaps in most cases two thirds of its length. *Cobbett* observes, and with truth, as far as our experience goes, that if the longest tap-roots "were put into the ground at full length with an iron bar, they would be sure to die all the way nearly up to the top." (*Woodlands*, 68.) Many trees, however, have no tap-roots, and these only require attention to the fibres. When the plants are newly taken up from the seed-bed, or nursery lines, they may be planted without cutting off the fibres; because these will retain their vitality uninjured.

3943. The operation of inserting the plants in the soil is performed in various ways; the most general mode, and that recommended by *Marshal* and *Nicol*, is pitting; in which two persons are employed, one to operate on the soil with the spade, and the other to insert the plant and hold it till the earth is put round it, and then press down the soil with the foot. Where the plants are three feet high or upwards, this is the best mode; but for smaller plants modes have been adopted in which one person performs the whole operation. This method of planting by pitting is what *Withers* calls the Scotch system, but which *Sir Henry Steuart* has shown (*Planter's Guide*, 2d edit. p. 468.) is not peculiar to Scotland, but is common in every country where trees are cultivated.

3944. *Sang* describes five kinds of manual operation employed by him in planting, and in part in sowing trees; by pitting; by slitting simply, or by cross or T slitting; by the diamond dibber; by the planting-mattock; and by the planter or ground adze. In filling an area with plants, he first plants those intended as the final trees, and afterwards the nurses; or one set of operators plant the former, while another follow with the latter, unless the time for removing the nurses, as in the case of evergreen pines and firs, should be later than that for planting the principals. "The plants, if brought from a distance, should be shoughed, i. e. earthed in; or they may be supplied daily from the nursery, as circumstances direct. All the people employed ought to be provided with thick aprons, in which to lap up the plants, the spadesmen, as well as the boys or girls; the latter being supplied by the former as occasion may require. All of them should regularly fill their aprons at one time, to prevent any of the plants being too long retained in any of the planters' aprons. One man cannot possibly set a plant so well with the spade, unless in the case of laying, as two people can; nor, supposing him to do it as well, can he plant half as many in the same space of time as two can. A boy ten years of age is equal, as a holder, to the best man on the field, and can be generally had for less than half the money. Hence this method is not only the best, but the least expensive." (*Plant. Kal.* 167.)

3945. *By pitting.* "The pit having been dug for several months, the surface will therefore be en-crustured by the rains, or probably covered with weeds. The man first strikes the spade downwards to the bottom, two or three times, in order to loosen the soil; then poaches it as if mixing mortar for the builder; he next lifts out a spadeful of the earth, or, if necessary, two spadefuls, so as to make room for all the fibres, without their being anywise crowded together; he then chops the rotten turf remaining in the bottom, and levels the whole. The boy now places the plant perfectly upright, an inch deeper than when it stood in the nursery, and holds it firm in that position. The man *trindles* in the mould gently; the boy gently moves the plant, not from side to side, but upwards and downwards, until the fibres be covered. The man then fills in all the remaining mould; and immediately proceeds to chop and poach the next pit, leaving the boy to set the plant upright, and to tread the mould about it. This in stiff wet soil he does lightly; but in sandy or gravelly soil he continues to tread until the soil no longer retains the impression of his foot. The man has by this time got the pit ready for the next plant, the boy is also ready with it in his hand, and in this manner the operation goes on. On very steep *hangs* which have been pitted, the following rule ought to be observed in planting:—To place the plant in the angle formed by the acclivity and surface of the pit; and in finishing, to raise the outer margin of the pit highest, whereby the plant will be made to stand as if on level ground, and the moisture be retained in the hollow of the angle, evidently to its advantage." (*Plant. Kal.* 167.)

3946. *Sir Henry Stewart* states that the pitting system, as already practised by most nations, though by some ignorantly and erroneously designated the Scotch method, if duly regulated by science, must be the best method for the planting of waste lands, or, in general, for large designs of wood, where the quality of timber is the main object; although particular spots, in all extensive woodlands, might be advantageously trenched and manured under peculiar circumstances. (*Planter's Guide*, 2d edit. p. 479.)

3947. *The slit method*, either simply or by the T method, is not recommended by Sang; but necessity may justify its adoption occasionally. "We would not recommend planting by the slit, unless where there is no more soil than is absolutely occupied by the fibres of the herbage which grows on the place. Except on turf, it cannot be performed; nor should it be practised, if the turf be found three or four inches thick. By pitting in summer, turf is capable of being converted into a proper mould in the space of a few months; and the expense of pitting, especially in small plantations, can never counterbalance the risk of success in the eyes of an ardent planter. The most proper time to perform the operation of slitting in the plants is when the surface is in a moist state. On all steep the plant should be placed towards the declivity, that the moisture may fall to its roots; that is to say, in planting, the spadesman should stand highest, and the boy lowest on the bank, by which arrangement the plant will be inserted at the lower angle of the slit." (*Plant. Kal.* 170.)

3948. *Planting with the diamond dibber*, he says, "is the cheapest and most expeditious planting of any we yet know, in cases where the soil is a sand or gravel, and the surface bare of herbage. The plate of the dibber (*fig.* 590. *a*) is made of good steel, and is four inches and a half broad where the iron handle is welded to it; each of the other two sides of the triangle is five inches long; the thickness of the plate is one fifth part of an inch, made thinner from the middle to the sides, till the edges become sharp. The length of the iron handle is seven inches, and so strong as not to bend in working, which will require six eighths of an inch square. The iron handle is furnished with a turned hilt, like the handle of a large gimlet, both in its form and manner of being fixed on. The planter is furnished with a planting-bag, tied round his waist, in which he carries the plants. A stroke is given with the dibber, a little aslant, the point lying inwards; the handle of the dibber is then drawn towards the person, while its plate remains within the ground; by this means a vacancy is formed between the back of the dibber and the ground, into which the planter, with his other hand, introduces the roots of the seedling plants, being careful to put them fully to the bottom of the opening; he then pulls out the dibber, so as not to displace them, and gives the eased turf a smart stroke with the heel; and thus is the plant completely firmed. The greatest error the planter with this instrument can run into, is the imperfect introduction of the roots. Green or unpractised hands are apt to double the roots, or sometimes to lay them across the opening, instead of putting them straight down, as above directed. A careful man, however, will become, if not a speedy, at least a good planter in one day; and it is of more importance that he be sure than quick. A careless or slovenly person should never be allowed to handle a dibber of this kind."

3949. *Planting with the planting-mattock* (*fig.* 590. *b*) is resorted to in rocky or other spots where pitting

is impracticable. "The helve or handle is three feet six inches long; the mouth is five inches broad, and is made sharp; length from it to the eye, or helve, is sixteen inches; and it is used to pare off the sward, heath, or other brush that may happen to be in the way, previously to easing the soil with the other end. The small end tapers from the eye, and terminates in a point, and is seventeen inches long." By this instrument the surface is skimmed off "for six or eight inches in diameter, and with the pick-end dug down six or eight inches deep, bringing up any loose stones to the surface; by which means a place will be prepared for the reception of the plant, little inferior to a pit. This instrument

may be used in many cases, when the plants to be planted are of small size, such as one-year larch seedlings, one year nursed; or two-year Scots pines, one year nursed; and the expense is much less than by the spade." (*Plant. Kal.* 385.)

3950. *Planting with the forest-planter or ground adze* (*fig.* 590. *c*). "The helve is sixteen inches long, the mouth is four inches and a half broad, and the length of the head is fourteen inches. The instrument is used in planting hilly ground, previously prepared by the hand-mattock. The person who performs the work carries the plants in a close apron; digs out the earth sufficiently to hold the roots of the plant; and sets and firms it without help from another: it is only useful when small plants are used, and in hilly or rocky situations." (*Plant. Kal.* pref. xxiv.)

3951. *Pontey prefers planting by pitting*, in general cases, the holes being made during the preceding summer or winter, sufficiently large, but not so deep into a retentive subsoil as to render them a receptacle for water. When the plants have been brought from a distance, he strongly recommends puddling them previously to planting; if they seem very much dried, it would be still better to lay them in the ground for eight or ten days, giving them a good soaking of water every second or third day, in order to restore their vegetable powers; for it well deserves notice, that a degree of moisture in soil sufficient to support a plant recently or immediately taken from the nursery, would, in the case of dry ones, prove so far insufficient, that most of them would die in it. The

puddling here reconmended may also be of great service in all cases of late planting where small plants are used: Pontey's method is (after puddling) to tie them in bundles of two or three hundreds each; and thus send them, by a cart-load at once, to their destination; where, being set upright close to each other, and a little straw carefully applied to their outsides, such bundles may remain without damage in a sheltered situation for any reasonable time necessary to plant them. Where loose soil happens to be convenient, that should be substituted in the place of straw.

3952. *Pontey's methods of planting* are in general the same as those of Sang: he uses a mattock and planter of similar shape; and also a two or three pronged instrument, which we have elsewhere denominated the *planter's hack*. (*Encyc. of Gard.* § 1305.) "This instrument," he says, "has been introduced of late years as an improvement on the mattock and planter, being better adapted to soils full of roots, stones, &c.; it is likewise easier to work, as it penetrates to an equal depth with a stroke less violent than the former: it is also less subject to be clogged up by a wet or tenacious soil. The length of the prongs should be about eight inches, and the distances between them, when with three prongs, one and a half, and with two prongs, about two inches: the two-pronged hack should be made somewhat stronger than the other, it being chiefly intended for very stony lands, or where the soil wants breaking, in order to separate it from the herbage, &c. These tools are chiefly applicable to plants of any size up to about two feet, or such as are generally used for great designs, and they are used as substitutes for the spade, in the following manner:—The planter being provided with a basket holding the plants required (the holes being supposed prepared, and the earth left in them), he takes a tree in one hand, and the tool in the other, which he strikes into the hole, and then pulls the earth towards him, so as to make a hole large enough to hold all its roots; he then puts in the plant with the other, and pushes the earth to its roots with the back of the planter; after which, he fixes the plant, and levels the soil at the same instant with his foot, so that the operation is performed by one person, with a degree of neatness and expedition which no one can attain to who uses the spade. It is known to all planters, that but few labourers ever learn to plant well and expeditiously in the common method, without an assistant; this method, however, requires neither help nor dexterity, as any labourer of common sagacity, or boy of fifteen, or even a woman, may learn to perform it well in less than half an hour. The facility with which these tools will break clods, clear the holes of stones, or separate the soil from herbage, the roots of heath, &c. (the former being previously mellowed by the frost), may be easily imagined." (*Prof. Plant.* 173.) The adoption of a small mattock for inserting plants, we recollect to have seen recommended in a tract on planting in the Highlands, by M. Laurin, a nurseryman, published at Edinburgh upwards of twenty years ago.

3953. *An expeditious mode of slit-planting* is described in the *General Report of Scotland*, as having been practised for many years on the duke of Montrose's estate. It is as follows: "The operator, with his spade, makes three cuts, twelve or fifteen inches long, crossing each other in the centre, at an angle of sixty degrees, the whole having the form of a star. (*fig.* 591.) He inserts his spade across one of the rays (a), a few inches from the centre, and on the side next himself; then bending the handle towards himself, and almost to the ground, the earth opening in fissures from the centre in the direction of the cuts which had been made, he, at the same instant, inserts his plant at the point where the spade intersected the ray (a), pushing it forward to the centre, and assisting the roots in rambling through the fissures. He then lets down the earth by removing his spade, having pressed it into a compact state with his heel; the operation is finished by adding a little earth, with the grass side down, completely covering the fissures, for the purpose of retaining the moisture at the root and likewise as a top-dressing, which greatly encourages the plant to push fresh roots between the swards." (*Vol. ii.* p. 283.)

3954. *The transplantation of large trees* is a subject more properly belonging to landscape-gardening than to agriculture; but it may not be improper shortly to notice the principles of the practice in this place. As the stability of a large tree depends in a great measure on its ramose roots extending themselves on every side, as a base to the superstructure, so, in preparing the tree for removal, these roots should be cut at as great a distance from the stem as can conveniently be accomplished. As the nourishment drawn up by a tree depends on the number of its fibrous roots, it is desirable, a year or two before removal, to concentrate these fibres, by limiting their production to such ramose roots as can be removed with the tree. Cut a circular trench, therefore, round the tree to be removed, at a greater or less distance, according to the size of the tree, and the exposure in which it is to be planted. Remove the earth from this trench, and also a good part of that which covers the roots which remain between the trench and the trunk. Substitute well pulverised rich soil; or mix the better part of what was taken out of the trench and off the surface with rich soil; replace it, and press the

whole firmly down. Let the tree remain two years, or three if very large, and then remove it, and carefully plant it where it is finally to remain.

3955. *Sir Henry Steuart*, who has had much experience in removing large trees, and who thinks that he has discovered a new theory or principle for doing so, recommends that no branches should be pruned from the head; and that to prevent the tree from being blown over by the wind, its position relatively to the prevailing wind of the locality should be reversed. The principle of not reducing the head in the same proportion as the roots may be reduced, was hinted at by *Miller*, but has been first systematically defended by *Sir Henry Steuart*. Experienced planters agree, that nothing ought to be cut from the head of a beech tree when it is removed; but they do not seem willing to concede to *Sir Henry's* theory, so far as it respects most other ramose trees. We are inclined to think that he may be right with respect to resinous trees, the beech, and perhaps one or two others; but that, as a general principle, whether in young trees or old, the top must be lightened more or less in proportion to the roots. When the tree has made a stock of fresh roots, and become firmly established in the soil, if an extraordinary exertion in its growth be then wanted, it may either be cut in or pruned severely, or cut down to the ground; and in either case, if it be a tree that stools, it will throw out vigorous shoots.

3956. *The principle of reversing the position of the tree relatively to the wind*, appears to be good; since, the broader the base of the head of the tree relatively to its height, the more obliquely will it receive the impulse of the wind. Those trees are fittest for being transplanted, which have grown in free open situations; because in them the bark is thick and coarse to resist the cold; the stems stout and short, and the head extensive with the lower branches spreading, to resist the wind.

3957. *The machine for transplanting large trees* adopted by *Sir Henry Steuart*, is an improvement of one which has been very long in general use. It consists of a pole (*fig. 592, a*) 15 feet long, attached to an axle and a pair of wheels, on which is placed a block (*b*), which may be of any convenient height, with a pillow (*c*), and two rings for attaching the draught chains (*d*). It is easy to conceive the application of this pole, axle, and wheels, to a large tree, and its removal by men or horses to its intended destination (*fig. 593*). (*Planter's Guide*, sect. viii. 2d edit.)

592

593

SECT. IV. *Mixture of Trees in Plantations.*

3958. *The object of mixing trees in plantations* is threefold: that of sheltering the weaker but ultimately more valuable kinds by the stronger and hardier; that of drawing as much profit from the soil as possible; and that of producing variety of appearance.

3959. *With respect to shelter*, many situations are so exposed, that it is extremely difficult to rear trees without some mode of protecting them from the cold winds of spring during their early growth. This is sometimes done by walls, the extent of whose influence, however, is but very limited; by thick planting; or by planting the more hardy and rapid-growing species, to nurse up and protect such as are more tender, but ultimately more valuable. The proportion of nurses to principals is increased according to the bleakness of the site: Pontey says, "Both authors and planters are in the habit of erring egregiously, in regard to the proportion of principals and nurses, as they generally use as many or more of the former than the latter, though it is very easy to show, that they ought to use three times as many of the latter as the former. For instance, when trees are planted at four feet apart, each occupies a surface of sixteen feet; of course, four of them will occupy sixty-four, or a square of eight feet; and, therefore, if we plant three nurses to one principal tree, all the former might be displaced gradually, and the latter would still stand only eight feet apart."

3960. *Nurse plants* should, in every possible case, be such as are most valued at an early period of growth. The larch and spruce fir should be used liberally, in every case where they will grow freely; still it is not intended they should exclude all others, more particularly the birch, which has most of the properties of a good nurse, such as numerous branches and quick growth, on any tolerable soil or situation. It is not, however, like the others, a wood of general application. (*Practical Planter*, p. 113.) Sang also adopts the proportion of three nurses to one principal, and employs chiefly the resinous tribe, and looks to them for reimbursement till the hard timber has attained to a foot in diameter, under which size hard timber is seldom of much value. His principals are planted at from six to ten feet apart, according to the soil and situation. (*Plant. Kal.* p. 166.)

3961. *In procuring shelter, much depends on the mode of commencing and continuing plantations on bleak sites.* Sang, who has had extensive experience in this part of planting, observes, that "every plain, and most fields and situations for planting in this country, have what may be called a windward side, which is more exposed to the destructive blast than any other. It is of great importance to be apprised of this circumstance, and to be able to fix upon the most exposed side of the proposed forest plantation. Fix, then, upon the windward side of the space which is to be converted into a forest, mark off a horizontal stripe or belt, at least a hundred yards in breadth. Let this portion of ground be planted thick, say at the distance of thirty inches, or at the most three feet, with a mixture of larch, sycamore, and elder, in equal quantities or nearly so, if the soil be adapted for rearing these; but if it be better adapted for Scots pines, then let it be planted with them at the distances prescribed for the above mixture. We have no other kinds that will thrive better, or rise more quickly in bleak situations, than those just mentioned. When the trees in this belt or zone have risen to the height of two feet, such hard-wood trees as are intended ultimately to fill the ground should be introduced, at the distance of eight or ten feet from each other, as circumstances may admit. At this period or perhaps a year or two afterwards, according to the bleak or exposed situation of the grounds, let another parallel belt or zone, of nearly equal breadth, be added to the one already so far grown up, and so on, till the whole grounds be covered. It is not easy here to determine on the exact breadth of the subsequent belt or zones; this matter must be regulated by the degree of exposure of the grounds, by the shelter afforded by the zone previously planted, and by such like circumstances." (*Plant. Kal.* p. 29.)

3962. *In situations exposed to the sea breeze a similar plan* may be successfully followed, and aided in effect by beginning with a wall; the first zone having reached the height of the wall, plant a second, a third, and fourth, and so on till you cover the whole tract to be wooded. In this way the plantations on the east coast of Mid Lothian, round Gosford House, were reared; in Sang's manner, the mountains of Blair and Dunkeld were clothed; and examples, we are informed, might be drawn from the Orkney and Shetland Islands.

3963. *The practice of mixing trees*, with a view to drawing as much nourishment from the soil as possible, and giving, as it used to be said, more chances of success, was till very lately generally approved of. Marshal advises mixing the ash with the oak; because the latter draws its nourishment chiefly from the subsoil, and the former from the surface. Nicol is an advocate for indiscriminate mixture (*Practical Planter*, p. 77.), and Pontey says, "Both reason and experience will fully warrant the conclusion, that the greatest possible quantity of timber is to be obtained by planting mixtures." (*Prof. Planter*, p. 119.) "We are clearly of opinion," says Sang, "that the best method is to plant each sort in distinct masses or groups, provided the situation and quality of the soil be properly kept in view. There has hitherto been too much random work carried on with respect to the mixture of different kinds. A longer practice, and more experience, will discover better methods in any science. That of planting is now widely extended, and improvements in all its branches are introduced. We, therefore, having a better knowledge of soils, perhaps, than our forefathers had, can with greater certainty assign to each tree its proper station. We can, perhaps, at sight, decide that here the oak will grow to perfection, there the ash, and here again the beech; and the same with respect to the others. If, however, there happen to be a piece of land of such a quality, that it may be said to be equally adapted for the oak, the walnut, or the Spanish chestnut, it will be proper to place such in it, in a mixed way, as the principals; because each sort will extract its own proper nourishment, and will have an enlarged range of pasture for its roots, and consequently may make better timber trees."

3964. *Cobbett*, who, though by no means a scientific cultivator, has in general very sound practical views, is decidedly in favour of planting in masses; and would have all the trees not only of one and the same sort, but of the same size and height. (*Woodlands*, § 85.)

3965. *By indiscriminately mixing* different kinds of hard wood plants in a plantation, there is hardly a doubt that the ground will be fully cropped with one kind or other; yet it very often happens, in cases when the soil is evidently well adapted to the most valuable sorts, as the oak perhaps, that there is hardly one oak in the ground for a hundred that ought to have been planted. We have known this imperfection in several instances severely felt. It not unfrequently happens, too, that even what oaks or other hard-wood trees are to be met with, are overtopped by less valuable kinds, or perhaps such, all things considered, as hardly deserve a place. Such evils may be prevented by planting with attention to the soil, and in distinct masses. In these masses are insured a full crop, by being properly nursed for a time with kinds more hardy, or which afford more shelter than such hard-wood plants. There is no rule by which to fix the size or extent of any of these masses. Indeed, the more various they are made in size, the better will they, when grown up, please the eye of a person of taste. They may be extended from one acre to fifty or a hundred acres, according to the circumstances of soil and situation: their shapes will accordingly be as various as their dimensions. In the same manner ought all the resinous kinds to be planted, which are intended for timber trees; nor should these be intermixed with any other sort, but be in distinct masses by themselves. The massing of *Arch*, the pine, and the fir of all sorts, is the least laborious and surest means of growing good, straight, and clean timber. It is by planting or rather by sowing them in masses, by placing them thick, by a timely pruning and gradual thinning, that we can with certainty attain this object. (*Plant. Kal.* 162 and 166.) Our opinion is in perfect consonance with that of *Sang*, and for the same reasons; and we may add, as an additional one, that in the most vigorous natural forests one species of tree will generally be found occupying almost exclusively one soil and situation, while, in forests less vigorous, on inferior and watery soils, mixtures of sorts are more prevalent. This may be observed by comparing New Forest with the natural woods round Lochlomond, and it is very strikingly exemplified in the great forests of Poland and Russia.

3966. *With respect to the appearance of variety*, supposed to be produced by mixing a number of species of trees together in the same plantation, we deny that variety is produced. Wherever there is variety, there must be some marked feature in one place, to distinguish it from another; but in a mixed plantation the appearance is every where the same; and ten square yards at any one part of it will give nearly the same number and kinds of trees as ten square yards at any other part. "There is more variety," *Repton* observes, "in passing from a grove of oaks to a grove of firs, than in passing through a wood composed of a hundred different species, as they are usually mixed together. By this indiscriminate mixture of every kind of tree in planting, all variety is destroyed by the excess of variety, whether it is adopted in belts, clumps, or more extensive masses. For example, if ten clumps be composed of ten different sorts of trees in each, they become so many things exactly similar; but if each clump consists of the same sort of tree, they become ten different things, of which one may hereafter furnish a group of oaks, another of elms, another of chestnuts or of thorns, &c. In like manner, in the modern belt, the recurrence and monotony of the same mixture of trees of all the different kinds, through a long drive, make it the more tedious, in proportion as it is long. In part of the drive at Woburn, evergreens alone prevail, which is a circumstance of grandeur, of variety, of novelty, and, I may add, of winter comfort, that I never saw adopted in any other place, on so magnificent a scale. The contrast of passing from a wood of deciduous trees to a wood of evergreens must be felt by the most heedless observer; and the same sort of pleasure, though in a weaker degree, would be felt, in the course of a drive, if the trees of different kinds were collected in small groups or masses by themselves, instead of being blended indiscriminately." (*Enquiry into Changes of Taste*, &c. p. 23.)

3967. *Sir William Chambers and Price* agree in recommending the imitation of natural forests in the arrangement of the species. In these, Nature disseminates her plants by scattering their seeds, and the offspring rise round the parent in masses or breadths, depending on a variety of circumstances, but chiefly on the facility which these seeds afford for being carried to a distance by the wind, the rain, and by birds or other animals. At last that species which had enjoyed a maximum of natural advantages is found to prevail as far as this maximum extended, stretching along in masses and irregular portions of surface, till circumstances changing in favour of some other species, that takes the precedence in its turn. In this way it will be generally found, that the number of species, and the extent and style of the masses in which they prevail, bear a strict analogy to the changes of soil and surface; and this holds good, not only with respect to trees and shrubs, but to plants, grasses, and even mosses.

SECT. V. Culture of Plantations.

3968. *A tree, when once planted, most men consider to be done with*; though, as every one knows, the progress and products of trees, like those of other plants, may be greatly increased or modified by cultivating the soil, by pruning, and by thinning. Before proceeding to these subjects, we shall submit some remarks on the influence of culture on the progress of the growth of trees, and on the strength and durability of timber.

SUBJECT. 1. General Influence of Culture on Trees.

3969. *The effect of culture on herbaceous vegetables* is so great, as always to change their appearance, and often, in a considerable degree, to alter their nature. The common culinary vegetables, and cultivated grasses, assume so different an appearance in our fields and gardens, from what they do in a state of wild nature, that even a botanist might easily be deceived in regard to the species. The same general laws operate upon the whole kingdom of vegetables; and thence it is plain, that the effects of culture on trees, though different in degree, must be analogous in their nature. (*Treatise on Country*

Resid. vol. ii.) In the same manner, the absence of culture, or the removing of the vegetable to a colder climate and a worse soil, tends to contract or consolidate the parts of the plant. (*Planter's Guide.*)

3970. *The effect of culture on woody plants* is similar to that on culinary vegetables and cultivated grasses; but the law operates of course less rapidly, owing to the less rapid growth of trees, from the lowest bush to the oak of the forest. In all of these, the culture of the soil tends to accelerate vegetation, and, by consequence, to expand the fibre of the wood. It necessarily renders it softer, less solid, and more liable to suffer by the action of the elements.

3971. *The effect of culture on the ligneous plants in common use in planting and gardening* is readily exemplified. Every forester is aware how much easier it is to cut over thorns or furze trained in hedges, than such as grow naturally wild, and are exempt from culture. Gardeners experience the same thing in pruning or cutting over fruit trees, or shrubs; and the difference in the texture of the raspberry, in its wild and in its cultivated state, is as remarkable; for, although the stem, in the latter case, is nearly double the thickness to which it attains in the former, it is much more easily cut. On comparing the common crab, the father of our orchards, with the cultivated apple, the greater softness of the wood of the latter will be found not less striking to every arboriculturist. The common oak in Italy and Spain, where it grows faster than in Britain, is ascertained to be of shorter duration in those countries. In the same way, the oak in the highland mountains of Scotland or Wales is of a much harder and closer grain, and therefore more durable, than what is found in England; though on such mountains it seldom rises to the fifth part or less of the English tree. Every carpenter in Scotland knows the extraordinary difference between the durability of Highland oak, and oak usually imported from England, for the spokes of wheels. Every extensive timber dealer is aware of the superior hardness of oak raised in Cumberland and Yorkshire, over that of Monmouthshire and Herefordshire; and such a dealer, in selecting trees in the same woods in any district, will always give the preference to oak of slow growth, and found on cold and clayey soils, and to ash on rocky cliffs, which he knows to be the soils and climates natural to both. If he take a cubic foot of park-oak, and another of forest-oak, and weigh the one against the other, (or if he do the like with ash and elm of the same descriptions,) the latter will uniformly turn out the heavier of the two. The Scotch pine does not stand longer than forty or fifty years on the rich and fertile land in both England and Scotland, where it is often planted, and where it rushes up with extraordinary rapidity. In the northern districts of Scotland, on the other hand, the difference between park pine and Highland pine is universally known and admitted, and the superiority of the latter is proved by its existence in buildings of great antiquity, where it is still found in a sound state; a difference which can be ascribed to no other cause than the mountainous situations (that is, the natural state) in which the former timber is produced, and where, the trees being of slower growth, the wood is consequently of a harder texture. A friend of Sir Henry Steuart's felled some larch trees, which had grown nearly fifty years in a deep rich loam, close to some cottages and cabbage gardens. The wood was soft and porous, and of no duration; it was even found to burn as tolerable fire-wood, which larch of superior quality is never known to do. (*Tr. on Coun. Res., and Planter's Guide.*)

3972. *The general effect of pruning* is to increase the quantity of timber produce. The particular manner in which it does this is by directing the greater part of the sap, which generally spreads itself in side-branches, into the principal stem. This must consequently enlarge that stem in a more than ordinary degree, by increasing the annual circles of the wood. Now, if the tree be in a worse soil and climate than those which are natural to it, this will be of some advantage, as the extra increase of timber will still be of a quality *not inferior* to what would take place in its natural state; or, in other words, it will correspond with that degree of quality and quantity of timber, which the nature and species of the tree admit of being produced. If the tree be in its natural state, the annual increase of timber, occasioned by pruning, must necessarily injure its quality, in a degree corresponding with the increased quantity. If the tree be in a better climate and soil than that which is natural to it, and, at the same time, the annual increase of wood be promoted by pruning, it is evident that such wood must be of a very different quality from that produced in its natural state (that is, very inferior). Whatever, therefore, tends to increase the wood in a greater degree than what is natural to the species, when in its natural state, must injure the quality of the timber. Pruning tends to increase this in a considerable degree, and, therefore, it must be a pernicious practice, in as far as it is used in these cases. Pruning is not here considered in regard to eradicating diseases, preventing injuries, or increasing the natural character and tendency of trees: for those purposes it is of great advantage. Mr. Knight has shown, in a very striking manner, that timber is produced, or rather, that the alburnum or sapwood is rendered ligneous, by the motion of the tree, during the descent of the true (or proper) sap. It

is also sufficiently known to all who have attended to the physiology of vegetables, and is greatly confirmed by some experiments laid before the Royal Society (*Phil. Trans.* 1803, 1804), that the solid texture of the wood greatly depends upon the quantity of sap which must necessarily descend, and also on the slowness of its descent. Now, both these requisites are materially increased by side branches, which retain a large quantity of sap, and by their junction with the stem occasion a contraction, and twisted direction of the vessels, which obstructs the progress of the (proper) juice. That this is true, in fact, is well known to those accustomed to make wine from maple and birch trees; for in this business it is found, that those trees which have fewest side branches bleed more freely than the others, but during a much shorter space of time. These hints, therefore, afford additional evidence against pruning, and particularly against pruning fir-trees; which, as Mr. Knight justly observes, have larger vessels than the others, and, therefore, when in an improved soil and climate, side branches, for the purposes above mentioned, are essentially necessary to them, if solid, resinous, and durable timber be the object in view. (*Sir Henry Stewart's Planter's Guide*, p. 444.)

3973. *Sir Henry Stewart*, concurring in these facts and observations, deduces the following practical conclusions respecting the influence of culture:—

3974. *First*; that all timber trees thrive best, and produce wood of the best quality, when growing in soils and climates most natural to the species. It should, therefore, be the anxious study of the planter, to ascertain and become well acquainted with these, and to raise trees, as much as possible, in such soils and climates.

3975. *Secondly*; that trees may be said to be in their natural state, when they have sprung up fortuitously, and propagated themselves without aid from man, whether it be in aboriginal forests, ancient woodlands, commons, or the like. That in such trees, whatever tends to increase the wood, in a greater degree than accords with the species when in its natural state, must injure the quality of the timber.

3976. *Thirdly*; that whatever tends to increase the growth of trees, tends to expand their vegetable fibre. That when that takes place, or when the annual circles of the wood are soft, and longer than the general annual increase of the tree should warrant, then the timber must be less hard and dense, and more liable to suffer from the action of the elements.

3977. *Fourthly*; that a certain slowness of growth is essentially necessary to the closeness of texture and durability of all timber, but especially of the oak; and that, whenever the growth of that wood is unduly accelerated by culture of the soil (such as by trenching and manuring), or by undue superiority of climate, it will be injured in quality in the precise ratio in which those agents have been employed.

3978. *Fifthly*; that, as it is extremely important for the success of trees, to possess a certain degree of vigour in the outset, or to be what is technically called, "well set off," the aid of culture is not in every case to be precluded, by a consideration of the general rule. That if trees be in a soil and climate worse than those that are natural to them, then culture will be of some advantage; as the extra increase of wood will be of a quality not inferior to what, in its natural state, it would obtain; or, in other words, it will correspond with that degree of quality and quantity of timber, which the nature of the species admits of being obtained: but culture in this case must be applied with cautious discrimination, and a sound judgment. That, on the other hand, if trees be in a better soil and climate than are natural to them, and, at the same time, that the annual increase of wood be promoted by culture (as already said), it will be a decided disadvantage, and deteriorate the wood. In the same way, if trees be in their natural state, the annual increase of timber, obtained by culture, will injure its quality, in a degree corresponding with the increased quantity.

3979. *Sixthly*; that such appears to be a correct, though a condensed view of the operation of those general laws respecting growth, which govern the whole vegetable kingdom, and especially of their effects on woody plants, and of the salutary restraints, which science dictates to be laid on artificial culture, of which pruning, as well as manuring, forms a constituent part, as has been explained above, at so much length. That it is by a diligent study of the peculiar habits of trees, and the characters of soils, illustrated and regulated by facts drawn from general experience, that rash or ignorant systems of arboriculture are to be best corrected, and science brought most beneficially to bear on general practice." (*Planter's Guide*, 2d edit. p. 478.)

SUBSECT. 2. *Culture of the Soil among Trees.*

3980. *With respect to the culture of the soil*, it is evident, that young plantations should be kept clear of such weeds as have a tendency to smother the plants; and though this is not likely to take place on heaths and barren sites, yet even these should be looked over once or twice during summer, and at least those weeds removed which are conspicuously injurious. In grounds which have been prepared previously to planting, weeding, hoeing by hand or by the horse hoe, and digging or ploughing (the two latter rarely), become necessary according to circumstances. The hoeings are performed in summer to destroy weeds, and render the soil pervious to the weather; the ploughing and diggings in winter are for the same purpose, and sometimes to prepare the soil for spring crops. These, both *Pontey* and *Sang* allow, may be occasionally introduced among newly planted trees; though it must not be forgotten that, relatively to the trees, the plants composing such crops are weeds, and some of them, as the potato, weeds of the most exhausting kind. *Sang* uses a hoe of larger size than usual. (*fig.* 590. *d.*) In preparing lands for sowing woods, *Sang* ploughs in manure, sows in rows six feet apart, by which he is enabled to crop the ground between with low-growing early potatoes, turnips, and lettuce; but not with young trees as a sort of nursery, as they prove more scourging crops than esculent vegetables; nor with grain, as not admitting of culture, and being too exhausting for the soil. *Marshal*, and some other authors, however, approve of sowing the tree seeds with a crop of grain, and hoeing up the stubble and weeds when the crop is removed.

3981. *Pontey* observes, "that wherever preparing the soil for planting is thought necessary, that of cultivating it for some years afterwards will generally be thought the

same; slight crops of potatoes with short tops, or turnips, may be admitted into such plantations with advantage for two or three years, as they create a necessity for annually digging or stirring the surface, and tend very materially to accelerate the growth of the plants. It may be objected, that such crops must impoverish the soil, and no doubt such is the fact, so far as common vegetables are concerned: but as to the production of wood, its support depends, in a great measure, on a different species of nutriment; and hence, I could never observe, that such cropping damaged it materially." (*Profit. Plant.* p. 153.)

3982. *Osier plantations*, for baskets, willows, and hoops, require digging and cleaning during the whole course of their existence; and so do hedgerows to a certain extent, and some ornamental plantations.

SUBJECT. 3. *Filling up of Blanks or Failures in Plantations.*

3983. *The filling up of blanks* is one of the first operations that occurs on the culture of plantations, next to the general culture of the soil, and the care of the external fences. According to Sang, "a forest plantation, either in the mass form or ordinary mixture, should remain several years after planting, before filling up the vacancies, by the death of the hard-wood plants, takes place. Hard-wood plants, in the first year, and even sometimes in the second year, after planting, die down quite to the surface of the ground, and are apparently dead, while their roots, and the wood immediately above them, are quite fresh, and capable of producing very vigorous shoots, which they frequently do produce, if allowed to stand in their places. If a tree, such as that above alluded to, be taken out the first or second year after planting, and the place filled up with a fresh plant of the same kind, what happened to the former may probably happen to the latter; and so the period of raising a plant on the spot may be protracted to a great length of time; or it is possible this object may never be gained

3984. *The filling up of the hard-wood kinds* in a plantation which has been planted after trenching or summer fallow, and which has been kept clean by the hoe, may be done with safety at an earlier period than under the foregoing circumstances; because the trees, in the present case, have greater encouragement to grow vigorously after planting, and may be more easily ascertained to be entirely dead, than where the natural herbage is allowed to grow among them.

3985. *But the filling up of larches and pines* may take place the first spring after the plantation has been made; because such of these trees as have died are more easily distinguished. In many cases where a larch or pine loses its top, either by dying down, or the biting of hares or rabbits, the most vigorous lateral branch is elected by nature to supply the deficiency, which by degrees assumes the character of an original top. Pines, and larches, therefore, which have fresh lateral branches, are not to be displaced, although they have lost their tops. Indeed, no tree in the forest, or other plantation, ought to be removed until there be no hope of its recovery.

3986. *If the filling up of plantations be left undone till the trees have risen to fifteen or twenty feet in height*, their roots are spread far abroad, and their tops occupy a considerable space. The introduction of two or three plants, from a foot to three feet in height, at a particular deficient place, can never, in the above circumstances, be attended with any advantage. Such plants may, indeed, become bushes, and may answer well enough in the character of underwood, but they will for ever remain unfit for any other purpose. It is highly improper then, to commence filling up hard-wood plantations before the third year after planting; or to protract it beyond the fifth or the sixth. March is the proper season for this operation. (*Plant. Kal.* 295.)

SUBJECT. 4. *Pruning and Heading down Trees in Plantations.*

3987. *Pruning is the most important operation of tree culture*, since on it, in almost every case, depends the ultimate value, and in most cases the actual bulk, of timber produced. For pruning, as for most other practical purposes, the division of trees into resinous or frondose-branched trees, and into non-resinous or branchy-headed sorts, is of use. The main object in pruning frondose-branched trees is to produce a trunk with clean bark and sound timber; that in pruning branchy-stemmed trees is principally to direct the ligneous matter of the tree into the main stem or trunk, and also to produce a clean stem and sound timber, as in the other case. The branches of frondose trees, unless in extraordinary cases, never acquire a timber size, but rot off from the bottom upwards, as the tree advances in height and age; and, therefore, whether pruned or not, the quantity of timber in the form of trunk is the same. The branches of the other division of trees, however, when left to spread out on every side, often acquire a timber-like size; and as the ligneous matter they contain is in general far from being so valuable as when produced in the form of a straight stem, the loss by not pruning off their side branches or preventing them from acquiring a timber-like size is evident. On the other hand, when they are broken off by accident, or rot off by being crowded together, the

timber of the trunk, though in these cases increased in quantity, is rendered knotty and rotten in quality.

3988. *Pruning frondose or resinous trees* is one of the greatest errors in the modern system of forest management. The branches of the different species of pines, and of the cedar of Lebanon, never attain a timber size, if growing in a moderately thick plantation; those of the fir tribe never under any circumstances. Provided pines and cedars, therefore, are planted moderately thick, no loss in point of timber can ever be sustained by omitting altogether to prune them; and in this respect the fir tribe, whether thick or thin on the ground, may be left to themselves. The important question is, how does the rotting off of the branches affect the timber in the trunk of the tree? Certainly no pine or fir timber can be sounder or better than that which is brought from the native forests of the north of Europe, and from America, where no pruning is ever given. The rotting off of the frondose branches, therefore, cannot be injurious in these countries. The next question is, can it be proved to be injurious in this country? We are not aware that it has, and do not believe that it can. The rotting off of the branch of a resinous tree is a very different process from the rotting off of a branch of a ramose-headed tree. This fact may be verified by observing what takes place in pine or fir woods, and by inspecting the interior of foreign pine or fir, cut up into planks. In the rotting off of side branches of deciduous trees, we find, that the principal part where decay operates, at least in all the soft woods, and even in the oak when it is young, is the heart; but in the rotting off of the side branches of resinous trees, we shall find them decaying chiefly on the outside, and wearing down the stump of the fallen branch in the form of a cone. On examining the sections of sound foreign deal, we shall find that the knots of the side branches always terminate in cones when the section is made vertically. This is a fact well known to every carpenter; and it is also known to a great many, that British pine and fir timber that has been pruned, has invariably a rotten space at every knot. The same thing is observable to a certain extent in the natural decay of the side branches of all trees. When the decay is natural, it commences at the circumference, and wears down the stump, till it ends in a small hard cone, which is buried in the increasing circumference of the tree, and is never found injurious to the timber: when the decay is artificial, or in consequence of excessive pruning, that is, suddenly exposing a large section to the action of the atmosphere, the bark protects the circumference, and the decay goes on in the centre, so as to end in forming an inverted cone of rotten matter, which serves as a funnel to conduct moisture to the trunk, and thereby render it rotten also. The conclusion which we draw from these facts is, that the pine and fir tribe should scarcely be pruned at all, and that no branches of ramose trees should be cut off close to the stem of a larger size than what may be healed over in one or at most two seasons. We agree with Cruickshank, therefore, when he says, "It would appear that the pruning of firs [the pine and fir tribe], supposing it harmless, can yet be productive of no positive good."

3989. *Cruickshank, Pontey, and Sang*, agree that the great object of pruning is to protect the leader or main stem or shoot from the rivalship of the side branches, in order that as much of the nourishment drawn from the soil may be employed in the formation of straight timber, and as little in the formation of branches and spray, as is consistent with the economy of vegetation. Without the agency of the leaves, the moisture absorbed from the soil could no more nourish a plant than the food taken into the stomach would nourish an animal without the process of digestion. The branches bearing the leaves are therefore just as necessary to the welfare of the tree as the roots. By taking away too many of the branches, only a small part of the fluid imbibed will be elaborated; by leaving the branches too thick and crowded, the leaves may be less perfect, and less fit for performing their office, than they otherwise would be. Exposure of a part of the branches to the light and air may therefore be a sufficient reason for thinning them, independently of increasing the trunk. "How," asks Cruickshank, "are we to know the exact number of branches that may be removed with safety in any given circumstances? Never, it is answered, displace any which have not already got, or seem in immediate danger of getting, the upper hand of the leader. These will be known by their equalling or approaching the leader in size; or, to speak less ambiguously, by their being of the same, or nearly of the same, girth at the place where they spring from the stem, as the stem itself is at their length from its top." In proceeding according to this plan, the pruner is not to regard, in the smallest degree, the part of the stem on which a shoot is situated. If it is too large, it must be displaced, should it be in the highest part of the tree: if it is not too large, it must remain, though it be close to the ground.

"But how will this method, the reader may be ready to ask, ever produce a clean stem? By repeating the pruning, it is answered, as often as the growth of the branches may make the operation necessary. Suppose, the first time a tree undergoes the process, that the branches removed are a considerable distance from the ground, and that there are several smaller ones left growing farther down the stem: these last will gradually increase in size, till they, too, must be lopped off; and thus the stem will be in the end as effectually cleared, though more gradually, and consistently with the health of the tree, as by the absurd method represented above.

"If any branches that were left at a former pruning low on the stem, appear at the next repetition of the process not to have increased in size, we may safely conclude that they have had no influence on the tree either good or bad; and as it would be in vain to leave them with the hope that they will any longer assist in the elaboration of the sap, they should be removed, as unsightly objects which it is no longer useful to preserve." (*Practical Planter*, p. 168.)

3990. *Billington* considers the leaves and branches of trees as of the greatest importance; he thinks every timber tree ought to have the trunk clothed with branches throughout; but these branches he would shorten in such a way that they should never engross any material part of the timber of the tree. To accomplish this, it is necessary to commence pruning when the trees are young, by which means the great bulk of the timber produced will be deposited in the main stem or trunk. This is what he calls *preventive pruning*. (*Gard. Mag.* vol. vi.) A similar system had been recommended by Mr. Blaikie of

Holkham, under the name of *foreshortening*, and is advocated by Sir Henry Stuart, under that of *terminal pruning*.

3991. *Most erroneous opinions on the subject of pruning resinous trees* have been propagated by Salmon, the experienced manager of the late Duke of Bedford, Pontey, forest-pruner to the same duke, and others of less note. Sang, on the other hand, argues against excessive pruning of the resinous tribe of trees as injurious to the health of the tree and the soundness of its timber. Elles, also, a gardener of scientific acquirements, and extensive experience in England, his native country, and in Scotland and Ireland, would never prune the pine and fir tribe at all, unless when very young, and when the side shoots could be pinched off with the finger and the thumb. At a more advanced age, if compelled by circumstances to prune, he would only shorten the extremities of the fronds. Of two trees, pines, firs, cedars, or larches, the one pruned and the other unpruned, there will be found, he says, most timber in the trunk of the unpruned one, while the branches are so much in addition to the value of the tree. He excepts, of course, those cases in which frondose branches take a ramose character, in consequence of the tree standing alone, as is frequently the case with the cedar of Lebanon, and sometimes with the Scotch pine.

3992. *Our own opinion* with respect to pruning the resinous trees is in accord with that of Elles and Cruickshank; and as to hard and soft wooded leaf trees, we think Cruickshank's practice and rule unexceptionable. We would prune the last description of trees much less than is generally done, and leave the pine and fir tribe in a great measure to nature, taking care, however, to thin betimes and occasionally from infancy till the maturity of the trees. We have no doubt of this, that when the larch and Scotch pine trees planted in the end of the last century, and severely pruned for the first twenty or twenty-five years of the present, shall come to be cut down and sawn up, their timber will be found full of faults, and of very little value, compared with timber of the same sorts from natural and unpruned woods, foreign and domestic.

3993. *With respect to the manner of pruning*, Sang observes, "Where straight timber is the object, both classes in their infancy should be feathered from the bottom upwards, keeping the tops light and spiral, something resembling a young larch (*fig. 594. a*). The proportion of their tops should be gradually diminished, year by year, till about their twentieth year, when they should occupy about a third part of the height of the plant; that is, if the tree be thirty feet high, the top should be ten feet (*b*). In all cases in pruning off the branches, the utmost care must be taken not to leave any stumps sticking out, but cut them into the quick. It is only by this means that clean timber can be procured for the joiner; or slightly stemmed trees to please the eye. It is a very general practice to leave snags or stumps (*c*): before the bole can be enlarged sufficiently to cover these, many years must elapse; the stumps in the mean time become rotten; and the consequence is, timber which, when sawn up (*d*), is only fit for fuel."

3994. *The general seasons of pruning* are winter and spring, and for the gean or wild cherry midsummer, as it is found to gum very much at any other season. Pontey says, "As to the proper seasons of pruning, there is only one difficulty; and that is, discovering the wrong one, or the particular time that trees will bleed. Only two trees have been found which bleed uniformly at certain seasons, namely, the sycamore and fir, which bleed as soon as the sap begins to move." There is, however, one season for pruning unquestionably preferable to all others, as far as the welfare of the tree, and the soundness of its future timber, is concerned. It is well known to physiologists and observing gardeners, that when the sap is returning, wounds heal with the greatest rapidity. Hence, in all plants which are difficult to strike from cuttings, the gardener makes choice of the point of a shoot in that particular stage of maturation when the sap is returning; that is, when the base of the shoot is beginning to assume a ligneous character. This, in hardy trees, is uniformly a week or a fortnight after midsummer, and it will be found that the wounds made by cutting off branches at that season, or any time within three weeks after midsummer, will, in the course of four or five weeks, be partly covered with a callosity proceeding from the lips of the wound. Wounds made by cutting branches off the same trees, five weeks after midsummer, will remain without the slightest indi-

cation of healing at the edges till the following spring; and if the tree is delicate, or the winter severe, they will then be in a worse condition than if they had not been pruned at all; the lips of the wounds will have begun to decay. The only seeming contradiction to this general law in trees is where what are called second growths are produced, as in the oak and some other trees, and in such cases there is of course a second returning sap, for the same reason that there was at first. (*Gard. Mag.* vol. vi. p. 94.)

3995. *In spring pruning*, desist when bleeding takes place. As a general rule, Pontey thinks "summer preferable to winter pruning; because, in proportion as wounds are made early they heal so much more in the same season." (*Forest Pruner*, 236.) Sang suspends pruning from the end of February to the middle of July, but carries it on during every other month of the year; pruning the wild cherry, or any other tree very apt to gum, only in July and August. (*Plant. Kal.* 268.)

3996. *With respect to the implements to be used*, Sang observes, "In every case where the knife is capable of lopping off the branch in question, namely, in the pruning of infant plants, it is the only instrument necessary. All other branches should be taken off by the saw. A hatchet, or a chisel, should never be used. Every wound on the stem or bole should be quite into the quick, that is, to the level and depth of the bark; nor should the least protuberance be left. The branch to be lopped off by the saw should, in all cases, be notched or slightly cut on the under side, in order to prevent the bark from being torn in the fall; and when the branch has been removed, the edges of the wound, if anywise ragged, should be pared smooth with the knife. If the tree be vigorous, nature will soon cover the wound with the bark, without the addition of any plaster to exclude the air. In the shortening of a strong branch, the position of which is pretty upright, it should be observed to draw the saw obliquely across it, in such a manner as that the face of the wound shall be incapable of retaining moisture; and afterwards to smooth the edges of the bark with a knife." (*Plant. Kal.* 181.) In every case where the branches are too large for the knife, Pontey prefers the saw, as the best and most expeditious instrument; and one, the use of which is more easily acquired by a labourer than that of either the bill or axe. In "large work" he uses the common carpenter's saw; for smaller branches, one with somewhat finer teeth, with the plate of steel, about twenty inches long.

3997. *The pruning of all deciduous trees should be begun at the top*, or at least those branches which are to be removed thence should never be lost sight of. "Having fixed upon what may be deemed the best shoot for a leader, or that by which the stem is most evidently to be elongated and enlarged, every other branch on the plant should be rendered subservient to it, either by removing them instantly, or by shortening them. Where a plant has branched into two or more rival stems, and there are no other very strong branches upon it, nothing more is required than simply to lop off the weakest clean by the bole, leaving only the strongest and most promising shoot. If three or four shoots or branches be contending for the ascendancy, they should, in like manner, be lopped off, leaving only the most promising. If any of the branches which have been left farther down on the bole of the plant at former prunings have become very strong, or have extended their extremities far, they should either be taken clean off by the bole, or be shortened at a proper distance from it, observing always to shorten at a lateral twig of considerable length. It is of importance that the tree be equally poised; and, therefore, if it have stronger branches on the one side than on the other, they should either be removed or be shortened. Thus, a properly trained tree, under twenty feet in height, should appear light and spiral, from within a yard or two of the ground to the upper extremity, its stem being furnished with a moderate number of twigs and small branches, in order to detain the sap, and circulate it more equally through the plant.

3998. *The subsequent prunings of trees of this size*, standing in a close plantation, will require much less attention; all that is wanted will consist in keeping their leading shoots single. From the want of air, their lateral branches will not be allowed to extend, but will remain as twigs upon the stem. These, however, frequently become dead branches; and if such were allowed to remain at all on the trees, they would infallibly produce blemishes calculated greatly to diminish the value of the timber; hence the impropriety of allowing any branch to die on the bole of a tree; indeed, all branches should be removed when they are alive; such a method, to our knowledge, being the only sure one to make good timber. From these circumstances, an annual pruning, or at least an annual examination, of all forests is necessary. (*Plant. Kal.*)

3999. *Heading down* such non-resinous trees as stole, we have already stated to be an important operation. After the trees have been three or four years planted, Sang directs, that "such as have not begun to grow freely should be headed down to within three or four inches of the ground. The cut must be made with the pruning-knife in a sloping direction, with one effort. Great care should be taken not to bend over the tree in the act of cutting. By so bending, the root may be split, a thing which too often happens. The operation should be performed in March, and not at an earlier period of the season, because the wounded part might receive much injury from the severe weather in January and February, and the expected shoot be thereby prevented from rising so strong and vigorous." (*Plant. Kal.* 297.) Buffon, in a *Memorial on the Culture of Woods*, presented to the French government in 1742, says he has repeated this experiment so often, that he considers it as the most useful practice he knows in the culture of woods.

4000. *For the purpose of producing bends for ship-timber*, various modes of pruning have been proposed, as such bends always fetch the highest price. According to Pontey, "little is hazarded by saying, that if plenty of long, clean, straight, free-grown trees could be got, steaming and a screw apparatus would form bends."

4001. *Monteith*, a timber valuator of great experience, and in extensive practice, says, the value of the oak, the broad-leaved elm, and Spanish chestnut, depends a good deal on their being crooked, as they are all used in ship building. He says he has seen trees successfully trained into crooked shapes of great value, in the following manner:—"If you have an oak, elm, or chestnut, that has two stems, as it were, striving for the superiority, lop or prune off the straightest stem; and if a tree that is not likely to be of such value be standing on that side to which the stem left seems to incline to a horizontal position, take away the tree, and thus give the other every chance of growing horizontally. At this time it will be necessary to take away a few of the perpendicular shoots off the horizontal branch; and, indeed, if these branches, which is sometimes the case in such trees, seem to contend, take away most of them; but if they do not, it is better at this time not to prune over much, except the crooked shoots on the horizontal branch, till they arrive at the height of fifteen or even twenty feet. By this time it will be easily seen

what kind of tree it is likely to form; and, if it inclines to grow crooked, lighten a little the top of the tree, by taking off a few of the crooked branches on the straighter side, allowing all the branches to remain on the side to which the tree inclines to crook, to give it more weight, and to draw most of the juice or sap that way, and it will naturally incline more to the crook; at the same time clearing away any other tree on the crooked side, that may be apt, with the wind, to whip the side of the tree to which it inclines to crook. Also taking away such trees of less value as may prevent it from spreading out to the one side more than to the other." He adds, "I have myself tried the experiment with several oak trees at about twelve feet high, that were a little inclined to crook, and that had also a main branch inclined to a horizontal position. In the course of less than twenty years, I had the pleasure of seeing some of these very trees grow so very crooked that the branch would work in with the main stem or body of the tree, to a complete knee or square, which is the most valuable of all trees; and, as ten trees of crooked oak are required for one straight one, it is of the most essential consequence to have crooked oak trees; and, besides, an oak tree, properly crooked, that will answer for a large knee (say the main branch, to be fit to work in with the body or trunk of the tree without much waste of wood), is nearly double in value to the same number of feet of a straight tree; and, indeed, knees of oak are extremely scarce, and difficult to be got."

4002. *Pontey* "knows of no way by which bends of tolerable scantlings (knees excepted) can be produced with certainty and little trouble, but from a side branch kept in a bent position by the branches of another tree or trees overhanging its stem." (*Forest Pruner*, 174.)

4003. *Coppice woods*, in so far as grown from poles or bark, require pruning on the same principle as timber trees, in order to modify the ligneous matter into stem, and produce clean bark. In as far as they are grown for fence wood, fuel, or besom spray, no pruning is required.

4004. *Osier holts* require the laterals to be pinched off the shoots intended for hoops; those of the basket-maker seldom produce any. The stools, also, require to be kept free from dead wood, and stunted knotted protuberances.

4005. *Hedges* require side pruning, or switching, from their first planting, so as gradually to mould them into "the wedge shape, tapering from bottom to top on both sides equally, till they meet in a point at the top. Two feet at bottom is a sufficient breadth for a five feet hedge; a greater or less height should have the bottom wider or narrower, accordingly. In dressing young hedges, either of the deciduous or evergreen kinds, the sides only should be cut till the hedge arrives at the proposed height, unless it be necessary, for the sake of shelter, to cut their tops over, in order to make the hedges thicker of branches. Such cutting of the upright shoots, however, is not of any great use in this respect; because every hawthorn hedge sends out a number of side shoots, which, if encouraged, by keeping the top wedge-shaped as above, will make it abundantly thick." (*Sang*, 447.) In pruning hedges, some use shears; but the hedge-bill is the most proper instrument, producing a smooth unfractured section, not so apt to throw out a number of small useless shoots which generally follow the crushing cut of the shears.

4006. *Hedge-row trees* require to be pruned to a tall, clean, erect stem, as at once producing more timber, and doing least injury to the ground under their drip and shade.

4007. *Trees in strips for shelter, or screens for concealment*, ought to be furnished with branches, from the bottom upwards; unless undergrowth supply this deficiency. Where this is not the case, care should be had that the trees be pruned into conical shapes, so as that the lower branches may be as little as possible excluded from the influence of the weather by the upper ones.

4008. *Trees for shade*, where shelter from winds is not wanting, should be pruned to ample spreading heads with naked stems; the stem should be of such a height that the sun's rays, at midday, in midsummer, may not fall within some yards of the base of the trunk; thus leaving under the trees, as well as on their shady side, a space for the repose of men or cattle.

SUBJECT. 5. *Thinning young Plantations.*

4009. *The properly thinning out of plantations*, *Sang* observes, "is a matter of the first importance in their culture. However much attention be paid to the article of pruning, if the plantation be left too thick, it will be inevitably ruined. A circulation of air, neither too great nor too small, is essential to the welfare of the whole. This should not be wanting at any period of the growth of the plantation; but in cases where it has been prevented by neglect, it should not be admitted all at once, or suddenly. Opening a plantation too much at once, is a sure way to destroy its health and vigour. In thinning, the consideration which should, in all cases predominate, is to cut for the good of the timber left, disregarding the value of the thinnings. For, if we have it in our choice to leave a good, and take away a bad plant or kind, and if it be necessary that one of the two should fall, the only question should be, by leaving which of them shall we do most justice to the laudable intention of raising excellent and full-sized timber for the benefit of ourselves and of posterity? The worst tree should never be left, but with the view of filling up an accidental vacancy."

4010. *Salmon*, from observations on the most orderly and thriving plantations at Woburn, deduces the following rule for thinning:—"Keep the distance of the trees from each other equal to one-fifth of their height. In the application of this rule for thinning, it is evident that each individual tree can never be made to comply; for the original distance (even if planted in the most regular order) will allow only of

certain modifications, by taking out every other tree, and so on; but even if the obtaining of such equal distance were practicable, experience would show that another way should be preferred, of which the eye must be the judge, by taking out such trees as are least thriving, stand nearest another good tree, &c. &c.; at the same time keeping in view the rule prescribed. By measuring a chain square, or any quantity of land, and counting the trees thereon; then trying the height of two or three trees in that quarter, and taking one fifth of such for the distance, it would be readily seen how many trees should be contained in the piece measured: or the practice may more simply be regulated by taking the distance of eight or ten trees added together, the average of which should be equal to a fifth of the height of the trees." (*Smith's Mechanics*, vol. ii. p. 358.)

4011. *In thinning mixed plantations*, the removing of the nurses is the first object which generally claims attention. This, however, should be cautiously performed; otherwise the intention of nursing might, after all, be thwarted. If the situation be much exposed, it will be prudent to retain more nurses, although the plantation itself be rather crowded, than where the situation is sheltered. In no cases, however, should the nurses be suffered to overtop or whip the plants intended for a timber crop; and for this reason, in bleak situations, and when perhaps particular nurse plants can hardly be spared, it may be sometimes necessary to prune off the branches from one side entirely. At subsequent thinnings, such pruned or disfigured plants are first to be removed; and then those which, from their situation, may best be dispensed with.

4012. *At what period of the age of the plantation the nurses are to be removed*, cannot easily be determined; and, indeed, if the nurses chiefly consist of larches, it may with propriety be said, that they should never be totally removed, while any of the other kinds remain. For, besides that this plant is admirably calculated to compose part of a beautiful mixture, it is excelled by few kinds, perhaps by none, as a timber tree. But when the nurses consist of inferior kinds, such as the mountain ash or Scots pine, they should generally be all moved by the time the plantation arrives at the height of fifteen or twenty feet, in order that the timber trees may not, by their means, be drawn up too weak and slender.

4013. *Before this time it may probably be necessary to thin out a part of the other kinds*. The least valuable, and the least thriving plants, should first be condemned, provided their removal occasion no blank or chasm; but where this would happen, they should be allowed to stand till the next or other subsequent revision.

4014. *At what distance of time this revision should take place* cannot easily be determined; as the matter must very much depend on the circumstances of soil, shelter, and the state of health the plants may be in. In general the third season after will be soon enough; and if the plantation be from thirty to forty years old, and in a thriving state, it will require to be revised again, in most cases within seven years. But one invariable rule ought to prevail in all cases, and in all situations, to allow no plant to overtop or whip another. Respect should be had to the distance of the tops, not to the distance of the roots, of the trees; for some kinds require more head room than others; and all trees do not rise perpendicular to their roots, even on the most level or sheltered ground.

4015. *With respect to the final distance to which trees, standing in a mixed plantation, should be thinned*, it is hardly possible to prescribe fixed rules; circumstances of health, vigour, the spreading nature of the tree, and the like, must determine. Whether the trees are to be suffered to stand till full grown, which of the kinds the soil seems best fitted for; whether the ground be flat or elevated; and whether the situation is exposed or sheltered, are all circumstances which must influence the determination of the ultimate distance at which the trees are to stand. It may, however, be said, in general, that if trees be allowed a certain distance, of from twenty-five to thirty feet, according to their kinds and manner of growth, they will have room to become larger timber.

4016. *Pontey* shows, that forty feet distances are necessary (or only about twenty-seven to the acre) to the unassisted growth of large oak trees, owing to the flat, spreading, and close form of their heads; but that the properly trained, open, high, and conical heads of such trees will admit of their standing at twenty-five feet distances, or about seventy trees on the acre, and of the most profitable kind. What an inducement to pruning and management! (*Farey's Derbyshire*, vol. i. p. 28.)

4017. *Plantations of Scots pine*, if the plants have been put in at three, or three and a half, feet apart, will require little care until the trees be ten or twelve feet high. It is necessary to keep such plantations thick in the early part of their growth, in order that the trees may tower the faster, and push fewer and weaker side branches. Indeed, a pine and a soft wood plantation should be kept thicker at any period of its growth, than plantations consisting of hard wood and nurses already mentioned; and it may sometimes be proper to prune up certain nurse plants, as hinted at above (4011.), for nurses in a mixed plantation. Those pruned-up trees are of course to be reckoned temporary plants, and are afterwards to be the first thinned out; next to these, all plants which have lost their leaders by accident, should be condemned; because such will never regain them so far as afterwards to become stately timber; provided that the removal of these mutilated trees cause no material blank in the plantation. Care should be taken to prevent whipping; nor should the plantation be thinned too much at one time, lest havock be made by prevailing winds; an evil which many, through inadvertency, have thus incurred. This precaution seems the more necessary, inasmuch as Scots pines, intended for useful large timber, are presumed never to be planted except in exposed situations and thin soils. At forty years of age, a good medium distance for the trees may be about fifteen feet every way. It may be worthy of remark, that after a certain period, perhaps by the time that the plantation arrives at the age of fifty or sixty years, it will be proper to thin more freely, in order to harden the timber; and that then this may be done with less risk of danger, from the strength the trees will have acquired, than at an earlier period; but still it should be done gradually.

4018. *Plantations of spruce and silver firs*, intended for large useful timber, should be kept much in the manner above stated, both in their infancy and middle age. As already remarked, planting and keeping them as thick as is consistent with their health are the best means of producing tall, straight, clean stems, and valuable timber. When planted for screens or for ornament, they require a different treatment. "To larch

plantations, the above observations will also apply, and indeed they are applicable to plantations of all kinds of resinous trees.

4019. *The exposed margin of all young plantations* should be kept thicker than the interior. The extent to which this rule should be carried must be regulated according to the degree of exposure of the situation, the age of the plants, the tenderness of the kinds, and other circumstances."

4020. *The proper season for thinning* is autumn, or very early in the spring, where the trees are to be taken up by the root and replanted elsewhere; winter for thinning for timber and fuel; but such trees as are valuable for their barks should be left untouched till the sap rises in April or May.

4021. *Copse-woods* require thinning when young, like other plantations, and when once established the stools require to be gone over the second year after cutting, and all superfluous suckers and shoots removed. This operation should be repeated annually, or every two or three years, in connection with pruning, till within three or four years of the general fall of the crop.

SECT. VI. *Improvement of Neglected Plantations.*

4022. *Neglected and mismanaged plantations* will include the greater number in Britain. The artificial strips and masses have generally never been thinned or pruned; and the natural woods, or copse-woods, have for the most part been improperly thinned or cut over. It is often a difficult matter to know what to make of such cases, and always a work of considerable time. "Trees," Sang observes, "however hardy their natures may be, which have been reared in a thick plantation, and consequently have been very much sheltered, have their natures so far changed, that, if they be suddenly exposed to a circulation of air, which, under different circumstances, would have been salubrious and useful to them, they will become sickly and die. Hence the necessity of admitting the air to circulate freely among trees in a thick plantation, only gradually, and with great caution." This precaution is particularly necessary in thinning plantations of Scotch pine. Trees which have been screened by each other for forty or fifty years, cannot bear the loss of their near neighbours.

4023. *A plantation which has become close and crowded*, having been neglected from the time of planting till perhaps its twentieth year, should only have some of the smallest and most unsightly plants removed; one, perhaps in every six or eight, in the first season; in the following season, a like number may be removed; and in two or three years afterwards, it should be gone over again; and so on till it be sufficiently thinned. It will be proper to commence the thinning at the interior of the plantations, leaving the skirts thicker till the last; indeed, the thinning of the skirts of such a plantation should be protracted to a great length of time. With thinning, pruning to a certain extent should also be carried on. "If the plantation," Sang observes, "consists of pines and firs, all the rotten stumps, decayed branches, and the like, must be cut off close by the bole. It will be needful, however, to be cautious not to inflict too many wounds upon the tree in one season; the removing of these, therefore, should be the work of two or three years, rather than endanger the health of the plantation. After the removal of these from the boles of the firs and larches, proceed every two or three years, but with a sparing hand, to displace one or perhaps two tiers of the lowermost live branches, as circumstances may direct, being careful to cut close by the trunk, as above noticed. In a plantation of hard wood, under the above circumstances, the trees left for the ultimate crop are not to be pruned so much at first as might otherwise be required; only one or two of their competing branches are to be taken away, and even these with caution. If it be judged too much for the first operation to remove them entirely, they may be shortened, to prevent the progress of the competition; and the remaining parts may be removed in the following season; at which time, as before observed, they must be cut close by the bole. (*Plant. Kal.* 467.) We cannot agree to that part of these directions which respects the removal of "perhaps two tiers of the lowermost live branches;" but, paying great deference to the opinion of Mr. Sang, we have judged it right, in a work of this nature, to lay it before our readers, and allow them to judge for themselves.

4024. *The operation of thinning and pruning, thickening or filling up, or renewing portions* that cannot be profitably recovered, should thus go on, year after year, as appearances may direct, on the general principles of tree culture; and for this purpose, the attentive observation and reflection of a judicious manager will be worth more than directions which must be given with so much latitude.

4025. *Pantey has noticed various errors in Kennedy's Treatise on Planting*, and even in Sang's *Kalendar*, on the simple subject of distances, which have originated in their giving directions for anticipated cases which had never come within their experience. "Most people," he says, "take it for granted, that if trees stand three feet apart, they have only to take out the half to make the distances six feet, though, to do that, they must take down three times as many as they leave. By the same rule, most people would suppose that twelve feet distance was only the double of six; but the square of the latter is only thirty-six, while that of the former is one hundred and forty-four, or four times the latter; so that, to bring six feet distances to twelve, three trees must be removed for every one left." (*Profitable Planter*, 256; and *Forest Pruner*, 21.)

4026. *Copse-woods are sometimes improved by turning them into woods, which requires nothing more than a judicious selection and reservation of the strongest of those shoots which proceed from the stools, and which spring more immediately from the collar. But a greater improvement of copse-woods consists in cutting over the overgrown and protuberant stools by the surface of the soil (fig. 595. a, b, c, d), which has been found by Monteith completely to regenerate them. The operation is performed with a saw, in a slanting direction, and the young shoots, being properly thinned and pruned, soon establish themselves securely on the circumference of large and perhaps rotten-hearted roots. (Forester's Guide, 60.)*

4027. *Neglected hedge-row timber may be improved by pruning according to its age. Blaikie recommends what he calls foreshortening, or cutting-in, as the best method*

both for young and old hedge-row timber. "This operation is performed by shortening the overluxuriant side-branches (fig. 596. a), but not to cut them to a stump, as in snag-pruning; on the contrary, the extremity only of the branch should be cut off, and the amputation effected immediately above where an auxiliary side-shoot springs from the branch on which the operation is to be performed (b); this may be at the distance of two, four, or any other number of feet from the stem of the tree; and suppose the auxiliary branch which is left (when the top of the branch is cut off) is also over-luxuriant, or looks unsightly, it should also be shortened at its sub-auxiliary branch, in the same manner as before described. The branches of trees, pruned in this manner, are always kept within due bounds; they do not extend over the adjoining land, to the injury of the occupier, at least not until the stem of the tree rises to a height (out of the reach of pruning, when the top branches can do comparatively little injury to the land. By adopting this system of pruning, the bad effects of close pruning on old trees, and snag-pruning on young ones, will be avoided, the country will be ornamented, and the community at large, as well as individuals, benefited."

SECT. VII. Treatment of Injured and Diseased Trees.

4028. *With respect to wounds, bruises, casualties, and defects of trees, such small wounds as are required to be made by judicious pruning, easily heal up of themselves; large wounds, by amputation of branches above six inches in diameter, should, if possible, never be made. Even wounds of six inches diameter or under will heal more quickly by the application of any material that excludes the air and preserves the wood from corruption; and we agree with Sang in recommending coal-tar, or the liquor produced from coals in manufacturing gas. It is, however, less favourable to the progress of the bark over the wound than a coating of clay or cow-dung covered with moss to keep it moist. Pontey recommends putty and two coats of paint over it. In case the wood, at a bruised or amputated place, has by neglect become already corrupted, the rotten or dead wood is to be pared out quite into the quick, and the wound is then to be dressed with tar or clay, covered with a piece of mat, sacking, or moss. A wound, hollowed out as above, may at first appear an unsightly blemish; but, in subsequent years, nature will lay the coats of wood under the new-formed bark thicker at that place; and probably may, in time, fill it up to be even with the general surface of the tree.*

4029. *All fractures, by whatever means produced, are to be managed as the circumstances of the case require. If a large branch be broken over at the middle of its length, it should be sawn clear off close by the lateral which is nearest to the bole of the tree: but if there is no lateral, or branch capable to carry forward the growth, cut the main or fractured branch in quite to the bole. In both cases, treat the wound as above recommended.*

4030. *Interior rotting, arising from the dampness of the soil, cannot, by the art of man, be cured; though it might have been prevented by timely draining. The hearts of trees frequently rot, where there is no excess of moisture, and especially of such as have been produced from old roots left in the ground by a previous felling. Such roots, when in good ground, send up very great shoots, with few leaves in proportion to their size; from*

the absence of a profusion of these, properly to concoct the juices so abundantly supplied by the roots, the fibre of the wood is loose and imperfect; the next season will produce more leaves in proportion to the supply of juices, yet not a sufficient number for making timber; several years may pass before this event will arrive: this crude and ill-digested timber, disposed to premature decay, is the foundation over which subsequent coatings of wood are laid: yet, however perfect these may be, they do not prevent the progress of decomposition going on in the interior. Nature thus teaches how necessary numerous leaves are to the preparation of the solid wood: the cotyledons and subsequent leaves of a one-year old tree are a thousand times greater, compared with its solid contents, than are the leaves to the solid contents of the first year's shoots from roots like the above. *Sang.*

4031. *Shakes* often arise from the weight and multiplicity of top branches, and might have been prevented by timely pruning. Shakes or rents in the boles of trees, however, often happen where there is no excess of tops. Sometimes the rain, running down from the branches, wets one part of the bole, while the rest is comparatively dry. If this circumstance is succeeded by an intense frost, before the wetted side becomes dry, the bole may be rent for a length, and perhaps to the depth of the core. Shakes or rents, like the above, are difficult to cure. The best method of helping them is to trace out their upper extremity, caulk it up with oakum, and pitch it over, to prevent the rain descending that way in future. (*Sang.*)

4032. *In cases of hollowness*, Pontey recommends probing to the bottom, letting out the water, if any, with an auger, drying the cavity with a cloth, filling it with dry sand, plugging it with wood and oakum, and then painting it over.

4033. *Stems or branches decorticated* by lightning or otherwise, if the soft wood is not much injured, will heal over and become covered with bark; and this the more certainly and rapidly if the air be excluded by a coating of adhesive matter, as cow-dung and quicklime, or by tying on moss or bandages of mat or cloth. Pontey gives an instance in which such treatment was successful in the case of an apple tree. (*Pruner*, 230.) We have witnessed it on an extensive scale on the trunk of a pear tree; and we are informed, on the best authority, of other cases now under progress, in the government garden of the Luxembourg, at Paris.

4034. *Withered or decayed tops* may arise from age and incipient decay; but also, as Pontey states, from improper pruning, or the want of it. We often see it from the improper pruning of elms, which, after having been close pruned to their summits for many years, are left entirely to nature; in that case they branch out luxuriantly below, and the top withers. By neglecting to thin out the branches on the stems of non-resinous trees the same effect may be produced.

4035. *Stunted bushy tops*, on very tall naked stems, show a deficiency of nourishment, from these circumstances; and those on short stems from defects of the soil. Obliquely placed misshapen heads, in detached trees, commonly proceed from the same causes and from want of shelter. Stunted growth, both in tops and stems, is also produced by ivy, and by lichens, mosses, mistletoe, and other parasites. Ivy compresses the bark, and precludes its expansion, as well as excludes air and moisture, by which the outer bark becomes rigid and corky.—Happily, both men and trees will live a long time under the influence both of deformity and disease.

4036. *Excessive exudations of gum and resins* are peculiar to resinous and some other trees when over-pruned, or pruned at improper times. Mildew, honeydew, and blight, three popular names applied to the effects of certain insects of the Aphis kind, attack the oak, beech, poplar, and many trees: all that can be said is, if proper regimen has been regularly attended to, trees will overcome these and all other enemies.

4037. *Insects and vermin*. Almost every tree has its particular insect of the Hemipterous and Dipterous families, and many of the Coleóptera are common to all. The foliage of the small-leaved elm of hedges is often almost entirely destroyed in the early part of the season by *Tenthredinidæ*; and those of the larch and Scotch pine have suffered materially in some seasons from aphides. The Aphis larvea L. (*Eriosóma* of Leach) increased to an alarming extent, from 1800 to 1802, on the larch, on account of three dry seasons following each other; but, though it retarded their growth, it ultimately destroyed very few trees. *Sang* says, he has known it since 1785; that it dirties more than injures the tree, and is now (1819) thought little of. Indeed, almost every species of tree has been known to have suffered in some one season or more, and in particular districts, from insects; for which, on so large a scale, there seems to be no applicable remedy, but patiently waiting till their excess, or the increase of other vermin their natural enemies, or a change of seasons, causes them to disappear. Trees properly cultivated and managed generally overcome such enemies. The hare is well known to be injurious to young trees, and especially to laburnums, by gnawing off their bark. Coating their stems with dung and urine, fresh from the cow-house, is said to be an effectual remedy. It may be put on with a brush to the height of two feet; a barrow-load will suffice for a hundred

trees, with stems of three or four inches in diameter; and its virtue, after being laid on, endures at least two years. (*Bull. in Cald. Hort. Mem. iv. 190.*)

SECT. VIII. *Products of Trees, and their Preparation for Use or Sale.*

4038. *The ordinary products of trees* made use of in the arts are leaves, prunings or spray, thinnings, seeds, flexible shoots, bark, branches, roots, and trunks. Trees also afford sap for wine and sugar, and extract for dyeing; but these products are of too accidental or refined a nature for our present purpose.

4039. *The brush-wood or spray of trees* may be turned into charcoal, substituted for thatch in roofing cottages, used as common fuel, formed into fences, or distilled for pyrolignous acid. Some sorts, also, as the spray of the oak, the willow, the birch, the mountain ash, and others, may be used in tanning. In a green state with the leaves on, the spray of the elm, the poplar, the lime, and others, may be used in feeding cattle; or the spray may be dried like hay, and stacked for that purpose, as in Sweden; or it may be rotted for manure. The spray of all trees not resinous may be used in the distillation of pyrolignous acid. This acid is much used in calico-printing works; and, according to Monteith, sold in 1819, in the neighbourhood of Glasgow, at from 1*l.* 2*s.* to 1*l.* 10*s.* per ton. The distillation is carried on in a cast or malleable iron boiler (*fig. 597.*), which should be from five to seven feet long, three feet wide, and

say four feet deep from the top of the arch, built with fire-brick. The wood is split or round, not more than three inches square in thickness, and of any length, so as to go into the boiler at the door. When full, the boiler door (*b*) is properly secured, to keep in the steam; then the fire is put to it in the furnace below, and the liquid comes off in the pipe above (*d*), which is condensed in a worm, in a stand (*e*) filled with cold water, by a spout (*f*), and empties itself, first into a gutter below (*g*), and from that it is let into barrels, or any other vessel; and thus the liquid is prepared. One English ton weight of any wood, or refuse of oak, will make upwards of eighty gallons of the liquid. There is also a quantity of tar extracted, which may be useful in ship-building. (*Gard. Mag. vol. ii.*)

4040. *The thinnings*, when not beyond a suitable age, and taken up properly, and at a proper season, may be planted in other situations, or as single trees and groups; or they may be used as hoops, hop-poles, poles for garden training, for fencing, for props in collieries; and for a great variety of purposes; those of which the bark is useful for tanning should not be cut down or rooted up till May, but the others at any time during winter. It is common to sort them into lots, according to their kind or size; and to faggot up the spray for fuel, besom stuff, or for distilling for bleachers' liquid.

4041. *The seeds of trees* in general cannot be considered of much use beyond that of continuing the species. The seeds of the oak, beech, and sweet chestnut, however, are valuable for feeding swine, and where they abound may either be swept together after they drop, and carried away and preserved dry in lofts or cellars for that purpose; or, if other circumstances are favourable, swine may be driven under the trees to collect them. These and other seeds, as the haw and holly, are eaten by deer. The seeds of the trees mentioned, and of all the resinous tribe, are in general demand by the nurserymen, for the purposes of propagation; and the seeds of almost all other trees and shrubs are in limited or occasional demand: they may also be collected for private sowing. Tree seeds generally ripen late in the season, and are to be collected in the end of autumn or

beginning of winter, with the exception of a few, such as the elm, poplar, willow, and one or two others, which ripen their seeds in May and June.

4042. *In osier grounds*, willows produce flexible shoots, and, whether intended for the basket-maker or cooper, should not be cut till the second season after planting, in order to strengthen the stools: but by the third autumn the crop will be fit for the basket-maker; and in the fourth, plantations intended for the cooper (hoops requiring the growth of two years) will be ready. The seasons for cutting are November and March; after the former period the wounds are apt to be injured by frost, and after the latter the sap is too far advanced; some is lost by bleeding, and the buds are developed too suddenly to admit of proper strength in the shoots. The cut should be made within three buds of the point whence the shoot issued, in a sloping direction, and the section on the underside. In cutting hoop-willows, the swell at the bottom of the shoot only should be left, that being furnished with abundance of buds for future growth. After being cut, the hoops are trimmed from any side-shoots, and tied up in bundles of a hundred, of six scores each, which, in 1820, sold for from four shillings to five shillings a bundle. The willows are sorted into three sizes and tied in bundles two feet in circumference, within a foot of the lower ends. When to be peeled, they are immediately after cutting set on their thick ends in standing water, a few inches deep, and there they remain till the sap ascends freely, which is commonly by the end of the succeeding May. "The apparatus for peeling is simply two round rods of iron, nearly half an inch thick, sixteen inches long, and tapering a little upwards, welded together at the one end which is sharpened, so as that it may be easily thrust down into the ground. When thus placed in a piece of firm ground, the peeler sits down opposite to it, and takes the willow in the right hand by the small end, and puts a foot or more of the great end into the instrument, the prongs of which he presses together with the left hand, and with the right draws the willow towards him; by which operation the bark will at once be separated from the wood: the small end is then treated in the same manner, and the peeling is completed. Good willows, peeled in the above manner, have been sold, for some seasons past, at from six shillings and sixpence to seven shillings the bundle of four feet in circumference. After being peeled, they will keep in good condition for a long time, till a proper market be found."

4043. *Copse-woods* are generally cut over when the shoots of the stools have attained from three to five inches' diameter at their bases; some grown chiefly for hop-poles, and ware or stuff for crates, hampers, or watted hurdles, are cut over earlier; and others, where small timber for fencing and other country purposes is wanted, are left later. In some parts of Herefordshire, where the oak grows with great rapidity, copse-woods are cut over every twelve years; in the highlands of Scotland, where it grows much more slowly, the time varies from twenty to twenty-five or thirty years. "The bark is there considered as having arrived at its utmost perfection and at its highest value, at the age of between twenty and thirty years: under that age, its virtues are weak; above it, the bark becomes coarse, and loses its sap. Another important reason for cutting down oak coppice-wood about the above period is suggested in the *Stirlingshire Report*, p. 218.; namely, 'that it is a fact established by experience, that it will not renew itself, if it remains uncut beyond the space of about forty years.' " (*Gen. Rep. of Scotland*, 218.) Where there is a considerable tract of copse-wood, it is common to divide it into portions, in number according to the period of cutting. These are to be cut in rotation, so that, when the last portion is cut over, the first is again ready for cutting.

4044. *The seasons for cutting* the kinds of trees whose barks are not made use of, are winter and early in spring; but the oak and other trees which are peeled, are left till the middle of April or May. Birch and larch woods will peel nearly a month earlier than the oak. Should there be no frost, birch and larch may be peeled about the beginning of April; but the birch is commonly allowed to stand till July, and the peeling of it is commenced after that of the oak has been completed. The reason is, there is an outer skin upon birch-bark which requires to be taken off, as it is of no use to the tanner, and renders that part which is of use more difficult to be ground; the month of July is the only time at which the two barks can be separated with ease, as at this time the juice or sap has made its circulation through the tree and bark, and this circumstance renders the separation more easy. From the beginning of May to the middle of July is the usual time for barking the oak. The earlier in the spring this operation is performed on the oak, both for the growth if a natural wood, and for the bark, the better. When the sap has begun to rise, the bark will easily be detached from the wood, and it ought then to be taken off without loss of time; and, if the whole could be taken off before the leaf is completely developed, the bark would be better. After the sap has arisen to the leaf and new growth, the bark becomes more dry, and requires more beating to separate it from the wood: and when what is called the black sap is descending the tree, the bark taken off is black, and loses its original colour; at this time also the bark begins to throw off a scurf, more especially young bark without much cork on it; this outer skin having less of the proper sap or juice, and being much drier when taken off, will weigh less, and consequently will not be so valuable. If possible, oaks should be barked by the middle of June, as every ton of bark taken off after the first of July will be deficient two cwt. per ton, compared with the same quantity taken off in May or early in June.

4045. *The termination of cutting* is generally fixed for the fifteenth day of July, and after this date there should not be a single stool of oak wood cut that is intended for the growth; and as soon as possible after the fifteenth, the whole of the wood and bark should be carried away, that the young growths may not be disturbed or injured, as at this time they will have made considerable progress; at any rate, there should neither be wood nor bark remaining within the new cut hag after the first of August;

nor should either horse or cart be permitted to enter it after that period; for, after the beginning of August, oaks make what is termed a Lammas growth, and the future prosperity and health of the coppice in a great measure depend on the first year's growth, as far as regards form and vigour of the shoots. (*Forester's Guide*, 63.)

4046. *The best mode of cutting* is evidently that of using a saw, and cutting the shoots over in a slanting direction close by the surface. When the stool, after having been cut several times, has acquired considerable diameter, it is customary in the midland counties, Marshal states, to hollow it out in the centre, from a notion that, by rotting away the central roots, the circumferential stems will grow more vigorously, and become as it were separate plants. This is in fact the case in very old copses. For several cuttings, however, it must evidently be the safer policy to keep the stool highest in the middle to throw off the rain, and preserve it sound.

4047. *Monteith* says, "It will be found, upon experiment, perfectly evident, that stools dressed down to the surface of the ground (taking care always not to loosen the bark from the root, or allow it to be peeled off in the smallest degree below the earth, but rounded down level to it) will send forth the most vigorous shoots, and stand the weather, and be the stoutest and best throughout the age of the coppice." (*Forester's Guide*, 61.) From the late season at which the trees to be barked are generally cut, they often receive considerable injury, both from that circumstance, and the manner in which the operation is performed. Monteith appears to us to have furnished the best directions for executing the work in a safe manner. He first sends a person furnished with a sharp cutting edge (*fig. 598, a*) through the copse, whose business is, "to trample down the long grass or foggage all round the root, and then to make a circular incision into the bark so deep as to reach the wood, at about an inch above the surface of the earth: thus the bark when taken off, will injure no part of that which is below the circular incision."

4048. *The root of the tree being thus prepared*, the cutters ought to proceed to their part of the work, not with an axe, however, as is most generally recommended, but with a saw; because, in cutting with the axe, unless the root of the tree be so small in diameter as to be severed in one or two strokes at most, the axe loosens the root to such a degree, that it not only loses the present year's growth, but often fails altogether to grow. Therefore, if the diameter of the root be six inches, or upwards, it should always be cut with a cross-cut saw, entering the saw about half an inch above where the circular incision has been made into the bark, if a small tree; but if the tree be ten or twelve, or more inches in diameter, the saw ought to be entered two inches above it.

4049. *There are two advantages to be derived from cutting with the saw*: it has no tendency to loosen the root of the tree, but leaves it in such a condition as to be more easily and properly dressed; it also saves a portion of the wood that would otherwise be destroyed by the axe. On no pretence should oaks of six inches' diameter be cut with an axe, but always with a saw. Having cut through the tree with a saw, take a sharp adze, and round the edges of the stool or root, going close down to the surface of the earth, taking with the adze both bark and wood, sloping it up towards the centre of the stool, taking particular care always that the bark and wood both slope alike, as if they formed one solid body, being sure always that the bark be not detached from the root. An objection has been made to this mode of cutting with the saw, as taking up too much time; but I have found that two men with a cross-cut saw, kept in good order, will cut as much as two men will with an axe. (*Forester's Guide*, 58.)

4050. *In the operation of barking trees*, "the barkers are each furnished with light short-handled mallets, made of hard wood, about eight or nine inches long, three inches square at the face, and the other end sharpened like a wedge, in order the more easily to make an incision in the bark, which is done all along the side of the tree which happens to be uppermost, in a straight line: and as two barkers are generally employed at one tree, it is proper, that whilst the one is employed in making an incision with the mallet, as above, the other being furnished with the barking-bill (*fig. 598, a*), cuts the bark

across the tree, in lengths of from two feet six inches to three feet. Having thus made the incision in the bark, both ways, the barkers being also each furnished with peeling irons of different sorts (*b, c, d, e*); if the tree or piece of timber to be barked is such as the two barkers can easily lift one end of it, this is placed on two pieces of wood three feet long, and called horses; these are about the thickness of a paling-stake, and have a forked end on each about six inches long, the other end being sharpened to go into the ground; two of these horses are placed in a triangular form against one another, one end of the piece to be peeled being raised on the horses, the two barkers standing opposite to each other, and entering the peeling-irons into the incision made by the mallet, and pressing the iron downwards between the bark and the timber. In this way it will be found very easy to take the bark off in one whole piece round the tree; and, if possible, let these pieces be as long as the incisions made in the bark. In some cases, where there is not much sap, the bark may require a little beating with the square end of the mallet, to cause it to separate easily from the wood; but the less beating with the mallet the better, as it has a tendency to blacken the bark in the inside or fleshy part of it, so that, when the tanner sees it, he supposes it to be damaged, and undervalues it. The branches of the tree being previously all lopped off with the axe, the persons, in number according to the extent of the work, with the bill smooth all the branches, cutting them in lengths of from two feet six inches to three feet, down as small as one inch in circumference. The barkers, principally women, are each provided with a smooth hard stone of about six or eight pounds' weight, beside which they sit down, and having collected a quantity of saplings, branches, or twigs, they hold the piece on the stone with one hand, and with the mallet in the other, they beat it till the bark be split from the wood, from the one end to the other, and taking it off all the length of the piece, if possible, then lay it regularly aside, till a bundle of considerable size is formed.

4051. *Drying the bark*. The point most particularly to be observed in this art is, putting the bark up to dry; which is done by setting it upon what are called the lofts or ranges. These are erected by taking forked pieces of the loppings, called horses, the one three feet long, the other two feet six inches, and driving them about four inches into the ground, opposite one another, about two feet asunder in the breadth, and as much betwixt them lengthways as will admit long small pieces of wood to be put upon them, and as many of these must be put together as will hold the bark of every day's peeling. These ought to be erected in as dry and elevated a spot as can be found in the margin of the wood, or better on its outside. The bark being carried and laid on this loft, with the thick ends of it all laid to the high side of the range, and the small bark laid on to the thickness of about six inches; and the bark taken off the largest of the wood laid regularly on the top, which serves for a covering, and the lofts or ranges having a declivity of about six inches, the rain will run off them readily, and if properly put up in this manner, they will keep out a great deal of rain. After it has lain in this state for three days, if the weather is good

and dry, it ought to be all turned over, and the small bark spread out, so as not to allow it to sit together, which, if much pressed, it is apt to do; and if it does so with the natural sap in it, it has a chance of moulding, which is extremely hurtful to the bark, and both lessens it in weight and in value. After the bark has stood on the ranges about eight or ten days, if the weather be good, it may either be put into a house or a shed, or if intended to be put up into a stack it may now be done. A stack of bark ought never to exceed eight feet in width, and twelve or fifteen feet in height, raised in the middle like a haystack. If it is to stand any length of time in the stack, it ought to be thatched, and in that state may remain all winter. The greatest care ought to be taken to preserve the colour of the inner parts of the bark, because the colour of it is generally looked to as a principal criterion of its value. Before being put into the stack, the natural sap ought to be dried out of it, in order to prevent its fermenting; because, if a fermentation takes place in one part of the stack, it generally goes through and spoils the whole. The same mode of treatment will do for all kinds of bark as well as the oak: but the birch has an outer or shredly skin upon it, that is rejected by the tanner, and, as already observed, must be peeled off.

4052. *Chopping the bark.* "When the bark is ready for the tanner, it has to undergo the work of chopping, which is done by driving in two or more stakes into the ground, with a fork on the upper end of each, leaving them about two feet six inches from the ground, and laying a long small piece of wood across between the two, where a number of people stand, and the bark is carried and laid down behind them, which they take up in their hands and lay on the cross tree, and then, with a sharp whittle or bill in the other hand, they cut it into small pieces, about three inches in length: when this is done, it is trampled into bags, which hold about two hundred weight each, and in these bags it is weighed when sold by the ton, in tons, hundred weights, quarters, and pounds, and in the above manner delivered to the merchant or tanner." (*Forester's Guide*, 199.)

4053. *The disbarbed timber* is prepared for sale by being sorted into straight poles of the largest size, stakes and other pieces fit for palings, faggots, fuel, &c. The unbarbed wood is similarly sorted, and affords, where there is much hazel or ash, cord wood or bundles of clean shoots for making packing crates, hampers, &c., poles for hoops, larger poles for fences, rails, paling-stakes, stakes and shoots for hurdles, besom stuff, spray for distillation, and a variety of other objects, according to the local demand, or the opportunity of supplying a distant market by land-carriage. The brush or spray of non-resinous trees is called in some places ton-wood, and is used for distilling the pyroligneous acid used in bleachfields and calico print-works. "When wood of this description is sent to Glasgow, where there are extensive works for the purpose of distilling it, it sells readily at from 17. 2s. to 17. 10s. per ton; but when there are large cuttings, particularly of young woods, it is worth while to erect boilers near the wood to distil it, as these boilers can be erected at no great expense, and in this case the liquid is easily carried in casks to where it is consumed, at less expense than the rough timber could be; of course it will pay much better. Small wood of this description is also used for charcoal: but in distilling it, there is part of it made into charcoal, which will supply the demand of that article, so that it is by far the most profitable way, when there is any great quantity to dispose of, to erect boilers and distil it; unless where the local situation of the wood will admit of its being shipped at a small expense, and carried to where the works mentioned are carried on. All kinds of non-resinous woods will give the extract in question; but oak, ash, Spanish chestnut, and birch, are the best." (*Forester's Guide*, 155.) Where the oak grows slowly, as in the Highlands, the but-ends of the poles are used for spokes for chaise wheels. "Long spokes are from thirty to thirty-two inches long by three inches and a half broad, and one inch and a half thick, and the short ones for the same purpose, from twenty-two to twenty-four inches long, and the same sizes otherwise. Cart-wheel spokes, from twenty-six to twenty-eight inches long, four inches broad by two inches thick. These are the sizes they require to stand when rough blocked from the axe. Small wood, when sold for this purpose, brought, in 1820, 2s. a cubic foot, measured down to three inches square." (*Monteith*.)

4054. *In some cases copse-woods are sown with grass-seeds, and pastured by sheep, horses, and cattle.* Some admit the animals the fifth year after the last cutting; others, not till the eighth: but Monteith thinks this should never be done till the fifteenth year. If the ground is properly covered with trees, it can seldom be advantageous to admit any species of stock, unless during a month or two in winter.

4055. *Pollard-trees*, which may be considered in most cases as injurious deformities, are lopped at stated periods like copse-woods; and the lop, whether to be barked or otherwise, is to be treated in all respects like that of copse.

4056. *The period at which trees are felled*, for the sake of their timber, is determined by various causes. By maturity of growth, or where the annual increase is so trifling as to render their standing no longer worth while in point of profit; when wanted for private use or sale; or when defects in the tree, or new arrangements in its situation, point out the necessity of its removal. "A timbered estate," Marshal observes, "should frequently be gone over by some person of judgment; who, let the price and demand for timber be what they may, ought to mark every tree which wears the appearance of decay. If the demand be brisk, and the price high, he ought to go two steps farther, and mark not only such as are full-grown, but such also as are near perfection." In trees, as in the human species, there are three stages, youth, manhood, and old age. In the period of youth, the growth is rapid; in manhood, that growth is matured; and in old age, it begins to decay.

4057. *The most profitable season for felling timber* is at what may thus be termed the beginning of manhood. After that time, though the tree may appear sound and healthy, its annual increase is so little, that it would be more profitable to cut it down and replant. The number of years that a tree may stand, before it arrives at this period, must vary in different soils and situations; and the period itself may easily be ascertained by the annual shoots, the state of the bark, and by taking the circumference of the tree at the same place for two or three successive seasons, and comparing the difference. In the view of profiting from timber produce, it is of great consequence to cut down plantations at maturity. Many trees will stand half, others a whole century, after they are full-grown, appear quite healthy, and at the same time make little or no increase of timber. But there are particular cases, arising from the nature and state of the markets, where it may even be more profitable to cut timber before it is arrived at a full growth. (*Treat. on Countr. Res.* ii. 571.)

4058. *Preparations for felling.* It has been strongly recommended to disbark trees a year or more before they are taken down, in consequence of the result of certain experiments commenced by Buffon in 1757. In May of that year, he disbarbed three oak trees, forty feet in height, where they stood. In the course of three years they died, and, on cutting them down, the outer wood was found hard and dry, and the internal wood moist and softer. After trying its strength, &c., he concludes that "timber which has been disbarbed and dried while standing, will weigh heavier, and prove stronger, than timber cut in its bark." Bosc and other French authors in *Cours Compl. d'Agr.* (cc. art. *Aubier, Bois, Quercus*, &c.) strongly recommend this practice, which is followed in some places on the Continent, and in this country

with the oak and larch; but not, as far as we have learned, with any other tree. Monteith finds it by far the most efficient way of seasoning larch timber. He barked some trees in spring, and did not cut them down till autumn, and others stood in the peeled state for two years. After various and extensive trials, he is "decidedly of opinion, that the larch treated in this way at thirty years of age will be found equally durable with a tree cut down at the age of fifty years, and treated in the ordinary way." (*Forester's Guide*, 152.)

4059. *As the dry rot* (Merùlius lâchrymans *Schum.*) is found to arise in a great measure from want of seasoning, or at least to proceed with the greatest rapidity in timber not well seasoned, this practice seems to deserve adoption at that point of view. (*Encyc. Brit. Suppl. art. Dry Rot.*) In some parts of the north of Europe, the trees are divested of their bark for a foot or two feet in height from the ground a year or more previous to that on which they are to be felled. We saw this done in Poland and Lithuania; but, though we made diligent enquiry there and in Sweden, we could not learn distinctly the extent to which it was practised in the latter country and Norway. It is occasionally practised in Poland, for the ostensible purpose of hardening the soft wood; but also accompanied by a deep incision made for the purpose of extracting tar; a practice evidently injurious to the timber, and therefore generally, in these countries, kept out of view. When trees stand close together, a very obvious preparation for felling is lightening the tops of such branches as would, in falling, do injury to the trees that are to be left, or to other adjoining objects.

4060. *The season of felling* is commonly winter, for timber not to be disbarked; but some, for the resinous tribe, recommend summer, as being the season in which it is generally felled in the north of Europe and in the Alps. But the summer season is there adopted from necessity, as in winter the woods are so filled up with snow that felling is hardly practicable. As the timber of these countries is generally squared for the market, the soft wood is chiefly removed; so that the season of felling does not seem to them to be of much consequence. Besides, the timber is never so full of sap in summer as it is in spring and autumn, and therefore, next to midwinter, midsummer may be the best time for felling all kinds of timber trees. Where the trees are disbarked at the base a year or more before felling, the soft wood will be partially hardened; but this practice is by no means general in the North.

4061. *Knowles*, in a recent work on preserving the British navy, and on dry rot, &c., after collecting the opinions of all the ancient and modern authors who have written on felling timber, concludes that the common notion that trees felled in winter contain less of sap or of the vegetable juices, than those cut down at any other season of the year, is not true; and that the method of barking standing trees in spring, and not felling them till the succeeding winter, has not in any way realised the expectations formed of the plan. After describing all the modes that have been adopted for seasoning timber, he concludes that the best is to "keep it in air, neither very dry nor very moist; and to protect it from the sun and rain by a roof raised sufficiently high over it, so as to prevent, by this and other means, a rapid rush of air." (*Inquiry into the Means of preserving the British Navy from Dry Rot, &c.* by Knowles, *Sec. to the Com. of Surveyors*, chap. iii.)

4062. *The operation of felling* is performed either by digging an excavation round the stem, and cutting the roots at two or three feet in distance from it, or by cutting over the stem at the surface. By the former mode the root is obtained for use, and the ground more effectually cleared and prepared for the roots of adjoining trees, or whatever crop is to follow. Where the tree is intended to stole, which can very seldom be advisable in the case of cutting full-grown timber, or where there is some nicety requisite in taking it down, so as not to injure other trees or adjoining objects, it is cut or sawn over, and the root, if to be removed, dug out afterwards. "In cutting large trees, in order to make the tree fall the way required, enter the cross-cut saw on that side of the tree it is intended to fall, and cut it about a third part through; then enter the saw at the other side, and when it is cut so far as to admit a wedge, place the wedge exactly opposite the way you want the tree to fall, and keep driving it slowly till the tree is nearly cut through." (*Monteith*.) The tree, being felled, is next divested of its branches, which are sorted into fence wood, fuel, ton-wood, &c., according to the kind of tree; and the trunk is generally preserved as entire as possible for the purchaser. Sometimes it is cut in two, and the root-cut, or but-end, being the most valuable, sold for one class of purposes at a higher price, and the top-cuts for others somewhat lower.

4063. *The seasoning of timber* consists in evaporating the fluid matter or sap by the natural warmth of the atmosphere, with the precaution of screening the timber both from the direct action of the sun and wind, otherwise it cracks, and receives much injury. As this process proceeds slowly and irregularly when conducted in the ordinary way, Mr. Langton has discovered a new method of seasoning timber, consisting in the removal of the greater part of the atmospheric pressure, and the application of artificial heat, by which the time necessary to season green timber, and render it fit for use, is only about twice as many weeks as the ordinary process requires years. In this process the power of an air-pump is added to draw the sap out of the interior of the wood; and the tendency of the fluid to the outside being thus increased, a higher temperature than that of the atmosphere can be applied, with less risk of causing the timber to split; consequently the process may be completed in less time, and a few trials will show the best relation between the time and heat for the different kinds of wood. The late Mr. Tredgold's opinion being asked, he gave it as decidedly in favour of Mr. Langton's process; and timber is now completely seasoned by Mr. Langton in eight or ten weeks after the tree is cut down. (*Newton's Journal*, vol. i. 2d series, p. 144.)

4064. *Seasoning timber by steeping*. "Some remarkable facts respecting the durability that may be given to timber by artificial means have been observed at Cloosburn. The proprietor of that estate has, for thirty years, been in the constant practice of soaking all fir and larch timber, after it is sawed into planks, in a pond or cistern of water strongly impregnated with lime. In consequence of this soaking, the saccharine matter in the wood, on which the worm is believed to live, is either altogether changed, or completely destroyed. Scotch fir-wood, employed in roofing houses, and other indoor work, treated in this manner, has stood in such situations for thirty years, sound, and without the vestige of a worm. In a very few years fir-timber so employed, without such preparation, would be eaten through by that insect." (*Monteith of Cloosburn*, in *Edin. New Phil. Journ.* June, 1828.)

4065. *The roots of trees* are the last product we shall mention. These should, in almost every case, be effectually eradicated; to aid in which, in the case of very large roots, splitting by wedges, rifting by gunpowder, tearing up by the hydrostatic press, or by a common lever, may be resorted to. Some compact ash or oak roots are occasionally in demand by smiths, leather-cutters, and others; but, in general, roots should be reduced to pieces not exceeding three feet long, and six inches in diameter, and put up in stacks not less than three feet every way, but commonly containing two cubic yards. These, when dry, are sold for fuel, or reduced to charcoal on the spot. In eradicating and stacking up coppice-woods, it is common to allow a certain sum per stack, and something for every acre of ground cleared; if there are no trees to bark, allowances are also made for the poles, faggots, &c., so that no part of the operation is performed by day work.

4066. *The usual method of charring wood* is as follows:—The wood being collected near the place intended for the operation, and cut into billets, generally about three feet

in length, the pits or stacks are usually formed in this manner :—A spot adapted to the purpose, of from about fifteen or twenty feet in diameter, of a conical form, is selected, and after being properly levelled, a large billet of wood, split across at one end, and pointed at the other, is fixed in the centre of the area, with its pointed extremity in the earth, and two pieces of wood, inserted through the clefts of the other end, forming four right angles ; against these cross-pieces, four other billets of wood are placed, one end on the ground, and the other leaning against the angles. A number of large and straight billets are afterwards laid on the ground, to form a floor, each being, as it were, the radius of the circular area ; on this floor, a proper quantity of brush or small wood is strewed, to fill up the interstices, when the floor will be complete : and in order to keep the billets in the same position in which they were first arranged, pegs or stumps are driven into the ground, in the circumference of the circle, about a foot distant from one another ; upon this floor a stage is built, with billets set upon one end, somewhat inclining towards the central billet, and on the tops of these another floor is laid, in a horizontal direction, but of shorter billets, as the whole is intended, when finished, to form a cone. The pile is then coated over with turf, and the surface generally plastered with a mixture of earth and charcoal dust.

4067. *Previously to the operation of setting fire to the pile, the central billet in the upper stage is drawn out, and pieces of dry combustible wood substituted in its place, to which the fire is applied. Great attention is necessary during the process, in the proper management of the fire, and in immediately covering up the apertures through which the flame obtrudes itself, until the operation be concluded, which is generally effected in the space of two or three days, according to circumstances. When the charcoal is thought to be sufficiently burnt, which is easily known from the appearance of the smoke, and the flames no longer issuing with impetuosity through the vents, all the apertures are to be closed up very carefully, with a mixture of earth and charcoal dust, which, by excluding all access of the external air, prevents the coal from being any further consumed, and the fire goes out of itself. In this condition it is suffered to remain, till the whole is sufficiently cooled ; when the cover is removed, and the charcoal is taken away. If the whole process is skilfully managed, the coals will exactly retain the figure of the pieces of wood : some are said to have been so dexterous as to char an arrow without altering even the figure of the feather. (Encyc. Brit. vol. v. art. Charcoal.)*

4068. *The method of charring wood, for the making of gunpowder, according to an improved system, adopted not many years ago, is however a much more costly operation, though the expense attending it is amply compensated by the superior excellence of the article when manufactured. It is done in iron cylinders, and in so complete a manner, that every particle of the wood is charred. The oily or tarry matter is also preserved, and may, so far as the quantity goes, be made use of instead of foreign tar or pitch. This mode of charring wood for making gunpowder is carried to the greatest perfection near Petworth in Sussex, and there is a manufacture of a similar nature near Chester. (Gen. Rep. for Scotland, vol. ii. p. 342.)*

SECT. IX. *Estimating the Value of Plantations and their Products, and exposing them to Sale.*

4069. *The valuation of timber forms a distinct profession, and can only be acquired by continued observation and experience : like other valuations of property, it depends on a great variety of considerations, some, of a general, but the greater part of a local nature. We have already offered some remarks on valuing young plantations, as a part of what may be called the inherent value of landed estates (3330.), and shall here confine ourselves to the valuation of saleable trees.*

4070. *In valuing saleable trees of any kind, their number per acre or their total number by enumeration being ascertained, and the kinds and sizes classed, then each class is to be estimated according to its worth as timber, fence-wood, fuel, bark, &c.*

4071. *In a coppice wood which cannot readily be measured, "the readiest method of counting the stools is, to cause two men to take a line, say about a hundred feet long or more, and pass it round as many of the stools as it will enclose, the one man standing while the other moves round a new number of stools : then count always the stools betwixt the two lines, causing the one man to move while the other stands still, and so on alternately. The valuator at the same time taking care to average every twenty stools as they go on, before losing sight of the counted stools. This way, too, is a very speedy and sure method of counting the number of trees in any plantation."*

4072. *Or the stools of a coppice wood may be counted and averaged "by two men going parallel to each other, and the person valuing going betwixt them ; the two men putting up marks with moss, or pieces of white paper, on a branch of the stools ; the one man always going back by the last laid marks, and the valuator always counting and averaging the stools betwixt the newly laid and the late made marks ; counting and averaging the stools always as the men go on, taking only twenty, or even ten stools at a time. To those who have been in the practice of doing this frequently, it will be found very easy, and will be done very speedily, and with a very considerable degree of accuracy. The proper method of learning to do this correctly is, when a person cuts an oak wood for the first time (or, even were the work repeated several times) ; he should then, in order to make himself perfectly acquainted with ascertaining the quantity of bark that a stool, or even the stump of a stool, will produce, go before the peelers, and select a stool or stem ; after having examined it narrowly, he supposes it to produce a certain quantity of bark, and marks this down in his memorandum book. He then causes a person to peel it by itself, dry it, and carefully tie it up and weigh it, and compare it with the weight he supposed it would produce, and he will at once see how far his calculation approaches the truth. A stem of oak, from a natural stool, suppose it to measure in girth two inches, by seven feet long, will contain two solid inches, and one third of an inch, according to the measurement of Hoppus. This stem or shoot will produce two pounds two ounces of bark. Again, a stem or shoot of natural oak, measuring four inches in*

girth, by nine feet in length, will be found to contain one solid foot of wood, and will produce thirteen pounds and a half of bark." (Forester's Guide, 170.)

4073. When growing trees are valued, an allowance is made from their cubic contents for the bark. The rule given by Monteith is, "When the girth or circumference is any thing from twelve inches up to twenty-four inches, then deduct two inches; from twenty-four to thirty-six, three inches; from thirty-six to forty-eight, four inches; from forty-eight to seventy-two, five inches; and above seventy-two, six inches. These deductions," he says, "will be found to answer in almost all trees; unless in such as are very old, and have rough and corky barks, or barks covered with moss, when an extra allowance is to be made." (Forester's Guide, 180.)

4074. In valuing measurable oak-trees, many persons proceed on the data that every cubic foot of timber will produce a stone (sixteen pounds) of bark. "This," Monteith says, "is not always correct;" and he states the following facts from his own experience, with a view to assist beginners in ascertaining the quantity of bark from different trees. "An oak-tree, about forty years old, measured down to four inches and a half as the side of the square, and weighing only the bark peeled off the timber that is measured, without including the bark of the spray, &c., every foot of measured timber will produce from nine to eleven pounds of bark. An oak-tree of eighty years old, weighing only the bark peeled off the measurable timber, as above, every foot will produce from ten to thirteen pounds of bark. Every foot of large birch timber, peeled as above, will produce fourteen pounds of bark. Every foot of mountain-ash, as above, will produce eleven pounds and a half of bark. Every foot of the willow, unless a very old one, will produce from nine to eleven pounds of bark. Every foot of larch fir, not exceeding thirty years old, will produce from seven to nine pounds of bark. The bark of trees, particularly the oak, is peeled off, every branch and shoot, down as small as an inch in circumference." (Forester's Guide, 189.)

4075. To facilitate the measuring of standing timber, various ingenious instruments and machines have been invented, by Monteith, Gorrie, Rogers, and others. Perhaps the most generally useful is Broad's callipers (fig. 599). This instrument is composed of two thin pieces of deal about thirteen feet long, with

599

a brass limb or index (a), on which are engraven figures denoting the quarter girth in feet and inches. Raising the instrument, the index end (a) is taken hold of, and the other applied to that part of the trunk where the girth is to be taken, opening it so wide as just to touch at the same time both sides of it, keeping the graduated index uppermost, on which the quarter girth will be shown, allowing one inch in thirteen for the bark. For taking the height of

600

a tree, rods of deal or bamboo, seven feet long, made so as to fit into ferules at the end of each other, tapering as in a fishing-rod, may be used. Five of them with feet marked on them would enable a man quickly to measure the height of a trunk of more than forty feet as he would reach above seven feet. Monteith's machine being described in the Encyclopaedia of Gardening (2d edit. § 6970), and Gorrie's in the Gard. Mag. (vol. ii. p. 9.), we shall here confine ourselves to the invention of Mr. Rogers.

4076. Rogers's autrometer (fig. 600) consists of a tripod stand, and a machine for taking angles horizontally as well as vertically. An upright stem arises from the top plate, at the end of which is a ball, with a hole perforated through it, to receive the horizontal stem of the instrument; b c may be called the base limb of the instrument, which is to be placed in a truly horizontal position, and adjusted by the suspended level (d). The limb (c) rises on a joint at e, and slides upon a vertical arch (f) which is graduated. At the joint (c) there is an eye-piece, through which the surveyor looks along the side of the bar (b) to a small point, or rising edge, at the end of the bar; the part of the tree cut by this line of observation will, if the instrument is properly adjusted, be perfectly horizontal with the eye-piece. An eye-piece is also placed at e, on the upper

side of the rising limb, for the purpose of looking along this limb to a point or rising edge (*e*) in its extremity. The surveyor elevates this limb, until that part of the tree intended to be noticed is exactly cut by the line of observation, and the angle subtended between that and the horizontal is shown upon the vertical arch (*f*). It is here to be remarked, that the graduations upon the arch (*f*) are not angles of altitude, but marks or graduations answering to feet and inches of a tangent line, extending from the horizontal point upwards, taken at a given distance from the tree; consequently, there are two or more rows of divisions, answering to the several distances at which the instrument may be planted. Twenty-four feet and forty-eight feet are proposed distances, and the graduations upon the arch (*f*) are made accordingly. For lofty trees, the longer distance is to be used; but for shorter trees, the distance of twenty-four feet will be sufficient. The horizontal angles which are to determine the diameter of the trunk, at the several points of observation, are ascertained by the limb (*g*), which slides laterally upon an arch or graduated plate (*h*) divided upon the same principles as the arch (*f*). The limbs (*b*) or (*c*) being fixed, so as to coincide with one side of the trunk, the limb (*g*) is then moved until it coincides with the other side of the trunk, and the angle subtended between the two shows, by the graduated plate (*h*), the diameter in feet and inches of the trunk at the points of observation. The length of the trunk, and its diameter in the several parts, being thus ascertained by the improved instrument, recourse must then be had to tables, calculations, or the ordinary sliding rule, for the purpose of obtaining from these admeasurements, the solid content of timber in each portion of the tree. There are adjusting screws, and circular racks and pinions for moving the limbs of the instrument, and altering their position, as circumstances may require; and when crooked arms, or bent parts of the trunk present themselves, the instrument may be turned upon its pin, in the ball at the top of the stem (*a*), and used in an inclined position. (*Newton's Jour.* vol. ix. p. 360.)

4077. *The price of timber*, like that of every other article in general use, varies with the supply and demand, and is easily ascertained from the timber-merchants at the different sea-ports; as is that of bark, charcoal, and fire-wood, from the tanners and coal-merchants.

4078. *The usual modes of disposing of timber trees* are, selling the trees standing, by auction, by receiving written proposals, or by bargain and sale; 2d, cutting down the trees, and selling them in the rough, by either of these methods; 3d, converting the fallen trees; that is, cutting them up into the planks or pieces to which they are best adapted, or which are most eligible in the given situation. The first method seems the best, especially on a large scale, and also for the disposal of copse wood or osier crops.

CHAP. X.

Formation and Management of Orchards.

4079. *The formation of orchards* is to be considered among the permanent improvements of an estate; and should be kept in view in its first arrangement or laying out. No temporary occupier could afford to plant an orchard without extraordinary encouragement from his landlord. Orchards in this respect may be ranked with timber plantations, and both subjects together agree in belonging equally to agriculture and gardening. Orchards have doubtless existed in Britain for many ages as appendages to wealthy religious establishments; but, as objects of farming or field culture, they do not appear to have been adopted till about the beginning of the seventeenth century. (*Lawson.*) They were then introduced by Lord Seudamore in Herefordshire, in which county, and in such parts of those adjoining as exhibit a red marly soil, are the best farm orchards in England. The chief produce of these orchards is cider and perry; but as these liquors are not in very general demand in this country, and are confessedly less wholesome and nourishing than malt liquors, their formation cannot be carried to any great extent. It seems desirable, however, that orchards of moderate size should be as generally introduced as possible; as the use of the fruit in pies, tarts, and sauces would add considerably to the comforts of the lower classes. Besides, there are some situations, as steep sheltered banks of good soil, which cannot be so profitably employed in any other branch of husbandry. The subject of orchards may be considered in regard to soil and situation, sorts of trees, planting, culture, and the manufacture or disposal of the produce.

SECT. I. *Soils and Situations most suitable for Orchards.*

4080. *The sites of all the best apple orchards*, and all the chief cider districts, have been discovered by W. Smith to be on the same stratum of red marl which stretches across the island from Dorsetshire to Yorkshire. Fruit of no kind, indeed, can be raised with much success on a soil that does not contain in its composition a portion of calcareous matter: though apple trees will thrive well on any description of clay which has a dry bottom, and pears and plums on any dry-bottomed soil whatever.

4081. *The most desirable aspect* is unquestionably a somewhat elevated and naturally sheltered declivity, open to the south and south-east; but, as the author of *The Herefordshire Survey* remarks, orchards are now found "in every aspect, and on soil of every quality, and under every culture." The most approved site, he says, is that which is open to the south-east, and sheltered in other points, but particularly in that opposite.

Much however depends on the character of the winds of a country; for in some parts of the island, the west, and in others the east or north wind, is the most injurious to vegetation.

4082. *The soil* which in Herefordshire is considered best adapted to most kinds of apples is a deep and rich loam when under the culture of the plough; on this, the trees grow with the greatest luxuriance, and produce the richest fruit. Some trees however, the stire and the golden pippins in particular, form exceptions to this general rule, and flourish most in hot shallow soils on a lime or sandstone. The best sorts of pear-trees also prefer the rich loam, but inferior kinds will even flourish where the soil will scarcely produce herbage. An orchard is generally raised with most success and at least expense in a hop-yard, the ground under this culture being always well tilled and manured, as well as fenced against every kind of enemy.

4083. *The soils and situations devoted to farm orchards in Scotland* are steep clayey banks sheltered from the more violent and injurious winds; and in whatever part of that country such situations occur, they can scarcely be more profitably employed. Fruit trees of the apple, pear, and cherry kind, especially of the hardier and tall vigorous-growing varieties, might be introduced in the hedge-rows of dry and moderately sheltered grass-lands in most parts of the British Isles. By thus rendering these fruits universal, there would be a considerable accession of enjoyment to the lower classes, and less temptation to break into gardens and orchards.

4084. *The commercial situation* most desirable for an orchard is, of course, near a market town, or near a ready conveyance to one; because though the making of cider affords a profit, yet the fruit sold for culinary or table use yields a much more considerable one. In *The Gloucestershire Report* it is stated that the fruit, which would fetch 8l. 16s. unground, would only bring in cider 3l. 15s.

SECT. II. *Sorts of Trees, and Manner of Planting.*

4085. *The most generally useful fruit* that can be grown in farm orchards is the apple; next the pear; then the plum for tarts or wine; and to these may be added the cherry, filbert, walnut, chestnut, and elder. In the cider countries, where the climate is more certain than in some others, it is customary to plant but a few good sorts; and not to mix above one or two sorts together in making cider: in the northern districts, on the contrary, it is a maxim to plant a considerable number of different sorts, both of those which blossom early and late; because, should the blossom of one variety be destroyed by a frosty wind, that of another may escape. In cold districts, it is advisable to plant orchards in sheltered hollows, exposed to the sun, and to plant thick: but in the warmer southern counties, many descriptions of cider and perry fruits may be grown to perfection in the hedge-rows, or as cultured trees in permanent pastures. The fittest trees for such purposes are those which grow tall, with upright shoots, and which bear fruit of a small size; such as the Siberian pippin apple, and squash teinton pear: such trees shade the hedges or pastures less than the spreading kinds, and their fruit, being small, is less likely to be blown down by high winds.

4086. *The most approved sorts of cider apples* we have enumerated and partially described in the accompanying table (4089). It will be particularly observed that some of the sorts form much more handsome trees than others, and should therefore be preferred for hedge-rows, and indeed in all cases where the quality of the fruit is not objectionable. Some also have smaller-sized fruit than others, and these are to be preferred for situations exposed to much wind.

4087. *The colours of good cider fruit* are red and yellow; the colour to be avoided is green, as affording a liquor of the harshest and generally of the poorest quality. The pulp should be yellow, and the taste rich and somewhat astringent. Apples of a small size are always, if equal in quality, to be preferred to those of a larger, in order that the rind and kernel, which contain the aromatic part, may be the more easily crushed with the pulp.

4088. *The sorts of baking apples most suitable for orchards* are the calvilles, of which there are several varieties, including the Hawthornden for early use; the reinettes, pearmain, and Northern greening for autumn use, and the russets and Padley's pippin for winter and spring. Many other sorts might be named, but an inspection of the fruit markets will prove that these are the best; and further details belong to books on gardening. Whoever intends to plant an orchard will do well to describe the soil, situation, climate, and object in view, to the nearest resident gardener or nurseryman of science and great experience; because the nomenclature of fruits is at present too uncertain to justify any one in trusting entirely to a selection of names taken from books. Ronalds of Brentford, Gibbs of Amptill and Old Brompton, and Pearson of Chilwell, near Nottingham, are very extensive growers of apple trees for sale, and have paid great attention to the merits of the different sorts.

4089. TABLE OF CIDER APPLES OF ESTABLISHED REPUTATION.

No.	Name.	Synonym.	How, when, and where originated, procured, or obtained.	Where figured.	Described.	Size.	Figure.	Colour.	Ripe in Last till	Consistence & flavour.	Bearer.	Character of the tree, and general reputation of the fruit.
1.	Siberian pippin	-	A seedling from Siberian crab and Loat's pear-main, by Knight	-	Kn. Tr. 176.	Small	Fl. orbic.	Yellow	Chms.	Firm and juicy	Great	Upright sm.-leaved, hardy tree. Specific grav. 1079, exceeds almost every apple formerly in culture as a cider fruit
2.	Grange pippin	-	A seedling by Knight, say originating by Knight	-	Hort. Tr. i. 229.	Small	Roundish	Yellow and red	Oct.	Firm, juicy, acid	Great	Upright sm.-leaved, hardy tree. Specific grav. 1079, exceeds almost every apple formerly in culture as a cider fruit
3.	Foxley	-	A new variety by Knight, say of Foxley	-	Kn. Tr. 177.	Very s.	Roundish	Orange and red	Chms.	Firm and juicy	Great	Upright, hardy tree
4.	Siberian Harvey	-	A seedling by Knight, say of Foxley	-	Hort. Tr. i. 229.	Small	Round	Bright red and green	Chms.	Firm and austere	Great	Elegant, upright, sm.-leaved tree
5.	Alban	-	A seedling by the Rev. T. Alban, of Hereford, in 1798	-	Kn. Tr. 175.	Small	Round	Red and green	Chms.	Firm and very harsh	Indif.	Delicate tree; spec. grav. juv. 1073
6.	Hoghead	-	A Herefordshire seedling	-	Kn. Tr. 174.	Med.	Roundish	Yellow & russet spots	Jan.	Firm and austere	Great	Small-leaved tree; specific gravity of juice, 1074
7.	Bead's kernel	-	A Herefordshire seedling	-	Forsyth, 96.	Small	Ovate	Yellow and red	Nov.	Firm and sharp	Good	An upright-twigged tree
8.	Large sire	-	A Herefordshire apple	-	Kn. Tr. 172.	Small	Ovate	Yellow and red	Jan.	Firm and juicy	Med.	A specific gravity of juice, 1067
9.	Brenton seedling	-	A Herefordshire seedling	-	Kn. Tr. 173.	Small	Round	Yellow	Jan.	Firm and austere	Good	A tree-growing tree; specific gravity of juice, 1050
10.	Briery's seedling	-	A Herefordshire seedling	-	Kn. Tr. 173.	Small	Round	Yellow	Jan.	Firm and austere	Good	A tree-growing tree; specific gravity of juice, 1050
11.	Hagloe	-	An escaped Herefordshire fruit	Pom. Her. t. 5.	Forsyth, 68.	bel. me.	Conical	Yellow	Jan.	Firm and tart	Great	Upright, small-leaved tree
12.	Woodcock	-	A Herefordshire variety	Pom. Her. t. 40.	Forsyth, 194.	ab. me.	Conical	Dark red and yellow	Jan.	Firm and austere	Great	Narrow-leaved, upright tree
13.	Yellow Siberian	-	A variety from the Siberian crab and Loat's pearmain, by Knight	Pom. Her. t. 1.	Kn. Tr. 175.	Very s.	Round	Very yellow	Jan.	Firm and austere	Great	Upright, bands, tree, one of the very best cider apples; specific gravity of juice, 1074
14.	*Malden's blush	-	-	-	Forsyth, 108.	Small	Roundish	Dark mahogany	Oct.	Firm and acid	Good	Hardy, upright-growing tree; much esteemed in the cider countries
15.	*New red must	-	-	-	Forsyth, 119.	Large	Round	Pale red and green	Dec.	Firm and acid	Great	Hardy, upright tree; much esteemed in the cider countries
16.	*Old red must	-	-	-	Pom. Her. t. 4.	Large	Ovate	Pale red and green	Jan.	Firm and acid	Great	Hardy, upright tree; much esteemed in the cider countries
17.	*Pawson	-	-	-	Pom. Her. t. 15.	bel. me.	Conical	Greenish yellow	Jan.	Firm and sharp	Great	Hardy, upright tree; much esteemed in the cider countries
18.	*Redstreak	Herefordshire reds	-	-	Pom. Her. t. 1.	Med.	Obovate	Green, streak with red	Jan.	Firm and sharp	Great	Hardy, upright tree; much esteemed in the cider countries
19.	*French crab	Short-stalked	A Herefordshire fruit	-	Forsyth, 49.	Large	Ovate	Deep green and red	Chms.	Firm, sharp	Great	Hardy, upright tree; much esteemed in the cider countries
20.	*Warwickshire	Warwick gold, p.	Resembles the golden pippin	-	Hort. Tr. ii. 104.	Small	Round	Gold and green	Nov.	Firm, aromatic	Great	Hardy, upright tree; much esteemed in the cider countries
21.	*Harvey's	-	-	-	Forsyth, 72.	Large	Ovate	Green russet	Chms.	Firm, aromatic	Great	Hardy, upright tree; much esteemed in the cider countries
22.	*Winton	-	-	-	Forsyth, 188.	Med.	Conical	Dark russet	Chms.	Firm and sweet	Great	Hardy, upright tree; much esteemed in the cider countries
23.	*White court	Corps pendu or hanging body	-	-	Forsyth, 186.	bel. me.	Conical	Russet, and some gr.	Chms.	Firm and aromatic	Good	Upright tree; much esteemed in the cider countries
24.	*Cornish	-	-	-	Forsyth, 24.	Med.	Long	Yellowish	Jan.	Firm and juicy	Good	Upright tree; much esteemed in the cider countries
25.	*Downon	-	-	-	Forsyth, 185.	Med.	Long	Yellowish	Jan.	Firm and juicy	Good	Upright tree; much esteemed in the cider countries
26.	*Bringwood	-	Seedling by Knight	Pom. Her. t. 9.	Hort. Tr. i. 145.	Small	Round	Yellow	Oct.	Firm and sweet	Good	Upright tree; much esteemed in the cider countries
27.	*Whitmore	-	Seedling by Knight	-	Hort. Tr. i. 69.	Small	Round	Reddish green	Sept.	Rich and sweet	Good	Upright tree; much esteemed in the cider countries
28.	*Yellow Ingestrie	Resembles gold, p.	-	-	Forsyth, 127.	Large	Round	Scar. white, red & yellow	May	Firm, sweet	Good	Upright tree; much esteemed in the cider countries
29.	*Yellow Ingestrie	Resembles gold, p.	-	-	Hort. Tr. i. 277.	Med.	Round	Yellow	Oct.	Firm, juicy	Good	Upright tree; much esteemed in the cider countries
30.	*Yellow Ingestrie	Resembles gold, p.	-	-	Hort. Tr. i. 277.	Med.	Round	Yellow	Oct.	Firm, juicy	Good	Upright tree; much esteemed in the cider countries
31.	*Eaton's yellow kernel	-	-	-	Hook. Pom. t. 229.	Large	Conical	Yellow and red	Oct.	Firm, juicy	Good	Upright tree; much esteemed in the cider countries
32.	*Eaton's yellow kernel	-	-	-	Forsyth, 40.	Med.	Round	Yellow	Jan.	Firm and vinous	Good	Upright tree; much esteemed in the cider countries
33.	*Skeohouse	-	-	-	Forsyth, 168.	Med.	Round	Orange, red, and yellow	Jan.	Firm and juicy	Great	Large-spreading tree; showy fr.
34.	*Trevoiler	-	-	-	Forsyth, 182.	Med.	Round	Yellow and red	Chms.	Firm and juicy	Good	Upright tree; much esteemed in the cider countries
35.	*Bovey redstreak	-	-	-	Forsyth, 12.	Med.	Round	Deep red and white	Jan.	Firm, sub-acid	Good	Upright tree; much esteemed in the cider countries
36.	*Cockage	-	-	-	Forsyth, 22.	Med.	Round	Red and yellow	Oct.	Soft and sharp	Great	Upright tree; much esteemed in the cider countries
37.	*Minshall crab	-	A Lancashire seedling, say	-	Forsyth, 114.	Med.	Roundish	Yellow, with brown spots	Sept.	Firm, sharp	Great	Upright tree; much esteemed in the cider countries
38.	*Redstreak	Longlet redstreak	Seedling of Wiltshire, say	-	Forsyth, 155.	Med.	Round	Yellow, streaked with red	Sept.	Soft and acid	Good	Upright tree; much esteemed in the cider countries

4090. *The dessert apples fit for orchards* are the rathripes or Margarets for earliest use; the Juneating, pomeroiy, summer pearmain, and Kentish codling for summer use; the golden, Downton, and other pippins, especially the ribston pippin, with the nonpareil and other small russets, for autumn, winter, and spring use. The following list is given by Nicol as including a fit collection both of kitchen and dessert apples for a private orchard; those marked thus * being preferable:—

Ribston pippin, *oslin ditto, *gogar ditto, *Kentish ditto, *royal codling, *Kentish ditto, *Carlisle ditto, *roval russet, Wheeler's ditto, *royal pearmain, *Loan's ditto (good), *golden reinette, *Kentish ditto (good), *grey Leadington, scarlet

ditto, summer greening, winter ditto, *Yorkshire greening, *margil (very good), Margaret apple (good), *white Hawthornden, *Norfolk beaufin (good), strawberry, *purple-mouth (very good).

4091. *The most approved sorts of cider pears* are the following:—

Barland, Pom. Her. t. 27., Forsyth, p. 143., fruit very austere, hardy upright tree. Holmore, Pom. Her. t. 20., Forsyth, p. 144., upright tree. Huficap, Pom. Her. t. 24., Forsyth, p. 144., fruit austere, large, hardy trees. Oldfield, Pom. Her.

t. 11., Forsyth, p. 144., large tree. Rough cap, Forsyth, p. 141., very austere, hardy free-growing tree. Squash teinton, Pom. Her. t. 15., Forsyth, p. 144., fruit very austere, upright tree, and great bearer.

4092. *In choosing pears for planting in orchards*, the description of the plant is a matter of very considerable importance, as pear trees attain a much greater age and size than apples. In our opinion the planting of pears in hedge-rows ought to be more encouraged than the planting of apples, as they are calculated, when dried, to be used in soups; or, when stewed green, to afford a light and agreeable nourishment; and perry is at least a more wholesome and exhilarating liquor to most constitutions than cider.

4093. *The baking and dessert pears fit for orchards*, according to Nicol, are the following:—

*Jargonelle, Crawford or lammas, *carnock or Drummond, *grey achan, swan's egg, *moorfoiw's egg, *yair, *golden knap (good), Longueville, *summer bergamot, *autumn ditto,

*Scot's ditto, musk robin (good), saffron, *hanging leaf (very good), the pound pear, cadillac, warden (for baking).

4094. *Gorrie (Gard. Mag. vol. iv. p. 11.)* recommends the Benvie (fig. 601. a), Golden Knap (b),

601

Elcho (c), Busked Lady (d), and Pow Meg (e), as handsome trees. But where high-flavoured fruit is the object, and the climate is not unfavourable to the Beurrés, the Bergamots, and other new French and Flemish sorts, should be preferred. The following sorts will succeed as standards in the neighbourhood of London. Their time of ripening is indicated, and also their qualities: very good (v. g.); good (g.); and moderate (m.).

July. *Muscat Berrot (m.), gros muscat. (g.)
 Aug. Epine verte d'été (g.), *jargonelle. (v. g.)
 Autumn. *Bergamote silvange (g.), *beurré rouge (g.), beurré vert. (g.)
 Sept. *Bergamote paysanne (v. g.), rousselet de Rheims. (v. g.)
 Sept. and Oct. Fondante d'Havay (v. g.), *bon chrétien d'été. (g.)
 Oct. Fondante de Brest (v. g.), epine d'hiver. (g.)
 Oct. and Nov. *Beurré Spence (v. g.), *Marie Christine. (v. g.)
 Nov. Beurré Capiaumont (v. g.), beurré crapaud (v. g.), beurré d'Alflichem (v. g.), Marie Louise (v. g.), *Napoleon (v. g.), *Urbaniste. (v. g.)
 Dec. Beurré diel (v. g.), pastorale (g.), *présent de Maires. (v. g.)

Winter. Josephine (v. g.), poire Canning. (v. g.)
 Dec. and Jan. *Gloxou moiceaux (v. g.), Roi de Rome. (g.)
 Jan. Bezi Vaat (v. g.), *Louise Bonne. (g.)
 Jan. and Feb. *Passe Colmar (v. g.), *Passe Colmar gris, dit Précel. (v. g.)
 Feb. and March. Orange d'hiver (m.), l'Incommunicable. (m.)
 March. Duchesse de Mars. (g.)
 March and April. Gros Romain (m.), *bergamote de Pâques (m.), *beurré rance. (v. g.)
 April. Fondante Batave (g.), la favorite. (g.)
 April and May. Muscat d'Allemagne (m.), bezi de Caissey. (g.)
 May and June. *Bergamote de Pentecôte (g.), Ramehier. (m.)

4095. *The best sorts of baking plums* are the following:—

Damson, balluce, muscle, winesour, and magnum bonum. Of these the damson is by far the best, and next the winesour,

which thrives only on a calcareous soil, and grows wild in abundance in the West Riding of Yorkshire.

4096. *The following are excellent dessert plums for an orchard:—*

*Green gage, Orleans, *damask (black, good), white perdigon, *blue ditto, blue gage, *white magnum bonum, red

ditto, or imperial, *drap d'or (yellow, good). Of these the green gage, Orleans, and damask are much the best.

4097. *Gibbs of Brompton* gives the following select list of orchard fruits from his own experience:—

Summer Table Apples. Early Margaret, red Astrachan, oslin, Mason's earl, Kerry, yellow Ingestrie, Carter's seedling, Thorle, red Quarenden, early Amphibill pippin.
 Summer Kitchen Apples. Keswick codlin, Maulden codlin, Carte's monster, French codlin, yellow harvest, Hollandbury, Autumn Table Apples. Ribston, Margil, court pendu, Downton, Newtown Spitzenburg, English peach apple,

Fearne's pippin, Wyken, Gravenstein, Ross nonpareil, pomme de neige.
 Autumn Kitchen Apples. Alexander, Howbury pippin, Hawthornden, Duchess of Oldenburgh, Nelson, dominie, Blenheim orange, Dutch and French collins (good for autumn as well as summer use).
 Winter and Spring Table Apples. Scarlet nonpareil, old

nonpareil, old golden pippin, Newton pippin, Wheeler's russet, nonpareil russet, Gibb's pippin, coat of Wick, Lemon greening, of very good quality, Cooper's russet, Sykehouse russet, American seek no further, golden Harver.

Winter and Spring Kitchen Apples. French crab, Norfolk beaufin, Norfolk Paradise, paywell, winter queen, winter greening, Yorkshire greening, roval russet, beauty of Kent, white Leasington, Fullwood's apple, lemon pippin, skinless pippin, marmalade pippin, winter pearmain.

Cider Apples. Ked-streak Somerset, redstreak Devon, redstreak late white Parson's, cocagee, Dufflin, woodcock, Styre, Downton, Solebury cider apple, Kingston black, Somerset sweeting.

Summer Table Pears. Citron des carmes, jargonelle, summer bon chretien, early bergamot, Julien archiduc d'été, green chisel, Lammas.

Summer baking and preserve Pears. Windsor, Edelcrantz, swan's throat, Crawford.

Autumn Table Pears. Gansell's bergamot, Cresanne, brown

4098. *Ronalds of Brentford*, who is perhaps better acquainted with English apples than any other individual, recommends the following sorts:—

Summer Table Apples. Hicks's fancy, Bell's fine scarlet, red Quenden, peach apple, chausse, summer shin, summer golden pippin, Duchy of Oldenburgh, Kerry pippin.

Summer baking Apples. Nonesuch, Spring-grove, Manks codlin, Hawthornden, fine striped General Arabus, Wormsley pippin, Carlisle codlin, early Julian, early spice apple.

Autumn Table Apples. Alingil, Downton pippin, Keddlstone pippin, Franklin's golden pippin, Delaware, aromatic russet, summer nonpareil, grange apple.

Autumn baking Apples. Hollandbury, beauty of Kent, Sapiopian apple, golden burr, Russian apple, Emperor Alexander, Carlisle codlin, Gravenstein, yellow bow (American).

Winter Table Apples. Nonpareil, Morris's russet, Bringwood pippin, King George, Sykehouse, Court Wyke pippin, Christie's

4099. *Pearson of Chilwell* recommends the following apples as very select:—

For early Dessert, the Egglestone summering, Waterloo pippin, and Perfect's Juneating. *For middle Season*, the Burgin, Lord Lennox, Pile's pearmain, and Blenheim orange.

For late Keeping, Wollaton pippin, Bess Pool, Keddlstone pippin, and Hartford's russet. *For Kitchen Use*, early, the

4100. *The cultivation of the plum* appears to us deserving of more encouragement than it generally meets with. Not only does the fruit make excellent pies and tarts, but it may be kept in large quantities, so as to be ready for that purpose at any period of the year. They also make a sort of wine, and with other fruits and ingredients form one of the best substitutes for port. The damson, bullace, and some other varieties, will grow and bear very high-flavoured fruit in hedges where the soil is dry below and not too thin. The fruit of the sloe is, for wine-making, superior to that of the plum, and nearly as good for tarts.

4101. *The cherry* is of more limited culture than any of the foregoing fruits; because chiefly used for eating, and not being of a nature to keep. Near large towns they may be cultivated to a certain extent. In Kent and Hertfordshire are the cherry orchards which afford the chief supplies for the London market. The sorts are chiefly the caroon, small black or Kentish, the May-duke, and the morello; but Holman's duke, the black heart, and the largé gean, will do well in orchards.

4102. *The walnut and Spanish chestnut* may be advantageously planted on the outskirts of orchards to shelter them, and a few of them in hedge-rows where the climate is likely to ripen their fruit. The chestnut can hardly be considered as ripening north of London, or the walnut north of Newcastle. Both trees, however, may be planted for their timber in moderately sheltered situations, in most parts of the British Isles.

4103. *The elder* is not beneath notice as an orchard tree. It need seldom be planted as a standard; but in unpruned hedges on a soft, deep, and rather rich soil, it yields great quantities of fruit, which is readily manufactured into a sort of wine esteemed by many persons when warmed, and forms a comfortable evening draught for the cottager. No tree requires less care: it propagates readily by cuttings or seeds, and requires little or no pruning; but, though it will grow in any soil whatever, it will produce no fruit worth mentioning on any but one tolerably deep and rich, and must be cut down when it begins to show indications of age.

4104. *The filbert, currant, gooseberry, raspberry*, and some other fruits, are cultivated extensively near large towns; but the treatment they require renders them in our opinion unfit for farm orchards.

4105. *In choosing trees for orchards*, standards, sufficiently tall to admit of horses and cattle grazing under them, should always be preferred. Maiden plants, or such as are only two years from the bud or graft, are the most certain of success; the apples being worked on crab, the pears on wilding, and the cherries on gean stocks. The common baking plums need not be grafted at all, but the better sorts should either be grafted or budded on damson stems. Where budded or grafted chestnuts and walnuts can be got, they should always be preferred as coming much sooner into bearing. The former may be had from the Devonshire nurseries, and some public gardeners about London are now attempting to inarch and bud the walnut.

4106. *With respect to the distance at which orchard trees may be planted*, every thing will depend on the use which is intended to be made of the ground. Where the soil is

beurré, Marie Louise, Napoleon, beurré Spence, sans pippin, poire Anana.

Autumn preserve and baking Pears. Chaumont-le, reine de poire, Scotch Cornuck, black achau, El-ingham, Aston-town.

Winter and Spring Table Pears. St. Germain, beurré d'hiver, poire Braddick d'hiver, poire d'Auch, bon chretien d'hiver, bergamote d'hiver, Venus d'hiver, beurré rance, winter verte longue, bergamote de l'aque, Van Mons, présent de Malines, bon Malinoise, Dillen.

Winter and Spring baking and preserve Pears. Cadillac, black pear of Worcester, Uvedales St. Germain, orange d'hiver, rousselot gros, merville.

Perry Pears. Aston-town, achau red, achau green, swan's egg, Windsor, grey beurré, orange bergamot.

Cherries. Couronne, black heart, black eagle, Elton, bigreau, white heart.

Plums. Orleans, green gage, winesour, Cooper's large red, bonum magnum, Coe's golden drop.

pippin, brandy apple, Robinson's pippin, new scarlet nonpareil, Fern's pippin, Kedley's pippin, Crofton pippin, nutmeg cockle pippin, Wykin pippin, russet pearmain, Parry's pearmain, new green nonpareil, new golden pippin, tulip apple, court penda plat rubra, golden Worcester, Dredge's golden pippin.

Winter baking Apples. Large russet, transparent, golden russet, French crab, Minhall crab, Norfolk paradise, French pippin, Franklin's pippin, new scarlet pearmain, Kirk's fame, Duke of Wellington, Yorkshire greening, Rymer, Deeping pippin, pound apple (American).

Cider Apples. Bitter sweet, Siberian Hervey, Foxley apple, cocagee, Pyrus (unique, Tartarian crab), Siberian bitter sweet crab, transparent crab, Deeping pippin, Downton pippin, Brentford crab, Girdler's large striped.

For long Keeping, Galidwell, Normanton wonder, and northern greening. All the foregoing will do well as dwarfs on Paradise stocks. (*Gard. Mag.* vol. vi.)

Manks codlin, American summering, and Hawthornden. *For middle Season*, Greenup's pippin, malster, and Barton free-bee. *For long Keeping*, Galidwell, Normanton wonder, and northern greening. All the foregoing will do well as dwarfs on Paradise stocks. (*Gard. Mag.* vol. vi.)

to be pastured or dug, they may be planted in quincunx and close: but where it is to be ploughed, they should either be planted in rows with sufficient space between for one broad ridge, or two ordinary ones; or they should be planted in squares to admit of ploughing both east and west, and north and south.

4107. *The Herefordshire orchardists* recommend that the rows should extend from north to south, as in that direction each part of every tree will receive the most equal portions of light and heat. The distance between each row, as well as the space between each tree, should depend on the situation and soil. Where the former is high and exposed, the trees should be closely planted to afford each other protection; and where the latter is poor and shallow, their growth will of course be less luxuriant, and they will consequently require less room. But in low and sheltered situations, and in deep and rich soils, wider intervals should be allowed. In the former instances, twelve yards between each row, and six between each tree, are sufficient; in the latter, twenty-four yards between each row, and eight between each tree, will not be too much.

4108. *As a general guide with regard to distance*, Nicol states the extreme limits at which apple and pear trees should stand, in a properly planted and close orchard, as from thirty to forty feet, less or more, according to the quality of the soil, taking, as the medium, thirty-six feet. In a poor soil and a bleak exposure, where the trees may not be expected to grow very freely, thirty feet are sufficient; whereas in good soil, and a sheltered situation, forty may not be too much. Cherries and plums may be planted at from twenty-four to thirty-six feet, according to soil and situation, as above, taking as a medium, thirty feet for the ultimate distance at which they are to stand clear of one another. But it would be advisable, in the first instance, to plant four trees for one that is intended ultimately to remain, planting the proper kinds at the above distances first, and then temporary plants between them each way. These temporary plants should be of the free-growing sorts that begin to bear early; such as the notesuch and Hawthornden apples, the May-duke cherry, and the Crawford and yair pears; or any others known to produce fruit sooner after planting. These should be considered and be treated as temporary plants from the beginning, and must give place to the principal trees as they advance in growth, by being pruned away bit by bit, and at last stubbed up entirely. In bleak situations, if forest and other hardy trees be planted among the fruit trees, it may not be necessary to plant so many (if any) temporary fruit trees; or these may chiefly consist of the hardier sorts, such as the Hawthornden apple, the May-duke and morello cherries, and the Scotch geans, which produce fruit the soonest.

4109. *In the operation of planting*, great care ought to be taken not to insert the plants deeper in the soil than they were before removal. This is a very common error in every description of tree planting; and in retentive soils is ruinous to the tree. Sir C. M. Burrel recommends, as a useful practice, in wet soils, or where the substratum is not suited to the apple or the pear, to plant the trees on hillocks of easy ascent, as for instance one foot higher in the centre than the level of the field, and sloping gradually to that level for three or four feet every way from the centre. By this practice, the roots will naturally follow the good surface earth; whereas, if they are planted in holes, the roots are apt to shoot into the prejudicial subsoil, to the eventual injury of the plants by canker and other diseases. When trees are thus planted on small hillocks, the under-drains may pass between the rows with greater utility.

SECT. III. *Cultivation of Farm Orchards.*

4110. *The trees being carefully planted, watered, and tied to tall strong stakes*, require little more than common attention for several years. Every autumn or spring they should be looked over, and all cross irregular shoots made during the preceding summer cut out, suckers (if any) removed from their roots, and side growths cleared from their stems.

4111. *The object in pruning young trees*, Nicol observes, is to form a proper head. Generally speaking, the shoots may be pruned in proportion to their lengths, cutting clean away such as cross one another, and fanning the tree out towards the extremities on all sides; thereby keeping it equally poised, and fit to resist the effects of high winds. When it is wished to throw a young tree into a bearing state, which should not be thought of, however, sooner than the third or fourth year after planting, the leading branches should be very little shortened, and the lower or side branches not at all; nor should the knife be used, unless to cut out such shoots as cross one another.

4112. *After an orchard-tree is come into bearing*, Abercrombie says, continue at the time of winter pruning either every year, or every two, three, or four years, as an occasion is perceived, to cut out unproductive wood, crowded spray, and decayed parts. Also reduce long and outrunning ramblers and low stragglers, cutting them to some good lateral that grows within its limits. Where fruit-spurs are too numerous, then cut the strongest and most unsightly. Also keep the tree pretty open in the middle. If it be necessary to take off large branches from aged trees, use a chisel or saw, and afterwards smooth the wound with a sharp knife. In case old wood is to be cut down to young shoots springing below, to make the separation in summer will be of more advantage to those young shoots, though it is not a common practice, on account of the liability of many stone-fruit bearers to exude gum, when a large branch is lopped in the growing season. Observe to keep the stem clear from all lateral shoots, and eradicate all suckers from the root.

4113. *On aged trees* that have run into a confusion of shoots and branches, and whose spurs have become clustered and crowded, the saw and the knife may be exercised with freedom, observing to cut clean away all useless spray, rotten stumps, and the like useless excrescences. Thin out the spurs moderately to let the air circulate freely among the

leaves and fruit in the summer season, and to admit the rays of the sun, so as to give the fruit colour and flavour.

4114. *In pruning the apple tree and all other standard trees*, Knight observes, the points of the external branches should be every where rendered thin and pervious to the light, so that the internal parts of the tree may not be wholly shaded by the external parts: the light should penetrate deeply into the tree on every side; but not any where through it. When the pruner has judiciously executed his work, every part of the tree, internal as well as external, will be productive of fruit; and the internal part, in unfavourable seasons, will rather receive protection than injury from the external. A tree thus pruned will not only produce much more fruit, but will also be able to support a much heavier load of it, without danger of being broken: for any given weight will depress the branch, not simply in proportion to its quantity, but in the compound proportion of its quantity and of its horizontal distance from the point of suspension, by a mode of action similar to that of the weight on the beam of the steel-yard; and hence a hundred and fifty pounds, suspended at one foot in distance from the trunk, will depress the branch which supports it no more than ten pounds, at fifteen feet in distance, would do. Every tree will, therefore, support a larger weight of fruit without danger of being broken, in proportion as the parts of such weight are made to approach nearer to its centre.

4115. *Where a tree is stunted, or the head ill-shaped*, from being originally badly pruned or barren, from having overborne itself, or from constitutional weakness, the most expeditious remedy is to head down the plant to within three, four, or five eyes (or inches, if an old tree), of the top of the stem, in order to furnish it with a new head. The recovery of a languishing tree, if not too old, will be further promoted by taking it up at the same time, and pruning the roots; for as, on the one hand, the depriving too luxuriant a tree of part even of its sound healthy roots will moderate its vigour; so, on the other, to relieve a stunted or sickly tree of cankered or decayed roots, to prune the extremities of sound roots, and especially to shorten the dangling tap-roots of a plant affected by a bad sub-soil, are, in connection with heading down, or very short pruning, the renovation of the soil, and draining, the most availing remedies that can be tried.

4116. *A tree often becomes stunted from an accumulation of moss*, which affects the functions of the bark, and renders the tree unfruitful. This evil is to be removed by scraping the stems and branches of an old tree; and on a young tree a hard brush will effect the purpose. Wherever the bark is decayed or cracked, Abercrombie and Forsyth direct its removal. Lyon, of Edinburgh, has lately carried this practice to so great a length as even to recommend the removal of part of the bark of young trees. Practical men, in general, however, confine the operation to cracked bark, which nature seems to attempt throwing off; and the effect in rendering the tree more fruitful and luxuriant is acknowledged by Neill in his *Account of Scottish Gardening and Orchards*, and by different writers in *The London and Caledonian Horticultural Transactions*.

4117. *The other diseases to which orchard trees are subject* are chiefly the canker, gum, mildew, and blight, which, as we have already observed, are rather to be prevented by such culture as will induce a healthy state, than to be remedied by topical applications. Too much lime, Sir H. Davy thinks, may bring on the canker, and if so, the replacing a part of such soil with alluvial or vegetable earth would be of service. The gum, it is said, may be constitutional, arising from offensive matter in the soil; or local, arising from external injury. In the former case, improve the soil; in the latter, apply the knife. The mildew, it is observed by T. A. Knight and Abercrombie, "may be easily subdued at its appearance, by scattering flour of sulphur upon the infected parts." As this disease is now generally considered the growth of parasitical fungi, the above remedy is likely to succeed. For caterpillars and other insects in spring, Forsyth recommends burning rotten wood, weeds, potato-hulm, wet straw, &c., on the windward side of the trees when they are in blossom. He also recommends washing the stems and branches of all orchard trees with a mixture of "fresh cow-dung with urine and soap-suds, as a whitewasher would wash the ceiling or walls of a room." The promised advantages are, destruction of insects and "fine bark;" more especially, he adds, "when you see it necessary to take all the outer bark off."

4118. *With the Herefordshire orchardists pruning is not in general use*; the most approved method is that of rendering thin and pervious to the light the points of the external branches, so that the internal branches of the tree may not be wholly shaded by the external parts. Large branches should rarely or never be amputated. The instrument generally used for the purpose of pruning is a strong flat chisel, fixed to a handle six feet or more in length, having a sharp edge on one of its sides and a hook on the other. (*Knight's Treatise on the Apple and Pear*.)

4119. *The culture of the soil among orchard trees* is always attended with advantage; though it can so seldom be properly conducted in farm orchards, that in most cases it is better to lay them down with grass seeds for pasture. To plough between the trees and take corn crops, even if manure is regularly given, cannot be any great advantage, unless

a radius of six or eight feet is left round each tree. If such a space is left, and yearly dug but not cropped, the trees will thrive well; and a ridge between each two rows may be sown with corn. The greater number of orchards in Herefordshire and Gloucestershire are under pasture; but the most productive are those trees grown in hop grounds. In Kent, in some instances, the interspaces of young orchards are occupied by hops, in others by filberts, and in grown orchards the latter are sometimes seen. Some old orchards are likewise in permanent sward, others under arable or garden crops, and some in saintfoin, while others are in lucern. In all cases where the subsoil is moist, or otherwise unfavourable, the ground of an orchard should neither be dug nor ploughed, in order not to prevent the roots from spreading themselves immediately under the surface. The effect of repeatedly stirring the surface to six or eight inches or more in depth is to cause the roots to descend. In all soils, this descent, by furnishing them more abundantly with moisture, tends to prolong the growth, and prevent the ripening of the wood and the formation of blossom buds; but, in the case of noxious subsoils, it brings on canker and other diseases. This is the reason why standard fruit-trees in kitchen gardens are generally less productive than in grass orchards: the productive trees in certain hop-grounds in Kent and other counties may seem an exception; but they are not so, the subsoil in these cases being good and dry.

SECT. IV. *Gathering and Keeping of Orchard Fruit.*

4120. *The gathering of orchard fruit*, and especially apples, should be performed in such a manner as not to damage the branches, or break off the fruit spurs or buds. Too frequently the fruit is allowed to drop, or it is beat and bruised by shaking the tree and using long poles, &c. Nicol directs that it should never be allowed to drop of itself, nor should it be shaken down, but should be pulled by the hand. This may be thought too troublesome a method; but every body knows that bruised fruit will not keep, nor will it bring a full price. The expense of gathering, therefore, may be more than defrayed, if carefully done, by saving the fruit from blemish.

4121. *With regard to the keeping of kernel fruits*, the old practice, which is recommended by Marshal and Forsyth, commences with sweating, though Nicol and other modern gardeners omit this process. It is evident from the general practice of both commercial and private gardeners, that sweating fruit is not essential to its keeping, though some persons continue to allege that, in consequence of that operation, it keeps better. Marshal, the author of *An Introduction to Gardening*, observes, that those fruits which continue long for use should be suffered to hang late, even to November, if the frost will permit; for they must be well ripened or they will shrink. Lay them in heaps till they have sweated a few days, when they must be wiped dry. Let them then lie singly, or at least thinly, for about a fortnight, and be again wiped, and immediately packed in boxes and hampers, lined with double or treble sheets of paper. Place them gently in, and cover them close, so as to keep air out as much as possible. Preserve them from frost through the winter: never use hay for the purpose. Kernel fruits and nuts keep no where better than when mixed and covered with sand in a dry cool cellar, in the manner of potatoes. Buried in pits well protected from moisture, russets have been found to keep perfectly fresh a year from the time of their being gathered. The keeping of cider fruits is not approved of, it being found best to crush them after they have been thinly spread for a few days on a dry boarded floor. Many of the Herefordshire growers carry them direct from the tree to the crushing-mill.

SECT. V. *Manufacture of Cider and Perry.*

4122. *Cider is commonly manufactured by the grower of the fruit*, though it would certainly be better for the public if it were made a distinct branch of business like brewing or distilling. "The true way to have excellent cider," Marshal observes, "is to dispose of the fruit to professional cider makers. The principal part of the prime cider sold in London and elsewhere is manufactured by professional men; by men who make a business of manufacturing and rectifying cider, even as distillers, rectifiers of spirit, and brewers follow their businesses or professions, and like them too conduct their operations, more or less, on scientific principles." (*Rev. of Agr. Rep.* vol. ii. p. 294.) It is allowed on all hands that the operation is performed in a most slovenly manner by the farmer, and that it is very difficult to procure this liquor in good quality. The operation of cider-making is as simple as that of wine-making or brewing, and will be perfectly understood from the following directions, chiefly drawn from the treatises of Crocker and Knight; so that any person possessing an orchard, or a few hedge-row fruit trees, may make a supply for his own use. The first business consists of gathering and preparing the fruit; the second, of grinding and pressing; and the last, of fermenting and bottling.

4123. *In gathering cider apples*, care should be taken that they are thoroughly ripe before they are taken from the tree; otherwise the cider will be of a rough, harsh taste, in spite of all the endeavours of the operator. It is observed by Crocker, in his tract

on *The Art of Making and Managing Cider*, that the most certain indications of the ripeness of apples are the fragrance of their smell, and their spontaneously dropping from the trees. When they are in this state of maturity, in a dry day, the limbs may, he says, be slightly shaken, and partly disburdened of their golden store; thus taking such apples only as are ripe, and leaving the unripe longer on the trees, that they may also acquire a due degree of maturity. It may not, he thinks, be amiss to make three gatherings of the crop, keeping each by itself. The latter gathering, as well as wind-falls, can, however, only be employed in making inferior cider: the prime cider must be drawn from the former gatherings.

4124. *On the proper mixture of fruits*, or rather on their proper separation, the merit of cider will always greatly depend. Those whose rinds and pulp are tinged with green, or red without any mixture of yellow, as that colour will disappear in the first stages of fermentation, should be carefully kept apart from such as are yellow, or yellow intermixed with red. The latter kinds, which should remain on the trees till ripe enough to fall without being much shaken, are alone capable of making fine cider. Each kind should be collected separately, as noticed above, and kept till it becomes perfectly mellow. For this purpose, in the common practice of the country, they are placed in heaps of ten inches or a foot thick, and exposed to the sun, air, and rain, not being ever covered, except in very severe frosts. The strength and flavour of the future liquor are increased by keeping the fruit under cover some time before it is ground; but unless a situation can be afforded it, in which it is exposed to a free current of air, and where it can be spread very thin, it is apt to contract an unpleasant smell, which will much affect the cider produced from it. Few farms are provided with proper buildings for this purpose on a large scale, and the improvement of the liquor will not nearly pay the expense of erecting them. It may reasonably be supposed, that much water is absorbed by the fruit in a rainy season; but the quantity of juice yielded by any given quantity of fruit will be found to diminish as it becomes more mellow, even in very wet weather, provided it be ground when thoroughly dry. The advantages therefore, of covering the fruit will probably be much less than may at first sight be expected. No criterion appears to be known, by which the most proper point of maturity in the fruit can be ascertained with accuracy; but it improves as long as it continues to acquire a deeper shade of yellow. Each heap should be examined prior to its being ground, and any decayed or green fruit carefully taken away. The expense of this will be very small, and will be amply repaid by the excellence of the liquor, and the ease with which too great a degree of fermentation may be prevented. (*Crocker.*) In Ireland a mixture of every sort of apple is considered as producing the best cider. A proportion of crabs is always admitted. "The taste, in consequence, is very sour, and less sweet than English cider: but this is matter of fancy; and, a relish for rough cider once acquired, the sweet kind loses much of its attractions. Owing to a considerable admixture of crabs, the Irish cider is always more sour than the English, and this is a quality, when not too predominant, for which it is valued by the natives." (*Lardner's Cyc. Dom. Econ.*)

4125. *In grinding*, the fruit should be so reduced that the rind and kernel should be scarcely discernible. In such a complete mixture it seems probable that new elective attractions will be exerted, and compounds formed which did not exist previously to the fruit being placed under the roller. The process of slow grinding, with free access of air, gives the cider good qualities it did not possess before, probably by the absorption of oxygen. To procure very fine cider, the fruit should be ground and pressed imperfectly, and the pulp spread as thin as possible, exposed to the air, and frequently turned during twenty-four hours, to obtain as large an absorption of air as possible. The pulp should be ground again, and the liquor formerly expressed added, by which the liquor will acquire an increase of strength and richness. (*Lardner's Cyclo. Dom. Econ.*)

4126. *Whether the pommage should, immediately after grinding, be conveyed to the press*, there to be formed into a kind of cake, or what is called the cheese; or whether it should remain some time in that state before pressing, ciderists have not agreed. Some say it should be pressed immediately after grinding; others conceive it best to suffer it to remain in the grinding trough, or in vats employed for the purpose, for twenty-four hours, or even two days, that it may acquire not only a redness of colour, but also that it may form an extract with the rind and kernels. Both extremes are, Crocker thinks, wrong. There is an analogy, he says, between the making of cider from apples, and wine from grapes; and the method which the wine-maker pursues ought to be followed by the cider-maker. When the pulp of the grapes has lain some time in the vats, and when he perceives, by the smell, that the luscious sweetness is gone off, and that his nose is affected with a slight piquancy, he immediately carries it to the press, and by a light pressure expresses his prime juice. In like manner should the ciderist determine

the time when his pulp should be carried to the press. If he carried it immediately from the mill to the press, he might lose some small advantage which may be expected from the rind and kernels, and his liquor might be of lower colour than he may wish. If he suffer it to remain too long unpressed, he will find to his cost that the acetous fermentation will come on before the vinous is perfected, especially in the early part of the cider-making season. He will generally find that his pulp is in a fit state for pressing in about twelve or sixteen hours. If he must of necessity keep it in that state longer, he will find a sensible heat therein, which will engender a premature fermentation; and he must not delay turning it over, thereby to expose the middle of the mass to the influence of the atmosphere. Knight's opinion is, however, that it should remain twenty-four hours before it is taken to the press; and in this opinion the author of the *Art of Cider Making*, in *Lardner's Cyclopædia, Domestic Economy*, vol. i. also concurs.

4127. *The pommage being carried to the press*, and a square cake or cheese made of it, by placing very clean sweet straw or reed between the various layers of pommage; or by putting the same into the hair-cloths, and placing them one on another. It is of importance that the straw or weed be sweet, and perfectly free from any fustiness, lest the cider be impregnated therewith. Particular care ought also to be taken to keep hair-cloths sweet, by frequently washing and drying, or the ill effects of their acidity will be communicated to the cider. To this cake or cheese, after standing awhile, a slight pressure is at first to be given, which must be gradually increased until all the must or juice is expressed; after which, this juice must be strained through a coarse hair sieve, to keep back its gross feculences, and be put into proper vessels. These vessels may be either open vats or close casks; but as, in the time of a plentiful crop of apples, a number of open vats may by the ciderist be considered an incumbrance in his cider-rooms, they should be generally carried immediately from the press to the cask. Thus far, says Crocker, cider-making is a mere manual operation, performed with very little skill in the operator; but here it is that the great art of making good cider commences; nature soon begins to work a wonderful change in this foul-looking, turbid, fulsome, and unwholesome fluid; and, by the process of fermentation alone, converts it into a wholesome, vinous, salubrious, heart-cheering beverage.

4128. *Fermentation* is an internal motion of the parts of a fermentable body. This motion, in the present case, is always accompanied with an evident ebullition, the bubbles rising to the surface, and there forming a scum, or soft and spongy crust, over the whole liquor. This crust is frequently raised and broken by the air as it disengages itself from the liquor, and forces its way through it. This effect continues whilst the fermentation is brisk, but at last gradually ceases. The liquor now appears tolerably clear to the eye, and has a piquant vinous sharpness upon the tongue. If in this state the least hissing noise be heard in the fermenting liquor, the room is too warm, and atmospheric air must be let in at the doors and at the windows. Now, continues Crocker, is the critical moment which the ciderist must not lose sight of; for, if he would have a strong, generous, and pleasant liquor, all further sensible fermentation must be stopped. This is best done by racking off the pure part into open vessels, which must be placed in a more cool situation for a day or two; after which it may again be barrelled, and placed in some moderately cool situation for the winter. The Herefordshire cider-farmers, after the cider has perfected its vinous fermentation, place their casks of cider in open sheds throughout the winter; and, when the spring advances, give the last racking, and then cellar it. In racking, it is advisable that the stream from the racking-cock be small, and that the receiving-tub be but a small depth below the cock, lest, by exciting a violent motion of the parts of the liquor, another fermentation be brought up. The feculence of the cider may be strained through a filtering-bag, and placed among the second-rate ciders; but by no means should it be returned to the prime cider. In this situation the cider will, in course of time, by a sort of insensible fermentation, not only drop the remainder of its gross lees, but will become transparent, highly vinous, and fragrant.

4129. *According to Knight*, after the fermentation has ceased, and the liquor is become clear and bright, it should instantly be drawn off, and not suffered on any account again to mingle with its lees; for these possess much the same properties as yeast, and would inevitably bring on a second fermentation. The best criterion to judge of the proper moment to rack off will be the brightness of the liquor; and this is always attended with external marks, which serve as guides to the cider-maker. The discharge of fixed air, which always attends the progress of fermentation, has entirely ceased; and a thick crust, formed of fragments of the reduced pulp, raised by the buoyant air it contains, is collected on the surface. The clear liquor being drawn off into another cask, the lees are put into small bags, similar to those used for jellies: through these whatever liquor the lees contain gradually filtrates, becoming perfectly bright; and it is then returned to the cask, in which it has the effect, in some measure, of preventing a second fermentation. It appears to have undergone a considerable change in the process of filtration.

Its colour is remarkably deep, its taste harsh and flat, and it has a strong tendency to become acetous; probably by having given out fixed and absorbed vital air. Should it become acetous, which it will frequently do in forty-eight hours, it must not on any account be put into the cask. If the cider, after being racked off, remains bright and quiet, nothing more is to be done to it till the succeeding spring; but if a scum collects on the surface, it must immediately be racked off into another cask, as this would produce bad effects if suffered to sink. If a disposition to ferment with violence again appears, it will be necessary to rack off from one cask to another, as often as a hissing noise is heard. The strength of cider is much reduced by being frequently racked off; but this arises only from a larger portion of sugar remaining unchanged, which adds to the sweetness at the expense of the other quality. The juice of those fruits which produce very strong ciders often remains muddy during the whole winter, and much attention must frequently be paid to prevent an excess of fermentation.

4130. *The casks, into which the liquor is put* whenever racked off, should always have been thoroughly scalded, and dried again; and each should want several gallons of being full, to expose a larger surface to the air.

4131. *The above precautions* neglected by the ciderist, the inevitable consequence will be this:—Another fermentation will quickly succeed, and convert the fine vinous liquor he was possessed of into a sort of vinegar; and all the art he is master of will never restore it to its former richness and purity. When the acetous fermentation has been suffered to come on, the following attempts may be made to prevent the ill effects of it from running to their full extent:—A bottle of French brandy, half a gallon of spirit extracted from the lees of cider, or a pailful of old cider, poured into the hogshead soon after the acetous fermentation is begun: but no wonder if all these should fail, if the cider be still continued in a close warm cellar. To give effect to either, it is necessary that the liquor be as much exposed to a cooler air as conveniently may be, and that for a considerable length of time. By such means it is possible fermentation may, in a great measure, be repressed: and if a cask of prime cider cannot thence be obtained, a cask of tolerable second-rate kind may. These remedies are innocent: but if the farmer or cider-merchant attempt to cover the accident, occasioned by negligence or inattention, by applying any preparation of lead, let him reflect, that he is about to commit an absolute and unqualified murder on those whose lot it may be to drink his poisonous draught.

4132. *Stumming*, which signifies the fuming of a cask with burning sulphur, may sometimes be advantageous. It is thus performed:—Take a stripe of canvas cloth, about twelve inches long and two broad; let it be dipped into melted brimstone: when this match is dry, let it be lighted, and suspended from the bung of a cask (in which there are a few gallons of cider) until it be burnt out. The cask must remain stopped for an hour or more, and be then rolled to and fro, to incorporate the fumes of the match with the cider; after which it may be filled. If the stumming be designed only to suppress some slight improper fermentation, the brimstone match is sufficient; but if it be required to give any additional flavour to the cider, some powdered ginger, cloves, cinnamon, &c. may be strewed on the match when it is made. The burning of these ingredients with the sulphur will convey somewhat of their fragrance to the whole cask of cider; but to do it to the best advantage, it must be performed as soon as the vinous fermentation is fully perfected.

4133. *Cider is generally in the best state to be put into the bottle* at two years old, where it will soon become brisk and sparkling; and if it possesses much richness, it will remain with scarcely any sensible change during twenty or thirty years, or as long as the cork duly performs its office.

4134. *In making cider for the common use of the farm-house*, few of the foregoing rules are attended to. The flavour of the liquor is here a secondary consideration with the farmer, whose first object must be to obtain a large quantity at a small expense. The apples are usually ground as soon as they become moderately ripe: and the juice is either racked off at once as soon as it becomes bright, or more frequently conveyed from the press immediately to the cellar. A violent fermentation soon commences, and continues until nearly the whole of the saccharine part is decomposed. The casks are filled up and stopped early in the succeeding spring, and no further attention is either paid or required. The liquor thus prepared may be kept from two to five or six years in the cask, according to its strength. It is generally harsh and rough, but rarely acetous; and in this state, it is usually supposed to be preferred by the farmers and peasantry. When it has become extremely thin and harsh by excess of fermentation, the addition of a small quantity of bruised wheat, or slices of toasted bread, or any other farinaceous substance, will much diminish its disposition to become sour.

4135. *Madeira Cider*. Take new cider from the press, mix it with honey till it bears an egg, boil it gently for a quarter of an hour, but not in an iron pot; take off the scum as it rises, let it cool, then barrel it, without filling the vessel quite full: bottle it off in March. In six weeks afterwards, it will be ripe for use, and as strong as Madeira. The longer it is afterwards kept, the better. (*Mech. Mag.*)

4136. *Perry* is manufactured on exactly the same principles as cider. The pears should not be quite ripe, and the admixture of some wildings will add much to the sprightliness of the taste. "It is thought by some to resemble champagne more than gooseberry wine does; and it is said, when of the best quality, to have been at times sold instead of champagne." (*Lardner's Cyc. Dom. Econ.*)

4137. *The produce of cider or perry by the acre* can only be guessed at, by first ascertaining the number of trees. From an orchard of trees in full bearing, half a hogshead of cider may, in seasons ordinarily favourable, be expected from the fruit of each tree. As the number of trees on the acre varies from ten to forty, the quantity of cider must vary in the same proportion, that is, from five to twenty hogsheads. Pear-trees, in equally good bearing, yield fully one third more liquor; therefore, although the liquor extracted from pears sells at a lower price than that produced from apples, yet the value by the acre, when the number of trees is the same, is nearly on a par.

SECT. VI. *Machinery and Utensils necessary for Cider-making.*

4138. *The machinery of the common ciderist* includes the mill-house, mill, press, cloth, vat, and cask, with their appurtenances.

4139. Marshal, in *The Rural Economy of Gloucestershire*, remarks, that a mill-house, on an orchard-farm, is as necessary as a barn. It is generally one end of an out-building, or perhaps an open shed, under which straw or small implements are occasionally laid up. The smallest dimensions, to render it any way convenient, are twenty-four feet by twenty; a floor thrown over it, at seven feet high; a door in the middle of the front, and a window opposite; with the mill on one side, the press on the other side, of the window, as much room being left in front, towards the door, for fruit and utensils, as the nature of the mill and the press will allow. The utensils belonging to a mill-house are few: the fruit is brought in carts or baskets, and the liquor carried out in pails.

4140. *Of the common cider-mill* there are several varieties, formed on the principles of the bark-mills of tanners. The circle enclosed by the trough is in Devonshire generally in one division (*fig. 602.*), and

is sometimes divided into compartments for containing different varieties of the same fruit. (*fig. 603.*) The size of the runner varies from two and a half to four

603

and a half feet in diameter, and from nine to twelve inches in thickness; which in general is equal, like that of a grindstone, not varying, like that of a millstone: the weight one or two tons. The bottom of the chace is somewhat wider than the runner, that this may run freely. The inner side rises perpendicularly, but the outer side spreads, so as to make the top of the trough some six or eight inches wider than the bottom, to give freedom to the runner, and room to scatter in the fruit, stir it up while grinding, and take out the ground matter. The depth is nine or ten inches. The outer rim of the trough is three or four inches wide; and the diameter of the inner circle, which the trough circumscribes, from four and a half to five feet, according to the size of the mill. This is sometimes raised by a table of thick plank fixed upon the stone, with a curb of wood, lessening to an angle, fixed upon the circumference of the trough, making the whole depth of the trough about equal to its width at the bottom. This lessens the quantity of the stone; and the plank upon the centre answers other purposes. The entire bed of a middle-sized mill is about nine feet; some are ten, and some few twelve, in diameter; the whole being composed of two, three, or four stones, cramped together as one; and worked, or at least finished, after they are cramped together. The best stones are raised in the Forest of Dean: they are mostly a dark-reddish gritstone (non-calcareous), working with sufficient freedom, yet sufficiently hard for this intention. The bed of the mill is formed, and the trough partly hollowed, at the quarry, leaving a few inches at the edge of each stone uncut out, as a bond to prevent its breaking in carriage. Much depends on the quality of the stone. It ought not to be calcareous, in whole or in part, as the acid of the liquor would corrode it. Some of the Herefordshire stones have calcareous pebbles in them, which being of course dissolved leave holes in the stone. Nor should it be such as will communicate a disagreeable tinge to the liquor. A clean-grained grindstone grit is the fittest for the purpose.

4141. *The runner*, as it has been seen (*fig. 602.*), is moved by means of an axle passing through the centre, with a long arm, reaching without the bed of the mill, for a horse to draw by; and with a short one passing to an upright swivel, turning upon a pivot, in the centre of the stone, and steadied at the top, by entering a bearing of the floor above. An iron bolt, with a large head, passes through an eye in the lower part of the swivel, into the end of the inner arm of the axis. Thus the requisite double motion is obtained, and the stone kept perfectly upright (which it ought to be) with great simplicity, and without stress to any part of the machine. This is the ordinary method of hanging the runner. There is a more complex way of doing it, but Marshal says he sees no advantage arising from it. There are some mills, it seems, with two runners, one opposite the other. On the inner arm of the axis, about a foot from the

runner, is fixed (or ought to be, though it is frequently wanting) a cogged wheel working in a circle of cogs, fixed upon the bed of the mill.

4142. *The diameter of the wheel* is determined by the height of the axis above the bed of the mill; the diameter of the ring of cogs, by the distance of the wheel from the centre of motion. The use of cog wheels is to prevent the runner from sliding, to which it is liable when the mill is full; the matter, when nearly ground, rising up in a body before the stone. Besides, by assisting the rotatory motion of the stone, it renders the work more easy to the horse. These wheels require to be made with great exactness; and in a country where carpenters are unaccustomed to them, a millwright should be employed in fixing them. The mill is placed so as to leave a horse-path, about three feet wide, between the bed and the walls; so that a moderately sized mill, with its horse-path, takes up a space of fourteen or fifteen feet every way.

4143. *A cider-mill in use in the south of France* (fig. 604.) is worked on a circular platform of boards, and instead of stone the wheel or conical roller (*a*) is of cast-iron. The fruit is spread thinly over the platform, and the roller moved round by one man or a woman. From the roller's covering more breadth than the narrow bark wheels in use in England, more fruit is crushed in a short time by this sort of mill than would at first sight be supposed.

4144. *An eligible description of mill*, where cider is only made for private use, consists of a pair of fluted rollers working into each other. These rollers are of cast-iron, hollow, about nine inches in diameter, with flutes or teeth, about an inch wide, and nearly as much deep. In general they are worked by hand, two men working against each other. Between these the fruit passes twice; the rollers being first set wide to break it into fragments, and afterwards closer to reduce the fragments and the seeds, the bruising of the latter being of essential use in making high-flavoured cider.

4145. *The apple-mill* is an iron machine. Where iron-mills have been tried, this metal has been found to be soluble in the acid of apples, to which it communicates a brown colour and an unpleasant taste. No combination has been ascertained to take place between this acid and lead; but as the calx of this metal readily dissolves in, and communicates an extremely poisonous quality to, the acetous juice of the apple, it should never be suffered to come into contact with the fruit or liquor. (*Knight on the Apple and Pear*.) In Ireland the cider-mill is composed of two horizontal wooden cylinders, covered with studs of iron like an organ barrel. These work into each other and crush the apples, which are afterwards beat in a vessel with wooden pestles.

4146. *The cider-press* in Herefordshire is a modification of the common screw-press. In Ireland the press bears a considerable resemblance to the common wine-presses of France, that being effected by a long lever which in England is effected by a screw. It will save some subsequent trouble if, in pressing out the juice, the action of the press be applied gradually, and very slowly increased. In this way the juices, at first running muddy, will at length come off perfectly transparent. (*Lardner's Cyclo. Dom. Econ.*)

4147. *Cider cloths* are used for containing the pommage in order to its being pressed. They are usually made of common hair-cloth; but such as is rather close in its texture is the best. The size is generally about four feet square; and they hold about two or three bushels, or as much as the mill can grind at once: and these are heaped over each other till the press is full. The larger presses will hold from eight to fifteen bags, which yield from one to two hundred gallons of liquor, according to the largeness of what is termed the cheese. To perform the work neatly, it is necessary to have two sets of these bags: for they clog and fur in pressing, and consequently become unfit for use till they have been washed and dried; so that, while this is doing, either the press must stand still or another set be ready to employ it. But some, instead of hair bags, lay long straw under the pommage, the ends of which they turn up over it; then cover the pommage entirely with fresh clean straw, upon which they spread another layer of pommage, and so on alternately, till the press is full. Either of the methods will do; but those who are desirous of doing the work in the neatest and best manner generally use bags.

4148. *The cider-vat* is a vessel made for the purpose of receiving the pommage, or the cider before it is racked off into the cask. Vessels of this kind should be made of wood, as where lead is employed it is liable to be corroded by the malic acid.

4149. *Cider casks*, when new, though the wood be ever so well seasoned, are apt to give a disagreeable relish, unless due caution be used before-hand. Frequent scalding with hot water, into which some handfuls of salt have been first thrown, or with water in which some of the pommage has been boiled, and washing afterwards with cider, are the usual remedies against this evil, and seldom fail of removing it effectually. Of old casks, beer-vessels are the worst, as they always spoil cider; and, in return, cider-casks infallibly spoil beer. Wine and brandy casks do very well, provided the tartar adhering to their sides be carefully scraped off, and they are well scalded.

CHAP. XI.

Laying out of Farm and other Culturable Lands.

4150. *The farming lands of an estate* are in general the grand source of its annual rental. The demesne lands are chiefly for enjoyment; the roads afford no direct income; the villages, manufactories, commonly the mines and fisheries, and often also

the woods, yield no income of consequence; but there remain the lands to be let out to the professional farmer, market-gardener, nurseryman, and cottagers: from these the landlord generally derives his principal return for the capital laid out on the estate. Having therefore disposed of all the other parts of the territory, it remains only to arrange the farming or culturable lands in farms of different characters and sizes, in cottage lands, gardens, or orchard grounds: these may be considered in regard to their extent and arrangement.

SECT. I. *Extent or Size of Farm and Cottage Lands.*

4151. *The proper size of farms*, or of land to be let in any way, must necessarily be that which best suits the markets: not altogether the market of the moment, for there may be a run for large or for small farms; but the market on an average of years, times, and circumstances.

4152. *The enlargement or diminution of farms* can proceed only for a time, and to a limited extent. The interest of the landlord, which gave the first impulse, is ever vigilant to check its progress, when it is attempted to carry the measure beyond due bounds. It is in this that the security of the public consists, if it were ever possible that the public interest should be endangered by the enlargement of farms. Accordingly, in most of our counties, a few tenants, of superior knowledge and capital, have been seen to hold considerable tracts of land, which, after a few years, were divided into a number of separate farms. The practice of these men is a lesson to their neighbours; and their success never fails to bring forward, at the expiration of their leases, a number of competitors. Whenever skill and capital come to be generally diffused, there can be few instances of very large farms, if a fair competition be permitted. No individual, whatever may be his fortune and abilities, can then pay so high a rent for several farms, each of them of such a size as to give full room for the use of machinery, and other economical arrangements, as can be got from separate tenants. The impossibility of exercising that vigilant superintendence, which is so indispensable in agricultural concerns, cannot long be compensated by any advantages which a great farmer may possess. His operations cannot be brought together to one spot, like those of the manufacturer; the materials on which he works are seldom in the same state for a few days, and his instruments, animated and mechanical, are exposed to a great many accidents, which his judgment and experience must be called forth instantly to repair.

4153. *If we examine the various sizes of farms in those districts where the most perfect freedom exists*, and the best management prevails, we shall find them determined, with few exceptions, by the degree of superintendence which they require. Hence, pastoral farms are the largest; next, such as are composed both of grazing and tillage lands; then such rich soils as carry cultivated crops every year; and, finally, the farms near large towns, where the grower of corn gradually gives way to the market gardener, cultivating his little spot by manual labour. The hills of the south of Scotland are distributed into farms of the first class; the counties of Berwick and Roxburgh into those of the second; and the smaller farms of the Lothians and of the Carse of Gowrie, where there seems to be no want of capital for the management of large farms, are a sufficient proof of the general principle which determines the size of farms. (*Sup. Encyc. Brit. art. Agr.*)

SECT. II. *Laying out Farms and Farmeries.*

4154. *The arrangement of farms* naturally divides itself into whatever relates to the farmery or home-stall, and what relates to the arrangement of the fields, roads, fences, and water-courses. In a country like Britain, long under cultivation, it is but seldom that these can be brought completely under the control of the improver; but cases occur where this may be done without restraint, as in the enclosure of large commons; and in Ireland and the highlands of Scotland the opportunities are frequent.

SUBJECT. 1. *Situation and Arrangement of the Farmery.*

4155. *The general principles of designing farmeries and cottages* having been already treated of: we have in this place chiefly to apply them to particular cases. Though the majority of farms may be described as of mixed culture, yet there are a number which are almost exclusively devoted to pasture, as mountain farms; to meadow culture, as irrigated or overflow lands, lands in particular situations, as in fenny districts, and those situated on the borders of some description of rivers: there are others in which peculiar crops are chiefly raised, as in the case of the hop and seed farms of Kent, Essex, and Surrey. All these require a somewhat different kind and extent of accommodation in the farm buildings.

4156. *The requisites for a farmery common to most characters of farms* are, a central situation, neither too high nor too low, shelter, water, exposure to the south or south-

east, in preference to other points; a level or flat area of sufficient extent for the buildings, yards, and gardens; grass-land sufficient for one small enclosure or more; and suitable outlets to the different parts of the farm, and to public roads and markets.

4157. *Some of these requisites may be supplied by art*, as shelter, by plantations; water, by wells and ponds; a flat, by levelling; and grass-lands, by culture: the direction of the roads depends entirely on the designer. But in some cases the situation of the farmery cannot be rendered central, as it frequently happens in the fenny districts of Cambridgeshire, where danger might be incurred from extraordinary floods; and in the case of mountainous sheep farms, where a central situation might be so elevated as to be deprived of most of the other requisites. Still, even in these cases, the general requisites ought to be attained as far as practicable; and there are degrees of attainment, as to a central situation, to be arrived at even among fens and mountains.

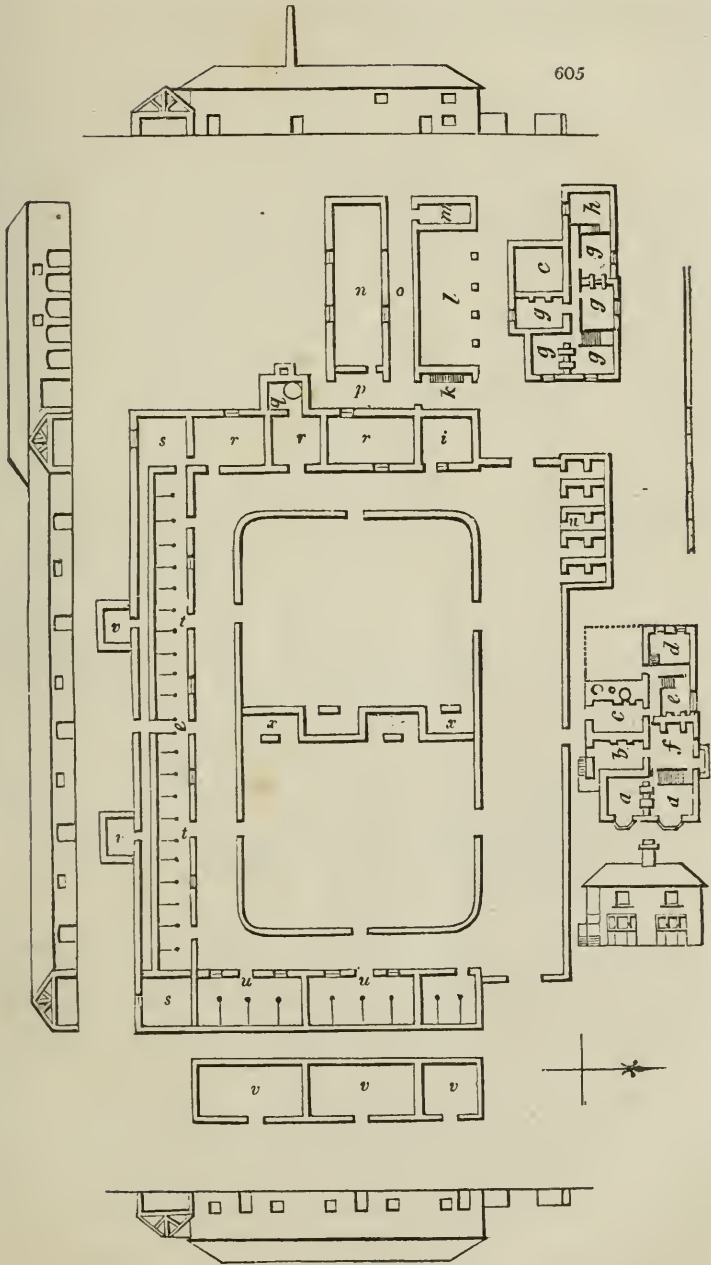

4158. *Excellent examples of different descriptions of farmeries* are to be found in Berwickshire, Northumberland, East Lothian, and on the Marquis of Stafford's estates in Shropshire, Staffordshire, and Sutherland. Besides a great number of cottages and farmeries of different descriptions, thirty-seven new farmeries have been erected by the Marquis of Stafford in Shropshire alone. Loch, Lord Stafford's agent, in describing these (*Account of Improvements on the M. of Stafford's Estates, &c.*), states, that "much attention and consideration have been given to the plans of these buildings, with the view of combining as many advantages as possible, and of arranging the different parts in such a way as to save the time of the tenant and his people, and in order that their extent might be reduced to the least size practicable, securing at the same time the accommodation required. The most approved plans in both ends of the island were consulted, and a gradual improvement has been made on them. The latter ones combine the advantages of the English and Scotch buildings, avoiding, it is hoped, their respective defects. To almost every one of these homesteads is attached a threshing machine, constructed on the best principles: wherever water could be obtained, that has been made use of as the impelling power; and, of late, some of the more extensive farms have been provided with steam-engines for that purpose."

4159. *In selecting a few of these examples*, the first we shall mention is that of Sidera, or Cider Hall, in Sutherland, erected in 1818. The soil of this farm is of a light and excellent quality, particularly suited to the Norfolk rotation of husbandry, which is followed by Rule, the new tenant, a native of the county of Roxburgh. The house and homestead cost 2200*l.* It is built, in the most sufficient manner, of stone and lime, and covered with Easdale slate, from the west coast of Scotland. In the garden, which is an old one, there are some of the finest holly trees to be met with any where, with several apple, pear, and gean, or small black cherry, trees, of so considerable a size as to show that there is nothing in the climate to prevent the growth of even the more delicate kinds of timber, if not exposed to the sea breeze.

4160. *The accommodations of the house* are, on the ground floor, a parlour, lobby, and staircase, family room, pantry, and kitchen; behind may be an open yard, and in front a flower-garden; the chamber story, a bedroom and bedcloset, two bedrooms, maid servant's room, and bedroom. The offices contain a cart-house, stable, tool-house, threshing-mill, and straw-house, horse-course, cattle-sheds, dairy, calf-pen, cow-byre, feeding-byre, booth (i. e. booth or lodge) for ploughmen; pigsties, and poultry above; paved way, and cattle-yards.

4161. *As an example of a Northumberland farmery* for a farm of from 400 to 500 acres, we have recourse to *The General Report of Scotland*. The accommodations are as follows:—In the dwelling-house are the entrance, stairs to chambers and cellars, and lobby, dining-room, pantry, coal-closet, parlour, business-room, kitchen, back-kitchen, dairy, store-room, poultry, farm-servants' kitchen, boiling-house, root-house, riding-horse stable. In the economical buildings are a cart-shed, straw-barn, and granary over; corn-barns, hinds, byre for three cows, byre for ten cows, with feeding passage in the centre; calf-house, loose-horse place, stable, feeding sheds for cattle, with feeding passage along the centre; pigs, dung-places, straw-yards, cart-shed, and open court. The aspect of the house is south, and the garden and orchard are in front of it.

4162. *As an example of a very complete farmery for a turnip and barley soil*, we give that of Fearn (*fig. 605.*), erected by the Marquis of Stafford in the parish of Escall Magna, in Shropshire, in 1820. The farm contains 460 acres of turnip soil; and the farmery the following accommodations, including a threshing machine driven by steam. In the house are two parlours (*a, a*), family-room (*b*), brew-house, two stories (*c*); pantry (*d*), milk-house (*e*), kitchen (*f*), bedrooms (*g*), menservants' bedroom (*h*). In the court offices a hackney-stable (*i*), stair under cover (*k*), waggon-shed and granary over (*l*), tool-house (*m*), cow-house (*n*), places for turnips and straw (*o, p*), steam-engine (*q*), barn (*r*), straw or other cattle-food (*s*), stall-fed cattle (*t*), stables (*u*), turnip-houses (*v*), piggeries, poultry, tools, and necessary (*w*), cattle-sheds to each yard (*x*).

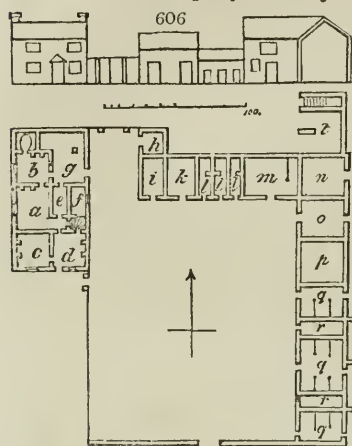

4163. As an example of a farmery to be managed by a bailiff, we give that of Skelbo, also in Sutherland. The farm consists of 450 acres, the greater part taken from a heathery waste. It contains a suitable house for the grievie or bailiff, and attached to the office is a threshing machine, combining a corn or meal-mill. Its accommodations

X x 4

are, a chaff-house, corn-rooms, threshing-mill, with water-wheel and straw-house; cattle-sheds, poultry-houses, and piggery; stables, byres, cart-shed, cattle-shed, dairy, meal-house, lodge for ploughmen, paved way, and cattle-yards.

4164. *As an example of a small farmery in the county of Stafford, we select that of Knollwall. (fig. 606.)* The extent is 104 acres; the soil is strong and rather wet, and there are some water and other meadows.

The house and yard-buildings are of brick and tile, and their accommodations are, a kitchen (a), a brew-house (b), parlour (c), sitting-room (d), pantry (e), milk-house (f), court-yard open (g), coals (h), hackney-stable (i), turkey-house (k), pigsties (l), waggon-horse stable (m), corn-bay (n), barn (o), straw-hay (p), cow-tyings (q), fodder-bins (r), calf-houses (s), and waggon-shed, granary over, connected with barn (t).

4165. *As an example of a middle-sized farmery on a clayey soil, we may refer to that of Newstead, in Staffordshire.* This farm contains 314 acres, and the tenant, Ford, is said to be an example to the whole country. The accommodations of the farmery are, in the dwelling-house, an outer kitchen, and kitchen, master's room, brew-house, dairy, pantry, parlour, bedrooms, cheese-room, attics. In

the court a shed for waggons, with granary over, hackney stable, waggon-horse stable, cattle-sheds, turnip-houses, fodder-house, straw-bays, threshing-mill with water-wheel, corn-bay, tool-house, workshop, bay for unthreshed corn, small granary, and pigsties.

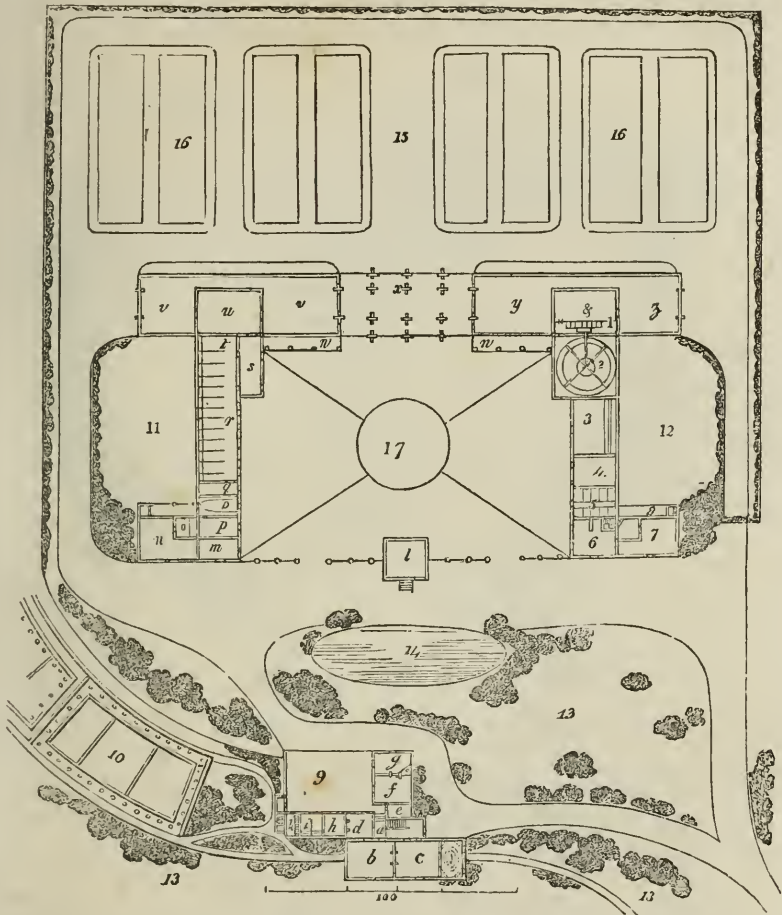

4166. *As an example of an economical farmery for a farm of 50 or 60 acres, we copy from The General Report of Scotland.* The accommodations are: — in the house, a kitchen, parlour, store-room, pantry, with three bedrooms, and a light closet over; closet, milk-room, and scullery. In the economical buildings are, a stable with a loose stall, byre for ten cows, cattle-shed, barn, cart-shed, with granary over; pigsties and cattle-yard. This appears one of the most compact and eligible plans for the farmeries of arable farms under 100 acres.

4167. *As an improved Berwickshire farmery, we submit another specimen from The General Report.* Its accommodations are calculated for a farm of 600 acres, and consist, in the dwelling-house range, of a porch, lobby, dining-room, parlour, kitchen, scullery, coal-place, store-room, dairy, pantry, business-room, poultry, steaming-house, bailiff's room. The economical buildings contain a riding-horse stable, tool-house, cart-shed, with granary over; corn-barn, straw-barn, feeding-house for 36 head of cattle, root-house, byre for cows, calf-pens, stable for ten horses, pigs, with yard and troughs, cattle-sheds, dung-basin, and urinarium under; cattle-yards, cart-road paved, rick-yard, mill track, open court, lawn, garden, and orchard.

4168. *A farmery for a turnip soil of from 600 to 900 acres, from the same work, deserves consideration as a very complete specimen of arrangement.* Omitting the farm-house, the economical buildings contain a stable, cow-house, servants' cow, root-house, young horses' stable, straw-barn, corn-barn, stable, cart-shed, place for pickling wheat, killing sheep, or other odd jobs; feeding-house, carpenter's workshop, pigs, geese, common poultry, turkeys, pigs, cattle-sheds, dung and straw courts, with urinarium in the centre of each, paved cart-road round, open court between the yard and dwelling-house, rick-yard, paddocks of old pasture, ponds for drinking and washing the horses' legs.

4169. *The accommodations for a farm-house, suitable to such a design and to the style of life which the person who can occupy such a farm is entitled to enjoy, are as follows: —* In the parlour story there is a lobby, with staircase to chambers and cellars, drawing-room, bedroom, a family work-room, dining-room, business-room, kitchen, barrack-room or manservant's room, store-room, dairy, &c. On the first floor are two best bedrooms, two other bedrooms, bed-closets, another closet, and a water-closet; over are servants' rooms.

4170. *As a farmery for an arable farm near London of 350 acres (fig. 607.), we shall give as an example one erected (with some variations) in the county of Middlesex, in 1810.* It is to be observed, that in Middlesex farming a great object is hay, especially meadow hay, for the London market, which gives rise to the covered spaces for loaded carts (x); it being the custom to load the carts at night, place them under cover, and yoke and go on the road early the following morning. The accommodations of this farmery

arc, in the dwelling-house, a lobby and stair (a), dining-room (b), drawing-room and green-house (c), a housekeeper's room, nursery or butler's pantry (d), dairy (e), kitchen (f), back kitchen and brew-house (g), gig-house or coach-house (h), small stable (i), harness-room and stair to men's room and hay-loft (k). In the economical buildings are a granary (l), pigs (m), carts or odd articles (n), water-closet (o), poultry (p), litter for the stable (q), stable for twelve horses (r), chaff-room (s), litter (t), room for cutting hay into chaff (u), places for horse food, or straw, hay, &c. (v), cattle-sheds (w), open colonade for loaded hay-carts (x), straw end of barn (y), corn-floor (z), unthreshed corn and corn-floor (s), machine (1), mill course (2), cows (3), cow-food (4), calves (5), bailiff's house (6), implements (7), wood-house, coals, &c. (8), kitchen-court to master's house (9), garden (10), poultry-yard (11), bailiff's garden (12), lawn, shrubbery, and sheep-walk (13), pond (14), rickyard (15), stack-stands (16), urinarium (17).

4171. In the elevations of this farmery (fig. 608.), some attention has been paid to effect, by intermingling trees, chiefly oaks, with thorns and honeysuckles.

4172. *An anomalous design of a farmery for a hay-farm (fig. 609.), calculated for effect and for inspection from the sitting-room (a, a), contains the following economical buildings: — A poultry-house with granary over (a), a chaise-house with men's room*

over (b), rabbits (c), tools (d), carts (e), open sheds for carts or other implements (f), sick horse or cow, &c. (g), pigs (h), stable (i), calves (k), cows (l), open passage lighted from above and pump (m), saddle-horse, &c. (n), straw (o), chaff-cutting room (p), hand-threshing-machine (q), unthreshed corn (r), loaded carts of hay (s, t), hay-ricks with roof movable on wheels to protect the hay while binding (u), ponds (v), lawn (w), yard (x). Sitting in the circular room (a, a), the master may look down the light passage which has a wire door, and along the oblique front of the buildings, and see every door that is opened. He may also, as appears by the elevation (fig. 610.) see the men binding hay under the movable covers.

611

4173. An anomalous design for a corn and stall-feeding farm (fig. 611.), in which the stacks are built on the tops of the stables, cattle, and cart-sheds (a), may be noticed, as pleasing in effect, but not likely to be so useful as the more simple plans.

612

The hay, roots, and straw, are stacked in the central circle (b), and very readily supplied to the stable (c), cow-stalls (d), or feeding-yards (e). The threshing-machine (f) is driven by water, which is supplied by a circuitous route (g), from the pond near the house (h). The elevation (fig. 612.) has a good effect when

all the stacks are in their places, and untouched; but as they are removed to the barn the appearance of the flat-roofed sheds will not be so consonant to established notions of beauty and neatness.

4174. *A farmery for a meadow-farm of 250 acres near London (fig. 613.), may be arranged as follows:—* The house may contain a porch, lobby, and stair to chambers and

cellars (a), parlour (b), bedroom or study (c), pantry (d), kitchen (e), lumber-room (f), business-room (g), back kitchen (h), coal cellar and maid's room over (i), wood-house (k), yard and pump (l), pigs (m), chaise (n), poultry (o), tools and roots, &c. (p), two stalls, and a saddle and harness place (q), harrows and large implements, &c. (r), bailiff's house or men's lodge (s), cows (t), chaff-cutting room, and granary over (u), straw-barn (v), corn-floor (w), unthreshed corn (x), stable and stall for litter (y), loaded or empty carts and implements (z), watering-trough (ξ), rick-stands (1), bailiff's garden (2), master's garden (3), lawn (4), paddock of old grass (5).

4175. *An anomalous design for a turnip-farm of 500 acres (fig. 615) contains a dwelling-house (a), on an eminence commanding not only the farmery (b), but great part of the farm. It is surrounded by the ricks for shelter (c), and by a pond (d), which drives the threshing-machine (e), and forms a foreground to the distant scenery. There are a large feeding-shed (f), a bailiff's house and garden (g), and the other usual accommodations. The elevation of the feeding-sheds and end of the barn looking towards the house is simple and not inelegant. (fig. 614.)* Farmeries of this sort are not sub-

614

mitted as examples for general imitation, but merely as sources of ideas to such as have the designing of this species of rural buildings, for employers who have a taste for design and for originality, and who can afford to gratify that taste. It is a poor business, and one which never can procure much applause, when a proprietor of wealth and cultivated mind erects for his own use the same sort of farmery, or, indeed, of any other buildings, as the tenants who support him. In East Lothian, Berwickshire, Northumberland, and on the Marquis of Stafford's estates both in England and Scotland, are some noble examples of substantial, commodious, and even elegant farmeries. (See *Gen. Rep. of Scotland*, and *Loch's Imp. on the Marq. of Stafford's Estates*, &c. 8vo. 1819.)

615

SUBSECT. 2. *Laying out Cottages.*

4176. *Cottage buildings* include a variety of habitations, from the farm-house downwards. On a large estate there will be cottages for tradesmen and mechanics, with and without fields and gardens; others for market-gardeners and nurserymen, surrounded by gardens and orchards; for operative manufacturers; for day-labourers; and, on the farm lands near the farmeries, for ploughmen and herdsmen. The extent of ground which ought to accompany these cottages must be determined entirely by the demand: the regular labourer and ploughman require the least; and the gardener and tradesman, who keep a horse or horses and cow, the most.

616

4177. *A cottage fit for a tradesman, mechanic, or bailiff*, given in *The General Report of Scotland*, contains the following accommodations: — A porch, lobby, living-room, two closets with beds, pantry and dairy, fuel and lumber-place, pig, and garden. The cow is kept at the farmery, if for a bailiff; the poultry over the fuel-place, and the bees on stands in the open garden.

4178. *A double cottage of only one floor* (fig. 616.) contains in each, the kitchen (a), with oven (b), pantry and dairy (c), lobby (d), two bedrooms (e, e), entrance door (f), front court-yard (g), pigs (h), necessaries (i). The gardens are at each end, and the cows supposed to be kept at the farmery.

4179. *A cottage on a smaller scale* contains the entrance and stair, parlour and bedroom,

with two good bedrooms over. Behind the main body of the house is a lean-to, containing the kitchen with dairy and pantry, brewing, fuel, and lumber-place. The usual appendages are detached.

4180. *A double cottage for two married ploughmen, given in The General Report of Scotland, contains a porch, and stair to bedrooms, living-room, pantry and dairy, back kitchen, cow or pig-house, gardens, and two good bedrooms to each.*

4181. *A labourer's cottage with cow-house and piggery (fig. 617.), as commonly constructed in the south of Scotland, is thus arranged:—The cow-house (a) and piggery (c) are in a lean-to. The dwelling contains, on the ground floor, an entrance and stair to bed-garret (b), large kitchen and living-room (e), dairy and pantry (d), coal and wood (g), necessary (h).*

4182. *A good mechanic's cottage (fig. 618.) is thus arranged:—Parlour (a), kitchen (b), closet (c), dairy and pantry (d), closet to parlor (e), tool-house (f), poultry (g), back entrance to the kitchen and fuel-place (h), back entrance to house and stair (i); over are two good bedrooms, behind is a small court-yard, and the garden surrounds the whole.*

4183. *Where cottages are erected as picturesque objects, various external forms and styles of design may be adopted, and at the same time the requisite degree of comfort preserved within. Three may be grouped together (fig. 619.) and each have the usual accommodation of kitchen (a) and parlour (b), with the usual closets and garret bedrooms. For cottages of upper servants, on the demesne lands of proprietors, Gothic elevations (fig. 620.), Chinese, Swiss, and Italian (fig. 621.), and every other variety, may be adopted.*

4184. *For entrance lodges* there are many elegant designs by Gandy, Robertson, Papworth, and others; some simple and modern, and others in imitation of the elder styles of building.

4185. *A very simple entrance lodge of one story* (fig. 621.) may contain a kitchen (a), parlour and bed-room opening into it (b), pantry (c), and closet (d). Towards the road there may either be a bow projection or porch. Detached, in the garden, and concealed by trees and shrubs, may be the usual appendages to comfortable cottages.

SUBSECT. 3. *Laying out the Farm Lands.*

4186. *In arranging farm lands*, the principal considerations are the size and shape of the fields, and the next the access to them and to the farmery by proper roads.

4187. *The form and size of fields* have too often been determined without much regard to the size of the farm, the exposure, and the equability of the soil. This is the more to be regretted in the case of live fences, which ought to endure for a long course of years, and which cannot be eradicated without considerable expense. In *The Code of Agriculture* it is observed, that when a whole farm is divided into fields of various sizes, it is difficult to form a plan so as to suit a regular rotation of crops, or to keep very accurate accounts. Whereas, by having the fields *in general* of a large size, the whole strength of a farm and the whole attention of the farmer are directed to one point; while an emulation is excited among the ploughmen, when they are thus placed in circumstances which admit their work to be compared. Some small fields are certainly convenient on any farm, for grazing and other purposes to be afterwards explained. On elevated situations, also, the shelter derived from small enclosures is of use.

4188. *A number of small enclosures*, irregularly shaped, surrounded with trees or high hedges, in corn farms, and more especially in corn lands situated in a flat country where shelter is unnecessary, is exceedingly injurious to the farmer. Besides the original expense of making the enclosures, the injury done to the crops of grain, produced by the want of a free circulation of air, and the harbour afforded to numbers of small birds; the very site of numerous hedges, with their attendant ditches, and the uncultivated slips of land on both sides of them, consume a much larger proportion of arable land than is commonly imagined. Hedges, especially if accompanied by rows of trees, greatly exhaust the ground of its fertility, nourish weeds, the seeds of which may be widely disseminated, and, by the exclusion of air, the harvesting of the crop is carried on more slowly. Even upon meadow land, small enclosures encircled by hedges are injurious, as they prevent the circulation of air for making or drying the hay. Small enclosures, with high hedges and trees, are also extremely injurious to the roads in their neighbourhood.

4189. *With fields of a considerable size* less ground is wasted, and fewer fences are to uphold. The crops of grain, being more exposed to wind, can be harvested earlier, and they suffer less from damp seasons. Small enclosures in pasture are more productive in winter, being better sheltered; but in summer the larger and more open the enclosures are the better; for in hot weather both cattle and sheep always resort to the most airy places. It is easier, also, when they are in pasture, to obtain a supply of water in large fields than in small ones: indeed, fields are sometimes so small, that it is very difficult to procure an adequate supply of water even in winter. But the conclusive argument in favour of large arable fields is this, that where fields are small, much time and labour are wasted by short turnings; and it is now ascertained, "that if fields are of a regular shape, and the ridges of a proper length, five ploughs may do as much work as six ploughs in fields of a small size and of an irregular shape; while every other branch of labour (such as dunging, sowing, harrowing, reaping, and carrying in the harvest,) can be executed, though not altogether, yet nearly, in the same proportion." (*Husb. of Scot.* vol. i. p. 41. and *Sup. Encyc. Brit.* art. *Agr.*)

4190. *The circumstances on which the size of fields ought to depend* are, the extent of the farm in which they are situated, the nature of the soil and subsoil, the rotations adopted, the inclination of the ground, its being in pasturage or otherwise, and the nature of the climate. (*Code.*)

4191. *Extent of the farm.* The size of fields ought certainly, in some measure, to depend upon the extent of the possession. In small farms near towns, from six to twelve acres may be sufficient; but where farms are of a considerable extent, fields from twenty to even fifty acres, and, in some particular cases, as high as sixty, may be used to advantage. In general, however, even on large farms, when permitted by local circumstances, fields of a medium size, as from fifteen to twenty-five English acres, are recommended by competent judges.

4192. *Soil and subsoil.* In dividing a farm into fields, the nature of the soil and subsoil ought to be kept in view. Where the soil is various, it would be proper to separate the light from the heavy. They are not only better calculated for different crops and different rotations, but are naturally adapted to be cultivated at different seasons. It is unfortunate, therefore, to have soils of a heterogeneous nature mingled in the same field. But where this partially takes place, for instance, where there is only an acre or two of light soil to ten or twenty of strong soil, let the following plan be adopted:—At any slack time, either in summer or winter, more especially when the field is under fallow, employ two carts and horses with four fillers, to cover the acre or two of light soil, with the strong soil contiguous, and the soil in the field will then become more uniform. In fields where light soils predominate, the plan might be reversed. This plan, though at first expensive, is attended with such advantages that, whenever it is necessary and practicable, it ought to be carried into effect.

4193. *The rotation adopted.* It may be considered as a good general rule, to divide a farm according to the course of crops pursued in it; that is to say, a farm with a rotation of six crops should have six fields, or twelve, according to circumstances. It is proper to have a whole field, if the soil be uniform, under one crop; and every farmer of experience knows the comfort of having the produce of the farm as equal every year as the soil and season will admit of.

4194. *Inclination of the ground.* It is, however, evident that the size of the fields must in some respects depend on the flatness or the hilly shape of the ground. Even on dry land, if there be a rise on the ground, from fifteen to twenty chains is sufficient length; for if the ridge be longer, the horses become much fatigued if compelled to plough a strong furrow up-hill beyond that length in one direction. This objection, however, to large fields, may in some measure be obviated, by giving the ridges and furrows in such fields as are on the sides of a hill, such an obliquity as may diminish the difficulties of the ascent.

4195. *Pasturage.* Where the systems of grazing and tillage alternately is followed (more especially where the fields are pastured for two or three years in succession), it is convenient to have the fields of from twenty to perhaps thirty English acres. The farmer is thus enabled to divide his stock, which he cannot well do with larger fields. The cattle or sheep remain more quiet than if a greater number were collected together, and less grass is destroyed by treading. When such a field has been pastured for some time, the stock should be removed to another, till the grass in the former has renewed, and is fit for being eaten. Such a size also, in general, suits graziers better than larger ones, and consequently fields of this extent, when in pasture, generally let for more rent.

4196. *Climate.* The last circumstance to be considered, in determining the proper size of fields, is the nature of the climate. In dry and cold climates, small enclosures are desirable on account of shelter; whereas, in wet countries, the fields under culture cannot be too open and airy, for the purpose of drying the ground, of bringing forward and ripening the grain, and of enabling the farmer more easily to secure it during an unfavourable harvest, by having a free circulation of air. But, though on large farms fields should in general be formed on an extensive scale, yet there is a convenience in having a few smaller fields near the farm-house for keeping the family cows; for turning out young horses, mares, and foals; for raising a great variety of vegetables; and for trying experiments on a small scale, which may afterwards be extended, if they shall be found to answer. When enclosures are too large for particular purposes, and where no small fields, as above recommended, have been prepared, large fields may be subdivided by sheep-hurdles, a sort of portable fence well known to every turnip-grower. In this way, great advantage may be derived from the constant use of land that would otherwise have been occupied by stationary fences; and the expense of subdivisions, which, on a large farm, would necessarily have been numerous, is thereby avoided. This fence is perfectly effectual against sheep, though it is not so well calculated for stronger animals.

4197. *The shape of fields* may be either square or oblong.

4198. *Square fields.* The advantage of having the fences in straight lines, and the fields, when large, of a square form, is unquestionable, as the ploughing of them under this arrangement can be carried on with much greater despatch. Some farmers, whose fields are of a waving or uneven shape, and who enclose with hedge and ditch, carry their fence through the hollows, or best soil, with a view of raising a good hedge; thus often sacrificing, for the sake of the fence, the form of their field. A straight line, however, is preferable, even though it should be necessary to take some particular pains to enrich the soil for the hedge, where it is thin and poor, on any elevation. By means of the square form, an opportunity is afforded of ploughing in every direction, when necessary; and less time is lost in carrying on all the operations of husbandry in a field of that form than of any other. When the waving form is necessary to secure proper water runs, plantations may be so disposed as to reduce the fields to squares or oblongs, and the fences to straight lines. Rectangular fields have another advantage, that in fields of that shape it may be known whether the ploughmen have performed their duty, the quantity of work done being easily calculated, from the length and breadth of a certain number of ridges.

4199. *Oblong fields.* When fields are small, an oblong shape should be preferred, that the ploughings may be dispatched with as few turnings as possible. This form has also other advantages: the fields are more easily subdivided, and water can in almost every case be got, by making proper ponds in the meeting or joining of three or four fields, whose gutters or ditches will convey water to the ponds. In turnip soils, where the shape is oblong, it is easier to divide the turnips with nets or hurdles, for the convenience of feeding them off with sheep. If the ridges are too long, and the field dry and level, the length may be reduced by making cross head-lands, or head-ridges, at any place that may be considered the fittest by the occupier. (*Code of Agr. 152 to 157.*)

4200. *Hedge-row trees* are very generally objected to by agriculturists. Notwithstanding the garden-like appearance which they give to the landscape, "it seems to be agreed by the most intelligent agriculturists that they are extremely hurtful to the fence, and for some distance to the crops on each side; and it is evident, that in many instances the high-ways, on the sides of which they often stand, suffer greatly from their shade. It has therefore been doubted whether such trees be profitable to the proprietor, or beneficial to the public; to the farmer they are almost in every case injurious, to a degree beyond what is commonly imagined." (*Supp. to Encyc. Brit. art. Agr.*)

4201. *The opinion of Loch,* a well informed and unprejudiced improver of landed property, is of an opposite description. He says: "There is no change in the rural economy of England more to be regretted, than the neglect which is now shown to the cultivation and growth of hedge-row timber. The injury which it does to the cultivation of the land is much exaggerated, especially if a proper selection of trees is made; but even the growth of the ash, so formidable to agriculturists, might be defended, on the ground that without it the best implements employed in the cultivation of the soil could not be made. It is well known that good hedge-row timber is by far the most valuable both for naval and domestic purposes; its superior toughness rendering it equally valuable to the ship-builder and to the ploughwright. The value which it is of in affording shelter is also material: besides, the raising of grain is not the only purpose of life, or the only matter to be attended to, nor the only object worthy of attention. The purposes of war and of national glory, the protection and the extension of our commerce, the construction and repair of buildings, and even the enjoyment arising from the rich and beautiful effect produced by such decoration and ornament, are all objects of material importance to the well-being and constitution of a highly cultivated state of society. Even upon the more narrow basis of individual utility, this practice might be defended and recommended; for it is not useless to consider how many families and estates have been preserved, when pressed by temporary difficulties (from which none are exempted), by a fall of hedge-row timber. One of the best legacies which a great proprietor can leave his country and his family, is an estate well stocked with such trees." Believing, as we do, that there can be no real and permanent beauty that is inconsistent with utility, we prefer, for arable lands, hedges wholly without timber trees. In pasture lands we would rather see the trees in scattered groups than in the hedges; because so placed they are only injurious to the pasture; whereas in the hedge they are injurious to that and the pasture also.

4202. *The gates of fields* should in most cases be placed in the middle of that side of the field which is nearest the road, because, in carting home produce, or in carting out manure, the labour of carting is less on a road than on the soft ground of the field, and because such carting always more or less injures this ground; a part of it along the head-lands being necessarily subjected to repetition in the same track; and not in an angle, or at one corner, unless particular circumstances point out this as the preferable mode. Some contend that the gates of fields should be placed in or near the corner next to the road or homestead; but our objection to this arrangement is, that, in carting out manure, or carting home the crop, the headland is liable to be much more severely injured by cart ruts than when the gate is in the middle.

4203. *The drainage and water-courses, if any, on farm lands, require to be attended to in laying out the fences, so as if possible to make the ditches of the latter serve as open drains; also, when opportunity offers, for conveying streams to be used in irrigation, or for driving machinery. The fences and roads will, to a certain extent, be guided by the course of such stream or streams.*

4204. *As an example of laying out farm lands from a newly enclosed common, we submit the case of a flat surface, a strong retentive clay soil, a moist climate, a situation distant from markets, with no other object in view than that of making as much of the lands as possible.*

4205. *A public road (fig. 623. a) passes the farm, and the farmery is approached by a private road (b).*

623

The size of the farm deemed proper is 350 acres; the most profitable mode of occupation is, 180 in arable, and the remainder in pasture. The arable subjected to a rotation of 1st, beans drilled, or naked fallow dunged; 2d, wheat; 3d, clover and rye-grass, fed off or mown for soiling cattle; 4th, wheat or oats, if the clover was mown, dunged. The grass-lands are supposed to be wholly fed off, chiefly with cattle, but also with ten cows, for butter and breeding, and a few sheep.

4206. *The buildings (c) are placed in the centre of the farm, and contain stabling for four work-horses, and open sheds for eight oxen; 130 feet of sheds for thirty fattening cattle; a barn, with threshing-machine impelled by wind; houses for ten cows, and other conveniences in proportion. There is a kitchen-garden, orchard, rick-yard, and two paddocks (d, f), adjoining the farmery.*

4207. *The grass-fields (g), contain only ten acres each, to admit of the great advantage of shifting the stock from one to another. They are most distant from the farmery, because requiring least cartage; and, some of them being in the lowest part of the farm, they may be irrigated. Trees are avoided in the fences, as injurious in flat surfaces and adhesive soils. For the purposes of shading cattle, one or two might be planted in the angles of the field; but a temporary shed of the rudest and slightest materials, and easiest taken down, removed, and reconstructed, is preferable, as calculated to distribute the manure produced by the cattle when at rest.*

and reconstructed, is preferable, as calculated to distribute the manure produced by the cattle when at rest.

4208. *The arable lands (h) are preserved in the centre, to save carting to and from the farmery; and the enclosures are four times the size of the grass-fields, each shift forming one large enclosure, containing four fields, divided only by open ditches for carrying off the surface water. The two small central fields shown under aration, are supposed alternately in turnips, potatoes, cabbages, &c. for cows, &c. and wheat. The paddocks and closes are for calves or colts.*

4209. *The chief, and almost sole, products of this farm will be wheat and beef: the former best worth sending to a distant market; the latter easily transported to any distance; and both staple commodities.*

4210. *With respect to roads, sometimes a farm is situated on both sides of a highway; in which case all the fields may be made to open into it, either directly or through an intervening field. Hence no private road is wanting, excepting a few yards to reach the farmery. But when, as is most generally the case, the lands are situated at a distance from a great road, and approached by a lane or by-road, then from that by-road a private road is required to the farmery, and a lane or lanes from it so contrived as to touch at most of the fields of the farm. In wet and clayey soils, these lanes must be formed of durable materials; but in dry soils, provided attention be paid to fill in the cart ruts as they are formed (by the leading out of dung, or home of corn), with small stones, gravel or even earth, the lane may remain green; and, being depastured by sheep or cattle, will not be altogether lost. It is essentially necessary to make a piece of road at the gate of every enclosure, that being the spot which is most frequently in use. Without this precaution, it often becomes a mire where corn is thrown down and spoiled in harvest, or, if it is attempted to avoid the mire, the gate-posts and neighbouring fence are often damaged. (Communications to the Board of Agriculture, vol. ii. p. 251.)*

4211. *With good private roads* a farmer will perform his operations at much less expense; the labour of the horses will be much easier; a greater quantity or weight of grain and other articles may be more expeditiously carried over them; manure can be more easily conveyed to the fields; the harvest can be carried on more rapidly; and wear and tear of every description will be greatly reduced. (*Code of Agriculture*, p. 158.)

BOOK III.

OF IMPROVING THE CULTURABLE LANDS OF AN ESTATE.

4212. HAVING completed the general arrangement of an estate, the next thing is to *improve the condition of that part of it destined to be let out to tenants*, which, as already observed, constitutes the chief source of income. The farm lands being enclosed and subdivided, and the farmeries and cottages built in their proper situations, in many cases no other improvements are wanted on the soil than such as are given by the tenant in the ordinary course of culture. But there are also numerous cases, in which improvements are required which could not be expected from an occupier having only a temporary interest in his possession; and these form the present subject of discussion. Such improvements are designated by agriculturists *permanent*, as conferring an increased purchasable value on the property, in opposition to improvements by a temporary occupier, the benefits of which are intended to be reaped during his lease. The latter class of improvements includes fallows, liming, marling, manuring, improved rotations, and others of greater expense, according to the length of lease, rent, and encouragement given by the landlord: the former, which we are now about to discuss, includes draining, embanking, irrigating, bringing waste lands into cultivation, and improving the condition of lands already in a state of culture.

CHAP. I.

Draining Watery Lands.

4213. *Draining* is one of those means of improvement, respecting the utility of which agriculturists are unanimous in opinion. Though practised by the Romans (143.), and in all probability in some cases by the religious fraternities of the dark ages, it was not till after the middle of the last century that its importance began to be fully understood in Britain; and that some individuals, and chiefly Dr. Anderson and Elkington, began to practise it on new principles. About the same time, the study of geology became more general, and this circumstance led to the establishment of the art on scientific principles. The public attention was first excited by the practice of Elkington, a farmer and self-taught professor of the art of draining in Warwickshire and the adjoining counties. On the practice of this artist most of the future improvements have been founded; and they have been ably embodied in the account of his practice by Johnston, from whose work we shall draw the principal materials of this section, borrowing also from the writings of Dr. Anderson, Marshal, Smith, Farey, Stephens, and some others on the same subject, and from the sixth and seventh volumes of the *Highland Society's Transactions*. After submitting some general remarks on the natural causes of wetness in lands, we shall consider in succession the drainage of boggy lands, hilly lands, mixed soils, retentive soils, and mines and quarries; and then the kinds of drains, and draining materials.

SECT. I. *Natural Causes of Wetness in Lands, and the general Theory of Draining.*

4214. *The successful practice of draining* in a great measure depends on a proper knowledge of the structure of the earth's upper crust, that is, of the various strata of which it is composed, as well as of their relative degrees of porosity, or capability of admitting or rejecting the passage of water through them, and likewise of the modes in which water is formed, and conducted from the high or hilly situations to the low or level grounds. In whatever way the hills or elevations that present themselves on the surface of the globe were originally formed, it has been clearly shown, by sinking large pits, and digging into them, that they are mostly composed of materials lying in a stratified order, and in oblique or slanting directions downwards. Some of these strata, from their nature and properties, are capable of admitting water to percolate or pass through them; while others do not allow it any passage, but force it to run or filtrate along their surfaces without penetrating them in any degree, and in that way conduct it to the more level grounds below. There it becomes obstructed or dammed up by meeting with impervious materials of some kind or other, by which it is readily forced up into the superincumbent layers where they happen to be open and porous, soon rendering them too wet for the purposes

of agriculture; but where they are of a more tenacious and impenetrable quality, they only become gradually softened by the stagnant water below them; by which the surface of the ground is, however, rendered equally moist and swampy, though somewhat more slowly than in the former case. It may also be observed, that some of the strata which constitute such hilly or mountainous tracts are found to be continued with much greater regularity than others; those which are placed nearest to the surface, at the inferior parts of such hills or elevations, being mostly broken or interrupted before they reach the tops or higher parts of them; while those which lie deeper, or below them at the bottom, show themselves in these elevated situations. Thus, that stratum which may lie the third or fourth, or still deeper, at the commencement of the valley may form the uppermost layer on the summits of hills or mountainous elevations. This arrangement or distribution of the different strata may have been produced partly by the circumstances attending the original elevation of such mountainous regions, and partly from the materials of the original exterior strata being dissolved and carried down into the valleys by successive rains and other causes, and thus leaving such as were immediately below them in an exposed and superficial state in these elevated situations. (*Darwin's Phytologia*, p. 258.)

4215. *These elevated strata frequently prove the means of rendering the grounds below wet and swampy*; for the general moisture of the atmosphere being condensed in much greater quantities in such elevated situations, the water thus formed, as well as that which falls in rain and sinks through the superficial porous materials, readily insinuates itself, and thus passes along between the first and second or still more inferior strata which compose the sides of such elevations, until its descent is retarded or totally obstructed by some impenetrable substance, such as clay: it there becomes dammed up, and ultimately forced to filtrate slowly over it, or to rise to some part of the surface, and constitute, according to the particular circumstances of the case, different watery appearances in the grounds below. These appearances are, oozing springs, bogs, swamps, or morasses, weeping rocks from the water slowly issuing in various places, or a large spring or rivulet from the union of small currents beneath the ground. This is obvious from the sudden disappearance of moisture on some parts of lands, while it stagnates, or remains till removed by the effects of evaporation, on others; as well as from the force of springs being stronger in wet than in dry weather, breaking out frequently after the land has been impregnated with much moisture in higher situations, and as the season becomes drier ceasing to flow, except at the lowest outlets. The force of springs, or proportion of water which they send forth, depends likewise, in a great measure, on the extent of the high ground on which the moisture is received and detained, furnishing extensive reservoirs or collections of water, by which they become more amply and regularly supplied. On this account, what are termed bog-springs, or such as rise in valleys and low grounds, are considerably stronger and more regular in their discharge, than such as burst forth on the more elevated situations or the sides of eminences. (*Johnston's Account of Elkington's Mode of Draining Land*, p. 15.)

4216. *The waters condensed on elevated regions* are sometimes found to descend, for a very considerable distance, among the porous substances between the different conducting layers of clayey or other materials, before they break out or show themselves in the grounds below; but they are more frequently found to proceed from the contiguous elevations into the low grounds that immediately surround them.

4217. *The nature of the stratum of materials on which the water descending from hills has to proceed* must considerably influence its course, as well as the effects which it may produce on such lands as lie below, and into which it must pass. Where the stratum is of the clayey, stiff marly, or impervious rocky kind, and not interrupted or broken by any other materials of a more porous quality, the water may pass on to a much greater distance, than where the stratum has been frequently broken and filled up with loose porous materials, in which it will be detained, and of course rise up to the surface.

4218. *These sorts of strata extend to very different depths in different situations and districts*, as it has been frequently noticed in the digging of pits, and the sinking of deep wells, and other subterraneous cavities. The clayey strata are, however, in general found to be more superficial than those of the compact, tenacious, marly kind, or even those of a firm, uninterrupted, rocky nature, and seldom of such a great thickness; they have, nevertheless, been observed to vary greatly in this respect, being met with in some places of a considerable thickness, while in others they scarcely exceed a few inches.

4219. *The intervening porous substances*, or strata, where clay prevails, are found, for the most part, to be of either a gravelly or loose rocky nature. Stiff marly strata, which approach much to the quality of clay, though in some instances they may present themselves near the surface, in general lie concealed at considerable depths under the true clayey strata, and other layers of earthy or other materials; they have been discovered of various thicknesses, from eight or ten feet to considerably more than a hundred. (*Darwin's Phytologia*, p. 259.) The intervening materials, where strata of this nature predominate, are most commonly of the more sandy kinds; possessing various degrees

of induration, so as in some cases to become perfectly hard and rocky, but with frequent breaks or fissures passing through them. The loose, friable, marly strata are capable of absorbing water, and of admitting it to filtrate and pass through them.

4220. *Thus the valleys and more level grounds must constantly be liable to be overcharged with moisture, and to become, in consequence, spouty, boggy, or of the nature of a morass, accordingly as they may be circumstanced in respect to their situation, the nature of their soils, or the materials by which the water is obstructed and detained in or upon them.*

4221. *Where lands have a sufficient degree of elevation to admit of any over-proportion of moisture readily passing away, and where the soils of them are of such a uniform sandy or gravelly and uninterrupted texture, as to allow water to percolate and pass through them with facility, they can be little inconvenienced by water coming upon or into them, as it must of necessity be quickly conveyed away into the adjacent rivers or small runlets in their vicinity.*

4222. *But where grounds are in a great measure flat, and without such degrees of elevation as may be sufficient to permit those over-proportions of moisture that may have come upon them from the higher and more elevated grounds to pass readily away and be carried off, and where the soils of the lands are composed or constituted of such materials as are liable to admit and retain the excesses of moisture; they must be exposed to much injury and inconvenience from the retention and stagnation of such quantities of water. Such lands consequently require artificial means to drain and render them capable of affording good crops, whether of grain or grass.*

4223. *Lands of valleys and other low places, as well as, in some cases, the level tracts on the sides or borders of large rivers and of the sea, must also frequently be subject to great injury and inconvenience from their imbibing and retaining the water that may be thus forced to flow up into or upon them, either through the different conducting strata from the hills and mountainous elevations in the neighbourhood, or the porous materials of the soils. In these ways they may be rendered swampy, and have bogs or morasses produced in them in proportion to the predominancy of the materials by which the water is absorbed and dammed up, and the peculiarity of the situation of the lands in respect to the means of conveying it away.*

4224. *To perform properly the business of draining, attention should not only be paid to the discrimination of the differences in regard to the situation of the lands, or what is commonly denominated drainage level; but also to the nature, distribution, and depth of the materials that constitute the soils or more superficial parts of them, as upon each of these some variety, in respect to the effects arising from water retained in them, may depend.*

4225. *The general origin of that wetness of land which it is the object of under-draining to remove, "will be found to be the existence of water in substrata of sand, gravel, open rock, or other porous substances, which either lead to the surface, or, having no natural outlet, become filled or saturated, while the pressure of more water coming from a higher source, forces that which is in the lower part of the stratum upwards through the superior strata to the surface; thus occasioning either bursts and springs, or a general oozing through the soil. The object in under-daining, therefore, is not to catch the surface-water, but that which flows through their inferior strata; and, for this purpose, it is necessary to make a sufficient channel, either at the lower parts of the porous stratum, or in such part of it as may most conveniently carry off the water, so as the pressure referred to may be relieved, or the water intercepted before it reaches the surface. It must always be kept in mind, then, that under-draining and surface-draining are operations essentially distinct; and every care must be used in practice not to blend them in the execution. If surface-water be allowed to get into covered drains, the sand and mud which it will carry into these subterraneous channels will soon choke them up, and occasion bursts, creating, as may be conceived, new swamps; while the expense of taking up and relaying the under-drains will be very great, and the execution imperfect, the sides being found never to stand a second time so well as when first formed." (Highland Society's Trans. vol. vii. p. 218.)*

4226. *Wetness of land, so far as it respects agriculture, and is an object of draining, may generally depend on the two following causes: first, on the water which is formed and collected on or in the hills or higher grounds, filtrating and sliding down among some of the different beds of porous materials that lie immediately upon the impervious strata, forming springs below and flowing over the surface, or stagnating underneath it; and, secondly, on rain or other water becoming stagnant on the surface, from the retentive nature of the soil or surface materials, and the particular nature of the situation of the ground. The particular wetness which shows itself in different situations, in the forms of bogs, swamps, and morasses, for the most part proceeds from the first of these causes; but that superficial wetness which takes place in the stiff, tenacious, clayey soils, with little inclination of surface, generally originates from the latter.*

4227. *The most certain and expeditious method of draining, in such cases, is that of*

intercepting the descent of the water or spring, and thereby totally removing the cause of wetness. This may be done where the depth of the superficial strata, and consequently of the spring, is not great; by making horizontal drains (*fig. 624. a*) of consi-

derable length across the declivities of the hills, about where the low grounds of the valleys begin to form, and connecting these with others (*b*) made for the purpose of conveying the water thus collected into the brooks or runlets (*c*) that may be near. Where the spring has naturally formed itself an outlet, it may frequently only be necessary to bore into it (*e*), or render it larger, and of more depth; which, by affording the water a more free and open passage, may evacuate and bring it off more quickly, or sink it to a level so greatly below that of the surface of the soil, as to prevent it from flowing into or over it.

4228. *Where the uppermost stratum is so extremely thick as not to be easily penetrated, or where the springs, formed by the water passing from the higher grounds, may be confined beneath the third or fourth strata of the materials that form the declivities of hills or elevated grounds, and by this means lie too deep to be penetrated to by the cutting of a ditch, or even by boring (Darwin's Phytologia, p. 263.); the common mode of cutting a great number of drains to the depth of five, six, or more feet, across the wet morassy grounds, and afterwards covering them in such a manner as that the water may suffer no interruption in passing away through them, may be practised with advantage, as much of the prejudicial excess of moisture may by this means be collected and carried away, though not so completely as by fully cutting off the spring.*

4229. *As water is sometimes found upon thin layers of clay, which have underneath them sand, stone, or other porous or fissured strata, to a considerable depth; by perforating these thin layers of clay in different places, the water which flows along them may frequently be let down into the open porous materials that lie below them, and the surface land be thus completely drained.*

4230. *Where morasses and other kinds of wetnesses are formed in such low places and hollows as are considerably below the beds of the neighbouring rivers, they may, probably, in many instances, be effectually drained by arresting the water as it passes down into them from the higher grounds, by means of deep drains cut into the sides of such hills and rising grounds, and, after collecting it into them, conveying it away by pipes, or other contrivances, at such high levels above the wet lands as may be necessary: or where the water that produces the mischief can, by means of drains, cut in the wet ground itself, be so collected as to be capable of being raised by means of machinery, it may in that way be removed from the land.*

4231. *The drainage of lands that lie below the level of the sea can only be effected by the public, and by means of locks erected for the purpose of preventing the entrance of the tides, and by windmills and other expensive kinds of machinery constructed for the purpose of raising the stagnant water.*

4232. *The superficial wetness of lands, which arises from the stiff retentive nature of the materials that constitute the soils and the particular circumstances of their situations, is to be removed in most cases by means of hollow surface drains, judiciously formed, either by the spade or plough, and filled up with suitable materials where the lands are under the grass system; and by these means and the proper construction of ridges and furrows where they are in a state of arable cultivation.*

4233. *Having thus explained the manner in which soils are rendered too wet for the purposes of agriculture, and shown the principles on which the over-proportions of moisture may, under different circumstances, be the most effectually removed, we shall proceed to the practical methods which are to be made use of in accomplishing the business in each case.*

SECT. II. *The Methods of Draining Boggy Land.*

4234. *In the drainage of wet or boggy grounds, arising from springs of water beneath them, a great variety of circumstances are necessary to be kept in view. Lands of this*

description, or such as are of a marshy and boggy nature, from the detention of water beneath the spongy surface materials of which they are composed, and its being absorbed and forced up into them, are constantly kept in such states of wetness as are highly improper for the purpose of producing advantageous crops of any kind. They are, therefore, on this account, as well as from their occupying very extensive tracts in many districts, and being, when properly reclaimed, of considerable value, objects of great interest and importance to the attentive agricultor. Wet grounds of these kinds may be arranged under three distinct heads: first, such as may be readily known by the springs rising out of the adjacent more elevated ground, in an exact or regular line along the higher side of the wet surface; secondly, those in which the numerous springs that show themselves are not kept to an exact or regular line of direction along the higher or more elevated parts of the land, but break forth promiscuously throughout the whole surface, and particularly towards the inferior parts (*fig. 625. a*), constituting shaking quags in every direction, that have an elastic feel under the feet, on which the lightest animals can scarcely tread without danger, and which, for the most part, show themselves by the luxuriance and verdure of the grass about them; and, thirdly, that sort of wet land, from the oozing of springs, which is neither of such great extent, nor in the nature of the soil so peaty as the other two, and to which the term *bog* cannot be strictly applied, but which in respect to the modes of draining is the same. (*Johnston's Account of Elkington's Mode of Draining Land*, p. 19.)

4235. In order to direct the proper mode of cutting the drains or trenches in draining lands of this sort, it will be necessary for the draining engineer to make himself perfectly acquainted with the nature and disposition of the strata composing the higher grounds, and the connection which they have with that which is to be rendered dry. This may in general be accomplished by means of levelling and carefully attending to what has been already observed respecting the formation of hills and elevated grounds, and by in-

625

specting the beds of rivers, the edges of banks that have been wrought through, and such pits and quarries as may have been dug near to the land. Rushes, alder-bushes, and other coarse aquatic plants, may also, in some instances, serve as guides in this business; but they should not be too implicitly depended on, as they may be caused by the stagnation of rain-water upon the surface, without any spring being present. The line of springs being ascertained, and also some knowledge of the substrata being acquired, a line of drain (*fig. 625. b, b*) should be marked out above or below them, according to the nature of the strata, and excavated to such a depth as will intercept the water in the porous strata before it rises to the surface. The effect of such drains will often be greatly heightened by boring holes (*c*) in their bottom with the auger. Where the impervious stratum (*fig. 626. a*), that lies immediately beneath the porous (*b*), has a slanting direction

626

through a hill or rising bank, the surface of the low lands will, in general, be spongy, wet, and covered with rushes on every side (*c*). In this case, which is not unfrequent, a ditch or drain (*d*), properly cut on one side of the hill or rising ground, may remove

the wetness from both. But where the impervious stratum dips or declines more to one side of the hill or elevation than the other, the water will be directed to the more depressed side of that stratum; the effect of which will be, that one side of such rising ground will be wet and spongy, while the other is quite free from wetness.

4236. *Where water issues forth on the surface at more places than one*, it is necessary to determine which is the real or principal spring, and that from which the other outlets are fed; as by removing the source, the others must of course be rendered dry. When on the declivity or slanting surface of the elevated ground from which the springs break forth, they are observed to burst out at different levels according to the difference of the wetness of the season, and where those that are the lowest down continue to run, while the higher ones are dry, it is, in general, a certain indication that the whole are connected, and proceed from the same source; and consequently that the line of the drain should be made along the level of the lowermost one, which, if properly executed, must keep all the others dry. But if the drain were made along the line of the highest of the outlets, or places where the water breaks forth, without being sufficiently deep to reach the level of those below, the overflowings of the spring would merely be carried away, and the wetness proceeding from that cause be removed; while the main spring, still continuing to run, would render the land below the level of the bottom of the drain still prejudicially wet, from its discharging itself lower down over the surface of the ground. This, Johnston states, was the custom, until Elkington showed the absurdity of the practice of drainers beginning to cut their trenches wherever the highest springs showed themselves between the wet and the dry ground, which not being of a depth sufficient to arrest and take away the whole of the water, others of a similar kind were under the necessity of being formed at different distances, to the very bottom of the declivity: these being afterwards in a great measure filled with loose stones, merely conveyed away portions of surface water, without touching the spring, the great or principal cause of the wetness. The effects of drains formed in this manner he asserts to be that of rendering the surface of the land in some degree drier, so long as they continue to run with freedom; but as they are liable soon to be obstructed and filled up by sand or other materials, the water is often forced out in different places and directions, and thus renders the land as wet as before, if not wetter. In addition to this, it is a more difficult task to drain the ground a second time in a proper method, from the natural appearance of the ground being so much changed, and the bursts of the old drains, as well as the greater difficulty of ascertaining the real situation of the springs.

4237. *It may sometimes happen, however, that where the highest are the strongest outlets, they may be the main or leading springs*; those which show themselves lower down in the land being merely formed by the water of the main spring overflowing, and finding itself a passage into the earth through an opening in the surface, or through the porous materials of the soil near to the surface, and being obstructed somewhat further down in the ground by some impervious stratum. This circumstance must, therefore, it is observed, be fully ascertained before the lines for the ditches or drains are marked out.

4238. *In cases where the banks or rising grounds are formed in an irregular manner* (fig. 627.), and, from the nature of the situation, or the force of the water underneath,

627

springs abound round the bases of the protuberances, the ditches made for the purpose of draining should always be carried up to a much higher level in the side of the elevated ground than that in which the water or wetness appears; as far even as to the firm unchanged land. By this means the water of the spring may be cut off, and the ground completely drained; which would not be the case if the trench or drain were formed on the line of the loose materials lower down, where the water oozes out, which is liable to mislead the operator in forming the conducting trench, or that which is to convey the water from the cross-drain on the level

of the spring to the outlet or opening by which it is discharged. But where the main or principal spring comes out of a perpendicular or very steep bank, at a great height above the level of the outlet into which it may discharge itself by means of a drain, it will neither be necessary nor of any utility to form a deep trench, or make a covered drain, all the way from such outlet up to it; as from the steepness of the descent the water

would be liable, when the drain was thus cut, from the thin strata of sand and other loose materials, always found in such cases, to insinuate itself under the bricks, stones, or other substances of which the drain was formed; to undermine and force them up by the strength of the current, or probably, in some instances, block the drain up by the loose sand or other matters, which may be forced away and carried down by it. In situations of this kind, Johnston observes, it is always the best way to begin just so far down the bank or declivity as, by cutting in a level, the drain may be six or seven feet below the level of the spring; or of such a depth as may be requisite to bring down the water to a level suitable to convey it away without its rising to the surface, and injuring the lands around it. The rest of the drain, whether it be made in a straight or oblique direction, need not be deep, and may, in many instances, be left quite open; it should, however, be carefully secured from the treading of cattle, and, where the land is under an arable system of cultivation, also from the plough. Where it is covered, the depth of about two feet may be sufficient. There will not, in such drains, be any necessity for the use of the auger in any part of them.

4239. *Where there is a difficulty in ascertaining the line of the spring, and consequently that of the cross-drain, either from its not showing itself on the surface, or from there not being any apparent outlet, it may, generally, be met with in carrying up the conducting drain for conveying away the water. As soon as the operator discovers the spring, he need not proceed any further, but form the cross-drain on the level thus discovered to such a distance on each side of the tail, or terminating part, of the strata, of whatever sort, that contains the water, as the nature of the land, in regard to situation or other circumstances, may demand. Where, in forming a cross-drain, the line indicated by the spirit or other level is found to be in some places below that of the spring, and where, in boring in this direction, water is not found to follow, it will be necessary to make short drains or cuts of the same depth with the cross-drain, from it quite up to the source of the spring; for, if the drain be cut below the line of the spring, the possibility of reaching it by means of an auger is lost, as where the under stratum is clay, and there is no under water, the use of the auger cannot be effectual; and if it be made above the line of the spring, it will be requisite to cut and bore much deeper, in order to reach it, the ground being in general higher in that part: besides, the portion of porous stratum below the drain may contain a sufficient quantity of water to render the land wet, and that may readily get down underneath the trench, between the holes formed by boring, and break out lower down.*

4240. *In situations where the extent of bog in the valley between two banks or eminences is so narrow and limited as that the stratum of rock, sand, or other materials, that contains the water, may unite below the clay at such a depth as to be readily reached by the auger (fig. 628. a), it will seldom be necessary to have more than one trench up the middle,*

628

well perforated with holes (*b*) by means of the auger, cross or branching drains being unnecessary in such cases. For notwithstanding the springs, that render the land injuriously wet in these cases, burst out of the banks or eminences on every side, for the most part nearly on the same level, the reservoir from which they proceed may be discovered in the middle of the valley, by penetrating with the auger through the layer of clay that confines and forces the water to rise up and ooze out round the superior edge of it, where it forms a union with the high porous ground. From the drain being made in the hollowest part of the land, and the porous stratum containing the water being then bored into, it is obvious that, the ditch or drain thus formed being so much lower than the ordinary outlet of the springs, the pressure of water above that level, which is the bottom of the drain, must be such as to force that which is under the drain or trench through the holes made by the auger, and in many instances, until a considerable quantity of the

water is evacuated, make it rise to a greater height than the level of its natural outlet. The effect of which must be, that the water forming the spring, having found by these means a fresh and more easy passage, will quickly relinquish its former openings, and thus be prevented from running over and injuring the ground that previously lay lower down than it.

4241. *But in swamps or bogs that are extensive and very wet, other drains or cuts than such as convey off the springs must be made; as, notwithstanding the higher springs which chiefly cause the wetness may be intercepted, there may be lower veins of sand, gravel, or other porous materials, from which the water must likewise be drawn off.* In cases of this nature, where the land is to be divided into enclosures, the ditches may be formed in such directions as to pass through and carry off collections of water of this kind, as well as those that may be retained in the hollows and depressions on the surface of the land. There are in many places very extensive tracts of ground that are rendered wet, and become full of rushes and other coarse plants, from causes of such a nature as cannot be obviated by the making of either open or covered drains, however numerous they may be. Lands in this situation are frequently termed holms, and mostly lie on the sides of such rivers and brooks as, from the frequency of their changing and altering their courses between their opposite banks, leave depositions of sand, gravel, and other porous materials, by which land is formed, that readily admits the water to filtrate and pass through it to the level of the last-formed channels, and which preserves it constantly in such a state of moisture and wetness, as to render it productive of nothing but rushes and other aquatic plants; and if a pit or ditch be made in lands under these circumstances, it quickly fills with water to the same level as that in the watercourse. This effect is, however, more liable to be produced, as well as more complete, where the current of the water is slow, and its surface nearly equal with that of the land, than where its descent is rapid. Under such circumstances, while the river or brook remains at the ordinary height, no advantage can be gained, whatever number of drains be formed, or in whatever direction they may be made. The chief or only means of removing the wetness of land proceeding from this cause is, that of enlarging and sinking the bed of the stream, where it can be effected at a reasonable expense: where there is only one stream, and it is very winding or serpentine in its course, much may however be effected by cutting through the different points of land, and rendering the course more straight, and thereby less liable to obstruct the passage of the water. But in cases where there are more than one, that should always be made the channel of conveyance for draining the neighbouring land, which is the lowest in respect to situation, and the most open and straight in its course. It may likewise, in particular instances, be advantageous to stop up and divert the waters of the others into such main channels, as by such means alone they may often be rendered deeper, and more free from obstruction: the materials removed from them may serve to embank and raise up the sides to a greater height, as while the water can rise higher than the outlets of the drains, and flow backwards into them, it must render the land as wet as it was before they were formed, and the expense of cutting them to be thrown away.

4242. *The collected rain-water, becoming stagnant on a retentive body of clay, or some other impervious material, as it can have no outlet of the natural kind, causes such lands to become soft and spongy, thus forming bogs of a very confined kind. As such bogs are often situated very greatly below the ground that surrounds them, the opening of a main drain, or conductor, to convey off the water collected by smaller drains, would be attended, in many instances, with an expense greater than could be compensated by the land after it had been drained. The thickness of the impervious stratum that retains and keeps up the water in such cases is often so great, that though the stratum below be of a porous and open nature, such as sand, rock, or gravel, the water cannot of itself penetrate or find a passage from the one into the other; consequently, by its continued stagnation above, all the different coarse vegetable productions that have for a great length of time been produced on its surface, and probably the upper part of the soil itself, are formed into a mass or body of peat earth, equal in softness to that of any bog originating from water confined below, and less productive, and which is only capable of sustaining the weight of cattle in very dry seasons, when the wind and sun have exhaled and dried up a great part of its surface moisture; but even then it is incapable of admitting the plough upon it.*

- 4243. *As these kinds of bogs differ materially in their origin from those which have been already noticed, their drainage must of course be accomplished in a different way. The following method of proceeding is recommended as perhaps the least expensive:—In the middle, or most depending part of the ground, the first drain (fig. 629. a), may be cut, into which all the others should be made to lead; the number and direction of which must be regulated by the extent of the bog. They should be cut through the peat, or moist spongy upper soil, to the surface of the clay, or other retentive stratum of materials, which must then be perforated or bored through in order to let the water down into the pervious stratum below, by which it may be absorbed and taken up. The same effect might be produced by digging one large well, or pit, in the middle or lowest part of the bog, through into the porous stratum below, and connecting the other drains with it, as by such a method the trouble and expense of boring along the drains would*

be saved. In these cases, when drains are made, they should always be cut as narrow as it is possible to make them, and, after the holes have been formed in them by boring, filled up with loose stones to within about a foot and a half of the surface, which space may be made up by a portion of the earth that had been taken out, putting in turf with the green side to the stones before the earth is thrown in. By this means the water and prejudicial moisture of the peat, or upper soil, may be taken away by the drains, and pass off through the holes that have been formed in their bottoms. But where pits are employed, these should only be filled with small stones to the level of the bottom of the drain, the filling being performed as soon as possible after they are formed. (*Anderson's Treatise on Draining*, p. 88.) Where there is a chalky stratum below, after taking it out, the flints contained in it may be made use of in this way with much advantage; and where the drains can be carried into quarries, where the stone is much fissured nothing more will be necessary. Where land of this sort is afterwards to be ploughed, great attention should be given to the forming of the ridges and giving them a regular descent towards the main drain, which will contribute greatly to the assistance of the others in conveying off heavy falls of rain-water when they occur.

4244. But a necessary precaution previously to any attempt to drain lands of this kind in the way that has been described, is to ascertain whether the porous stratum under the clay be dry, and capable of receiving the water when let down into it; or already

so loaded with moisture itself, as, instead of receiving more from above, to force up a large quantity to the surface, and thus increase the evil it was intended to remove. This may be the case in many instances, and the substratum contain water which affords no appearances of wetness on the surface, at the place on account of the compact body of clay that is placed over it, but which, from its being connected with some spring that is higher, may flow up when an opening or passage is given it, either by means of a pit or the auger. In this way a greater quantity of water might be brought to the surface, which, from its being confined by the surrounding banks, would render the ground much more wet than before, and in particular situations produce very great degrees of wetness. When the surrounding high ground declines lower than the bog, though it may be at a considerable distance, by the aid of the level, and the appearance of the surface, the nature of the stratum underneath may, in some degree, be ascertained; and, notwithstanding it may already contain water, a drain may be formed into it to carry off that water, and what may likewise be let down into it from the retentive stratum that lies above it. It must be confessed, however, that cases where surface water can be let down through a retentive stratum to a porous one that will actually carry it off, are very rare. When these occur, it is chiefly in limestone or coal districts, where the surface is hilly or rugged (*fig. 630.*), and more calculated for

the pursuits of the mineralogist than those of the agricultor.

SECT. III. *Draining Hilly Lands.*

4245. *Draining hilly lands* is not in general attended with great expense, as the drains need seldom be covered or filled up, only in such places as may be sufficient for passages for the animals to cross by: and though, where the depth of the trench does not come to the water confined below, it may be necessary to perforate lower, there need not be any fear that the holes will fill up, even where the drain is left open; as the impetuosity of the water itself will remove any sand or mud that may fall into them, where much flood or surface water does not get in. Small openings may, however, be made along the upper side of the trench, in order the more effectually to secure them against any obstructions; and in these the perforations may be made, leaving the mouth of the holes about six inches higher than the bottom of the drain, which will be without the reach of the water that may be collected during the time of heavy rains.

4246. One of the greatest improvements of the hilly sheep-pastures of Holland has been effected by drainage, while the expense is comparatively small. The depth and width of the small ones are only those of the spade. They are usually carried across the face of the hills in a slightly inclined direction, so as to avoid the injury of too rapid a descent after heavy rains; and these small cuts open into a few larger, formed with due regard to the same principle; the whole at last, for an extent of several hundred acres, being led into one still larger, which discharges itself into the nearest rivulet. Improvements of this kind are, perhaps, of greater benefit to the individual proprietors of land who undertake them than any other.

4247. The sides or declivities of many hills, from the irregularity of the disposition of the strata that compose them, are often covered with alternate portions or patches of wet and dry ground. By the general appearance of the surface and the vegetable products that are grown upon it, the nature and direction of the internal strata may frequently be ascertained with so much certainty as to determine the line or direction of a drain without the necessity of examining below the surface of the land. As the ease or difficulty

of draining such grounds depends solely on the position of the different strata of which the hill or elevation may be formed, and upon the erect or slanting direction of the rock, or other retentive body in which the water is contained; where the rock has a slanting or horizontal inclination, the whole of the different springs or outlets, that show themselves on the surface, may originate from or be connected with the same collection or body of water, and may be all drained and dried up by cutting off, or letting out, the main body of water, by which they are supplied, at the inferior part of the reservoir, or that part where the water would of its own accord readily run off if it were not confined beneath an impervious covering of clay or some other material.

4248. *But in cases where the rock lies in an erect or perpendicular form, and contains only partial collections of water, in some of the more open cracks or fissures of the stone, which discharge themselves at various openings or outlets that have not the least connection with each other, it would be an idle and fruitless endeavour to attempt the cutting of them off by means of one drain (fig. 631. a), or by boring into any one of them in*

particular, without cutting a drain into each (a, b, c). In this case it is more advisable to make the main drain wholly in the clay, with small cuts made up to each outlet, than along the place where the springs burst out; as in that line of direction it would be

too much in the rock, and consequently be extremely difficult to cut, on account of the nature and disposition of the stone. When the water passing out on the line of the springs can be found by the auger in the main drain, at the point of junction, it will be the more completely cut off; but where this is not practicable, the depth of the small cuts may reduce it to such a level as will prevent its flowing over and injuring the surface of the land below it.

4249. *In such hills as are constituted of alternate strata of rock, sand, and clay, the surface of the last may frequently be wet and swamp, while that of the sand is dry, and capable of producing good crops of grass; in all such cases, in order to drain the land completely, as many cuts will be necessary as there may happen to be divisions of wet and dry soil. The summit, or most elevated part of such hills, being mostly formed of loose porous materials, the rain and other water descends through it till its passage becomes obstructed by some impervious bed or stratum, such as clay, when it is forced up to the surface, and runs or oozes over the obstructing stratum; after having overflowed the upper clay surface, it is immediately absorbed and taken up by the succeeding porous one, and, sinking into it in the same way as before, passes out again at the lower side, rendering the surface of the next clayey bed prejudicially wet, as it had done that of the first. In this way the same spring may affect all the other strata of the same kind, from the highest part down the whole of the declivity, and produce in the basin, or hollow at the bottom, a lake or bog, should there not happen to be a passage or opening to take away the water. In order effectually to drain hills of this kind, it will be most advisable to begin by forming a trench along the upper side of the uppermost rushy soil, by which means the highest spring may be cut off; but as the rain and other water that may come upon the next portion of porous soil may sink down through it to the lowest part, and produce another spring, a second cut must be made in that part, to prevent the water from affecting the surface of the succeeding clayey bed. Similar cuts must be formed so far down the declivity as the same springs continue in the same way to injure the land, and in some cases a sufficiency of water may probably be obtained to irrigate the land below, or for some other useful purpose.*

SECT. IV. *Methods of draining Mixed Soils.*

4250. *Where the soil is of a mixed and varied nature, but the most prevailing parts of the clayey kind, the business of draining is considerably more tedious and difficult than where the superficial and internal parts have greater regularity. In such lands, as the collections of water are completely separated by the intervening beds of clay, each becomes so much increased in the time of heavy rains, as to rise to the level of the surrounding surface; when the water, finding a free passage, as it would over the edges of a bowl, overflows and saturates the surface of that bed of clay, rendering it so wet and sour that its produce becomes annually more scanty, and the soil itself more sterile and unproductive.*

4251. *From the sand-beds (fig. 632. a, a, a) in such cases having no communication with each other, it must evidently require as many drains (b, b, b) as there are beds of this kind, in order fully to draw off the water from each of them. A drain or trench is therefore recommended to be cut from the nearest and lowest part of the field intended*

to be drained (c), up to the highest and most distant sand-bank (d), in such a line of direction as, if possible, to pass through some of the intermediate sand-beds, and prevent the labour and expense of making longer cuts on the sides, which would otherwise be requisite.

4252. Where the different beds of sand and clay are of less extent, and lie together with greater regularity, they can be drained in a more easy manner with less cutting, and of course at less expense. Below the layers or beds of sand and clay that lie, in this manner, alternately together, and nearly parallel to each other, is generally a body of impervious clay, which keeps up the water contained in the sand, which sand being constantly full, the adjacent clay is thereby rendered moist, and in wet seasons the water runs or trickles over it. As in these cases, the principal under-stratum of clay is rarely more than four or five feet below the surface, it is advisable to cut a drain (fig. 633. a)

to that depth through the middle of the field, if it have a descent from both sides; but if it decline all to one side, the drain must be made on that side (b), as the water will more readily discharge itself into it; and, unless the field be of great extent, and have more than one depression or hollow in it, one drain may be quite sufficient for the purpose, as by crossing the different beds that retain the water, it must take it off from each.

4253. A principal difficulty in draining ground of this nature, and which renders it impracticable by one drain, is when the direction of the alternate layers, or beds of clay and sand, lies across the declivity of the land (fig. 634. a, a), so that one drain can be of no other service than that of conveying away the water after it has passed over the different strata, and would naturally stagnate in the lowest part of the field, if there were no other passage for it.

Where the land lies in this way, which is frequently the case, it will therefore be necessary, besides the drain in the lowest part (b), to have others cut up from it in a slanting direction across the declivity (c, c), which, by crossing the different veins, or narrow strata of sand (d, d, d), may be capable of drawing the water from each of them.

4254. In forming the drains in these cases, it is recommended that, after laying the bottom in the manner of a sough, or in the way of a triangle, it be filled some way up with small stones, tough sods with the green side downwards being placed upon them before the mould is filled in. But where stones cannot be readily procured, faggots may be employed, the under part of the drain being laid, or coupled, with stones, so as to form a channel for the conveyance of the water that may sink through the faggots, and for the purpose of rendering them more durable; as, where the water cannot get freely off, which is generally the case where there is not an open passage made of some solid material, it must, by its stagnation, soon destroy the faggots, and choke up the drain.

4255. The estate of Spottiswoode in Berwickshire affords an interesting example of successful drainage of mixed soil and strata. It was begun in 1815, under the direction of Mr. Stephens, an eminent draining engineer, and author of a useful work on the subject (*The Practical Irrigator, &c.*, Edin. 8vo. 1829); and eighteen miles and a half of drains, some parts of which were thirteen feet deep, but the medium depth of which was from five to seven feet, had, in 1830, rendered between five and six hundred acres of land most valuable, which had been before of little value.

4256. The grounds to be drained at Spottiswoode "consisted of a soil of various depth, under which commonly lay a stratum of clay from two to three feet deep, then a thin bed of sandy or gravelly substance, of a foot deep, or more, containing water; after that another bed of clay, of two or more feet deep; and lastly, a bed of sand, gravel, or slaty rock, containing the larger quantity of water. Upon reaching the

lower of these porous strata, the water disappeared in the upper one : and hence generally the expediency of not stopping at the first, but of working down till the main stratum was reached. Several instances occurred where the strata lay too deep to be reached by a drain ; in which cases it was deemed necessary to sink wells or pits at certain distances along the line of the drain, from ten to eighteen feet deep, or more, in order to reach the open strata, so that the water, rising through the wells to the bottom of the drains, might be conveyed away without reaching the surface. It was never thought sufficient to have reached the first seam containing water, unless it were at the depth of four feet or more, and evidently appeared to be that containing the main body of water which occasioned the wetness of the surface." (*Trans. Highl. Soc.*)

4257. *The first operation in the process of draining* "was to ascertain the depth and nature of the strata in which the water was contained, and the overflowing of which, where no outlet existed, produced, as was before remarked, either springs or bursts of water, or a general oozing. Along the line of these springs, or in the upper part of the wet ground, pits were sunk in various places. The place of each being marked out, a man was sent to dig each pit, breaking the ground nearly in the direction of the intended drain, six feet long and three feet wide, which is sufficient space to allow a man, or sometimes two, to work freely. The earth was then thrown to the lowest side, and well off from the pit, to prevent the sides from breaking in : these pits were made to the depth of five or six feet, or to a greater depth if necessary, according to the nature of the ground, or until the bed of sand, gravel, or rock, which contained the water, was reached. Sometimes it became necessary, after having gone as deep as a man could work, and when no water appeared, to bore down with boring-rods, in order to ascertain at what depth the stratum containing the water lay. In some instances, where the surface was wet from a general oozing, and no regular spring appeared, it became necessary to go down to the depth of thirteen feet, when, in breaking through a thin cake of freestone, not above an inch in thickness, the water burst up, and filled the pit to the brim in the following morning. This species of examination prevents the working at random in laying out the lines of drains, affords data for judging of the depth and dimensions to which they should be formed ; and, by giving a knowledge of the substances to be dug through, enables one to enter into contracts with the workmen with greater certainty." (*Trans. Highl. Soc.*)

4258. *A general idea being thus obtained of the ground to be drained*, and men employed to sink the pits, the next operation is to mark out these lines on the ground. In doing this, a hand sketch (fig. 635.)

indicating the direction of the drains and their depth will be found useful. "On the ground, the lines may be marked in various ways. When the land is in grass, a plough may be made to follow the director, as he walks deliberately along his intended line, a man leading the horses by the head, if necessary, and walking between them. If it is inconvenient to use a plough, the lines may be marked by pins, or small pits, a spade's breadth square, made at convenient distances, by cutting out a turf clean by four cuts of a spade, and laying it upside down at the side of the hole, in the line of the drain." The drains were next dug out, and formed; some of them three feet wide at the top, six feet deep, and two feet wide at bottom, and others of different widths and depths, but generally in the same proportion. The following are Mr. Stephens's directions for building :—

4259. *The side walls of the drain*, supposing it to be six feet deep, and two feet wide at bottom, "must be well built with dry stone, all laid on the proper bed (and not set up edgeways), nine inches thick by six inches high, forming an aperture of six inches square, the covers for which must be sufficiently strong to sustain the pressure of the incumbent weight of stone and earth ; and should project, at least, three inches over the inside of each side wall, — two feet of stone must be well packed above the cover of the aperture. The first foot of stone above the cover of the aperture may be put into the drains from three to four pounds weight, the upper part must be broken as small as common road-metal, and should be made quite smooth or level, so that every part of the drains may have an equal depth or thickness of stone. A thin covering of straw should be laid on the top of the broken stones, to prevent the loose earth from falling through the aperture of the drains. The drains may be then filled with earth, nine inches above the natural level of the surface of the ground. Wells must be sunk along the lowest side of the lines of drains, in every place where the above mentioned depth of six feet does not reach the porous bed that contains water. These wells may be made from five to six feet square, or sufficiently wide to allow a person to work with freedom ; and must be sunk through the impervious strata into the pervious stratum of sand, gravel, or rock, where the water flows freely. The wells may then be filled with small clean stones, thrown in promiscuously, till the stones in the wells come in contact with the stones in the drains. The upper part of the wells above the level of the stones in the drains may be filled with earth." (*fig. 636.*) (*Trans. Highl. Soc. vol. vii. p. 222.*)

4260. *The stones of which the drains at the bottom of the conduit are to be built*, and with which the drain is afterwards to be filled to the depth of two feet or more, as is shown above, should be laid down on the upper side of the line, as near to it as possible, that they may be the more easily handed in. They are laid on the upper side, for the convenience of throwing out the earth on the lower side. It is very desirable that the stones should be, if possible, laid down before the drain is begun to be dug, as it is often necessary to build and fill it as fast as it is dug, to prevent the sides from falling in, which, when it occurs, occasions a very great deal of extra work, and the drains themselves are never so well constructed. This most frequently happens in ground under tillage, the sides being more tender than when in grass, where the turf is the means of preserving the sides from the pressure of the earth thrown out, and of the stones laid down. When the sides are evidently likely to fall in before the drain can be built, they may be kept up for a time by a board laid flat to each side of the drain near the top, and cross sticks put in to keep the boards asunder. Circumstances frequently occur, which prevent the stones from being laid down beforehand, and they are then brought forward as the work of cutting the drain is going on. Under the eye of an intelligent and attentive director, this may be done without danger ; but, even then, unforeseen occurrences sometimes prevent the possibility of getting the materials forward for several days ; and if any rainy weather intervene, and the drains are in a clayey soil, there is a certainty of slips and falls, occasioning much extra labour, and requiring, in consequence of the additional breadth of the drain, a much larger quantity of stones to fill the opening. Where a piece of drain seems likely to fall in, it should always, if possible, be built and filled before night, or the sides kept asunder by means of boards, as before mentioned." (*Trans. Highl. Soc. vol. vii.*)

4261. *Drains may be dug*, and, when built, the earth may be filled in by contract work ; but in general day work is to be preferred. "The conduit is built in the bottom of the drain by a confidential person, either a mason, or any other workman

who, by practice, is equally competent; this person always working at daily wages, to prevent him from having any interest in hurrying over this most important part of the operation."

4262. *The drains may be cut* only "two feet wide, with the sides perfectly perpendicular, provided that, from the tenacity or hardness of the substances dug through, the sides will stand till the stones are put in. It is usual, however, to break the ground somewhat wider at the top, and so to give it a slight slope to the bottom. The work of cutting is always done by contract at so much per rood or yard, and several labourers generally join in making one drain, and arrange the work among themselves. The casting or cutting, it is scarcely necessary to observe, is always commenced by the workmen at the lower end, and worked upwards to the higher ground, and never downwards. They usually begin by working about two feet deep in the first instance, several roods in length, then going over the ground again, deepening it to four or five feet, and afterwards going over it the last time, and finishing the bottom, by making it perfectly level and ready for the mason to build the conduit in the bottom. The bottom must, for this purpose, be completely two feet wide, though, when free-stone is employed, the width may be less." (*Trans. Highl. Soc.*)

4263. *In building the drain*, "the mason has an assistant, generally a female, at the top, who hands him the stones he requires. He begins with small flat stones to build the wall on each side of the bottom of the drain, nine inches broad, and six inches high, so as to leave six inches for the conduit in the middle. This he does roughly, but in such a manner that the stones shall be laid solidly on one another. When the ground at the bottom is solid, either dry gravel, or clay, or rock, the mason's foot, with his ordinary clog or shoe, standing in the centre, is the measure of the width of the conduit. When the land is inclined to be wet and soft, a plank six inches broad is used for him to stand upon. When the bottom is a wet spongy clay, or sand of the nature of a quicksand, or very soft, it is often necessary to flag the bottom of the conduit with very thin stones or slates." (*Trans. Highl. Soc. vol. vii.*)

4264. *When a perfect quagmire has been met with*, "which has happened chiefly in red clay, the faster the wet clay has been thrown out, the faster it has boiled up from below. In these cases, it has been found necessary to lay planks on the bottom of the drain, and build upon them. But this will very seldom be necessary where proper precautions are used. On first meeting with quagmires of this kind, attempts were made to dig them out; for which purpose a strong wooden frame was made, large enough for four men to work in with freedom, composed of different pieces, so that the workmen might add to the sides of the frame as they worked downwards. Notwithstanding the frame's being made very strong, the pressure became so great, that the sides came together, and stopped the operation. The consequence was, that, after great labour and active exertion in taking out large quantities of wet clay, which thus continued to boil up (but the very taking out of which undermined the banks from beneath), the sides of the drain fell in masses, and made great gaps, which increased the longer the work was carried on. In these circumstances, it became necessary to use planks to build the conduit, and to fill in the stones as fast as possible, by employing a great number of persons at once. The weight of these superincumbent stones then kept the planks and conduit at their proper place, so much so that the worst of these parts never exhibited any symptom of imperfection, though made ten years ago. On all occasions afterwards, however, when any of these quagmires were found, the process of taking out the bottom of the drain was followed, yard by yard, by flagging the bottom, building the conduit, covering it, and filling the stones over it; and in this way the quagmire was prevented, by the immediate pressure from above, from boiling up. It never failed to be seen that the longer these operations were delayed, the softer and more intractable the interior of the drain became. After building the side walls for a yard or two in length, the mason, according to circumstances, cleans out the conduit with a narrow hoe, and then covers it with such large broad stones as he can procure, from fifteen inches in length to two feet, being the utmost width of the drain itself. These are handed down carefully to him by his attendant; and, after he has laid three or four of them, he takes smaller flat stones, as the larger are always uneven at the edges, and covers every interstice; and afterwards, with similar stones, packs carefully the ends of the covers, before finishing any particular portion of the work so as to prevent them from shifting; and still further to cover every hole through which any thing might be carried into the conduit, he has a rolled up wisp of straw which he puts in the mouth of the conduit, which allows the water to pass out, but prevents mud and sand from getting in. His attendant then throws the remainder of the stones in promiscuously to the depth of two feet, or sometimes more, if the materials are plentiful, and particularly where there are two seams con-

637

taining water; for in this case it is generally desirable to raise the stones above the level of the bottom of the upper seam, so as to convey away any water which may remain in it, to the conduit beneath (fig. 637. *a*, sand or gravel; *b*, clay); and it was a circumstance very generally observed in the course of operations, that where the upper stratum containing water was only a few feet in depth or thickness, another open stratum was generally found a few feet deeper.

4265. *Stones.* When the stones to be used are only brought forward at the time of cutting the drain, the carts are often run back to the edge of it, and the stones, after the conduit is built, tumbled straight out of the cart into the drain; but, in this case, it is necessary to take care that the sides of the drain be not injured by the cart-wheels or otherwise, lest the earth should fall into the drains, and so through the intervals of the stones. A part of the stones for filling were recommended by Mr. Stephens to be broken like large road metal. This, however, is very expensive, and was found by experience not to be necessary, though usually large stones should be broken. When the stones are small, that is, ten or twelve ounces, it is as well; but no inconvenience has been found from the constant use of stones of a much larger and very unequal size. When a sufficient quantity of stones has been thrown in, the mason levels them at the top, filling up the intervals of larger stones with smaller ones, so as to make the top of them level. If the sod which has been cut off the surface of the drain is sufficiently solid, it should be laid carefully by itself on the upper edge of the drain at the side of the stones. It should again be laid with its grassy side undermost, on the top of the stones, as a covering, to prevent the earth from getting down amongst them. If the sods are not sufficiently coherent or plentiful to cover the whole completely, old coarse hay, or straw, or heath, may be used as a substitute. When all this is completely done, the earth is shovelled in upon the top, until the drain is full. It is then heaped up, somewhat after the manner of a grave, to allow for the earth's subsiding to the level of the surface. It is a circumstance deserving of notice, that, in digging the trial-pits, the earth taken out is in most cases insufficient to fill them again, if allowed to lie open for any time; so that, in fact, contrary to what would be naturally inferred, the earth must become more compact by being removed.

4266. *Repairs.* When the drain is thus completed, it is still necessary, and particularly when the land is under tillage, carefully to inspect it from time to time, and to see that no surface-water finds its way into it. If any hole is found, it ought to be immediately stopped up, as a channel of this kind will sometimes very speedily carry enough of mud into a conduit to choke it entirely, and spoil the drain. Under-draining, it will be kept in mind, will not supersede the necessity of surface-drains, where these are necessary to carry off water stagnant upon the ground. Besides the danger to drains by the flowing in of surface-water, there are other sources of injury which must be guarded against by a vigilant care. Animals, by burrowing in the earth, or finding their way from any course in the conduit, are sometimes apt to injure it, and cause the earth to crumble in; but a more frequent source of injury is from vegetable substances, as roots of trees, and particularly of the ash. As an instance of this, there happened, on this property, to be an ash tree growing near a drain, the fibres of which took possession of the conduit, and so obstructed the passage of the water, as to produce a new swamp, in consequence of which it became necessary to lift the materials of the drain, and form it anew. It is often very difficult to eradicate certain plants, whose long and creeping roots get intervened in the interstices of the conduit. The advance of those larger animals which enter the conduits for safety, or in pursuit of prey, may be prevented by an iron grating at the outlet. (*Trans. Highl. Soc.* vol. vii.)

SECT. V. *Methods of draining Retentive Soils.*

4267. *The mode of draining retentive soils* is materially different from that which has been described above. Many tracts of level land are injured by the stagnation of a superabundant quantity of water in the upper parts of the surface materials, which does not rise up into them from any reservoirs or springs below. The removal of the wetness in these cases may, for the most part, be effected without any very heavy expense. From the upper or surface soil, in such cases, being constituted of a loose porous stratum of materials, to the depth of from two to four or five feet, and having a stiff retentive body of clay underneath it, any water that may come upon the surface, from heavy rains, or other causes, readily filtrates and sinks down through it, until it reaches the obstruct-

ing body of clay; the consequence of which is, that the porous open soil above is so filled and saturated with water, as to be of little utility for producing crops of either grain or grass. Land thus situated is frequently said by farmers to be wet-bottomed. In order to remove this kind of wetness, it seldom requires more than a few drains, made according to the situation and extent of the field, of such a depth as to pass a few inches into the clay, between which and the under surface of the porous earth above there will obviously be the greatest stagnation, and consequently the largest collection of water, especially where it does not become much visible on the surface. In these cases there is no necessity for having recourse to the boring instrument, as there is no water to be discharged from below.

4268. *When the field to be drained has only a slight declination, or slope, from the sides towards the middle, one drain cut through the porous superficial materials into the clay, in the lowest part of the ground (fig. 638. a), may be sufficient to bring off the whole of the water detained in the porous soil. This effect may likewise be greatly promoted, by laying out and forming the ridges so as to accord with the direction of the land, and by the use of the plough or spade in removing obstructions, and deepening the furrows. In such*

638

situations, where the drain has been formed in this manner, the water will flow into it through the porous surface materials, as well as if a number of small trenches were cut from it to each side, as is the practice in Essex and some other parts of the country; but which is often an unnecessary labour and expense. The drain made in the hollow may frequently serve as a division of the field (a), in which case it may be open;

but in other circumstances it may be more proper to have it covered.

4269. *Where a field of this description has more than one hollow in its surface (fig. 639. a, b), it will obviously be requisite to have more than one main drain; but when it is nearly level, or only inclines slightly to one side, a trench or drain along the lowest part, and*

639

the ridges and furrows formed accordingly, may be sufficient for effecting its drainage. There may, however, be cases, as where a field is large and very flat, in which some side-cuts from the principal drain may be necessary, which must be made a little into the clay, and as narrow as they can be wrought, and then filled up with stones or other suitable materials.

4270. *What is called the Essex method of draining in ploughed springy lands, where the surface soil is tenacious, is described by Kent, and consists in substituting small under-drains (fig. 640. a) for open furrows; or in some cases having a small under-drain beneath*

640

(b) every other or every third furrow. These drains lead to side or fence ditches (c), where they discharge themselves.

4271. *Where the clay constitutes the surface, and the porous body is underneath, the injurious stagnant water cannot possibly get off, without the assistance of drains formed for the purpose. Soils of this nature are drained with difficulty, and require a much greater number of trenches or cuts than those of any other kind, as they must be marked out and disposed in such a way as to collect and convey the water every where from the surface; because it can only force itself off into them from above, being prevented from*

sinking in through the clay, as in soils of a contrary kind. Where there happen to be hollows or irregularities in the surface of the land, water may often be observed to continue standing in them, at a distance of but a few feet from the drain. In draining such lands, it will always be necessary, in the first place, to make a large or conducting drain at the lowest part, or the end of the field, for the purpose of receiving and conveying away the water collected by the smaller collateral cuts which it may be necessary to make on each side of it. Where it suits for the purpose of dividing the land, this principal drain may be better open than covered, as by that means the mouths or outlets of the different small drains that come into it may be conveniently examined, and cleared out when necessary.

4272. *The construction of the ridges in such soils, so that they may accord with the declivity, is a matter which must be carefully kept in view. They should in all such cases have a degree of elevation or roundness in the middle, sufficient to afford the water a ready fall into the furrows, which likewise should have such a depth and fall as may take it quickly into the drains. The ridges, besides being well laid up, should have small open drains formed in a slanting direction across them, in such a manner as to form communications with one another, and with the furrows; by which means they are made to perform the office of drains; the water coming upon the ridges being thus readily conveyed into the furrows, along which it proceeds till impeded in its course by the rising of the ground or other cause; it then passes through the open cross-drains into others where the descent is greater, and is ultimately conveyed off into the ditch, or other passage, at the bottom of the enclosure. The elevation of the ridges should probably, too, be made greater for the winter than the summer crops, as there must be much more injurious moisture at the former than the latter season. This may be easily accomplished at the time of ploughing the land. Some useful observations on this description of drainage will be found in Marshal's work on *Landed Property*, and in Dr. Anderson's *Treatise on Draining*.*

SECT. VI. *Methods of draining Mines, Quarries, Pits, Ponds, and Lakes.*

4273. *Where pits, mines, or quarries, happen to be formed at the bottom of declivities, and are inconvenienced or wholly obstructed, either in the digging or working, by the water contained in them, it may be possible, in many cases, to prevent its coming into such mines or pits, by cutting or boring into the lower parts of the porous strata (fig. 641. a). In order to accomplish this object, it will be necessary to ascertain if any*

porous stratum presents itself higher up the elevation than the place where the mine or pit is formed, that may conduct the water it contains to the porous body below it; as by cutting into such stratum, where discovered, much of the water may be drawn off and prevented from passing down. But notwithstanding the water from above may be cut off in this way, a quantity sufficient to inconvenience the working of the mine or pit may still filtrate from the sides of the porous bed, even though it may incline in the direction of the lower ground. When this is the case, it may, however, be readily taken away at some place in the bed. To accomplish this, and thereby obviate the effects of the water, the termination of the porous stratum (fig. 641. a) below the pit must be ascertained; and where there is any mark of a natural outlet at the place, a large drain should be formed, in order to permit the water to flow off with more expedition. Where, however, there is a thick bed of some impervious substance, such as clay, placed upon

the termination of the porous material, the drain need only be cut a little way into that, as by boring through the rest a sufficient passage may be given to discharge the water. In this way, the draining of such grounds as lie above or near to mines or pits may be of great advantage.

4274. *Where a quarry or other pit to be dried (fig. 642. a) is situated above a porous stratum, whether*

of rock or gravel, it may sometimes be drained by boring into the latter (b). In this way different chalk pits and lime quarries have been

drained in Kent and Hertfordshire. (See the Reports of these Counties.) In marl-pits also, which, from the nature of their situation, mostly require much cutting through some part of their sides, in order to remove the water that prevents their being wrought, the mode of letting the water down by means of pits dug through the upholding stratum below the bed of marl into the porous materials underneath, might be economically practised. In such cases, the number of the pits must be proportioned to the space occupied by the marl; and when they are required to be of such depths as to be liable to give way, they should be built up, or nearly filled with loose stones, so as to admit the water to pass off, such lateral drains as are necessary communicating with them. In some situations of the pits, as where the bank slopes lower on the contrary side than the level of the water, an easier mode may be practised; such as by forming a drain in it, and then perforating with a horizontal boring-instrument into the terminating part of the stratum that holds the water; thereby removing and keeping it below the level of the marl. In addition to these, in some cases, as where the water of such pits proceeds from springs in the high grounds above them, it may be useful to intercept and convey it away before it reaches the marl-pits.

4275. *The drainage or drying up of lakes or ponds comes occasionally within the practice of the drainer, especially in countries with an irregular surface. There are, perhaps, few natural lakes indeed, the surface of the water of which might not be very considerably lowered, by deepening their natural outlets, the consequence of which would be, in many cases, a very considerable accession of generally rich land round their margins, a better drainage for the surrounding country, and an improved climate. Much, it is said, might be done in this way in Ireland; but there can be no doubt that in every country in the world a great deal may be done. In flat countries nearly on a level with the sea, like Holland and parts of the counties of Cambridge and Huntingdon, the water will in general require to be raised by machinery; but in by far the greater number of cases, deepening the natural outlet will be found amply sufficient.*

4276. *Bar Loch, in the county of Renfrew, was reduced in size by drainage and embanking, in 1814, at an expense of nearly 10,000*l.*, which has since returned 13 per cent. per annum; 250 acres have been laid dry upwards of 200 of which have been since under crop. A very interesting account of this drainage will be found in the Highland Society's Transactions, vol. vii. p. 375.*

4277. *Steam-engines have lately been employed, both in Cambridgeshire and Lincolnshire, as substitutes for the very uncertain power of wind, to raise the water from the low lands, and deliver it into the drains and rivers by means of scoop wheels working like a grinding-stone in its trough. Wheat and other corns have thus been sown on lands never before ploughed. The improvement indeed is one of the greatest that has taken place in fenny countries, since they were first attempted to be drained and embanked. (Mech. Mag. vol. v. p. 179. and Gard. Mag. vols. iv. and v.)*

SECT. VII. Formation of Drains, and Materials used in filling them.

4278. *Drains should be formed with as much truth and exactness as possible: such labourers as are not dexterous in using their tools seldom make them well. The most general method of performing this sort of work is by admeasurement, at so much a rod, or a score of rods, which necessarily induces the workmen to do as much as they possibly can: they should, therefore, be frequently inspected, to see that they keep to the proper and required depth, that the earth taken out be laid in such a manner as not to fall down again into the drains in time of filling them, and that the surface mould be kept on one side free from the clayey or other material of the inferior stratum.*

4279. *When there is any declivity in the ground, drains should be made in a slanting direction across it, instead of the old method of conducting them according to the nature or inclination of the slope. By attending to the former mode of cutting the drains, the wetness is not only more effectually removed, but, by allowing the water to pass away in an easy current, they are rendered less liable to be choked, or, as it is frequently termed, blown up, by which artificial ooziings of water are sometimes formed in such places. But where grounds are either quite or nearly level, it has long been a general practice to cut the drains at the different distances of about sixteen, twenty-four, and*

thirty-two feet from each other, across the fields from the different ditches, according to the circumstances of the lands; or, indeed, where the drains, either from some slight unevenness of the surface, or other causes, can only be made to flow at one end, to avoid cutting them further on one side than where the ditch is capable of taking away the wetness. In cases where the declivities of a piece of ground are various, and have different inclinations, the drainer should constantly attend to them, and direct the lines of his drains in such a manner as that they may cross the higher sides of the different declivities in a slanting direction.

4280. *The depth of drains* must depend upon the nature of the soils, the positions of the land, and a great variety of other more trifling circumstances. It was formerly the custom to make them three or four feet in depth, but by modern drainers the most general depth is two and a half to three feet. As the main drains have more water to convey away, and are generally of greater length than the lateral ones, they should always be cut somewhat deeper; and where the materials of the soils are porous, the deeper they are cut, the more extensively they act in lowering the wetness of the land: when, however, the operator reaches any material through which the moisture cannot pass, it will be useless to dig the trench to a greater depth. If it be clay, by going a few inches into it, a more safe passage for the moisture may however be secured. It must notwithstanding be invariably attended to, that the depth of the drains be such as that the treading of heavy cattle may not displace, or in any way injure, the materials employed in constructing or filling them. It may be noticed too, where the horses in ploughing tread in the bottom of the furrow, at the depth of four inches or more below the surface, that, if eight or ten be allowed for the materials with which the drains are filled, when the depth of the trenches does not exceed twenty-four inches, there will only be nine or ten inches of earth for the support of the horses when ploughing. Where the earth has been stirred, such a depth must undoubtedly be too little, and this in some measure proves that drains of such a depth are not sufficient. By cutting them down to the depth of two feet and a half in the stiffer soils, they will seldom be penetrated to, or have too great a depth; and in the pervious ones a still greater depth is highly useful, and constantly to be practised.

4281. *Cutting the drains as narrow as possible*, which has of late been much practised, is of importance, as it causes a considerable saving of the matters employed in filling them up, whether wood or straw; but in cases where bricks or stones are used, this cannot be so much attended to; however, a greater width than about a foot is seldom necessary, provided the stones be coupled at the bottom, or thrown in in a mixed way; nor more than sixteen inches where laid in the manner of a sough or channel. But of whatever depth the materials may be, the earth or mould by which they are covered up should not be less in depth than a foot; in arable lands it should be more.

4282. *The different sorts of drains in use* may be classed in two divisions; drains of conveyance (fig. 643. a, b,) alone, and drains of conveyance and collection jointly. (fig.

643. c, d.) In the former, all that is necessary is a channel or passage for the water, of sufficient dimensions, which may be formed by pipes of different kinds, arched or barrel drains (b), and box or walled drains (a). The construction of the latter requires not only an opening for conveying the water, but a superincumbent or surrounding stratum (e, f,) of sufficient porosity to permit and induce all latent water to find its way to the channel of conveyance. The most complete drain of conveyance is a large pipe of metal, masonry, or brick-work; and the most complete collecting drain, one formed of a channel built on the sides, and covered with flat stones, with diminishing to the size of gravel as they rise to the surface, and there covered with the common soil. As the best constructions, however, are not always practicable, the following are a few of the leading sorts adapted for different situations.

a superstratum of round stones or splinters,

4283. *For drains of conveyance*, there are the walled or box drain (fig. 643. a), the barrel drain (b), the walled or the triangular drain (c), and arched drain. (fig. 644.)

4284. *Drains of collection* are formed of stone, brick, gravel, cinders, wood, spray, straw, turf, and earth alone.

4285. *The boxed and rubble drain* (fig. 644.) has been already described as a drain of conveyance and col-

lection. The common rubble drain is formed of rough land-stones of any sort, broken so as not to exceed two or three inches in diameter. No good drainer uses stones six or eight inches in diameter in any part of a rubble drain, least of all at the bottom. The point kept in view is to use such small stones at the bottom as may allow the water a great many channels; so that, if a few should become impermeable, there should be many others remaining. The nearer the

4287. On the Marquis of Stafford's estate, "an allowance of draining tiles is made, wherever the exertions of the tenants seem to merit such a reward. In order to secure the drains being properly filled up with stones above the tiles, the tenant is obliged to drive a sufficient quantity of stones or cinders from the furnaces, and lay them on the ground, previously to an order being made for the delivery of the tiles. Without attending to this important circumstance, much draining would be thrown away. The park at Trentham is a complete illustration of this remark. The draining of this spot was conducted under the direction of Elkington. The wetness with which these lands are affected does not arise from any line of springs bursting out from the upper grounds, to which that gentleman's system of deep drains could be applied; but is occasioned almost entirely by the retentive nature of the subsoil, and by its being intermixed with small basins of sand, which lie detached and unconnected with each other, in the bed of clay. To cure this species of wetness, a number of small drains, well filled up, with one cut into each of these beds of sand, is necessary. In pursuance of this plan, a great part of the park at Trentham has been lately drained over again, by making a number of small shallow drains, about fifteen feet asunder, in some instances above the old ones, taking particular care to fill them up as well as possible, and not to permit any clay to be laid over the stones. This has proved effectual." (Loch.)

4288. The gravel or cinder drain is seldom made deep, though, if the materials be large, they may be made of any size. In general they are used in grass lands; the section of the drain being an acute-angled triangle, and the materials being filled in, the smallest uppermost, nearly to the ground's surface.

4289. The wood drain is of various kinds. A very sufficient and durable construction consists of poles or young fir-trees stripped of their branches and laid in the bottom of the drain lengthways. They are then covered with the branches and spray. Another form is that of filling the drain with faggot-wood with some straw over. A variety of this mode (fig. 648.) is formed by first setting in cross stakes to prevent the faggots from sinking; but they are of no great use, and often occasion such drains to fail sooner than common faggot drains, by the greater vacuity they leave after the wood is rotten. In some varieties of this drain the brushwood is first laid down alongside the drain, and formed by willow or other ties into an endless cable of ten or twelve inches in diameter, and then rolled in; which is said to form an excellent drain with the least quantity of materials, and to last a longer time than any of the modes above mentioned. Some cut the brushwood into lengths of three or four feet, and place them in a sloping direction with the root end of the branch in the bottom of the drain; others throw in the branches at random, with little preparation, and cover them with spray, straw, or rushes, and finally the surface soil.

4290. The spray drain is generally, like the gravel drain, of small size, and formed, like it, with an acute-angled bottom. In general, the spray is trod firmly in; though in some cases it is previously formed into a cable, as in the brush-wood drain. Drains of this sort are much in use in grass lands, and when the spray of larch wood,

heath, or ling can be got, they are of great durability.

4291. The straw drain, when reeds, rushes, and bean straw are used, is sometimes made like the spray drain, by pressing the loose material down, or forming a cable; but in general the straw is twisted into ropes as big as a man's leg, by the aid of a machine (2562.), and three or more of these (fig. 649, a) laid in the bottom of a triangular drain, with or without the protection of three turves (b). Where some sorts of moss, as Sphagnum or Lycopodium, can be got, these drains are of unknown durability. Drains formed in this manner, through tough and retentive clays, will be found, in a short time after the work is finished, to have formed over the straw with which the drain was filled, an arch of sufficient strength to support the incumbent weight of the soil and the casual traffic of the field. In twelve or

eighteen months it may be observed that the straw, being of one uniform substance, is all rotted and carried away, leaving a clear pipe through the land in every drain. The passage of the water into these drains

may be much facilitated by a due attention to filling them with the most friable and porous parts of the surface the field may afford.

any convenient depth, but it must be at least the breadth of a turf at bottom. The drain being dug out as if it were to be filled with stones or any ordinary material; the operator next, with a spade three inches wide, digs a narrow channel along its centre (a), clearing it out with the draining scoop; and over this the turves (b) are laid without any other preparation, or any thing put over them but the earth that was excavated. This is found to be a very cheap, and, considering the materials, a surprisingly durable method of draining; answering, in pasture-fields especially, all the purposes that the farmer can expect to derive from drains constructed with more labour, and at a much greater expense. They are said to last frequently twenty years and upwards: but the period which it can be supposed they will continue to prove effectual, must depend on the nature of the soil and the current of water.

The drain is then cut to the depth required, but is contracted to a very narrow bottom. The sods are

then set in with the grass side downwards, and pressed as far as they will go. As the figure of the drain does not suffer them to go to the bottom, a cavity is left which serves as a watercourse; and the space above is filled with the earth thrown out. The work is performed by means of three spades of different sizes. The first may be a common spade of moderate breadth, with which the surface clay may be taken off to the depth of eight or ten inches, or not quite so much, if the clay be very strong. The breadth of the drain, at top, may be from a foot to fifteen inches; but it never should be less than a foot, as it is an advantage that the sides should have a considerable slope; and the two sides should slope as equally as possible. Another workman follows the first, with a spade six inches broad at the top, and becoming narrower towards the point, where it should not exceed four inches. (fig. 653. a.) The length of the plate of this second spade should be fourteen inches, and with it a foot or fourteen inches in depth can easily be gained. A third workman, and he should be the most expert, succeeds the second, and his spade should be four inches broad at top, only two inches broad at the point, and fourteen or fifteen inches in length (b). With this spade a good workman can take out at least fifteen inches of clay. A sort of hoe or scoop, made of a plate of iron, formed nearly into the shape of a half cylinder of two inches diameter, and a foot or fourteen inches long, and fastened, at an acute angle of perhaps 70°, to a long wooden handle (c), is now employed to scrape out the bottom of the drain, and remove any small pieces of clay that may have fallen into it. The grassy side of the turf being turned undermost, they are put down into the drain, the workman standing upon them after they are put in, and pressing them down with his whole weight till they are firmly wedged between the sloping sides of the drain. The ends of the turfs being cut somewhat obliquely, they overlap each other a little; and by this means, although there is sufficient opening for the surface water to get down, nothing else can. The open space, below the turf, ought to be five or six inches in depth, three inches wide at top, and an inch and a half or two inches at bottom. (Trans. Highl. Soc. vol. vi. p. 571.)

4294. The hollow furrow drain is only used in sheep-pastures. Wherever the water is apt to stagnate, a deep furrow is turned up with a stout plough (fig. 654. a.)

After this, a man with a spade pares off the loose soil from the inverted sod, and scatters it over the field, or casts it into hollow places. The sod, thus pared, and brought to the thickness of about three inches, is restored to its original situation, with the grassy side uppermost, as if no furrow had been made (b). A pipe or opening two or three inches deep is thus formed beneath it, in the bottom of the furrow, sufficient to discharge a considerable quantity of surface water, which readily sinks into it. These furrows, indeed, are easily choked up by any pressure, or by the growth of the roots of the grass; but they are also easily restored, and no surface is lost by means of them.

4295. The earth drain, called also the clay-pipe drain, is better calculated for the purpose of an aqueduct, or conveyance of water, than for drying the soil. A drain is dug to the necessary depth, narrow at bottom, in which is laid a smooth tree or cylindrical piece of wood, ten or twelve feet long, six inches in diameter at the one end, and five at the other, having a ring fastened in the thickest end. After strewing a little sand upon the upper side of the tree, the clay or toughest part of the contents of the trench is first thrown in upon it, and then the remainder, which is trod firmly down. By means of the ring and a rope through it, the tree is drawn out to within a foot or two of the small or hinder end, and the same operation repeated. A gentleman who has tried this experiment says, this clay pipe has conducted a small rill of water a considerable way under ground for more than twenty years, without any sign of failing.

4296. Pipe drains of turf are sometimes formed

where the surface soil is a strong clay, as it is only turves from such a surface that are sufficiently durable. A semicylindrical spade (fig. 655. a) is used to dig the turves, the ground-plan of which (b) presents a series of semicircles or half pipes. The drain (c) being dug out to the proper depth, one turf is laid in the bottom (d); and another being placed over it (c), completes the pipe. The same sort of pipe drain has been formed out of solid beds of clay, and has served for a time to convey water. As collecting drains, of course, they can be of little or no use. Hannay, an ingenious farmer in Wigtonshire, adopted this mode for the purpose of conveying water through running sand, in which only a pipe drain will last for a moderate time. After a number of years the clay turves were found effective in conveying away the water, and preventing the running away of the sandy sides of the drain.

4297. Pearson's method of pipe-draining will be found described at length in the *Transactions of the Society of Arts*, vol. xlvii. for 1829. The ground is first opened by a plough, with what is called a horn-share. (fig. 658.) With four horses and the horn-share (a), a furrow nine or ten inches deep by ten inches is taken out. The horns are then removed, the coulters (b b) added, and eight horses attached. This cuts the soil to an additional depth

of ten inches (c), and it is immediately removed with narrow spades, and larger and smaller draining

656

scoops. (figs. 653, c, and 661. a, b.) A second pair of coulters cuts the soil to the depth required, which is also taken out by the scoops. The total depth is now about twenty-six inches, the width at top ten inches, and at bottom about one inch. A slide (fig. 657. a) is then dropped to the bottom of the drain,

657

commencing at its lowest level, so as to work up hill. A windlass (b) is next placed at the full length of the rope, which is attached to the slide. Clay is next rammed firmly down on the slide with a heavy rammer to the depth of three or four inches, and the slide is next pulled forward, leaving a cylindrical drain of three or four inches in diameter, according to the diameter of the slide. (*Trans. Soc. Arts*, vol. xvii. p. 30.)

4298. A mode of turf-draining in use in Cheshire is as follows:—The surface of the ground where the drain is intended to be cut, is marked out in parallelograms about the size of bricks on one side (fig. 658. a), and that opposite is left of the width of a common sod; i. e. nine inches wide. These sods are taken out at a spade's depth, and laid carefully by the side of the drain for covers. The sods (a), resembling bricks in their size and shape, are then dug, and laid carefully on the same side as the sods intended for covers. The drain is then sunk to its proper depth, and the stuff taken out is thrown to the other side. The bottom is levelled with proper draught for the water, and set with the sods like bricks (a), two in height on each side (c); these are covered with the larger sods set obliquely (b), the grass side of each sod being turned downwards. (*Agr. Rep. of Cheshire*, 214.)

4299. The mole drain (fig. 659.) is formed by the draining-plough of that name already described (2643.) with the manner of using it. It is chiefly useful in pasture-lands, and especially in such as have some declivity, or are formed into ridges.

4300. The wheel drain is a very ingenious invention, described in *The Agricultural Report of the County of Essex*. It consists of a draining-wheel of cast-iron, that weighs about 4 cwt. It is four feet in diameter; the cutting-edge or extremity of the circumference of the wheel is half an inch thick, and increases in

thickness towards the centre. At fifteen inches deep it will cut a drain half an inch wide at the bottom, and four inches wide at the top. The wheel is so placed in a frame, that it may be loaded at pleasure, and made to operate to a greater or less depth, according to the resistance made by the ground. It is used in winter when the soil is soft; and the wheel tracks are either immediately filled with straw ropes, and lightly covered over with earth, or they are left to crack wider and deeper till the ensuing summer; after which the fissures are filled with ropes of straw or of twisted twigs, and lightly covered with the most porous earth that is at hand. Thus, upon grass or ley lands, hollow drains, which answer extremely well, are formed at a trifling expense. It is said that twelve acres may be fully gone over with this draining-wheel in one day, so as to make cuts at all necessary distances.

658

4301. *Surface-gutters made by cart-wheels* have been used by Middleton, on meadows in Surrey. To the felly of a common cart-wheel (fig. 660. a), is added a piece of wood, the section of which is a truncated triangle (b), and on this is fixed a piece of iron completing the triangle (c). The cart is loaded and driven so as the prepared wheel may run in the furrow; or, if there are no furrows, both wheels may be prepared, and the loaded cart drawn by two horses, may be led over the whole field, forming parallel gutters, four or five feet distant. The advantage of this mode of surface draining is, that the herbage is only pressed down, not destroyed, and rises up again in spring. The operation, for that reason, requires to be renewed every winter. It certainly seems a barbarous mode, but it may have answered better than one who has never seen it practised might be led to imagine.

4302. *In forming small drains, chiefly for retentive soils*, the common plough has been used in many places, and with some advantage. The method practised by Young, as described in *The Annals of Agriculture*, is this:—When he has marked the drains in a field usually a rod asunder, he draws two furrows with a common plough, leaving a baulk betwixt them about fifteen inches wide; then with a strong double-breasted plough, made on purpose, he splits that baulk, and leaves a clean furrow fourteen or fifteen inches below the surface; but where the depth of soil requires it, by a second ploughing he sinks it to eighteen or twenty inches: it is then ready for the land-ditching spade, with which he digs, fifteen inches deep, a drain as narrow as possible. But the method followed by some farmers, who do not possess ploughs made on purpose for the work, is this—With their common plough, drawn by four or five horses, and usually stirring about four or five inches deep, they turn a double furrow, throwing the earth on each side, and leaving a baulk in the middle. This baulk they raise by a second bout, in the same manner: then they go in the open furrow twice, with their common double-breast plough, getting what depth they can. After this they shovel out all the loose mould and inequalities to the breadth of about a foot; and thus having gained a clear open furrow, the depth varying according to the soil and ploughs, but usually about eight or nine inches, they dig one spit with a draining spade sixteen inches deep, thus gaining in the whole twenty-four or twenty-six inches. But as this depth is seldom sufficient, when necessary they throw out another, or even two other spits, which makes the whole depth from thirty to forty inches.

4303. *The best season for marking out and forming drains* is the spring or beginning of summer; because then the land springs, being still in vigour, are more easily discovered and traced than at a later period. When the ground is soft on the surface, it is a useful precaution, after the line is indicated, to cart on the materials for filling before digging the drain, as the weight of the carriages and horses is apt to press in the sides. In the case of straw, turf, or earth drains, where the ground is of a firm texture, this precaution does not apply. In filling drains, the earth should always be raised somewhat above the general surface, to make allowance for sinking.

4304. *The duration of drains* must necessarily depend on the nature of the materials with which they are filled, and in some measure on the quality of the soil, as certain species of land have the power of preserving wood or other perishable materials much longer than others. Stones last till accidental causes impede the flowing of the water, and may last for ever. Wood perishes in certain periods, but it does not follow that the drains should stop; if the earth arches, the water will necessarily continue to flow, which is found to be the case when wood, straw, and stubble are rotten and gone. Drains that have been filled with bushes and straw, both which were rotten, have been observed to run well forty years after making.

4305. *The expense of drains* will of course vary with the soil, depth, price of labour, &c.; and these circumstances are so different in different districts, and even in different parishes, that it accounts for the various reports of writers on the subject. Those farmers who are most solicitous to have the work well performed, contract with men only for digging and leaving clean, in order that the filling may be done by men paid by the day,

as a greater security that it should be executed with all possible care. Whatever may be the expense and trouble incurred in draining, it may be safely asserted that, if the work is judiciously contrived and properly executed, no kind of outlay will prove so beneficial to the cultivator.

4306. *The enemies of drains*, according to Marshal, are moles, field mice, and the roots of trees: the first two may be kept under by traps or other devices; but the last enemy is not easily guarded against, except in the laying out of the drain, which should always, if possible, be kept distant from trees or woody plants of any description.

SECT. VIII. *Of the Implements peculiar to Draining.*

4307. *The tools peculiar to draining* are chiefly of the spade kind: there are also boring instruments of different kinds.

4308. *The draining-scoop* (fig. 661. *a, b, c*.) is a crooked kind of tool made use of in some cases for clearing out the loose materials from the bottoms of drains. It is formed of different sizes and breadths, according to the drains, and in working is drawn or pushed along the bottom.

4309. *The draining shovel* (*d*) is another sort of implement employed for the same purpose as the above. It is made with a crooked handle, and the edge of the shovel part is turned up, in order to prevent the materials from falling off.

4310. *The draining sod knife* (*e*) is an implement made use of with great benefit in scoring or cutting out the sward in forming drains.

4311. *Draining spades* (*f, g, h*.) are made of different breadths, so as to follow each other, and cut the drains narrow at the bottoms. An upper and pointed draining spade (*g*) is in general use, and a wooden one (*h*) is employed in peat soils.

4312. *The draining straw-twisting engine* is a machine of very simple construction, already described (2562.), and capable of being readily removed, contrived for the purpose of twisting straw into ropes for the filling of drains.

4313. *A variety of boring implements, including Good's and the peat-borer*, have been already described. (2507. to 2519.)

4314. *The common draining auger* (fig. 662.) consists of four parts, the shell or wimble, the chisel, the rod, and the handle. The auger shell, or wimble (*e*), as it is variously called, for excavating the earth or strata through which it passes, is generally from two and a half to three and a half inches in diameter; the hollow part of it one foot four inches in length, and constructed nearly in the shape of the wimble used by carpenters, only the sides of the shell come closer to one another.

The rods (*a*) are made in separate pieces of four feet long each, that screw into each other to any assignable length, one after another, as the depth of the hole requires. The size above the auger is about an inch square, unless at the joints, where, for the

sake of strength, they are a quarter of an inch more. There is also a chisel and punch (*b*), adapted for screwing on in going through hard gravel, or other stony substances, to accelerate the passage of the auger, which could not otherwise perforate such bodies. The punch is often used, when the auger is not applied, to prick or open the sand or gravel, and give a more easy issue to the water. The chisel is an inch and a half or two inches broad at the point, and made very sharp for cutting stone; and the punch an inch square, like the other part of the rods, with the point sharpened also. There is a shifting handle of wood (*d*), fastened by means of two iron wedges affixed to it, for the purpose of turning round the rods in boring; and also two iron keys (*f, c*), for screwing and unscrewing the rods, and for assisting the handle when the soil is very stiff, and more than two men required to turn it.

4315. *To judge when to make use of the borer* is a difficult part of the business of draining. Some have been led into a mistaken notion, both as to the manner of using it and the purpose for which it is applied. They think that if, by boring indiscriminately through the ground to be drained, water is found near enough the surface to be reached by the depth of the drain, the proper direction for it is along these holes where water has been found; and thus they make it the first implement to be used. The contrary is the case; and the auger should never be used till after the drain is cut; and then for the purpose of perforating any retentive or impervious stratum, lying between the bottom of the drain and the reservoir or strata containing the spring. Thus does it greatly lessen the trouble and expense that would otherwise be requisite in cutting the trench to a depth which, in many instances, the level of the outlet will not admit.

4316. *The manner of using it* is simply thus:—In working it, two, or rather three men are necessary. Two, standing above, one on each side of the drain, turn the auger round by means of the wooden handles, and when it is full they draw it out; and the man in the bottom of the trench clears out the earth, assists in pulling it out, and directing it into the hole, and he can also assist in turning with the iron handle or key, when the depth and length of rods require additional force to perform the operation. The workmen should be cautious, in boring, not to go deeper at a time, without drawing, than the exact length of the shell; otherwise the earth, clay, or sand through which it is boring, after the shell is full, makes it very difficult to pull out. For this purpose the exact length of the shell should be regularly marked on the rods, from the bottom upwards. Two flat boards, with a hole cut into the side of one of them, and laid side by side across the drain, are very useful for directing the rods perpendicularly in going down, for keeping them steady in boring, and for the men to stand on when performing the operation.

4317. *The horizontal auger* (fig. 663.) is another boring instrument employed in particular cases. It was invented by Halford, of Hathern, in Leicestershire, but is little used. The advantages of it are, in some cases, considerable, by lessening the expense of cutting, and performing the work in a much shorter time. Where a drain or water-course has to pass under a bank, road, hedge, wall, rivulet of water, or fer

drying marl-pits, &c., it may be used to advantage in excavating a sufficient passage for the water, without opening a trench. In laying leaden pipes for the conveyance of water, it is also useful in making a hole

in which the pipe may be laid, without opening a cut on purpose. For tapping springs, or finding water at the bottom of a hill, either for the supply of a house, or for draining the ground, it may likewise be used with success; as the water of the spring, when hit on, will flow more easily and in greater abundance through a horizontal or level, than through a perpendicular outlet.

4318. *The manner of using it is this:*—Suppose a lake or pond of water, surrounded with high banks, to be emptied, if the ground declines lower on the opposite side, find the level of the bank where the perforation is to be made. There smooth the surface of the ground so as to place the frame nearly level with the auger, pointing a little upwards. It requires two men to turn the handles at top (*a*), in order to work it; and when the auger or shell is full, the rods are drawn back by reversing the lower handle (*b*). Other rods are added at the joint when the distance requires them. In boring through a bank of the hardest clay, two men will work through from thirty to forty feet in a day, provided there is no interruption from hard stones, which will require the chisel to be fixed on in place of the shell, and longer time to work through. If the length to be bored through is considerable, or longer than the whole length of the rods, a pit must be sunk upon the line, down to the hole, for placing the frame when removed, and the operation carried on as before.

CHAP. II.

Embanking and otherwise protecting Lands from the Overflowing or Encroachment of Rivers or the Sea.

4319. *Lands adjoining rivers or the sea* are frequently liable to be overflowed or washed away, or to be injured by the courses of rivers being changed during great floods. These evils are guarded against by embankments and piers; or by these constructions joined to deepening or straightening the courses of rivers, and we shall therefore treat in succession of embankments and of improving the courses of rivers.

SECT. I. *Embanking Lands from Rivers or the Sea.*

4320. *The great value of alluvial soil* to the agriculturist no doubt gave rise to the invention of banks, or other barriers, to protect soils from the overflowing of their accompanying rivers. The civilised nations of the highest antiquity were chiefly inhabitants of valleys and alluvial plains; the soil, moisture, and warmth of which, by enlarging the component parts and ameliorating the fruits of the vegetable kingdom, afforded to man better nourishment at less labour than could be obtained in hilly districts. The country of Paradise and around Babylon was flat, and the soil saponaceous clay, occasionally overflowed by the Euphrates. The inhabited part of Egypt was also entirely of this description. Historians inform us that embankments were first used by the Babylonians and Egyptians, very little by the Greeks, and a good deal by the Romans, who embanked the Tiber near Rome, and the Po for many stadia from its embouchure. The latter is perhaps one of the most singular cases of embankment in the world.

4321. *The oldest embankment in England* is that of Romney Marsh; as to the origin of which, Dugdale remarks, “there is no testimony left to us from any record or historian.” (*History of Embanking and Draining.*) It is conjectured to have been the work of the Romans, as well as the banks on each side of the Thames, for several miles above London, which protect from floods and spring tides several thousand acres of the richest garden ground in the neighbourhood of the metropolis. The commencement of modern embankments in England took place about the middle of the seventeenth century, under Cromwell. In the space of a few years previous to 1651, 425,000 acres of fens, moorasses, or overflowed muddy lands, were recovered in Lincolnshire, Cambridgeshire, Hampshire, and Kent; and let at from 2s. 6d. to 30s. an acre. (*Harte's Essays*, p. 54, 2d edit.) Vermuyden, a Fleming by birth, and a colonel of horse under Cromwell, who had served in Germany during the thirty years' war, was the principal undertaker of these works. Some farther details of the history of embanking will be found in the

Repertory of Patent Inventions, for January, 1826, and in the *Bulletin des Sciences Agricoles*, for November, 1827.

4322. *Very little has been written on the subject of embankments*, as a separate branch of art, by British authors. Dugdale's work is entirely historical and topographical. But the writings of Smeaton, Young, Gregory, &c., contain the general principles on which is founded the art of embanking, and every other operation connected with water; and Beatson, (in *Communication to Board of Agriculture*,) Dr. Anderson, Marshal, and some others, have written on the practice of the art. The works of this sort constructed in our own times will be found described in the *Agricultural Reports* of the maritime counties, especially of Lincolnshire, by Arthur Young. We shall first submit some general remarks on the principles of designing embankments, and next describe the principal kinds of banks, with their application.

SUBJECT. I. *General Principles of designing Embankments.*

4323. *The theory of embanking*, Marshal observes, is beautifully simple. The outward waters having been resisted by a line of embankment, and having receded, those that have collected internally are enabled, by their own weight, to open a valve placed in the foot of the bank, and effect their escape: thus securing the embanked lands from inundation, though beset on every side with water.

4324. *The pressure of still water against the sides of the vessel containing it being as its depth*, it follows, that a bank of any material whatever, impervious to water, whose section is a right-angled triangle, and the height of whose perpendicular side is equal to that of the water it is to dam in, will balance or resist this water, whatever may be the breadth of the surface of the latter; and therefore that, as far as width or extent is concerned, it is just as easy to exclude the Atlantic Ocean as a pond or a river of a few yards in width.

4325. *Embankments* may be considered in regard to their situation, direction, construction, and materials.

4326. *The situation of the bank* should be such that its base may not be unnecessarily exposed to the immediate action of the waves or the current; and where the quantity of water is limited, as in the case of land-floods in a particular river, the more room it has to spread, the less height and strength the bank will require; and the power of the current will be proportionally lessened. It is to be recollected, however, in all cases where the channel of the water is liable to be warped or filled up by siltage, that the narrower the space is, in which the water is confined, the stronger will be its current, and the less silt will, in ordinary cases, be deposited.

4327. *The direction of embankment* should be free from sharp angles, so as to occasion the least possible resistance to the current, whether of a land-flood or the tide.

4328. *In the construction or form of the bank* there are certain principles to be observed. Its height and strength ought ever to be proportioned to the depth and the pressure of water which it will have to sustain; and, to increase its firmness, the inner face should lean towards it, as a buttress. But it is on the construction of the outer face its strength, firmness, and durability principally depend. This ought to be made sloping, to a degree of flatness; for the twofold purpose of preventing resistance and taking off the weight of water. In difficult cases, the outer surface may form an angle with a perpendicular line of 45 to 60 degrees, according to the force to be guarded against, and the materials to be employed.

4329. *The materials of the body of the bank* (as well as of the inner face), where the foundation is sound and firm, and the bank can be carried up at a proper season, without great molestation from the water, may generally be the natural soil of the lands to be embanked; and, where merely the weight of stagnant or slowly moving water is to be guarded against, the outer slope may be of the same material. But where force, whether of waves or a strong current, will act immediately upon the bank, its outer face ought to be made proof against it; and its base should be particularly guarded, to prevent its being undermined; the most mischievous and irreparable disaster of embankments. Hence, when the foundation is not sufficiently firm, piles, timber, and masonry may be required, to ensure success; and no man ought to begin a work of this nature without attentively guarding it against every probability of miscarriage.

4330. *A system of drains and floodgates* is requisite for the purpose of freeing the embanked lands from internal waters.

4331. *In designing and setting out the main drain, or discharging channel*, on the outside of the embankment, there are points which require particular attention. The situation of the outfall, or mouth, with respect to the current of the water into which it opens, is of considerable importance. It ought to be such that the current of the water received will not warp up the channel of the drain; but such, on the contrary, as will tend to clear the mouth and keep the channel free. If it were not to preserve the requisite character of an elementary work, it might be deemed unnecessary to add, that the mouth of the discharging drain should be situated as low beneath the floodgate of the embankment as given circumstances and a prudent expenditure will allow; in order that, by inducing a sufficient current, the floodgate, as well as the mouth of the channel, may become free from obstructions. Against the open sea, or a wide estuary, where there is no disgorging channel, but where the waves reach the foot of the embankment, two floodgates may be required: one on the outer side, to sustain the force of the waves, and prevent their blowing up the inner works; the other within, to secure the passage the more effectually. The outer gate in this case is liable to be lifted with the addition of the waves, and thereby to admit much water; but the inner valve, being in an undisturbed situation, effectually stops its progress.

4332. *Where the discharge is made immediately behind a shifting beach*, and especially where the floodgate is necessarily placed level with or beneath the general surface of the gravel bank, through which the waters have been wont to force a channel, the valve is liable to be buried, and the channel to be closed up by every spring tide, and by every gale of wind which sets in upon it; and cannot be kept free but by unceasing labour and expense. In an obstinate case of this kind on Lord Cawdor's estate, in Pembroke-shire, the discharging floodgate is defended by a covered channel, carried out through the line or ridge of beach into the sea; being made strong enough to sustain the weight of the heaviest breakers. This, it is true, has been effected at a great expense, but nevertheless, the improvement being of considerable magnitude, with great profit. In every case where an external valve is required, and where it is liable to be silted up, or loaded with sand or gravel, great attention to the outward channel is necessary, or some defence must be constructed; for the floodgate, when loaded, cuts off all communication between the pent up waters and the materials that impound them. They cannot, by loosening the obstructing matter, as

nature would otherwise direct them, force their way through it; nor, by surmounting it, can they wear down a channel, and thus set themselves at liberty.

4333. *In ordinary cases*, the outer floodgate may be guarded by a pile fence or jetty, run out from the foot of the embankment, across the known drift of the beach; and in such a manner as not to interrupt the outfall channel of the water; the gravel, &c. which such a safeguard may accumulate, being removed from time to time as occasion may require.

4334. *The best construction of the flood-gate* for the uses now under consideration is the common valve, hinging at the top, swinging outward and falling into a rabbeted frame. In forming and hanging a floodgate of this construction, there are a few particulars worthy of attention. It should be made of seasoned wood, and ought to be double; the boards or planks of which it is formed being made to cross each other, to prevent its casting. It should fall truly, and fit neatly within a surrounding rabbet (to lessen the power of the waves to lift it); but not so closely or tight as to stick when swelled by moisture. To prevent this, as well as to give it additional tightness, its edges should not be square, but should bevel somewhat inward in the manner of a bung; the rabbet in the frame being made to answer it. In fixing the frame, it ought to be suffered to lean or batter inward; in which position the door will shut closer, and be less liable to the action of the waves in an exposed situation than it would if it were hung perpendicularly. It ought not, however, to lie so flat or heavy as to prevent the free escape of the internal waters. The floodgates or self-acting sluices, at Bar Loch embankment fall against a flat surface. (fig. 664.)

664

A writer in the *Perth Miscellany* states, (vol. i. p. 41.) that many of the tunnels in the embankments of the Tay have only wooden valves with iron hinges, and a lid of lead or iron nailed on for weight to keep them down. These, he says, are not to be depended on, and he has accordingly had some tunnels made of two inch plank with the end cut at an angle of 45° for the valve, and placed on a slope of 8 inches in 18 feet, the water being discharged on a broad piece of pavement. He had an iron plate "cast the exact size of the mouth of the tunnel, and about half an inch thick, with holes drilled two inches apart, and three-fourths from the edge of the plate, for riveting a piece of saddler's leather, or shoemaker's brown sole, which extended at least two inches beyond the plate, and covered the whole end of the tunnel, the upper end of the leather nailed to the wood serving as hinges, and the edges of the mouth previously lined with the same material. Thus the strength of the tide never raises the valves, and completely prevents the water from getting in." (p. 42.)

4335. *The internal waters* which rise within or fall upon the area of the embanked lands, are to be collected by a main drain, continued upward from the floodgate; and furnished with branches to spread over every part of the field of improvement, so as to draw the water from every dip and hollow place as it collects, and thus free the surface effectually from stagnant water; saving such only as may be wanted for the use of pasturing stock.

4336. *If alien waters* have a natural and accustomed channel through the embanked area, it may be found necessary to raise a suitable bank at a proper distance on each side of the stream, in order to prevent its overflowing the area in time of floods. Where it is found that an outlet cannot be had low enough to free the area entirely from surface water, it is requisite (though no alien waters intrude) to form an embanked channel or reservoir, to gain the required outfall; and to throw the waters which lodge on the lower grounds into this receptacle, by a draining mill, of which there are a great variety of constructions.

4337. *An embanked channel*, if the banks are raised high enough, or are placed wide enough asunder so as to contain a sufficient body of water, may have a further use, which, in some cases, may be of the highest importance to an improvement of this nature. For, by the help of folding floodgates, such as are commonly seen in use for the locks of navigable canals, placed at the lower end of this canal or reservoir, a body of water may be collected and rapidly discharged; by which easy means, not only the channel of the outer drain, but its mouth, if judiciously contracted, may from time to time be cleared from obstructions. Where alien waters of a good quality pass through the field of improvement, an embanked channel may be profitably applied in watering the lands; and where alien waters, which have not a natural or fortuitous passage through it can be commanded, and conducted to it at a moderate expense, they may prove highly beneficial, for either or both of these purposes.

SUBJECT. 2. *Different Descriptions of Banks in general Use for excluding Waters.*

4338. *Mounds or banks for excluding rivers or the sea* are generally formed of earth, but sometimes also of masonry and even of wood. Embankments of common earth are sufficient for resisting occasional floods: if this earth be loose, the bank will require to be spread out at the base, at the rate of one foot and a half or two feet horizontal for every foot in height; that is to say, a bank of loose earth three feet high will require to be nine feet or twelve feet broad. If the earth to be made use of is a compact clay, or if turf of a solid and compact body can be procured, the slope of the bank may be much steeper, according to its height and the depth of water which may be expected to press against it.

4339. *The earthen wall* (fig. 665.) is the simplest description of embankment, and is

665

frequently erected by temporary occupiers of lands on the general principle of enclosing and subdividing, which is sometimes made a condition of tenure between the landlord and tenant. This wall applies to lands occasionally, but rarely, overflowed or inundated; and is set out in a direction generally parallel to the river or shore. Its base is commenced on the surface, from two to five feet wide, regularly built

of turf on the outsides, with the grassy sides underneath. The middle of the wall is filled up with loose earth. The wall is carried up with the sides bevelled towards the

centre, so as to finish in a width of one foot or eighteen inches, at five or six feet in height. Collaterally with such walls, and at the distance of three or four feet, a small open drain is formed, as well to collect the surface water of the grounds within, as that which in time of floods will necessarily ooze through a wall of this construction. The water so collected is let through the wall by tubes, or tunnels of boards, with a valve opening outwards on their exterior extremity. When the flow of water from without approaches, it shuts the valve, which remains in this state till the flood subsides, when, the height of the water within being greater than that without, it presses open the valve and escapes. Walls and valves of this kind are common enough in the drier parts of the fenny districts of Lincolnshire and Cambridgeshire.

4340. *The earthen mound* (fig. 666.) is the most general description of embankment,

and, as it is executed at considerable expense, is only undertaken by such as have a permanent interest in the soil. This barrier applies to sea lands overflowed by every spring tide, and to alluvial plains inundated by every flood. It is set out in a direction parallel to the shore, and to the general turns of the river, but not to its minute windings; and it is placed farther from or nearer to the latter, according to the quantity of water in time of floods, the rapidity of the current from the declivity of the bed, the straight course of the stream, and the intended height of the bank. The two sides of such a mound are generally formed in different slopes. That towards the land is always the most abrupt, but can never be secure if more so than 45° ; that towards the water varies from 45° to 15° ; the power of the bank to resist the weight of the water, as well as to break its force when in motion, being inversely as its steepness. The power of water to lessen the gravity of bodies, or in other words, to loosen the surfaces over which they flow or stand, is also lessened in a ratio somewhat similar.

4341. *The formation of the earthen mound* consists merely in taking earth from the general surface of the ground to be protected, or from a collateral excavation, distant at least the width of the mound from its base line, and heaping it up in the desired form. The surface is then in general cases covered with turf, well rolled in order to bind it to the loose earth. The earth of such mounds is generally wheeled in barrows; but sometimes it is led in carts placed on a wooden roller instead of wheels, which, with the treading of the horses, serves in some degree to consolidate the bank.

4342. *The excavation* serves the same purposes as the open drain in the earthen wall; and similarly constructed sluices or valves are introduced on a larger scale. Sometimes, also, the interior water is drawn off by windmills, and thrown over the mound into the river. This is very common in Huntingdonshire, and might be greatly improved on by employing steam engines for entire districts, one of which, of a ten horse power, would do the work of twenty mills, and this in calm weather, when the latter cannot move.

4343. *Embankments of this description are the most universal of any*, and their sections vary from a scalene triangle of ten feet in base, and three feet in height, as on the Forth near Stirling, and the Thames at Fulham, to a base of 100 feet, and a height of ten feet, as in the great bank of the Ouse, near Wisbeach. The great rivers of Germany and Holland are embanked in this way, when so far from the sea as to be out of the reach of the tide; as the Vistula at Marienwerder, the banks of which, near Dantzic, are above fifteen feet in height; the Oder, the Elbe, &c. All these banks are closely covered in every part with a grassy surface, and sometimes ornamented with rows of trees.

4344. *Near the sea, where such banks are washed by every tide* when the course of the wind is towards the shore, and by all land floods and spring-tides, grass is only to be found on and near their summits. The rest of the bank is bare, and to preserve it from the action of waves, currents, and the stones, pieces of wood, and other foreign matters which they carry with them, the surface is covered with gravel, reeds, or straw kept down by pieces of wood; faggots, wicker hurdles, nets of straw ropes, straw ropes laid side by side and fastened, or handfuls of straw fixed in the ground with a dibber (*Neale's Travels in Germany*, &c. chap. i.), or any other contrivance, according to the situation, to prevent the washing away of the bank. It is common to attribute to these coverings the power of breaking the force of the waves; but this power depends, as we have already stated, on the slope of the bank and its smoothness; and the use of the surface covering, and of the constant attention required to remove all obstacles which may be left on it by floods and tides, is to prevent the loosening power of the water from wearing it into holes. For this purpose, a sheet of canvas or straw-netting is as good, whilst it lasts, as a covering of plate iron or stone pavement.

4345. *All banks whatever require to be constantly watched in time of floods or spring-tides*, in order to remove every object, except sand or mud, which may be left by the water. Such objects, put in motion by the water, in a short time wear out large holes. These holes, presenting abrupt points to the stream, act as obstructions, soon become much larger, and if not immediately

filled up, turfed over, and the turfs pinned down, or the new turfs rendered by some other means not easily softened and raised up by the water, will end in a breach of the bank. A similar effect is produced by a surface formed of unequal degrees of hardness and durability. The banks of this description in Holland, at Cuxhaven, and along the coast of Lincolnshire, are regularly watched throughout the year; the surface protection is repaired whenever it goes out of repair; as is the body of the bank in the summer season.

4346. *The mound with puddle wal.* (fig. 667.) It generally happens that the earth of

such banks is alluvial, and their foundation of the same description; but there are some

cases where the basis is sand, silt, or gravel; or a mud or black earth, as in some parts of Cambridgeshire and Lincolnshire, which does not easily become so compact. Here it is common, before beginning the bank, to bring up from the solid substratum (*a*) what is called a puddle-ditch, or section of clay in the centre of the highest part of the mound in the direction of its length, and of three or five feet wide, according to the depth of the stratum of silt (*b*), and the intended height of the bank (*c*). When the clay of this puddle-ditch is well worked, either by men's feet or clay rammers, the bank will be perfectly impervious to water, and if against a mild stream or shore, need not contain such an accumulation of earth as where the imperviousness of the bank to water depends chiefly on the mass of materials. As already observed, the important point to attend to in this variety of mound is, to found the section, or wall of clay, so deeply as to be in contact with a stratum (*a*), either by induration, or its argillaceous nature, impervious to water. In the drainage of the Bar Loch in the county of Renfrew, considerable difficulty was experienced in some places in getting to the bottom of the sandy subsoil, so as to bring up the

puddle wall from the retentive stratum. Such was the difficulty in some cases, that the puddle could not be carried up perpendicularly, but a puddle wall being raised within the bank, as high as the natural surface, it was joined horizontally to another puddle wall in the body of the bank. (fig. 668.)

4347. *Puddling* is often found defective, owing to the imperfect working of the materials. Many think that when clay is used, if it be worked into the consistence of dough, it is sufficient; but this is a mistake: it should be slaked and so decomposed by the labour of proper tools and treading, and so completely saturated with water, that the whole mass becomes one uniform and homogeneous body, and almost fluid.

4348. *Mounds with reversed slopes.* In some cases of embanking rivers, as where they pass through parks, it is desirable to conceal, as much as possible, the appearance of a bank from the protected grounds. Hence the mound is simply reversed, the steepest side being placed next the water. It is proper to observe, that such banks are not so strong, by the difference of the weight of the triangle of water which would rest on the prolonged slope, were it placed next the river, and are more liable to be deranged in surface in proportion to the difference of the slopes, the water acting for a longer period on every part of the slope.

4349. *Mound faced with stones.* This is the same species of mound, with a slope next the water of forty-five or fifty degrees, paved or causewayed with stones or timber. In Holland this pavement or causeway is often formed of planking or bricks; but in England generally with stones, and the mortar used is either some cement which will set under water, or, what is better, plants of moss firmly rammed between them. The objections to such banks are their expense, and their liability to be undermined invisibly by the admission of the water through crevices, &c. They are, therefore, chiefly used where there is little room, or where it is desirable to narrow and deepen the course of a river.

4350. *The bank formed with piles, brushwood, and stones,* is occasionally used for protecting moving sands, or directing the course of streams flowing through a sandy shore. A dike or bank for the latter purpose (fig. 669.) has been erected on the river Don in Aberdeenshire.

It consists of piles or poles, being the thinnings of plantation of Scotch pine and larch, driven six feet into the sand (*a a a*): the spaces between these piles (*b b*) are filled in with furze or other spray or small branches; and on the top of them, are wedged in stones to

keep them down. On the side of this row of piles next the river, stones (*c*) from 50lbs. to half a ton weight each, are precipitated from a punt, until they form a bank of an angle of nearly 45°. On the outside of this bank and piles, the sand (*d*) gradually drifts up, and forms a bank, which, being planted with *Arundo arenaria* and other grasses, gradually becomes covered with verdure. (*Highland Soc. Trans.* vol. vii. p. 91.)

4351. *Mound protected by a wicker hedge.* This is a Dutch practice, and, where appearance is no object, has the advantage of not requiring watching. Wicker-work, however, subjected to the strain of waves, will be obviously less durable, than where it lies flat on the ground, and can only decay chemically. This wicker hedge is sometimes a series of hurdles supported by posts and studs; but generally in Britain it is a dead hedge or row of stakes, wattled or wrought with bushes presenting their spray to the sea or river. Besides placing such a hedge before a bank, others are sometimes placed in parallel rows on its surface; the object of which is to entrap sand, shells, and sea weeds, to increase the mass of mound, or to collect shells for the purpose of carrying away as manure.

4352. *The sea wall (fig. 670.)* is an embankment formed to protect abrupt and earthy

shores or banks of rivers, and consists of a wall, varying in thickness, and in the inclination of its surface, according to the required height, and other circumstances. Belidor, in his *Traité de Hydraulique*, has given the exact curve which the section of such a wall ought to have (*a, b*), in order to resist loose earth, and which is somewhat greater than where the earth behind the wall is supposed to be chiefly firm. Some fine examples of such walls, for other purposes, occur in the Caledonian Canal; and perhaps the finest in the world are the granite walls which embank the Neva at Petersburg, the construction of which may serve as an example of a river cased with stone on a foundation of soft bog earth.

4353. *Embankments for fixing drifting-sands, shells, or mud.* In several tracts of coast, the sea at ordinary tides barely covers a surface of sand; and these sands, in dry weather, during high winds, are drifted and blown about in all directions. Great part of the north shores of the Solway Frith, of Lancaster Bay, and of the coast of Norfolk, is of this description. Young, in his *Farmer's Letters*, informs us, that a considerable part of the county of Norfolk was drift sand, and even as far inland as Brandon in Suffolk, before the introduction of the turnip culture; and Harte (Essay I.) states that some of what is now the richest land in Holland, was, about the middle of the sixteenth century, of this description. The suggestion of any mode, therefore, by which, at a moderate expense, such tracts could be fixed, and covered with vegetation, must be deemed worthy of notice. The mode which nature herself employs is as follows: After the tides and wind have raised a marginal steep of land as high as high water-mark, it becomes by degrees covered with vegetation, and chiefly by the *Elymus arenarius*, *Triticum junceum*, various species of *Juncus*, and sometimes by the *Galium verum*. With the exception of the first of these plants (the leaves and stalks of which are manufactured into mats and ropes in Anglesea, and the grain of which is sometimes ground and used as meal in Ireland), they are of no other use than for fixing the sands, which, being composed in great part of the debris of shells, expand as they decay, and contribute to raising the surface still higher, when the fibrous roots of good grasses soon destroy the others. The *Arundo arenaria* is planted in Holland for the purpose of binding sands, and was extensively introduced into the Highlands of Scotland for the same purpose, by Macleod of Harris, in 1819. (*Trans. Highl. Soc.* vol. vi. p. 265.)

4354. *To assist nature in fixing drift-sands*, it is only necessary to transplant the *Elymus*, which is to be had in abundance on almost every sandy coast in Britain; and as it would be liable to be blown away with the sands, if merely inserted in the common way, it seems advisable to tie the plants to the upper ends of willow or elder rods, of two or three feet in length, and to insert these in the sand, by which means there is the double chance of the grass growing, and the truncheon taking root. The elder will grow exposed to the sea breeze, and no plant throws out so many and such vigorous roots in proportion to its shoots.

4355. *The mode by which such sands were fixed in Holland* was by the formation of wicker-work embankments, and by sticking in the sands branches of trees, bushes, furze, &c. in all directions. These obstructed the motion of the sands, and collected masses of sand, shells, or mud, and sea-weeds around them, which were immediately planted with some description of creeping grass; or, what was more frequent, covered with a thin coating of clay, or alluvial earth, and sown with clover. Though the most certain and least expensive mode of gaining such lands is undoubtedly that of seconding the efforts of nature, by inserting bushes and planting the *Elymus* in this way; yet it may sometimes be desirable to make a grand effort to protect an extensive surface, by forming a bank of branches, which might, in a single or several tides, be filled with sand and shells. It is evident, that such a bank might be constructed in various ways; but that which would be most certain of remaining firm, and effecting the purpose, would be one regularly constructed of framed timber, the section of which would resemble a trussed roof; each truss being joined in the direction of the bank by rafters, and the whole inside and surface stuck full of branches. To retain it firm, piles would require to be driven into the sand, to the upper parts of which would be attached the trusses. The height of such a barrier would require to be several feet above that of the highest spring-tides; and the more its width at base exceeded the proportion of that of an equilateral triangle the better.

4356. *A mode suited to a less extensive scale of operation*, is to intersect a sandy shore in all directions, with common dead or wicker-work hedges, formed by first driving a row of stakes six or eight feet into the ground, leaving their tops three or four feet above it, and then weaving among these stakes, branches of trees, or the tops of hedges. The Dutch are said to weave straw ropes in this way, and thereby to collect mud in the manner of *warping*. This mode, being little expensive, seems to deserve a trial in favourable situations; and in so doing, it must not be forgotten, that much depends on the immediate management of the surface, after it is in some degree fixed. In an extensive trial of this sort at present in progress on the west coast of Scotland, under an English gentleman, seeds and roots are baked in a mixture of loam, dung, and gravel, and then formed into masses, and scattered over a sandy surface. These, from their weight, will not, it is thought, be moved by the water or the wind; but, becoming more or less covered with sand, the mass will be kept moist, and the seeds and roots will grow, and, fixing themselves in the soil, will in time cover the surface with verdure. The experiment is ingenious, and we hope will be crowned with success.

4357. *Embankments of cast iron* have been proposed to be constructed by Deeble, a civil engineer of London. He proposes to combine a series of caissons, made of cast iron, in ranges, agreeable to the required form of the intended embankment. The caissons are to be fastened together by dovetails, and, being hollow, are, when fixed in their intended situations, to be filled with stones and other materials, making them up solid. (*Newton's Journal*, vol. ii. p. 202.)

SECT. II. *Guarding the Banks and otherwise improving the Courses of Rivers and Streams.*

4358. The subject of *guarding the banks of rivers* is of considerable interest to the proprietors of lands situated in hilly districts, where, in the valleys and on the hill sides, the streams often produce ravages on the banks, and sometimes change their courses.

4359. The natural *licence of rivers*, Marshal observes, is not only destructive of landed property, frequently of lands of the first quality; but is often the cause of disputes, and not unfrequently of legal contentions, between neighbouring proprietors. A river is the most unfortunate boundary line of an estate. Even as a fence, unless where the water is unfordable, a river, or rapid brook, which is liable to high floods, is the most tormenting and inefficient. Proprietors have therefore a double interest in accommodating each other, as circumstances may require, with the lands of river banks, so as to be able to fix permanent boundary lines between their properties. When the owners of estates cannot, by reason of entails or settlements, or will not for less cogent reasons accommodate each other, they have a line to tread which they cannot deviate from with prudence, much less with rectitude; namely, that of cautiously guarding their own lands, without injuring those of their neighbours; for a lawsuit may cost ten times the value of the sand banks and islets of gravel to be gained by dexterity of management.

4360. *The operations for improving rivers* have for their object that of preventing them from injuring their banks, of accelerating their motion, and of lessening the space of ground which they occupy, or altering their site. These purposes are effected by piers or guardes for altering the direction of the current; works for protecting the banks; and by changing or deepening the river's course.

4361. *The principles on which these operations are founded* are chiefly two; first, that water, like every other body when it impinges on any surface, is reflected from it at a similar angle to that at which it approached it; and, secondly, that the current of water, other circumstances alike, is as the slope of the surface on which it runs. On the first of these principles is founded the application of piers for reflecting currents; and on the second, that of straightening rivers, by which more slope is obtained in a given length of stream, and of course greater rapidity of motion obtained.

SUBSECT. 1. *Guarding River Banks.*

4362. *A common cause of injury to the banks of rivers* is produced during floods. A tree or branch carried down by a stream, and deposited, or accidentally fixed or retained, in its banks, will repel that part of the stream which strikes against it, and the impulse (counteracted more or less by the general current) will direct a substream against the opposite bank. The effect of this continual action against one point of the opposite bank is, to wear out a hole or breach; and immediately above this breach it is customary to place a protecting pier to receive the impulse of the substream, and reverberate it to the middle of the general stream. But if this pier is not placed very obliquely to the substream, as well as to the general stream, it will prove injurious to the opposite bank by directing a subcurrent there as great as the first; and, indeed, it is next to impossible to avoid this; so much so, that Smeaton, in almost every instance in which he was consulted in cases of this sort, recommended removing the obstacle where that could be done, and then throwing loose stones into the breach.

4363. *Injuries by floods*, according to Marshal, are to be remedied in two ways; the one is to sheath the injured banks of the bays (fig. 671. a, b, c) with such materials

as will resist the circuitous current; and let the river remain in its crooked state. The other, to erect piers (d), to parry off the force of the current from the bank, and direct it forward; with the twofold intention of preventing further mischief, and of bringing back the course of the river to its former state of straightness. It is to be observed, that the operation of guarding the immediate bank of a sharp river bend, against a heavy current meeting with great resistance, by sheathing it with stones, is generally a work of much

difficulty and expense, even where materials can be easily procured: while that of diverting the current by a pier may frequently be accomplished at a comparatively small cost; and its effect be rendered infinitely more salutary and permanent. For it is plain that, if the accidental obstruction mentioned had been timely removed, no bad effect would have ensued: and the river would have continued its direct course. Or if, through neglect, it had been suffered to remain awhile, until its mischief was discoverable; even then, if it had been moved from its station to the opposite side of the river, and placed in the part affected, this small counterpoise might have recovered the balance of the current, and directed it into its wonted channel; and, in almost any case, by judiciously placing, in a similar manner, a pier or other obstruction proportioned to the magnitude of the power to be counteracted, the like effect may be produced.

4364. *In the use of piers great caution is requisite*, for a very little reflection will show that they are more likely to increase than to remedy the evil they are intended to cure. We have seen the injurious effects of such piers on the Tay and the Dee; and on a part of the Jed near Crailing they are so numerous, that the stream is, to use a familiar phrase, banded about like a foot-ball, from one shore to the other; behind every pier an eddy is formed, and if the stream does not strike the pier exactly, a breach in the bank takes place. Many of these piers have, in consequence, been taken down. The use of such piers can only be justified where the obstruction, from ill-neighbourhood or some such cause, cannot be removed from the opposite bank; or where, as is sometimes the case, it arises from an island of sand or gravel thrown out by the river near its middle, which, however absurd it may appear, the interested parties cannot agree as to who may remove. The case of buildings also being in danger may justify such a pier for immediate protection; but if such breaches are taken in time, a few loads of loose stones dropped in the breach, as recommended by Smeaton, will effect a remedy without the risk of incurring or occasioning a greater evil.

4365. *In the construction of piers*, attention is required to secure the foundation, either by first throwing in a quantity of loose stones, which the water will in a great measure dispose of so as to form a flat surface; or by the use of piles either under, or in single or double rows around, those parts of its base in contact with the river. (*fig. 672, a.*) The elevation (*b*), where the current is not required to act with great violence on the opposite shore, ought to be bevelled back on all sides exposed to the water, towards the middle of the structure (*c*). In the most important cases stones are the only fit materials, and these

should be regularly jointed and laid in cement according to the best practice of masonry. But, in general, a case of wicker work, of the proper shape, may be filled in with loose stones, some earth, together with the roots of such plants as *Tussilago Petasites*, *Elymus arenarius*, *Galium*, &c. These will form a barrier of considerable durability for some years, and probably till the evil is so far subdued that, when the wicker case decays, its contents will have sufficiently consolidated to effect the object without further care. If not, the wicker case may be renewed. In ordinary cases, a mere wicker hedge projecting into the water will effect the object without further trouble.

4366. *The sheath, or land-guard of loose stones*, which Marshal recommends, and which, in effect, is the mode already mentioned (4362.) as preferred by Smeaton, is applicable to the following cases:—First, where the river, in the part required to be bent, is confined, by rocks or otherwise, to an unalterable channel, as it frequently is in subalpine situations; and, secondly, where a deep pool occurs in that part, at low

water, so as to render it difficult to get a proper foundation for a pier. Where the foot of the injured bank is covered with a pool at low water, shelve off the brink of the bank, and shoot down loose stones from the top of it; suffering them to form their own slope, in the action of falling, and by the operation of succeeding floods: continuing to pour them down, until the bank be secured, at least from minor floods, and then slope back the upper part, to give freedom to floods of greater magnitude.

4367. *When the channel of a rapid river is narrow, and the banks undermined and washed away by the torrents, what Marshal terms the land-guard is to be used.*

4368. *In forming a land-guard for this purpose, he says, the foundation should be laid pretty deep, to guard against any accidental scoopings from the floods. The wall ought to be carried up dry, or without mortar, the stones being laid with their ends outward, their inner ends pointing to the same centre, like those of an arch, and to be backed with gravel, or earth, rammed in firmly behind, as the facing is carried up. The coping or uppermost course of the stones is to be securely bound, with thick tough sods (8 or 10 inches deep), whose surfaces, when beaten down, ought to lie even with that of the stonework; and similar sods require to be laid, with a gently rising slope, until they unite smoothly with the natural turf of the land to be defended; so that the waters of floods, when they rise above the stonework, may have no abruptness to lay hold of, but may pass away smoothly over the surface of the land, as they commonly do over smooth greensward, without injury. Finally, the stones are to be beaten forcibly into the bank, with a rammer, a mallet, or a small battering-ram, adapted to the purpose; thus rendering the whole compact and firm, to resist the current. Where vacancies or fissures still appear, long splinters of stone are to be driven in, as wedges, to increase the firmness, and prevent the current from tearing out an unguarded stone. It follows, of course, that the largest and longest of the stones ought to be used where the greatest resistance is known to be required.*

4369. *The repairs of a bulwark of this sort, like every other species of river fence, require to be attended to from time to time, especially after great floods. If the foundation be laid bare, it requires to be re-covered with rough gravel, or with stones thrown loosely against it. If any of the facing stones be displaced or loosened, they are to be wedged in afresh, or their place supplied by others. Or, if the turf which binds them at the top be disturbed, the torn part should be cut out square, and be firmly and completely filled up with fresh turves.*

SUBSECT. 2. *Changing the Courses of Rivers, deepening their Beds, or raising their Waters to a higher Level.*

4370. *A river whose course is in a straight line, or nearly so, hardly ever makes any encroachment on its banks, except perhaps very large rivers, when they rise above their usual level, either by an increase in their own waters, or from their flow being in some degree interrupted by the tides. Hence, whenever a river is narrow in its channel and winds considerably, any mischief it commonly occasions may be prevented by deepening and straightening the course of the stream. (Code of Agr. p. 319.)*

4371. *The alteration of the course of a river or brook is attended with difficulty and expense, according to the particular circumstances. In a simple case, in which one straight cut only is required, the principal difficulty, and that which requires the best skill of the artist, lies in directing the current of the first flood, out of the old into the new channel: but if a bend of the old channel can be made use of, this difficulty may be said to vanish. The mouth of the new cut receives the current with a straight course; consequently, if it be made of sufficient capacity, the river, in a flood, can have no propensity left towards its old channel: and the loose materials which rise in forming the mouth of the new cut, will generally be sufficient to turn the stream at low water into it. But if a suitable bend cannot be approached by the new cut, a directing pier will be required to bend the flood current, and give it a straightforward course into the new channel: a watertight dam being formed between the point of the pier and the firm bank of the new channel to prevent the water from regaining its wonted course.*

4372. *An entirely new bed or channel, however, is much to be preferred where it can be obtained: for in an altered course, when the stream passes alternately through new soil and through a part of its old bed, its action on surfaces which are so different in regard to induration ends, if great care is not taken, in holes and gulleys in the new bank, which require to be constantly filled up with loose stones thrown in, and left to be fixed by the pressure and motion of the water. In the case of a river passing near a house (fig. 673.) this is sometimes of great importance.*

4373. *Cutting the new channel is merely a work of manual labour; being attended with no other difficulty than what may arise from the expense, which will depend on the size of the river, the nature of the ground to be cut through, and the value of labour in the given district. It is mostly to be ascertained with sufficient accuracy by previous calculations. (See 3323.)*

4374. *The size of the new cut, on account of its greater depth, may be small, compared with that of the*

old channel. For the current of floods, by carrying off the earthy particles with which they come in contact, will soon enlarge it. It is nevertheless right to give ample room in the new channel, lest the first flood should prove high, and, by bursting its bounds, force its way back to its former course.

4375. A new river course requires to be carefully attended to, during a few years after it is opened, to see that its channel preserves its straightness, and that no breaches are made or threatened in its banks. Considering the uncertainty of extraordinary floods, it cannot be said to be out of danger in less than three years: hence it becomes prudent, when a work of this nature is contracted for, or undertaken to be done by measurement at an estimated price or prices previously agreed upon (as it generally ought), that the undertaker should agree to preserve the straightness of the channel, and uphold its banks during that or some other time fixed upon; and to deliver them up, at the end of the term, in the state and condition specified in the contract.

4376. A case of straightening the course of a river is given in *The Code of Agriculture*. The waters, which in their crooked course were formerly almost stagnated, now run at the ordinary rate of the declivity given them. They never overflow their banks. Cattle can now pasture upon those grounds in which they would formerly have been swamped. The surface of the water being now in general four, and sometimes six feet below that of the adjacent fields, this cut serves as a general drain to the whole valley; so that three hundred acres of meadow may be converted into arable land; sixty acres of moss may be improved into meadow; and five hundred acres of arable land are rendered of double their former value. (p. 319.)

4377. Raising rivers to a higher level. As rivers and streams may require to be

deepened for the purpose of drainage, so may their waters require to be raised for the purpose of irrigation, impelling machinery, or producing cascades or waterfalls for the purpose of ornament. Dams or weirs for this purpose should be constructed so as to form a segment of a circle across the bed of the stream, with the convex side pointing up the stream, and the ends abutting against a natural or artificial bank (fig. 674.) By this construction, the force of the

water, however great, will be effectually resisted, and the structure remains secure. The

greater the slope towards the upper side, the better, but the lower side should be nearly perpendicular, that the water may fall over it without coming in contact with the face of the building. (fig. 675.)

The wall (a) should be built of regularly hewn stone, as should the abutments (b); next the wall there should be a mass of clay as a puddle (c), and above that gravel or earthy matter of any kind to a considerable slope (d). Beneath the dam a considerable portion ought to be paved (e). (*Gen. Rep. Scot.* vol. ii. p. 669.)

4378. Heads, or banks of earth, for the confinement of water in artificial lakes or ponds, are often constructed at great expense, and, not being properly formed, often break out, and occasion considerable damage. The error in their construction is commonly owing to the want of breadth at the base in proportion to their height, and their not having a sufficient slope towards the water, nor a proper section of puddle in the centre. (*Ibid.*)

4379. Heads of loose stones of a large size (fig. 676.) may be had recourse to in slow running rivers not subject to high floods, and where there is such a superabundance of water that no loss is sustained by the quantity which flows through the stones. Where it is required to retain the whole of the water, a puddle bank should be carried up the middle of the dam. (*Ibid.*)

CHAP. III.

Irrigation, or the Improvement of Culturable Lands and Farmeries by the means of Water.

4380. The improvement of lands by water is of three kinds:—irrigation, or the application of water to the surface of the soil, and especially of grass lands, as a species of culture; warping, or the covering of the soil with water to receive a deposition of earthy matter; and the procuring or preserving of water by wells, reservoirs, and other means, for the use of farmeries, live stock in the fields, or the domestic purposes of the farmer or cottager.

SECT. I. *Irrigation, or the Preparation of the Surface of Lands for the profitable Application of Water.*

4381. *Irrigation* in its different forms may be considered an operation of culture as well as of permanent improvement. It is accordingly in many cases effected by tenants, but always, as in the case of improving wastes, in consequence of extraordinary encouragement from the landlord, by long leases, money advanced, or other advantages.

4382. *The application of water to the surface of lands* for the purpose of promoting vegetation has been practised, as we have seen (141.), from the earliest ages in warm countries. Solomon made him gardens, and orchards, and pools of water to water therewith the wood that bringeth forth the trees. (*Ecclesiastes.*) The art was taught by nature in the overflowing of the Nile and other rivers. Water is an essential article for the culture both of the cereal and pasture grasses, and indeed of most herbaceous crops, in all the tropical climates, and even in a great degree in the South of Europe. In the greater part of Italy and Spain, few crops are raised without being irrigated; and even in the south of France, potatoes, maize, madder, and sometimes vines, and orange trees, (as at Hieres,) have water applied to their roots, by furrows and other gutters and trenches formed on the surface. The system of watering grass lands was revived in Italy in the ninth century, and seems to have been practised in a few places in Britain from the time of the Romans; there being meadows near Salisbury which have been irrigated from time immemorial. In 1610, the public attention was called to it by Rowland Vaughan, in a work entitled, "Most improved and long experienced Water Works; containing the manner of summer and winter drowning of meadow and pasture, by the advantage of the least river, brook, fount, or water mill adjacent; thereby to make those grounds (especially if they be dry) more fertile ten for one."

4383. *Irrigation in former times*, and in all countries, however imperfect, was probably much more frequent than it is now. In light and gravelly tracts of country, the greatest difficulty in farming was to procure a sufficient supply of fodder for their cattle in winter. Meadows were therefore indispensable, and to increase the crop of hay, watering in a dry spring, and immediately (in dry summers) after the first crop was off, was constantly followed. Since the practice of sowing artificial grasses, and the introduction of the turnip husbandry, the custom of watering has been in such situations given up; not only because it has become less necessary than it was heretofore, but because *watered* meadow hay is of inferior quality as well as value in the market. It is nevertheless true that the herbage of very coarse boggy meadows is improved, and that of cold meagre soils is accelerated and increased by it.

4384. *But the principal scientific efforts in watering lands* have been made during the latter end of the last and beginning of the present century, in consequence of a treatise on the subject by George Boswell, published in 1780, and various others by the Rev. Thomas Wright, of Auld, in Northamptonshire, which appeared from 1789 to 1810. The practice, however, has been chiefly confined to England, there being a sort of national prejudice, as Loch has observed (*Improvements on the Stafford Estates, &c.*), against the practice in Scotland, though its beneficial effects may be seen as far north as Sutherland, where rills on the sides of brown heathy mountains never fail to destroy the heath plants within their reach, and these are succeeded by a verdant surface of grasses. A valuable treatise on the subject of irrigation in Scotland, by Dr. Singer, will be found in *The General Report of Scotland*, vol. ii. p. 610. In England the best examples of watering are to be found in Gloucestershire and Wiltshire. In our view of this subject, we shall first consider the soils and situations suitable for irrigation, and next the different modes of effecting it, known as flooding, irrigating, warping, irrigation on arable lands, and subterraneous irrigation.

SUBJECT. 1. *Soils and Situations suitable for Watering.*

4385. *The theory of the operation of water on lands* we have already developed. It appears to act as a medium of conveying food, as a stimulus, as a consolidator of mossy soils, as a destroyer of some descriptions of weeds or useless plants, and as the cause of warmth at one season, and of a refreshing coolness at another. From these circumstances, and also from what we observe in nature, there appears to be no soil or situation, nor any climate, in which watering grass-lands may not be of service; since the banks of streams between mountains of every description of rock, and in every temperature from that of Lapland to the equator, are found to produce the richest grass. One circumstance alone seems common to all situations, which is, that the lands must be drained either naturally or by art. The flat surfaces on every brook or river, after being covered with water during floods, are speedily dried when they subside, by the retiring of the waters to their channel.

4386. *The most proper soils for being watered* are all those which are of a sandy or gravelly friable nature, as the improvement is not only immediate, but the effects more

powerful than on other descriptions of land. There are also some strong adhesive sour wet lands, such as are common in the vicinity of large rivers, which are also capable of being improved by watering; but the beneficial effects are not in such cases so soon produced as on the first sorts, nor is the process so advantageous to the farmer, on account of the very great expense to which he must, in many cases, be put by previous draining. There are some other lands, as those which contain coarse vegetable productions, as heath, ling, rushes, &c. which may likewise be much improved by watering. It must be kept constantly in mind, in attempting this sort of improvement, that, the more tenacious the soil is, the greater should be the command of water for effecting the purpose; as a stream, capable of watering fifteen or twenty acres of light dry land, would be found to be beneficial in but a small degree when applied to watering half the same quantity of cold clayey ground such as in its natural state abounds with coarse plants. On all soils of the latter kind a considerable body of water for the purpose of floating them is required to produce much benefit, and where a sufficient quantity cannot be procured, this mode of improvement will seldom answer the farmer's intention or be advantageous in the result.

4387. *Smith, an experienced irrigator*, supposes that "there are only a few soils to which irrigation may not be advantageously applied: his experience, he says, has determined, that the wettest land may be greatly improved by it, and also that it is equally beneficial to that which is dry." (*Obs. on Irrigation, &c.*) But, as many persons unacquainted with the nature of irrigation may be more inclined to the latter supposition than the former, he explains the reason of wet land being as capable of improvement from flooding as that which is completely dry. It is, that, in the construction of all water meadows, particular care must be taken to render them perfectly dry when the business of floating shall terminate; and that the season for floating is in the winter and not in the summer, which those who are unacquainted with the process have too generally supposed. All peat bogs are certainly of vegetable origin, and those vegetables are all aquatic. It follows that the same water which has produced the vegetables of the bog would, under due management upon the surface, produce such grasses, or other vegetables, as are usually grown by the farmer; and he has hitherto had reason to think that this may be considered as a general rule for determining the situation of any experiments with water. The lands that permit of this sort of improvement with the most success are such as lie in low situations on the borders of brooks, streams, or rivers, or in sloping directions on the sides of hills.

4388. *The purity of the water to be used in irrigation* is supposed by some to be a matter of the first importance; but it is now fully proved, by the accurate experiments of an able chemist, and by the extraordinary growth of grasses in Pristley meadow, in Bedfordshire, that ferruginous waters are friendly to vegetation, when properly applied. (*Smith's Observations on Irrigation*, p. 28.) Lead or copper never does good, and it is well known, that waters of that description, after they have been brought into fields, by levels cut at a considerable expense, have again been diverted, and suffered to flow in their original channels. Waters impregnated with the juices that flow from peat-mosses, are considered by many not worth applying to the soil. It is objected to them, that they are soon frozen, that they convey no material nutriment, and that they are commonly loaded with such antiseptic substances as, instead of promoting, will retard vegetation. (*Dr. Singer's Treatise*, p. 579.) It is urged, on the other hand, that a want of sufficient slope in the meadow, or of proper management in regard to the water, may have occasioned the disappointments experienced in some cases, when bog-waters have been applied. (*Derbyshire Report*, vol. ii. p. 463.)

4389. *The advantages of watering lands* must, in a material degree, depend on the climate. It is evident that the benefit to be derived from this process in Sweden, for example, where the summers are short, must be greatly inferior to what it is in Lombardy, where grass grows all the year; and that in Perthshire, where grass ceases to grow for at least three and often four months in the year, it must be much less than in Gloucestershire or Ireland, where its growth is not interrupted above a month or six weeks, and sometimes not at all: most grasses vegetating in a temperature of 33 or 34 degrees. Still, however, as the most luxuriant pastures are found on lands naturally watered, both in Sweden and Perthshire, it would appear worth while to imitate nature in cold as well as in warm countries. According to many writers on the subject, the benefits attending watering in England are immense. In *Davis's Survey of Wiltshire*, it is calculated that 2000 acres of water meadow will, on a moderate estimate, produce, in four or five years, 10,000 tons of manure, and will keep in permanent fertility 400 acres per annum of arable land.

4390. *Watering poor land*, especially if of a gravelly nature, is stated in *The Code of Agriculture* to be by far the easiest, cheapest, and most certain mode of improving it. "Land, when once improved by irrigation, is put in a state of perpetual fertility, without any occasion for manure, or trouble of weeding, or any other material expense. It becomes so productive, as to yield the largest bulk of hay, besides abundance of the very best support for ewes and lambs in the spring, and for cows and other cattle in the autumn of every year. In favourable situations, it produces very early grass in the spring, when it is doubly valuable; and not only is the land thus rendered fertile, without having any occasion for manure, but it produces food for animals, which is converted into manure, to be used on other lands, thus augmenting, in a compound proportion, that great source of fertility." Were these advantages more generally known, or more fully appreciated, a large proportion of the Kingdom might become like South Cerney, in Gloucestershire, where every spring, or rivulet, however insignificant, is made subservient to the purpose of irrigation, fertilising, in proportion to its size, either a small quantity or a large tract of land. (*Gloucestershire Report*, p. 280.)

4391. *Irrigation by liquid manure* may occasionally be practised in the neighbourhood of towns and cities to the greatest advantage. In the neighbourhood of Edinburgh, we

are informed by Stephens, upwards of 200 acres are so irrigated from the principal common sewer, and that, although the formation of these meadows is irregular, and the management very imperfect, the effects of the water are astonishing: they produce crops of grass not to be equalled, being cut from four to six times a year, and the grass given green to milch cows.

SUBJECT. 2. Implements made Use of in Watering Lands; and the Terms of Art peculiar to such Operations.

4392. *The principal instruments made use of in the preparation of lands for watering are the following:—*

4393. *The level, of which different descriptions have already been given, is necessarily employed to take the level of the land at a distance, compared with the part of the river, &c. whence it is intended to bring the water, to know whether it can or cannot be made to float the part intended to be watered. Bringing the water after them to work by is found very useful in undertakings of this nature, especially when on a large scale, though the workmen too frequently dispense*

with it. In drawing a main, they begin at the head, and work deep enough to have the water to follow them; and in drawing a tail drain, they begin at the lower end of it, and work upwards, to let the water come after them. The level should, however, be made use of, as being more certain and correct. Brown, an experienced irrigator in the west of England, recommends a level (fig. 677. a), which when not in use may be closed (b) like a walking-stick. There is also a compass level (fig. 678.), which may be used in the same way.

4394. *A line and reel, and a breast-plough, or turf spade (fig. 211.), are likewise absolutely necessary. The use of the two former are well known; but as the line is mostly used in the wet, it should for this purpose be larger and stronger than those employed in gardening. The turf spade should be of the best description, being principally employed in cutting turfs for the sides of the channels.*

4395. *The spades made use of in this sort of work (fig. 679.) should have the stems considerably more crooked than those of any other kind; the bit being of iron, about a foot wide in the middle, terminating in a point; a thick ridge running perpendicularly down the middle, from the stem almost to the point; the edges on both sides should be drawn very thin, and as they are obliged to be kept very sharp, they should be often ground and whetted. This necessarily wears them away, and they soon become narrow; they are then used for the narrow trenches and drains, whilst new ones are used for the wider. From the stems being made crooked, the workmen, standing in the working position in the bottom of the trench or drain, are enabled to make it quite smooth and even. Shovels of different forms (fig. 680. a, b), and a scoop for lifting water (c), are also requisite.*

4396. *The crescent (fig. 679. b) is a tool made like the gardener's edging iron, only much*

larger, having the form of a crescent, being very thin and well steeled, with a stem about three feet long, and a cross handle to bear upon. It is used for tracing out the sides of the mains, trenches, drains, &c.

4397. *The turf knife (fig. 681.) has a cimeter-like blade, with a tread for the foot (a) and a bent handle (b): it is used for the same purpose as the crescent, and by some preferred.*

4398. *Wheelbarrows also become necessary to remove the clods to flat places: they may be open, without sides or hinder parts.*

4399. *Handbarrows are likewise sometimes made use of where the ground is too soft to admit of wheelbarrows, and where clods require to be removed during the time the meadow is under water.*

4400. *Three-wheeled carts, &c. are necessary, when large quantities of earth are to be removed, particularly when it is carried to some distance.*

4401. *Scythes, of different sorts (fig. 682. a, b), are required to mow the weeds and grass, when the water is running in the trenches, drains, &c. The crooks (b) should be made light, and have long stems, to reach wherever the water is so deep that the workmen cannot work in it.*

4402. *Besides these, forks (c), and long four or five lined haks, are requisite to pull out the roots of the sedge, rushes, reeds, &c. which grow in the large mains and drains.*

682

4403. *Stout large wateproof boots*, having tops so as to draw up half the length of the thigh, are indispensable; they must be large enough to admit a quantity of hay to be stuffed down all round the legs, and be kept well tallowed, to resist the running water for a length of time.

4404. *The terms made use of are various:—*

4405. *A wear* is an erection across a river, brook, rivulet, main, &c., made often of timber only, sometimes of bricks, or stones and timber, with from two to eight or ten thorough (openings) to let the water through, according to the breadth of the stream. Its height is always equal to the depth of the stream compared with the adjacent land. Its use is, when the hatches are all in their proper places, to stop the whole current, that the water may rise high enough to overflow the banks, and spread over the adjoining land; or, by stopping the water in its natural course, to turn it through mains cut for conveying it another way, to water some distant lands.

4406. *A sluice* (fig. 653. a, b) is made exactly as a wear, only it has but one thorough; for if there are more than one, it becomes a wear.

683

4407. *A trunk* is a covered sluice, being a necessary construction in all cases where two streams of water are to cross each other, to serve as a bridge for that stream which is to pass over or under the other.

4408. *A carriage* is a sort of small wooden or brick aqueduct, built open, for the purpose of carrying one stream over another, and is the most expensive conveyance belonging to the business of watering.

4409. *A drain sluice, or drain trunk*, signifies such as are placed in the lowest part of a main, as near to the head as a drain can be formed, and situated low enough to drain the main, &c. It is placed with the mouth at the bottom of the main, being let down into the bank; and from its other end a drain is cut to communicate with the nearest trench-drain. It is a contrivance to carry off the leakage through the hatches when they are shut down, to convey the water to other grounds, or to repair the main, &c.

4410. *Hatches* (fig. 653. c) are floodgates, variously constructed. A particular kind, which has about a foot to take off, so as to permit the water to flow over that much of the hatch where it appears to be useful in irrigation, has been employed, but is not found to answer. They are best when made whole. They may be made of any timber, but oak and elm are the best.

4411. *Head main* is a term used to signify a ditch drawn from the river, rivulet, &c. to convey the water out of its usual current to water the lands laid out for that purpose, through the means of lesser mains and trenches. The head main is drawn of various breadths and depths, according to the quantity of land to be watered, to the length, or to the fall or descent of the land it is cut through. Smaller mains are frequently taken out of the head main, at, or nearly at, right angles, to which they are usually cut. They are much smaller than the head main, and this constitutes the only difference. The use of both the large and small mains is to feed with water the various trenches which branch out into all parts of the meadow. These smaller mains are by some called carriages, but improperly, for it is confounding them with the open trunk, called by that name, as seen above.

4412. *The trench* is a narrow shallow ditch, for conveying the water out of the mains to float the land. It ought always to be drawn in a straight line from angle to angle, with as few turnings as possible. It is never made deep, but the width is in proportion to the length it runs, and the breadth of the pane between it and the trench drain. It narrows gradually to the lower end.

4413. *The trench drain* is cut parallel to the trench, and as deep, when necessary, as the tail drain water will admit. It ought always to be cut, if possible, so as to come down to a firm stratum of sand, gravel, or clay; if the latter, a spade's depth into it will be of great advantage. Its use is to carry away the water immediately after it has run over the panes from the trench. It need not be drawn up to the head of the land, by five, six, or more yards, according to the nature of the soil. Its form is the reverse of the trench, being narrower at the head, or upper part, and gradually wider, till it comes to the lower end and empties itself into the tail drain.

4414. *The tail drain* is a receptacle for all the water that runs out of the other drains, not so situated as to empty themselves into the river; and therefore it should run nearly at right angles with the trenches, but, in general it is drawn in the lowest part of the ground, and used to convey the water out of the meadow where there is the greatest descent. This is generally found in one of the fence ditches; for which reason a fence ditch is mostly used, at once fencing the meadow and draining it.

4415. *A pane of ground* is that part of the meadow which lies between the trench and the trench drain, and is the part of which the grass grows that is mown for hay; it is watered by the trenches, and drained by the trench drains, consequently there is one on each side of every trench.

4416. *A way pane* is the part of the ground which, in a properly watered meadow, lies on that side of a main where no trench is taken out. It is watered the whole length of the main over its banks, and a drain runs parallel with the main to drain the way pane. Its use is to afford a road for conveying the hay out of the meadow, and prevent the teams from crossing all the trenches.

4417. *A bend* is a stopping made in various parts of those trenches which have a quick descent. It is formed by leaving a narrow rib of ground across the trench, where the bend is intended to be, cutting occasionally a wedge-shaped piece out of the middle of it. Its use is to check the water, and force it over the trench into the pane; for if it were not for those bends, it would run rapidly on in the trench, without flowing over the lands as it passed along. The great art of watering meadows consists in giving to every part of each pane an equal quantity of water.

4418. *A gutter* is a small groove cut out of the tails of those trenches, where the panes run longer at one corner than the other. Its use is to carry the water to the extreme point of the pane. Those panes which are intersected by the trench and tail drains meeting in an obtuse angle, want the assistance of these gutters to convey the water to the longest side; and when, from insufficient levelling, some parts of the panes lie higher than they ought, a gutter is drawn from the trench over that high ground, which otherwise would not be overflowed. Without this precaution unless the flats were filled up (which ought always to be done when materials can be had), the water would not rise upon it; and after the watering season was past, those places would appear rusty and brown, whilst a rich verdure would overspread the others; at hay-time, also, the grass in those places would be scarce high enough

for the scythe to touch it, whilst that around them, which had been properly watered, would from its luxuriance lie down. Though this method of treating such places is mentioned, their existence ought always to be reprobated; for every inequality in water meadows should either be levelled down or filled up. Here the irrigator's skill is shown, in bringing the water over those places to which it could not rise of itself, and in carrying it off from others where it would otherwise stagnate.

4419. *Catch drain* is a term sometimes applied to a method made use of to irrigate the land when the water is scarce, and the method is this: when a meadow is pretty long, and has a quick descent, the water is made to run swiftly down a drain or drains, in which it is stopped at different distances so as to spread it over the adjoining surface. (See fig. 686, p. 728.)

4420. *The bed of a river, main, trench, &c.*, is the bottom of it.

4421. *Pond* means water standing upon the land, or in the tail drain, trench drains, &c., so as to injure the ground near them; and is occasioned sometimes by the flats not having been properly filled up; and at other times, when, a ware being shut close, to water some high ground above it, the water is thrown back upon the ground contiguous. In this case the lesser evil, whichever it is, must be borne with.

4422. *A turn of water* means so much land in a meadow as can be watered at one time. It is done by shutting down the hatches in all those weirs where the water is intended to be kept out, and opening those that are to let the water through. The quantity of land to be watered by one turn must vary with the size of the river, main, &c. as well as with the plenty or scarcity of water.

4423. *The head of a meadow* is that part into which the river, main, &c. first enters; and the tail of a meadow is that part out of which the river, &c. last passes.

4424. *The upper side of a main, or trench*, is that side which (when the main or trench is drawn at, or nearly at, right angles with the river, &c.) fronts the part whence the river entered. Consequently the lower side is the reverse.

4425. *The upper pane* in a meadow is that pane which lies upon the upper side of the main, or trench, drawn at right angles with the river: that is, when the river, &c. runs north and south, entering at the north, and the mains and trenches are drawn east and west, all those panes which lie on the north side of the main, &c. are called the upper panes, those on the south side are called the lower. But it may be noticed, that where the mains, trenches, &c. run parallel with the river, the panes on either side are not distinguished from each other.

4426. *Meadows are of two sorts*: flowing, calculated for a flat country; and catch-work, for sloping grounds.

4427. *Flowing meadows*. Where the ground is flat, the soil is formed into beds, or broad ridges, like those met with at bleachfields. They are commonly from 50 to 40 feet wide, and nine or ten poles in length; as, in such situations, the great object is, when once brought on, to be able to carry off the water quickly. Hence it is necessary to throw up the land in high ridges, with drains between them. More of the failures in irrigation arise from the ridges not being sufficiently high, and the slopes not being sufficiently steep, than from any other cause. (Code.)

4428. *Catch-work meadows*. It is difficult to give an intelligible written description of the mode of making these meadows. To be properly understood, the operation must be seen. It may, however, in general be remarked, that the system is calculated for sloping grounds, and that, after the water is brought from the original stream, into a new cut, it is stopped at the end, on as high a level as the case admits of, by which means it is made to fill the trench, and run over at the side, flooding the land below. But as the water would soon cease to run equally, and would wash the land out in gutters, it has been found necessary to cut small parallel trenches, at the distance of from 20 to 50 feet, to catch the water again (hence the name originated), and the same plan of spreading or diffusing is continued, until the water reaches the main drain at the bottom of the meadow. It is a great advantage attending the catch-work system, that it is not only less expensive, but the same quantity of water will do much more work. (Code.)

SUBJECT. 3. Preparation of Surfaces for Irrigation.

4429. *Artificial irrigation*, Smith observes, is produced by diverting the water of a brook out of its accustomed channel (where there is a fall) in such a manner that, the new watercourse being kept nearly level, the space between the old and new channel may be floated; the water being brought upon the land by the new channel and taken away by the old one. Thus a constant discharge and succession of water is maintained, without such an accumulation as would make it appear bright upon the land, or without such a deficiency as would leave any part of it not perfectly floating; for the art of irrigation may be most properly called floating, not soaking nor drowning. Soaking the soil, similar to the effects produced from a shower of rain, is not sufficient for the general purposes of irrigation, nor will damming up water, and keeping it stagnant upon the surface, like that in a pond, or on the fens, produce the desired effect.

4430. *Stagnating water on land* may properly be called drowning, because it drowns or covers all the grass, thereby rendering the plants beneath it in some degree aquatic, or the herbage disposed to make such a change; whereas the herbage of a water meadow should, by the construction and good management of the latter, enjoy the full benefits of both the elements of air and water. Practice has proved that there is no better method of doing this than by keeping water passing over the surface of the land with a brisk current; not so brisk as to wash away the soil, and yet in sufficient quantity to cover and nourish the roots; but not too much to hide the shoots of the grasses: hence appears the nicety of adjusting the quantity of water; and hence it also appears, that one main drain to bring the water on the upper side of the mead, and another on the lower side to take it away, will not be adequate to all the purposes of such an accurate regulation. If the space between the upper channel or main feeder and the lower one or main drain, should therefore be wider than is proper for the good adjustment of the water, that is, so that every part of the space shall have enough water passing over it and no part too much, then that space must be divided into smaller spaces by intermediate drains, which shall catch and re-distribute the water. As the water is brought by the main feeder upon the higher

side of a piece of ground which slopes towards the main drain, and down which sloping surface the water will run very readily, it does not, to persons unacquainted with irrigation, at first sight appear necessary to make such a number of intermediate catch drains; but it is proved by experience, that, however regular the slope of ground may appear to the eye, the water will find a number of irregularities, forcing itself into gutters or channels, and defeating the purposes of irrigation; in the hollow places by excess, and in high ones by the want of water. Hence the water, which was scattered over the surface of the first space, being all collected in the catch drain, may by the skill of the floater be let out upon those parts of the bed below which appear to need the most assistance.

4431. *The work should always be well formed at first in all cases of improvements of this nature.* Temporary means of making dams and hatches to divert the water out of its usual channel may, says Smith, suffice to try an experiment, or for a tenant who has but a short term in the grounds to be irrigated; but every land-owner who enters upon such work in this temporary manner sadly mistakes his own interest: indeed, it is frequently more difficult to repair than to renew upon large streams, when the foundations are often destroyed by the force of the water. The same principle holds good upon small streams, and even in the drains and feeders of a water meadow. Wherever the channels are so constructed as to make a fall, or much increase the rapidity of the stream, it is constantly disposed to wear away the sides of its channel, or undermine a dam. To repair these defects, land must be dug away and wasted each time it is replaced, with the loss of labour. The consequent ill management of the water renders it more advisable, and perhaps cheaper, to make all such works of masonry. When works are well done at first, the owner ever finds much pleasure in viewing them; and even the labourers feel much more interested in their good management.

4432. *The expenses of making a water meadow are not easily estimated.* Much depends on the original state of the ground, the size and fall of the streams to be used, the cost of hatches, and length of the main feeders which may be necessary for diverting the water out of its original channel, and even upon the charge for levelling land, which differs materially. Some soils are much harder and more difficult to move than others, and, in certain situations, building materials are very scarce and dear. This last circumstance must make a considerable variation in the price of the hatches, where the stream is large. It is also impossible to tell, with any degree of certainty, what proportion these expenses should bear to the quantity of land irrigated, for some situations will require much more masonry than others.

4433. *Before entering upon the execution of a water meadow, it is necessary to consider fully, whether the stream of water to be made use of will admit of a temporary wear or dam to be formed across it, so as to keep the water up to a proper level for covering the land without flooding or injuring other adjoining grounds; or if the water be in its natural state sufficiently high without a wear or dam; or can be made so by taking it from the stream higher up more towards its source; and by the conductor keeping it up nearly to its level till it comes upon the meadow or other ground: and still further, whether the water can be drawn off the meadow or other ground in as rapid a manner as it is brought on.* Having, in addition to these, an attention to all such other difficulties and obstructions as may present themselves, from the lands being in lease, through which it may be necessary to cut or form the mains or grand carriers, from the water being necessary for turning mills, from the rivers or brooks not being wholly at the command of the irrigator, and from small necks of land intervening so as to prevent the work from being performed to the greatest advantage, the operator may be in a situation to commence his operations.

4434. *In order to have an equal distribution and prevent waste,* Smith states, that no part of a meadow, either in catch-work or beds, should be so formed as to be floated directly from the main feeder; but all the main feeders should be kept high enough to discharge the water into the small feeders with considerable velocity and through a narrow opening. The motion of water is truly mechanical: it requires a great deal of ingenuity, and a perfect knowledge of lines and levels, to make it move over the ground in a proper manner. No two pieces of land being exactly alike, renders it still more difficult to set out a water meadow; but even if the figure of two pieces be alike, the inequalities of surface will probably vary. Each meadow, therefore, requires a different design, unless the landowner makes up his mind to the heavy expenses of paring off banks, and filling up such hollows as may be necessary to reduce it to some regular method; the construction to be varied according to the nature of the ground. This constitutes the difference between the water meadows of Berkshire and Devonshire. Those of the latter are upon small streams carried round the sides of the hills, and are chiefly catch-work; those of the former, being near large rivers and boggy ground, are thrown up into ridges to create a brisk motion in the water, and also for the essential purpose of draining off all superfluous moisture, which might be injurious to the grasses when shut up for feeding or mowing. Where there is much floating to be done with a little water, or rather where the great fall of a small stream will admit of its being carried over a vast quantity of ground and used several times, it is desirable to employ it in such

a way as that the earthy particles it may contain may be deposited as equally as possible over the whole surface to be irrigated. But it is to be observed, that this mode of applying water must not be exhibited as a perfect model. If it should answer the purpose of a coat of manure, upon such an extent of ground, it is all that can be expected, and will amply repay the expense. Losing fall is wasting water.

4435. *The drains of a water meadow* require no greater declivity than is necessary to carry the water from the surface; therefore the water ought to be collected and used again at every three feet of the fall, if it be not catch-work. It is sometimes difficult to do this in bed-work meads; but where the upper part of the meadow is catch-work or in level beds, and the lower part not too much elevated, it may be done. By collecting and using the water again in the same piece of ground before it falls into the brook, a set of hatches is saved; and it is not necessary to be very particular about getting the upper part into high ridges, since that part of the meadow which is near the hatches generally becomes the best, and the lower end of the field, being often the wettest or most boggy in its original state, requires to be thrown up the highest. If the land is of a dry absorbent nature before floating, it is not necessary that it should be thrown up into high beds, but merely as much inclined as will give the water a current.

4436. *Inclined planes are absolutely necessary for the purpose of irrigation.* To form these between straight and parallel lines, it is necessary to dig away land where it is too high, and move it to those places where it is too low, to make such a uniformity of surface. The new-made ground will of course settle in hollows proportioned to the depth of loose matter which has been recently put together, but this settlement will not take place until the new soil has been completely soaked and dried again; therefore these defects cannot be remedied before the second or third year of watering: it will therefore require more skill to manage a water meadow for the first three or four years, than afterwards.

4437. *Properly to construct a water meadow* is much more difficult than is commonly imagined. It is no easy task to give an irregular surface that regular yet various figure which shall be fit for the overflowing of water. It is very necessary for the operator to have just ideas of levels, lines, and angles; a knowledge of superficial forms will not be sufficient; accurate notions of solid geometry (obtained from theory or practice) are absolutely necessary to put such a surface into the form proper for the reception of water, without the trouble and expense of doing much of the work twice over. (*Obs. on Irrigation, &c.*)

4438. *As an example of irrigating a meadow from both sides of a river,* we take the following case from Boswell's treatise. From the upper part of the grounds, two main drains (fig. 684 *a, a*)

are formed at right angles to the river, one running north, the other south, across the meadow, to within about six yards of the fence ditches which surround it (*b*) and are used for tail drains: by means of these fence ditches the water is discharged into the river. A wear erected across the river forces the water into either of the main drains, which is done by shutting the other wear close. When there is not water enough, or it is not convenient to water both parts of the meadow at once, by shutting close one of the wears, the current is forced into that main whose wear is open, thence to be conveyed through the trenches over the panes, to water that side of the meadow; then by shutting that, and opening the other, the opposite main is filled, and by means of the trenches that side of the meadow is watered in the same manner; and lastly, by shutting them both, and opening the river wear, the water flows in its usual course, and the land on both sides is laid dry. From the main drains (*a, a*) the

water flows along the highest part, or crowns of the ridges in the trenches (*c*), and is carried off to the tail drains by the trench drains (*d*).

4439. *As an example of an irregular surface watered from one side of a river,* we shall have recourse

to the same author. There is a wear (fig. 685. *c*) erected across the river, and another across the head-main (*a*), from which proceed three main and branch trenches (*g, g, g, and f, f*), which water the whole meadow. There is a tail drain (*b*) for carrying off the whole of the water by means of the drain trenches (*d, d*). The water, having thus passed over the field, is returned to the river by the tail drain already mentioned. When it is desired to withhold the water, the wear of the head main (*a*) is shut, and that of the river (*c*) opened. It will be observed, that in this design there are branch trenches (*f, f*), and various gutters (*h, h*), taken out of the ends of some of the trenches, to carry the water to the longest corner of the panes, and sometimes taken out of different parts of the trenches, to water some little irregularities in the panes, which, without such assistance, would not have any water upon them. There

is a sluice (*i*) erected at the end of one of the small mains, to force the water into the branch trench adjoining it (*f*), that being the highest ground.

440. A very complete piece of irrigation (fig. 686.) was formed for the Duke of Bedford, by Smith, at Pristley. The water is supplied from a brook (a), to a main feeder, with various ramifications (b, b); the

686

surface is formed into ridges (c, c), over which the water flows, and is carried off by the drains in their furrows (d, d), to the main drains (e, e), and to the brook at different places (f, f). There are bridges (g) over the main feeders, small arches over the main discharging drains (h), and three hatches (i).

441. As an example of catch-work watering, we may refer to a case (fig. 687.), given in a recent work

687

by John Brown. (*Treatise on Irrigation*, 1817.) In this the field of operations being on the steep side of a hill, a main carrier is led from the sluice (a), directly across the declivity (b), and lateral feeders (c) taken out from it at regular distances. These feeders have stops of turf, at regular distances (d), by which means the water is dispersed. After watering a space of from twenty to forty feet in breadth, it is again collected by the small drains in the furrows, and returned lower down to another feeder. The advantage of this method, Browne observes, "relates more materially to the sides of hills, and to porous soils that are by some thought incapable of being watered. The chief point is to get the water to the highest level possible; and in case the soil be porous, one main carrier only will require puddling, in order to prevent the water from sinking away: when that is done, no difficulty whatever is found in taking it in small streams vertically, or directly down the slope (c), and putting stops (d) to arrest its progress occasionally, which will throw it on each side; and when those stops are placed one above another, it will have the effect of spreading the water on the land, somewhat similar to a fan when extended. The stops need only be sods or turfs, one laid lengthways in the gutter, and one across it, which may be raised or lowered according to the declivity: these sods or turfs will require probably a small wooden peg to fasten them at first; and by the time the land requires a second watering, the roots of the grass will have sufficiently fastened them; and they need not be removed, unless occasionally for the purpose of watering any separate part below, when the stream may be too small to water the whole piece at once; and the small cuts for conveying the water will be less expensive in cleaning, not being so liable to choke up as

those carried on what is termed horizontal or level gutters. In some places in Essex, it is the practice to irrigate during winter by means of the water of occasional floods. Sometimes this water is obtained from the ditches along the sides of the roads, and from the drainages of villages; and in these cases is more or less enriched by carthy materials.

4442. *As an example of the benefit of flooding*, we refer to Loch Ken, in Kireudbrightshire, the most striking instance known in Great Britain of advantage being derived from the inundations of a lake. At the head of that beautiful piece of water, there is a flat of about 240 statute acres, which is rendered, by flooding, one of the richest spots in Scotland. Many acres in it produce at the rate of three tons of hay each, and some parts of it have been cropped with grain for twenty-five years in succession, without any manure, except what it receives from the inundations it experiences. These, however, leave behind them a variety of enriching substances. (*Statistical Account of Scotland*, vol. iv. p. 260.)

4443. *Floating upwards.* The ancient and now obsolete practice of flooding, or, as it was termed, of floating upwards, was practised in various parts of the kingdom. For that purpose, the water was penned, in times of floods, by means of a dam or floodgate across the bottom of the meadow or flat to be watered. The waters were not suffered to remain long upon the land, but were let off as soon as it was judged that they had deposited their sediment. The benefit arising from this method of using floodwaters, it is said, was considerable; but when the improved mode of irrigation by floating ridges was introduced, and found more advantageous, the other was discontinued. (*Marshal's Midland Counties*, Minute 27.)

4444. *Watering land by machinery.* If the land be put in a proper form for irrigation, and supplied with a good stream at proper seasons, there can be no difference from the method of getting it on the surface; and if all other circumstances are equally favourable, the same fertility may be expected from water thrown up by a drain-mill, as from that which runs from a brook. (*Smith's Observations on Water Meadows*, &c. p. 93.) A cheap and effectual power for raising water in sufficient quantities to flow about ten acres at a time, would be an invaluable acquisition; for a productive water meadow is probably the true mark of perfection in the management of a farm. (*Middlesex Report*, p. 322.)

4445. *Sea water.* Smith suggests the idea of employing machinery to raise not only fresh but even sea water for irrigation. (*Observations*, p. 87.) It is well known how much all kinds of stock are improved by salt marshes, and how beneficial to them is a moderate quantity of saline matter. There are many parts of the kingdom where, by the aid of machinery, these advantages might be obtained at a moderate expense. (*Code*.)

4446. *The expense of irrigation* varies according to the nature of the work. Where the catch-work system is practicable, in favourable situations, the forming may be done as low as ten shillings per acre. This fact is, in many cases, decisively in favour of this natural and simple mode, which requires also much less water, and often answers fully as well as flat flooding. (*General Report*, vol. ii. p. 598.) The expense of bed-work, as it is called, is, however, considerable. If the ground to be flooded be smooth on its surface, or in regular ridges, and if the water can easily be brought to the meadow, with a temporary wear, supposing the extent to be almost twenty acres, it may be done at from 5*l.* to 10*l.* per acre: but if the land be of large extent, with an irregular surface; if a large conductor and a proper wear shall be required, with hatches both in it and also in the feeders; and if the aid of a professional person, to lay out and oversee the work, be necessary (which is generally the case), the expense will vary from 10*l.* to 20*l.* per acre. (*General Report*, vol. ii. p. 598.) Nay, in Wiltshire, where they are anxious to have their meadows formed in the most perfect manner, with that regularity which the nice adjustment of water demands, the expense per acre has amounted to 40*l.* (*Smith's Observations on Irrigation*, p. 56.)

4447. *Objections to irrigation* have been made on the supposition that it renders a country unhealthy; but as the water is continually kept in motion, this is not likely to be the case, and indeed is found not to be so in Gloucestershire, Lombardy, and other places where it is extensively practised. It is also thought that though the produce may be increased, it becomes in a few years of so coarse a nature, mixed with rushes and water plants, that cattle frequently refuse to eat it; and when they do, their appearance proclaims that it is far from being of a nutritious quality. (*Rutland Report*, p. 114.) But this objection is never applicable to meadows skillfully made and properly managed; and whenever the grasses are coarse, if intended for hay, they should be cut earlier. Rushes and water plants are proofs that the meadow lies too flat and is ill managed. (*Code*.)

4448. *The principal impediments to irrigation* are the claims of different individuals on one stream, as millers, canal owners, &c.; the intermixture of property and interests; and the existence in some cases of adverse leases.

4449. *The formation and arrangement of surfaces* for irrigation, however simple in principle, is in practice one of the most difficult operations of agricultural improvement. Whoever, therefore, contemplates extensive and intricate works of this kind will find it desirable to call in the assistance of a professor and contractor of reputation. In Gloucestershire there are a class of men known as "flooders," who have under them a com-

pany of men accustomed to every part of the work, and who accompany their chief to execute works in any part of the country.

SECT. II. *Warping, or the Improvement of Land by muddy Water.*

4450. *Warping* is a mode of fertilising lands by depositing a coat of mud on their surface. This may be practised on the borders of large rivers and estuaries into which sea tides flow, or where floods are frequent; provided, however, that in either case the waters contain alluvial matters in a state of suspension. According to the best information that can be obtained (*Marshal, in R. Econ. of York., 1788. Day, West Riding Report, p. 171.*), warping was first practised on the banks of the Humber, by one Barker, a small farmer at Rawcliff, between 1730 and 1740: it was afterwards extended by Richard Jennings, of Armin, near Howden, in 1743; but, till about the year 1753, it was not attempted by any other person. It was first brought into notice by Marshal, in 1788, and subsequently in the *Report of the West Riding of Yorkshire*, and is now practised by various proprietors and farmers on the Humber, the Trent, and other rivers. It has been long practised in Italy in a manner something different from that employed in this country. It may be considered as of Egyptian origin.

4451. *The theory of warping* is thus given by Arthur Young: —

4452. *The water of the tides* that come up the Trent, Ouse, Dun, and other rivers which empty themselves into the great estuary of the Humber, is muddy to an excess; inasmuch that in summer, if a cylindrical glass, twelve or fifteen inches long, be filled with them, it will presently deposit an inch, and sometimes more, of what is called warp. Where this warp comes from is a dispute: the Humber, at its mouth, is clear water; and no floods in the countries washed by the warp rivers bring it, but, on the contrary, do much mischief by spoiling the warp. In the very driest seasons and longest droughts, it is best and most plentiful. The improvement is perfectly simple, and consists in nothing more than letting in the tide at high water, to deposit the warp, and permitting it to run off again as the tide falls: this is the aim and effect: but to render it efficacious, the water must be at command, to keep it out and let it in at pleasure; so that there must not only be a cut or canal made to join the river, but a sluice at the mouth to open or shut, as wanted: and, that the water may be of a proper depth on the land to be warped, and also prevented from flowing over contiguous lands, whether cultivated or not, banks are raised around the fields to be warped, from three or four to six or seven feet high, according to circumstances. Thus, if the tract be large, the canal which takes the water, and which, as in irrigation, might be called the grand carrier, may be made several miles long: it has been tried as far as four, so as to warp the lands on each side the whole way, and lateral cuts made in any direction for the same purpose; observing, however, that the effect lessens as you recede from the river; that is, it demands longer time to deposit warp enough for producing benefit.

4453. *The effect of warping* is very different from that of irrigation: for it is not the water that wears the effect, but the mud; so that in floods and in winter the business ceases; and it is not the object to manure the soil, but to create it. The nature of the land intended to be warped is not of the smallest consequence: bog, clay, sand, and peat, are alike eligible; as the warp raises it in one summer from six to sixteen inches thick, and in the hollows or low places, two, three, or four feet, so as to leave the whole piece level. Thus a soil of any depth you please is formed, which consists of mud of a vast fertility, though containing not much besides sand and gravel.

4454. *The method of executing the work* is described in the following manner by Lord Hawke, in *The Agricultural Survey of the West Riding of Yorkshire*: —

4455. *The land to be warped* must be banked round against the river. The banks are made of the earth taken on the spot from the land: they must slope six feet; that is, three feet on each side of the top or crown of the bank, for every foot perpendicular of rise: their top or crown is broader or narrower, according to the impetuosity of the tide, and the weight and quantity of water; and it extends from two feet to twelve: their height is regulated by the height to which the spring tides flow, so as to exclude or let them in at pleasure. In these banks, there are more or fewer openings, according to the size of the ground to be warped, and to the choice of the occupier; but in general they have only two sluices; one called the floodgate, to admit, the other, called the clough, to let off, the water gently: these are enough for ten or fifteen acres. When the spring tide begins to ebb, the floodgate is opened to admit the tide, the clough having been previously shut by the weight of the water brought up the river by the flow of the tide. As the tide ebbs down the river, the weight or pressure of water being taken from the outside of the clough next the river, the tide water that has been previously admitted by the floodgate opens the clough again, and discharges itself slowly but completely through it. The cloughs are walled on each side, and so constructed as to let the water run off, between the ebb of the tide admitted and the flow of the next; and to this point particular attention is paid. The floodgates are placed so high as only to let in the spring tides when opened: they are placed above the level of the common tides. Willows are also occasionally planted on the front of the banks, to break the force of the tides, and defend the banks by raising the front of them with warp thus collected and accumulated; but these willows must never be planted on the banks, as they would destroy them by giving the winds power to shake them.

4456. *The season for warping* begins in the month of July, and continues during the summer; and as this sort of business can only be performed at that season, every occasion of having it executed should be embraced, by having the work in perfect repair, that every tide may be made to produce its full effect. With regard to the advantage of doing this work in the summer months, it may be remarked that at these times the lands not only become the soonest dry, a circumstance which must always fully take place before the process of cultivation can be carried on; but the tides are less mixed with fresh water, in which condition they are constantly found the most effectual.

4457. *The expense of this mode of improving lands* must differ much in different cases, according as the circumstances of situation and distance vary; but it can seldom exceed

12l. or 15l. the acre, according to Young, and in most instances it must be greatly below such estimates.

4458. *That no estimate can be made without viewing the situation of the lands to be warped, and the course and distance it will be necessary to carry the warp to such lands, is remarked by Day, in the Agricultural Survey of the same district.* 1st, The situation of the lands must be considered; 2d, The quantity of land the same drains and cloughs will be sufficient to warp; 3d, The expense of building the cloughs, cutting the drains, embanking the lands, &c. An estimate of these expenses being made, it will then be necessary to know the number of acres such cloughs and drains will warp, before any estimate can be made; as the greater the quantity of land the same cloughs and drains will warp, the lighter the expense will be per acre. In Day's opinion, there is a great deal of land in the country capable of being warped at so small an expense as from 4l. to 8l. per acre, which is nothing in comparison to the advantages which arise from it. He has known land raised in value by warping, from 5l. to upwards of 40l. and 50l. per acre. The greatest advantages arise upon the worst land, and the more porous the soil the better, as the wet filters through, and it sooner becomes fit for use. The advantages of warping are very great; as, after lands have been properly warped, they are so enriched thereby that they will bring very large crops for several years afterwards without any manure; and, when it is necessary, the lands might be warped again, at a very trifling expense, by opening the old drains, and would bring crops in succession for many years, with very little or no tillage at all, if the lands were kept free from quick grass and other weeds, which must be the case in all properly managed lands; besides, the drains which are made for the purpose of warping are the best drains that can be constructed for draining the lands at the time they are not used for warping, which is another very great advantage in low lands.

4459. *The best mode of cultivating new-warped land must depend principally on the nature of the warp and of the subsoil.* In the *Code of Agriculture* it is recommended to sow it with clover, and to let it lie under that crop for two years, in order that it may be brought into a state fit for corn. Even though fallowed, it does not answer to sow land with wheat immediately after it is warped; but after white or red clover for two years, a good crop of wheat may generally be relied on. Nor is it proper, when land is warped, to plant it with potatoes, or to sow it with flax, being at first of too cold a nature; though, if the land be not too strong for potatoes, these crops may answer, after it has been for two or three years in cultivation. In the quality of warped land, there are most essential differences; some will be very strong, and in the same field some will be very friable. The land nearest the drain is in general the lightest, owing to the quantity of sand that is deposited as soon as the water enters the field: the land farthest from the drain is in general the best. The produce of warped land varies much, but in general it may be stated as abundant. (*Code*, 315.)

SUBJECT. 1. *Irrigation of Arable Lands, and Subterraneous Irrigation.*

4460. *The irrigation of arable lands is universal in warm countries, and even in the south of France and Italy.* The land is laid into narrow beds, between which the water is introduced in furrows during the growth of the crop, and absorbed by the soil. In other cases the crop is grown in drills, and the water introduced in the furrow between each row. In this mode of irrigation no collecting drains are required, as the whole of the water laid on is absorbed by the soil. The principal expense of the operation is that of preparing the lands by throwing the surface into a proper level or levels. The main or carrier is conducted to the higher part of the field, and the rest is easy. A particular description of the practice, as carried on in Tuscany, is given by Sigismondi. (*Agr. de la Toscane.*) Some account also of the practice in Italy and the East Indies will be found in our outline of the agriculture of these countries. (267 and 921.) In the *General Report of Scotland*, vol. iii. p. 361. it is stated, that a field of waste land, which had been flooded during winter with stagnant water, was thus, without manure, rendered capable of yielding a good crop of oats; but this is more of the nature of warping than of that description of irrigation which is practised in warm countries on arable lands, during the growth of the crop.

4461. *Subterraneous irrigation appears to have been first practised in Lombardy, and first treated of by Professor Thouin. (Annales du Musée, &c.)* It consists in saturating a soil with water from below, instead of from the surface, and is effected by surrounding a piece of ground by an open drain or main, and intersecting it by covered drains communicating with this main. If the field is on a level, as in most cases where the practice is adopted in Lombardy, nothing is more necessary than to fill the main, and keep it full till the lands have been sufficiently soaked; but if it lies on a slope, then the lower ends of the drains must be closely stopped, and the water admitted only into the main on the upper side: this main must be kept full till the land is soaked, when the mouths of the lower drains may be opened to carry off the superfluous water. The practice is applicable either to pasture or arable lands.

4462. *In Britain, subterraneous irrigation has been applied in a very simple manner to drained bogs and morasses, and to fen lands.* All that is necessary is to build a sluice in the lower part of the main drain where it quits the drained grounds, and in dry weather to shut down this sluice, so as to dam up the water and throw it back into all the minor open drains, and also into the covered drains. This plan has been adopted with success, first, as we believe, by Smith, of Swineridge Muir, in Ayrshire, and subsequently by Johnston, in the case of several bog drainages executed by him in Scotland.

It is also practised in Lincolnshire, where it was introduced by the advice of the late engineer Rennie, after the completion of a public drainage at Boston.

SECT. III. *Artificial Means of Procuring Water for the Use of Live Stock.*

4463. *Water is supplied by nature in most parts of the British isles, and retained with little art both at farmeries and in fields.* There are exceptions, however, in different districts, and especially in chalky soils, gravels, and some upland clays. In these cases water is procured for cattle by some of the following means:—By conducting a stream from a distant source, as in a work of irrigation; by collecting rain-water from roads, ditches, or sloping surfaces, in artificial ponds, or reservoirs; by collecting it from the roofs of buildings, and preserving it in covered cisterns; by sinking a well, or a pipe, either in the field or the farm-yard; and by artificial springs.

4464. *An artificial stream* will in most cases be found too expensive an operation to be undertaken for the supply of drinking-water for live stock; but this purpose may frequently be combined with that of watering lands or driving machinery. In the North Riding of Yorkshire, there is a tract extending for many miles entirely destitute of water, except what flows along the bottoms of the deep valleys by which it is intersected; and little relief could consequently be afforded, by streams thus distantly and inconveniently situated, to the inhabitants of the uplands, or their cattle. About the year 1770, a person of the name of Ford devised the means of watering this district, by means of rills brought from the springs that break out at the foot of the still loftier moorland hills that run parallel to, and to the north of, this tract, in some instances at the distance of about ten miles. The springs he collected into one channel, which he carried, in a winding direction, about the intervening space, according to its level, and along the sides of the valleys, until he gained the summit of the arid country which he wished to supply with water; and when this was accomplished, the water was easily conveyed to the places desired, and also to the ponds in all the fields, over a considerable tract of ground.

4465. *Collecting rain-water from roads, &c. in ponds or drinking pools.* Formerly, it is probable, something of this art was practised throughout the kingdom: most villages, and many old farmsteads, have drinking pools for stock, which appear to have been formed or assisted by art. In strong-land grazing districts, pits have evidently been dug, to catch the rain-water fortuitously collected by furrows and ditches, or by land-springs. On the chalk hills of the southern counties, the art has been long established, and continued down to the present time.

4466. *An improved practice* was introduced on the wolds or chalk hills of Yorkshire by Robert Gardner, of Kilham, which gained an establishment towards the end of the last century, and has spread rapidly over the adjacent heights, with great profit to the country. In every dry-land situation, it may be practised with high advantage to an estate, and is well entitled to attention.

4467. *The mode of constructing these collecting ponds* is described in *The Annals of Agriculture* (vol. vi.), and illustrated by a section. (fig. 688.) The ground plan is circular, and generally forty or fifty feet

688

thickness, is finely and uniformly spread. Next is another layer of clay of about one foot in thickness (*d*), which is to be trodden and rammed down as the former. Upon this are spread stones or coarse gravel (*e*), of such thickness as may prevent the pond receiving any injury from the treading of cattle, which would otherwise break through the body of the clay and lime, and by so doing let out the water. After this, the pond will remain five feet deep and forty-five feet in diameter; the size they are usually made.

4468. *Brick-clay is by no means required* for the ponds; any earth sufficiently tenacious to bear beating into a solid compact body, though not approaching to a pure clay, will answer the purpose very well.

4469. *The preferable situation to make the pond* is a little valley, or at the bottom of a declivity, or near a high road, in which situation a stream of water may be brought into it after sudden showers or thaws, the object being to get it filled as soon as possible after it is made, that the sun and winds may not crack the clay. If it is not likely to be filled soon, some straw or litter must be spread over it; but in general, after it is once filled, the rains that fall in the course of the year will keep it full, no water being lost otherwise than by evaporation and the consumption of cattle.

4470. *The whole excellence of the pond depends upon the lime*: care must be taken to spread it regularly and uniformly over the surface of the lower bed of clay. It is well known that ponds made of clay alone, however good its quality, and whatever care may be bestowed in the execution, will frequently not hold water: these, with the above precautions, rarely fail. By what means the lime prevents the loss of water is not exactly known: one of these two is probably the cause: either the lime sets like terrace into a body impervious to water; or its causticity prevents the worms in dry weather from penetrating through the clay in search of the water: certain, however, it is, that, with lime thus applied, ponds may be made in sand, however porous, or on rocks, however open, in neither of which situations are they to be depended upon when made with clay alone. On this mode of making ponds for the use of live stock, there are several circumstances of the process more fully detailed in *The Rural Economy of Yorkshire*.

4471. *In constructing ponds in loamy soils*, all that is necessary is to coat the bottom over with clay or loam to the depth of eighteen inches or two feet, and then to puddle or work this well with water till it becomes a homogeneous layer impervious to that element. If clay or loamy earth cannot be obtained, any earth not very much inclined to sand may be substituted, but it will require more labour in puddling.

On clayey soils very little more is necessary than smoothing the surface of the excavation, and perhaps watering it and beating it to a smooth surface with rammers. The pond being now formed, the next operation is to coat it over with coarse gravel to the depth of at least eighteen inches; or, what is preferable, chalk and flints with gravel; or, best of all, to causeway or pave it. It is also very desirable

to pave or gravel the surface for the breadth of at least two yards round the pond, in order to prevent the cattle from poaching it when they come to drink.

4472. On clayey soils an economical mode of forming ponds is often adopted, where gravel or stone for paving is scarce. It consists in employing the horse-shoe form as the ground plan of the excavation, and cutting all the sides steep, or at an angle of 45 or 50 degrees, except the part answering to the heel of the shoe (fig. 689 a), which is well gravelled or paved, as the only entrance for the cattle. The excavated earth serves to raise the high side of the pond (b), which is generally guarded by a fence, or a few trees. The disadvantage of such ponds is, that one is required for every field, or at least for every two fields;

whereas a pond sloped on all sides may supply four fields, or even a greater number. (fig. 690.)

4473. The Gloucestershire ponds are made either of a square or a circular shape, and generally so situated as to furnish a supply to four fields. (fig. 690.)— Three layers of clay, free from the smallest stone or gravel, are so worked in as to form an impenetrable cement. The whole is afterwards covered with sand, and finished with pavement. (*Gloucestershire Report*, p. 31.)

4474. The Derbyshire artificial meers, or cattle ponds, are made in their dry rocky pastures, with great success. Having selected a low situation for the purpose, they form an excavation ten or twenty yards across, and spread over the whole a layer, about five inches thick, of refuse slaked lime and coal cinders; then they spread, trample, and ram down a stratum of well tempered clay, about four inches thick; and upon this they spread a second bed of clay, in a similar manner, of the same thickness; the whole of the bottom and edges of the meer is then paved with rubble stones; and small rubble stones, several inches thick, are spread upon the pavement. (*Derbyshire Report*, vol. i. p. 494.)

4475. The situation of field ponds, where practicable, should be at the intersection of fences, so that one may serve as many fields as possible. This, however, cannot be the best situation in every case, because it may happen that water cannot there be collected. At the same time a low situation is not always desirable, because it may be so circumstanced that too much dirty water may run into it during rains.

4476. Trees are frequently planted round ponds, and with seeming propriety, as their effect is beautiful, and they shade the water from the direct influence of the sun during summer; but in autumn their leaves certainly tend to render the water impure for a time. As most leaves are of an astringent quality, perhaps there may be no injury sustained by cattle from drinking such water at first; but after some time the leaves begin to decay, and occasion a sort of fermentation, which, till it subsides in the beginning of frosty weather, renders the water somewhat unhealthy and very unsightly. Leaves therefore ought to be drawn off with long open rakes as they fall from the trees.

4477. Wells, where no better method of procuring water can be devised, may be resorted to, both for fields and farmeries; but the great objection to them is the labour required to pump up or otherwise raise the water, and the consequent risk of neglect. Before proceeding to dig a well, it ought first to be determined on whether a mere reservoir for the water which oozes out of the surface soil is desired or obtainable, or a perpetual spring. If the former is the object in view, a depth of fifteen or twenty feet may probably suffice, though this cannot be expected to afford a constant supply, unless a watery vein or spring is hit on: if the latter, the depth may be very various, there being instances of 300 and 500 feet having been cut through before a permanent supply of water was found. (*Middlesex, Surrey, and Hampshire Reports*.)

4478. The art of well-digging is generally carried on by persons who devote themselves exclusively to that department. The site being fixed on, the ground-plan is a circle, generally of not more than six or eight feet in diameter: the digger then works down by means of a small short-handled spade, and a small implement of the pick-axe kind; the earthy materials being drawn up in buckets by the hand or a windlass, fixed over the opening for the purpose. Where persons conversant with this sort of business are employed, they usually manage the whole of the work, bricking round the sides with great facility and readiness; but in other cases it will be necessary to have a bricklayer to execute this part of the business.

4479. Steining. There are two methods of building the stone or brick within the well, which is called the steining. In one of these a circular ring is formed, of the same diameter as the intended well; and the timber of which it is composed is of the size of the brick-courses with which the well is to be lined. The lower edge of this circle is made sharp, and shod with iron, so that it has a tendency to cut into the ground; this circular curb is placed flat upon the ground, and the bricks are built upon it to a considerable height, like a circular wall. The well-digger gets within this circle, and digs away the earth at the bottom; the weight of the wall then forces the kurb and the brickwork with which it is loaded to descend into the earth, and as fast as the earth is removed it sinks deeper, the circular brick wall being increased or raised at top as fast as it sinks down; but when it gets very deep, it will sink no longer, particularly if

it passes through soft strata; in this case, a second kirk of a smaller size is sometimes begun within the first. When a kirk will not sink from the softness of the strata, or when it is required to stop out water, the bricks or stones must be laid one by one at the bottom of the work, taking care that the work is not left unsupported in such a manner as to let the bricks fall as they are laid: this is called under-pinning.

4480. *Noxious air.* Well-diggers experience sometimes great difficulty from a noxious air which fills the well, and suffocates them if they breathe it. The usual mode of clearing wells of noxious air is, by means of a large pair of bellows, and a long leathern pipe, which is hung down into the well to the bottom and fresh air forced down by working the bellows.

4481. *The use of the auger* is common in well-digging, both in ascertaining before commencement the nature of the strata to be dug into, and also in course of digging for the same purpose; and because, by boring in the bottom of a well to a considerable depth, the spring is sometimes hit upon, and digging rendered no longer necessary.

4482. *The use of the borer alone may procure an adequate supply of water* in particular situations. This mode appears to have been long resorted to in this and other countries. From what we have already stated as to the disposition of strata, the conditions requisite for its success will be readily conceived; viz. watery strata connected with others on a higher level: the pressure of the water contained in the higher parts of such strata on that in the lower will readily force up the latter through any orifice, however small. All that is necessary, therefore, is to bore down to the stratum containing the water, and, having completed the bore, to insert a pipe, which may either be left to overflow into a cistern, or it may terminate in a pump. In many cases, water may be found in this way, and yet not in sufficient quantity and force to rise to the surface; in such cases a well may be sunk to a certain depth, and the auger-hole made, and the pipe inserted in it in the bottom of the well. From the bottom it may be pumped up to the surface by any of the usual modes.

4483. *As an example of well-digging combined with boring*, we give that of a well dug at a brewery at Chelsea, Middlesex, in 1793. The situation was within 20 or 30 feet of the edge of the Thames, and the depth 39½ feet, mostly through a blue clay or marl. At the depth of nearly fifty feet a quantity of loose coal, twelve inches in thickness, was discovered: and a little sand and gravel was found about the same depth. The well-digger usually bored about ten, fifteen, or twenty feet at a time lower than his work as he went on; and on the last boring, when the rod was about fifteen feet below the bottom of the well, the man felt, as the first signal of water, a rolling motion, something like the gentle motion of a coach passing over pavement: upon his continuing to bore, the water presently pushed its way by the side of the auger with great force, scarcely allowing him time to withdraw the borer, put that and his other tools into the bucket, and be drawn up to the top of the well. The water soon rose to the height of two hundred feet.

4484. *In a case which occurred in digging a well at Dr. Darwin's*, near Derby, the water rose so much higher than the surface of the ground, that, by confining it in a tube, he raised it to the upper part of the house. (*Rees's Cyclopædia*, art. *Well*, and *Derbyshire Rep.*)

4485. *The process of boring the earth for spring water* has of late been practised, with great success, in various parts of England, chiefly by a person named Goode, of Huntingdon. In the neighbourhood of London, many fountains of pure spring-water have lately been obtained by these means. We may particularly name those at Tottenham, Middlesex, and Mitcham, Surrey, both of which afford a continuous and abundant flow of water, at one time equal to about eight gallons per minute, but now reduced to a much smaller quantity, in consequence of the great number of holes that have been bored into the supplying strata.

4486. *The operation of boring for water* (fig. 691.) is thus performed:—The situation of the intended well being determined on, a circular hole is generally dug in the ground, about six or eight feet deep, and five or six feet wide. In the centre of this hole, the boring is carried on by two workmen, assisted by a labourer above. (fig. 691.)

691

The implements used may either be those of Goode, already described (§ 2507.) as the best, or any other instruments in repute. For variety's sake, we shall here describe the process by the instruments formerly in most general use about London. The handle (fig. 691. a) having a female screw in the bottom of its iron shank, a wooden bar or rail passing through the socket of the shank, and a ring at top, is the general agent, to which all the boring implements are to be attached. A chisel (b) is first employed, and connected to this handle by its screw at top. If the ground is tolerably soft, the weight of the two workmen, bearing upon the cross-bar and occasionally forcing it round, will soon cause the chisel to penetrate; but if the ground is hard or strong, the workmen strike the chisel down with repeated blows, so as to pick their way, often changing their situation by walking round, which breaks the stone, or other hard substances, that may happen to obstruct its progress.

4487. *The labour is very considerably reduced* by means of an elastic wooden pole placed

horizontally over the well, from which a chain is brought down, and attached to the ring of the handle. This pole is usually made fast at one end as a fulcrum, by being set into a heap of heavy loose stones; at the other end the labourer gives it a slight up and down vibrating motion, corresponding to the beating motion of the workmen below,

by which means the elasticity of the pole in rising lifts the handle and picker, and thereby very considerably diminishes the labour of the workmen.

4488. *When the hole has been thus opened by a chisel, as far as its length would permit, the chisel is withdrawn, and a sort of cylindrical auger (c) attached to the*

handle (a), for the purpose of drawing up the dirt or broken stones, which have been disturbed by the chisel. A section of this auger (d) shows the internal valve. The auger being introduced into the hole, and turned round by the workmen, the dirt or broken stones will pass through the aperture at bottom (shown at e), and fill the cylinder, which is then drawn up, and discharged at the top of the auger, the valve preventing its escape at bottom.

4489. *In order to penetrate deeper into the ground, an iron rod (f) is now to be attached to the chisel (b), by screwing on to its upper end, and the rod is also fastened to the handle (a), by screwing into*

its socket. The chisel, having thus become lengthened by the addition of the rod, is again introduced into the hole, and the operation of picking or forcing it down is carried on by the workmen as before. When the ground has been thus perforated, as far as the chisel and its rod will reach, they must be withdrawn, in order again to introduce the auger (c), to collect and bring up the rubbish, which is done by attaching it to the iron rod, in place of the chisel. Thus, as the hole becomes deepened, other lengths of iron rods are added, by connecting them together (f and g when joined form h). The necessity of frequently withdrawing the rods from the hole, in order to collect the mud, stones, or rubbish, and the great friction produced by the rubbing of the tools against its sides, as well as the lengths of rods augmenting in the progress of the operation, sometimes to the extent of several hundred feet, render it extremely inconvenient, if not impossible, to raise them by hand. A tripod standard is therefore generally constructed, by three scaffolding poles tied together, over the hole (fig. 691.), from the centre of which a wheel and axle, or a pair of pulley blocks, are suspended, for the purpose of hauling up the rods, and from which hangs a forked hook (i). This forked hook is to be brought down under the shoulder, near the top of each rod, and made fast to it by passing a pin through two little holes in the claws. The rods are thus drawn up, about seven feet at a time, which is the usual distance between each joint, and at every haul a fork (k) is laid horizontally over the hole, with the shoulders of the lower rod resting between its claws, by which means the rods are prevented from sinking down into the hole again, while the upper length is unscrewed and removed. In attaching and detaching these lengths of rod, a wrench (l) is employed, by which they are turned round, and the screws forced up to their firm bearing.

4490. *The boring is sometimes performed for the first sixty or a hundred feet, by a chisel of two and a half inches wide, and cleared out by a gouge of two and a quarter diameter, and then the hole is widened by another tool (m). This is merely a chisel, four inches wide, but with a guide (n) put on at its lower part, for the purpose of keeping it in a perpendicular direction; the lower part is not intended to pick, but to pass down the hole previously made, while the sides of the chisel operate in enlarging the hole to four inches. The process, however, is generally performed at one operation, by a chisel four inches wide (b), and a gouge of three inches and three quarters (c).*

4491. *Placing and displacing the lengths of rod is done every time that the auger is required to be introduced or withdrawn; and it is obvious that this must of itself be extremely troublesome, independently of the labour of boring; but yet the operation proceeds, when no unpropitious circumstances attend it, with a facility almost incredible. Sometimes, however, rocks intercept the way, which require great labour to penetrate, but this is always effected by picking, which slowly pulverises the stone. The most*

unpleasant circumstance attendant upon this business is, the occasional breaking of a rod in the hole, which sometimes creates a delay of many days, and an incalculable labour in drawing up the lower portion.

4492. *When the water is obtained* in such quantities and of such quality as may be required, the hole is dressed or finished by passing down it the diamond chisel (*c*): this is to make the side smooth previously to putting in the pipe. This chisel is attached to rods, and to the handle, as before described; and in its descent the workmen continually walk round, by which the hole is made smooth and cylindrical. In the progress of the boring, frequent veins of water are passed through; but as these are small streams, and perhaps impregnated with mineral substances, the operation is carried on until an aperture is made into a main spring, which will flow up to the surface of the earth. This must, of course, depend upon the level of its source, which, if in a neighbouring hill, will frequently cause the water to rise up and produce a continued fountain. But if the altitude of the distant spring happens to be below the level of the surface of the ground where the boring is effected, it sometimes happens that a well of considerable capacity is obliged to be dug down to that level, in order to form a reservoir, into which the water may flow, and from which it must be raised by a pump: while, in the former instance, a continued fountain may be obtained. Hence, it will always be a matter of doubt, in level countries, whether water can be procured which would flow near to or over the surface: if this cannot be effected, the process of boring will be of little or no advantage, except as an experiment to ascertain the fact.

4493. *In order to keep the strata pure and uncontaminated* with mineral springs, the hole is cased for a considerable depth with a metallic pipe, about a quarter of an inch smaller than the bore. This is generally made of tin (though sometimes of copper or lead), in convenient lengths; and as each length is let down, it is held by a shoulder resting in a fork, while another length is soldered to it, by which means a continued pipe is carried through the bore as far as may be found necessary, to exclude land-springs, and to prevent loose earth or sand from falling in and choking the aperture. (*Newton's Journal*, vol. vi. p. 146.)

4494. *The manner of forcing down lengths of cast-iron pipe, after the bore is formed*, is this:—The pipe (*fig. 693. a*) has a socket in its upper end, in which a block of wood (*b*) is inserted. From this block a rod (*c*) extends upwards, upon which a weight (*d*) slides. To the weight (*d*) cords are attached, reaching to the top of the bore, where the workman alternately raises the weight and lets it fall, which, by striking upon the block (*b*), beats down the pipe by a succession of strokes; and when one length of pipe has by these means been forced down, another length is introduced into the socket of the former. Another tool for the same purpose (*fig. 694.*) is formed like an acorn, the point of the acorn strikes against the edge of the pipe, and by that means it is forced down the bore.

4495. *Wrought-iron, copper, tin, and lead pipes*, are occasionally used for lining the bore; and as these are subject to bends and bruises, it is necessary to introduce tools for the purpose of straightening their sides. One of these tools (*fig. 695. a*) is a bow, and is to be passed down the inside of the pipe, in order to press out any dents. Another tool for the same purpose (*b*) is a double bow, and may be turned round in the pipe for the purpose of straightening it all the way down. A pair of clams (*c*) is used for turning the pipe round in the hole while driving.

4496. *In raising pipes*, it is necessary to introduce a tool to the inside of the pipe, by which it will be held fast. The pine-apple stool for this purpose (*d*) has its surface cut like a rasp, which passes easily down into the pipe, but catches as it is drawn up, and by that means brings the pipe with it. There is a spear for the same purpose (*fig. 696*) which easily enters the pipe by springing; at the ends of its prongs there are forks which stick into the metal as it is drawn up, and thereby raise it.

4497. *Mr. Goode* suggests the employment of long baskets with valves opening upward in their bottoms, for the purpose of drawing water from these wells when the water will not flow over the surface; also lift-pumps, with a succession of buckets, for the same purpose. (*Newton's Journal*, vol. viii. p. 249.)

4498. *Mommon* has invented a new apparatus for guiding the operation of boring, which seems very ingenious; but we are not aware that it has yet been adopted in practice. Engravings, accompanied by a copious description, will be found in the *Mechanics' Magazine*, vol. iv.; in which work are also various other articles on the same subject.

4499. *Of the various modes of raising water from deep wells*, the pump is the most convenient, and the ever and bucket the most simple. When a constant supply is wanted from a very deep well, machinery (fig. 697.) may be erected over it, and driven by an old horse or ass. While one bucket is filling, the

other is emptying. In order to effect the filling of the bucket, the handle (b), which is of iron, is attached by iron swivel rivets, on which it readily turns, below the centre of gravity of the bucket (c). In order that it may empty itself, a horizontal handle (a) is attached, which, when the filled bucket attains a certain height, is caught by a hook (e) fixed in the trough which conveys away the water raised (f). The horse or ass may be made to work in this machine without the attendance of a man, by the following training:— Attach a bell to the lever of draught (h); use eye-blinders to prevent the animal from seeing whether or not any one is in attendance, and from becoming giddy by going constantly round. Put the animal in motion, and the bell will not stop ringing till he stops. The moment he stops, and the bell ceases to ring, apply the whip severely. Continue to do this every time the animal stops, till the two hours' labour are completed; then unyoke and feed. After one or two hours, or whatever period may be deemed necessary for rest and refreshment, yoke again, and proceed as before. Go on in this way for two days, and the terror of receiving chastisement when the bell ceases to ring, will have frightened the animal into a habit of working two hours at a time without attendance. This mode is practised successfully in France, Italy, and Spain. (*Curs, &c. Art. Puit à Roue.*)

4500. *Pumps* are of various kinds, as the lifting-pump; the forcing-pump, for very deep wells; the suction pump; and the rotatory pump, a recent invention for such as do not exceed thirty-three feet in depth, and of which there are several varieties, but by far the best is that by Siebe. A good pump for urine pits or reservoirs, where the water is not to be raised above twenty-eight or thirty feet, is that of Robertson Buchanan, author of *A Treatise on Heating by Steam, &c.*; because this pump will raise drainings of dunghills, the contents of cesspools, privies, &c., or even water thickened by mud, sand, or gravel. "The points in which it differs from the common pump, and by which it excels it, are, that it discharges the water below the piston, and has its valves lying near each other. The advantages of this arrangement are:—that the sand or other matter which may be in the water is discharged without injuring the barrel or the piston-leathers; so that, besides avoiding unnecessary tear and wear, the power of the pump is preserved, and it is not apt to be diminished or destroyed in moments of extraordinary exertion, as is often the case with the common and chain pumps: that the valves are not confined to any particular dimensions, but may be made capable of discharging every thing that can rise in the suction-pipe without danger of being choked; and that if, upon any occasion, there should happen to be an obstruction in the valves, they are both within the reach of a person's hand, and may be cleared at once, without the disjunction of any part of the pump. It is a simple and durable pump, and may be made either of metal or wood, at a moderate expense." Where clear water only is to be raised, Aust's (of Hoxton) *curvilinear* pump is preferable to the common sort. The advantages depend on the curvilinear form of the barrel, which allows,

and indeed obliques, the rod, the handle, and the lever on which it works, to be all in one piece. Hence simplicity, cheapness, precision of action, more water discharged in proportion to the diameter of the barrel, and less frequent repairs. (*Repertory of Arts*, Jan. 1821.) Perkins' square-barrelled pump is a powerful engine (*London Journal*, &c.); but this and other contrivances for raising water, though promising advantages, cannot often be made available by the improver, from their not having come into general use.

4501. *Siebe's rotatory pump* (fig. 698.) appears to us by far the best of modern improvements on this machine. It is used for drawing, raising, and forcing all fluids and liquids, and may be worked by manual labour, steam, or any other power. By the rotation of a roller (a) having paddles or pistons (b) a vacuum is produced within the barrel (c), and in consequence the water flows up the rising trunk (d) through the space into the barrel, and as the paddles go round they force the water through an opening, which conducts it wherever it may be wanted, and by that means produces a continual stream without an air vessel. It is evident that this pump may, by an ascending tube (e), and a cock on the horizontal spout (f), be used as a common pump, or a forcing

pump at pleasure. (*Newton's Journal*, vol. ii. 2d series, p. 90.)

4502. An old but ingenious mode of raising water from a well to the upper part of a house (fig. 699.)

is sometimes adopted on the Continent. A post is fixed close to the well; this is connected with the opening in the upper part of the house, where the water is to be introduced, by a fixed cord (a). On this cord a wooden collar (b) is placed, and slides freely from one end to the other: the bucket rope is put through a hole in the collar, and over a pulley in the window in the upper part of the house, and thus the bucket is first raised perpendicularly from the water in the well till it comes in contact with the collar, when, the power being continued, the collar slides along the fixed rope till it reaches the operator at the window. (*Last. Col. de Machines, &c.*)

4503. *Artificial springs.* Marshal seeing the formation of natural springs, and observing the effect of subsoil drains, and being, at the same time, aware of an objection to roof water, which, though more wholesome, is seldom so well tasted as spring water; was led to the idea of forming artificial land springs, to supply farmsteads with water, in dry situations. He proposes arresting the rain-water that has filtered through the soil of a grass ground situated on the upper side of the buildings, in covered drains, clayed and dished at the bottom, and partially filled with pebbles or other open materials: thus conveying it into a well or cistern, in the

manner of roof water: and by this means uniting, it is probable, the palatableness of spring water with the wholesomeness of that which is collected immediately from the atmosphere.

4504. *Water for common farm-yard and domestic purposes* may be obtained in most situations, by collecting that which falls on the roofs of the farmery and dwelling-house. This is done by a system of gutters and pipes, which, for the farmery, may lead to a cistern or tank under ground; and for the family, that from the roof of the dwelling-house may be conducted to a tub. According to Waistell, a sufficient supply of water has been collected from the roof of a cottage to answer every purpose of the family during the driest season, by preserving the water so collected in a tank. The quantity of water that falls annually upon every hundred superficial feet, or square of building, is about 1400 gallons. Before using the water so collected, it should be filtered; and it seems very desirable that it should undergo this operation before it enters the tank.

4505. *The operation of filtering* may be performed in various ways:—

4506. *A very simple mode* is by having two casks two or three feet high, and of any convenient width (fig. 700.) One of these casks (a) may receive the water from the roof, or from any other supply; the other (b) should have a false bottom (c) perforated with holes and covered with flannel; on this flat bottomed equal quantities of sand and charcoal may be laid to the depth of twelve or fourteen inches, and covered with another false bottom similar to the first (d); the remainder of the cask will contain the filtered water, which may either be drawn off as wanted by a cock (e), or allowed to pass into an underground tank by the same means. The grosser impurities will always be deposited at the bottom of the filtering tank (b), and these may be drawn off at pleasure by a cock (f), placed immediately above the bottom of the barrel. The sand and charcoal may also be freed from any impurities which they may contract, by first allowing both barrels to be quite full, and then turning the bottom cock (f), in consequence of which the filtered water will descend through the filter and clear it. The advantage of having two barrels for the purpose of filtering the water from a roof is partly to retain a larger quantity,

on the supposition that there is not a reservoir or tank under ground, and partly to admit of supplying the first barrel, from ponds or other sources, in seasons when the roof is unproductive. Where the water is to be preserved in a tank under ground, only one barrel (b) is necessary, the pipe from the roof (g) proceeding, in that case, at once to the bottom of the filtering barrel, and entering where, in the case of two barrels, the junction-pipe (h) enters. In all cases of preserving water, whether filtered or unfiltered, it is of great importance to preserve a steady and a low temperature, and for this purpose an underground reservoir is highly desirable.

4507. *The best form for a tank*, according to Waistell, is a circular plan; the bottom in the form of a flat dome reversed, and the top also domical, with an opening left in the centre of sufficient size to admit a man to clean it out occasionally. "The top of this opening should be a little above the surface of the ground, and should be covered with an oak flap, with several holes bored in it for ventilation; or the cover may be an iron grating, horizontal, and a little elevated, or conical. These tanks may be constructed of various dimensions: the depth and width should be nearly equal; a hole should also be left for the service-pipe, or that which conveys the water into the tank, and also for the pipe for the pump, if the water be drawn out by that means. The water may be filtered previously to its entering the tank; the hole for the service-pipe ought, therefore, to be near the top, and on that side most convenient for the filtering chamber; this may be about four feet in diameter, and three feet deep; across this, about twelve

inches from the side next the tank (fig. 701.) a slate partition from the top to within about six inches from the bottom, should be fixed; at the bottom of the box should be put clean coarse sand or pounded charcoal, about a foot in thickness. The pipe or opening from the filter to the reservoir should be of ample dimensions, and be made at about eighteen or twenty inches from the bottom, in the small division or space behind the slate (b). Above this opening, and in any part most convenient (w), in the large division of the filter, should be an opening or drain to carry off the water when the tank is full. This filter should also have a cover, that it may be cleaned out, and fresh sand or other purifiers put in as often as may be found requisite. Of course the water as it comes from the roof is to be first conveyed into the large division of the filtering chamber, on the opposite side to the slate partition (c), and passing through the sand it rises in the small division purified, when it is fit to pass into the tank. If there are two or more of

these filtering chambers, or if they are of greater depth, the water may be passed through the greater quantity of sand, &c. in them, and be still more purified. Both the tanks and the filters should be water-tight: if constructed of brick, the inner course may be built with Roman cement, and afterwards the whole of the inside covered with a coat of about three quarters of an inch thick. Water, from drains formed in the ground for the purpose of collecting it for domestic purposes, may be purified, by passing it through a sand filter previously to its entering the tank or reservoir. Sponge and flannel may also be used as filters. In constructing tanks of the above description, care must be taken to have the earth to have the earth closely filled around the brick-work, and to allow sufficient time for the work to get properly settled, previously to admitting any great weight of water." (*Agricultural Buildings*, p. 15.)

4508. *Filtering water on a large scale may be effected by emptying one pond into another on a lower level, through a conduit of any kind filled with gravel, sand, and charcoal.*

4509. *A filtering apparatus for salt water*

has been invented, but we are unable to say how far it has succeeded: it, at any rate, will succeed well with fresh water, and, we have no doubt, to a certain extent also with that of the sea. Fig. 702. a a is a cylindrical vessel of wood, or any other suitable material, which is lined on the inside with cement as far as the filterer extends; b is the bottom of the filterer, formed with a grating, which is supported by the rame of a stool; c is a pipe extending from the under part of a cask (d), containing the salt water, and which pipe opens to the lower part of the vessel a below the filterer. Over the grating (b) there are placed several thicknesses of woven horse-hair, or a quantity of wool, and above this the vessel is filled with sand. On the top of the sand there is a plate (e) like a piston pressing upon the sand and keeping it compact, the plate being held down by a screw (f). The salt water thus delivered from the cask (d) by the pipe (c), fills the lower part of the vessel (a), and by the superincumbent pressure of the column descending from the cask, the water is forced upwards through the mass of sand, and runs off at the cock (g) in a purified state. There are man holes (h, h) for the purpose of getting access to the interior when it is required to remove the sand or other matters, and the internal surface of the filterer is rendered rough in order to prevent the water from sliding up the sides of the vessel, instead of passing through the sand. (*Newton's Journal*, vol. 1. 2d series, p. 158.)

4510. *The distillation of palatable water at sea has been effected by P. Nicole, of Dieppe, by simply causing the steam arising from boiling sea water in a still to pass through a stratum of coarsely powdered charcoal, in its way to the condenser, or worm-tub. (*Mechanics' Magazine*, vol. iv. p. 280.)*

4511. *Water cisterns, formed of blue slate, or Yorkshire*

paving-stones, are much better than those made of wood, and lined with lead. (*Waistell's Agricultural Buildings*, p. 15.)

CHAP. IV.

Improvement of Lands lying Waste, so as to fit them for Farm-Culture.

4512. *Of waste lands*, many descriptions are best improved by planting, and therefore are to be considered as disposed of in that way in the laying out or arrangement of an estate; but there are others which may be more profitably occupied as farm-lands, and it is the preparing or bringing of these into a state of culture, which is the business of the present chapter. Such lands may be classed as mountainous or hilly grounds, rocky or stony surfaces, moors, bogs, or peat-mosses, marshes, woody wastes or wealds, warrens or downs, and sea-shores or beaches. In the improvement of these, many of the operations are such as are performed by temporary occupiers or farmers; but, as in this case such occupiers have always extraordinary encouragement from the landlords, either in the shape of a low rent, of money advanced, of long leases, or of all of these; we consider it preferable to treat of them as permanent, or fundamental improvements, than to consider them as parts of farm-culture. The delusive prospects of profit, from the improvement of wastes, held out by speculative men, have an unhappy tendency to produce disappointment in rash and sanguine adventurers, and ultimately to discourage such attempts as, with judicious attention to economy, would, in all probability, be attended with great success. Those who are conversant with the publications that have lately appeared on this subject must be aware with what caution the alleged results of most of these writers

ought to be examined; and how different has been the experience of those who have ventured to put their schemes in practice, from what they had been led to anticipate. (*Gen. Rep. Scot.*)

SECT. I. *Mountainous and hilly Grounds and their Improvement.*

4513. *The upper parts of mountains* may be considered as among the least improvable parts of the earth's surface, from the impossibility of ever ameliorating their climate. "The highest peaks and ridges are mostly naked granite, slate, or volcanic productions. Their more elevated sides, and the tops of those of moderate height, are usually covered by a thin soil, producing a short dry herbage, which is frequently mixed with a dwarf, or stunted heath. Where the soil is not injured by moisture, these are best calculated for sheep. When the height of mountains exceed 800 feet of elevation above the level of the sea, unless covered either with natural woods or artificial plantations, they can only be profitably used in pasture." (*Code.*)

4514. *The hills, or lands less elevated than mountains*, have, in general, a deeper and moister soil, and produce a more luxuriant herbage, but of a coarse quality; hence they are better adapted for small hardy cattle. Though the summits of hills are generally unfit for raising grain, yet the plough is gradually ascending along their sloping sides, and within the last thirty years many thousand acres in such situations have been reclaimed in the United Kingdom.

4515. *Steep lands along the sides of rivers* and small streams are often inaccessible to the plough, and unfit for tillage. The more rugged of these are well calculated for woods or coppice; while those in more favourable situations and climates may be converted into orchards. (*Code of Agr.* 161.)

SECT. II. *Rocky or Stony Surfaces.*

4516. *Rocky and stony lands* are common in the valleys of a hilly or mountainous country, and sometimes, as in Aberdeenshire, they cover immense tracts of flat surface.

4517. *When rocks* protrude from the surface here and there in fragments of a few tons, and it is considered desirable to render the field or scene fit for aration, the only mode is to rend them asunder by gunpowder, and then carry off the fragments for walls, drains, roads, or buildings; or, if they are not wanted for these or any other purpose, to bury them so deep in the ground as to be out of the reach of the plough. But where rocks rise in considerable masses of several poles in diameter, it will generally be found preferable to enclose and plant them. Clefs and crevices are found in all rocks which have been long exposed to the air and weather, and in these may be inserted young plants, or seeds, or both. Such masses being enclosed by rough stone walls, formed from the more detached fragments, or from loose stones, will grow up and be at once highly ornamental and useful as shelter. It is true they will interrupt the progress of the plough in a straight line, but not more so than the rock if left in a state of nature. When a rocky surface is not intended to be ploughed, all that is necessary is to remove as many of the solitary rocks as possible, and either enclose and plant the rest, or cover them with earth.

4518. *The stones* which impede the improvement of land are either loose, thrown up when the land is trenched, or ploughed; or fixed in the earth, and not to be removed without much labour and expense.

4519. *Loose stones* may often be converted into use for the purpose of forming covered drains, of constructing walls or fences, or of making and repairing the roads on the farm or in the neighbourhood; and, on these accounts, are sometimes worth the trouble of collecting. They may be removed, with the least inconvenience, when the land is followed. Where loose stones are of a moderate size, they are sometimes found advantageous rather than detrimental, as in the stone-brash soils of Somersetshire and other districts. They prevent evaporation, and thus preserve moisture in the soil. Hence the old remark, that farmers have been induced to bring back again to their corn-fields those very stones they have been induced to carry off. (*Code.*)

4520. *Where stones are large* and fixed in the earth, if they appear above the surface, they should be removed before the ploughing of the waste commences; but where they are concealed under the surface, various modes to get rid of them have been adopted. In some parts of Yorkshire, the whole surface is gone over with sharp prongs, which, at the distance of every twelve or fourteen inches, are thrust into the ground to the depth of about a foot, to ascertain where stones are to be met with. The spot is marked by a twig, and the stones are removed before the land is ploughed. Sometimes the plough is used without such previous examination, and the place marked where stones are encountered, that they may be taken away; and sometimes, in order to discover and remove such stones, the land is trenched by the spade (*Communications to the Board of Agriculture*, vol. ii. p. 253.)

4521. *Stones above the surface* may be avoided by the ploughman, though not without loss of ground; but stones under the surface are often not discovered till the plough is drawn against them, and perhaps broken, by which a day's work is sometimes lost. A wooden bolt, however, to unite the horse-trees to the chain of the plough, may prevent mischief by giving way. Clearing the ground from stones not only prevents such mischiefs, but is attended with actual profit. When removed, they may be used for various purposes, and are often less expensive than if dug, or purchased at a quarry. The soil round a large stone is likewise, in general, the best in the field, and is bought at a low rate by the expense of taking out the stone, as the plough has thus access to all the land around it. In stony land the plough must proceed slowly, and cannot perform half so much work as it ought to do; but, after such impediments have been removed, the field may be ploughed with the usual facility and cheapness, and in a much more perfect manner. It frequently happens, that when working stony land, more expense is incurred in one season by the breaking of ploughs, besides the injury done to the horses and harness, than would cure the evil. (*Gen. Rep. of Scot.* vol. iii. p. 256; *Kaimes's Gent. Farmer*, p. 53.)

4522. *There are various modes of getting rid of stones.* These are generally of such a size as to admit of being conveyed away in carts or other vehicles calculated for the purpose. Some ingenious artificers have constructed machines for raising them, when large. On some occasions, pits have been dug close to large stones, and the latter have

703

been turned into the former, at such a depth as to lie out of the reach of the plough: but it is frequently necessary to reduce their size by the force of gunpowder before they can be removed. Loose stones are commonly moved by levers, and rolled on a sledge; but sometimes they are raised by a block and tackle attached to a triangle with a pair of callipers to hold the stone (fig. 703.)

The stone may also be raised by boring a hole in it obliquely and then inserting an iron bolt with an eye (fig. 704.), which, though loose, will yet serve to raise the stone in a perpendicular direction.

704

4523. *Richardson's machine for raising large stones* (fig. 705.)

705

706

consists of a frame-work supporting a five-fold tackle, with blocks ten inches in diameter, and a roller seven inches in diameter turned by two long iron levers. A hole is made in the stone to be raised by means of the tool well known to masons as a *jumper*; in this hole a simple plug may be driven tightly; or a compound plug (fig. 706.) may be introduced; or, what is simplest, the hole may be made obliquely. (Smith's Compendium of Practical Inventions.)

4524. *The mode of bursting or rending rocks or stones by gunpowder* is a simple though dangerous operation. When a hole is to be made in a rock for the purpose of blasting with gunpowder, the prudent workman considers the nature of the rock, and the inclination or dip of the strata, if it is not a detached fragment, and from these determines the calibre, and the depth and direction of the bore or recipient for the gunpowder. According to circumstances, the diameter of the hole varies from half an inch to two inches and a half, the depth from a few inches to many feet, and the direction varies to all the angles from the perpendicular to the horizontal. The implements for the performance of this operation are rude, and so extremely simple

and familiar as hardly to require description; and the whole operation of boring and blasting rocks is so easily performed, that, in the space of a few weeks, an intelligent labourer may become an expert quarryer. A writer in the *Mechanics' Magazine* has proposed to increase the effect of the gunpowder, by widening the lower extremity of the bore, and this he thinks may be effected, after the bore is made of the proper length, by introducing an instrument with a jointed extremity which would work obliquely.

707

4525. *The operation of ramming* frequently gives rise to accidents; but a recent improvement, that of using a wadding of loose sand, or of any earthy matter in a dry state, answers all the purposes of the firmest ramming or wadding. It has been used for upwards of ten years at Lord Elgin's extensive mining operations at Charlestown in Fifeshire, and also in removing immense bodies of rock from the Calton hill at Edinburgh, by Stevenson, an eminent engineer, whose article on the subject of blasting, in the *Sup. to the Encyc. Brit.* deserves the attention of such as use the process in working quarries or clearing rocky or stony grounds.

4526. *Dr. Dyce of Aberdeen* has communicated to Dr. Brewster's *Journal* an account of a cheap and effectual method of blasting granite rock, which deserves the particular attention of the owners and workers of quarries. It is beautifully scientific, and may be summed up under the three following heads: viz. 1. To ignite the gunpowder at the bottom of the charge, by means of sulphuric acid, charcoal, and sulphur. 2. To take advantage of the propelling power

of gunpowder, as is done with a cannon ball, only, instead of a spherical ball, to employ one of a conical form (fig. 707.), by which the full effect of the wedge is given in every direction at the lower part of the charge, but particularly downwards. And, in the last place, to add to the effect of the whole, to insure a fourth part of the depth of the bore at the bottom (b) to be free from the gunpowder; so that, when inflammation ensues, a red heat may be communicated to the air in the lower chamber, whereby it will be expanded to such a degree as to have the power of at least one hundred times the atmospheric pressure, and thereby give this additional momentum to the explosive power of the gunpowder. (*Dr. Brewster's Edin. Journ.* Oct. 1826. p. 343., and *Gard. Mag.* vol. ii. p. 467.)

4527. *The Assamese* close the mouth of the hole by driving in with a mallet a stout wooden plug some inches in length, through which a touch-hole is bored. Between the powder and the lower part of the plug, an interval of several inches is left. The communication is perfected by means of a tin tube filled with powder, and passing through the centre of the plug. (*Monthly Magazine.*)

SECT. III. Improving Woody Wastes or Wealds.

4528. *With surfaces partially covered with bushes and stumps of trees, ferns, &c.*, the obvious improvement is to grub them up, and subject the land to cultivation according to its nature.

4529. *The growth of large trees* is a sign that the soil is naturally fertile. It must also have been enriched by the quantity of leaves which in the course of ages have fallen and rotted upon the surface. Such are the beneficial effects of this process, that after the trees have been cut down, the soil has often been kept under crops of grain for a number of years without interruption or any addition of manure; but land thus treated ultimately becomes so much reduced by great exhaustion, that it will not bear a crop worth the expense of seed and labour. (*Comm. to the Board of Agr.*, vol. ii. p. 257.) It is evident, however, that this deterioration entirely proceeds from the improvident management previously adopted. In reclaiming such wastes, the branches of the felled trees, are generally collected and burnt; and the ashes, either in whole or in part, are spread on the ground, by which the fertility of the soil is excited. Indeed, where there is no demand for timber on the spot, nor the means of conveyance to any advantageous market, the whole wood is burnt, and the ashes applied as manure.

4530. *Much coppice land has been grubbed up* in various parts of England, and brought into tillage. Sometimes woods are grubbed for pasture merely. In that case the ground should be as little broken as possible, because the surface of the land, owing to the dead wood and leaves rotting time out of mind upon it, is much better than the mould below. It soon gets into good pasture as grass land, without the sowing of any seed. (*Comm. to the Board of Agr.* vol. iv. p. 42.) But by far the most eligible mode of converting woodland into arable is merely to cut down the trees, and to leave the land in a state of grass until the roots have decayed, cutting down with the scythe from time to time any young shoots that may arise. The roots in this way, instead of being a cause of anxiety and expense, as they generally are, become a source of improvement; and a grassy surface is prepared for the operation of sod burning. (*Marshal's Yorkshire*, vol. i. p. 316.)

4531. *Natural woods and plantations* have been successfully grubbed up in Scotland. In the lower Torwood in Stirlingshire, many acres of natural coppice were cleared; and the land is now become as valuable as any in the neighbourhood. (*Stirlingshire Report*, p. 213.) On the banks of the Clyde and the Avon, coppices have been cut down, and the land, after being drained, cultivated, and manured, has been converted into productive orchards. In Perthshire, also, several thousand acres of plantations have been rooted out, the soil, subjected to the plough, converted into good arable land, and profitably employed in tillage. (*Perthshire Report*, p. 329.)

4532. *For pulling up or rending asunder the roots of large trees*, various machines and contrivances have been invented. Clearing away the earth and splitting with wedges constitute the usual mode; but blasting is also, as in the case of rocks and stones, occasionally resorted to. For this purpose a new instrument,

called the *blasting-screw* (fig. 708.), has been lately applied with considerable success to the rending or splitting of large trees and logs of timber. It consists of a screw (a), an auger (b, c), and charging-piece (d). The screw is wrought into an auger-hole, bored in the centre of the timber: here the charge of powder is inserted, and the orifice of the hole in the log is then shut up or closed with the screw, when a match or piece of cord, prepared with saltpetre, is introduced into a small hole (a), left in the screw for this purpose, by which the powder is ignited. The application of this screw to the purposes of blasting is not very obviously necessary; because, from what we have seen (4525.), it would appear that the auger-hole, being charged with powder and sand, would answer every purpose. One great objection to the process of blasting applied to the rending of timber is, the irregular and

uncertain direction of the fracture, by which great waste is sometimes occasioned. It may, however, be necessary to resort to this mode of breaking up large trees, when cut down and left in inaccessible situations, where a great force of men and implements cannot easily be procured or applied; and certainly it is one of the most effectual modes of tearing their stools or roots in pieces. (*Sup. Encyc. Brit. art. Blasting.*)

4533. *Land covered with furze, broom, and other shrubs*, is generally well adapted for cultivation. The furze, or whin (*Ulex europæa*), will grow in a dense clay soil; and where found in a thriving state, every species of grain, roots, and grasses, may be cultivated with advantage. The broom, on the other hand, prefers a dry, gravelly, or sandy soil, such as is adapted for the culture of turnips. A large proportion of the arable land, in the richest districts of England and Scotland, was originally covered by these two plants; and vast tracts still remain in that state, which might be profitably brought

one great objection to the process of blasting applied to the rending of timber is, the irregular and

under cultivation. For this purpose, the shrubs ought to be cut down, the ground trenched, or the plants rooted out by a strong plough, drawn by four or six horses, and the roots and shrubs (if not wanted for other purposes), burnt in heaps, and the ashes spread equally over the surface. (*Com. to the Board of Agr.* vol. ii. p. 260.) In many places, shrubs and brushwood may be sold for more than the expense of rooting them out.

When coal is not abundant, and limestone or chalk can be had, the furze should be employed in burning the lime used in carrying on the improvement. (*Oxfordshire Report*, p. 232.) It requires constant attention, however, to prevent such plants from again getting possession of the ground, when restored to pasture. This can best be effected, by ploughing up the land occasionally, taking a few crops of potatoes, turnips, or tares in rows, and restoring it to be depastured by sheep. In moist weather, also, the young plants should be pulled up and destroyed. (*Code.*)

4534. *Fern* (*Pteris* and *Osmúnda*) is a very troublesome weed to extirpate, as, in many soils, it sends down its roots into the under stratum, beyond the reach of the deepest ploughing; but it is a sign of the goodness of any soil where it grows to a large size. June and July are the best seasons for destroying it; the plants are then full of sap, and should be frequently cut. They are not, however, easily subdued, often appearing after a rotation of seven years, including a fallow, and sometimes requiring another rotation, and repeated cutting, before their final disappearance can be effected. Lime in its caustic state is peculiarly hostile to fern; at the same time, this weed can hardly be completely eradicated but by frequent cultivation, and by green crops assisted by the hoc. (*Oxfordshire Report*, pp. 234. 240.)

4535. *The heath* (*Erica*) is a hardy plant, palatable and nutritious to sheep; and under its protection coarse grasses are often produced. When young, or in flower, it may be cut and converted into an inferior species of winter provision for stock; but where it can be obtained, it is desirable to have grass in its stead. For this purpose, the land may in some cases be flooded, and in others the heath may be burned, and the land kept free from stock for eighteen months; in consequence of either of these modes, many new grasses will spring up, from the destruction of the heath, and the enriching quality of the deposit from the water or the ashes. The improvement is very great; more especially if the land be drained, and lime or compost applied. (*Gen. Rep. of Scot.* vol. ii. p. 359.) But if the land be too soon depastured, the grasses being weak and tender, the sheep or cattle will pull them up with their roots, and will materially injure the pasture. (*Statistical Account of Scotland*, vol. iv. p. 465.) Where it is proposed to cultivate the land for arable crops, the lime applied should be in a finely powdered state, highly caustic, and as equally spread as possible. (*Com. to the B. of Agr.* vol. ii. p. 264.) Lime in a caustic state is an excellent top dressing for heath. It is astonishing to see white clover spring up, after lime has been some time applied, on spots where not a green leaf could be detected before.

4536. *Paring and burning* is a speedy and effectual mode of bringing a surface covered with coarse herbage into a state of culture. Some have recommended making a compost of the pared surface, with lime; or building folds or earthen walls of the sods, which, by the action of the atmosphere, become friable and fertile; but these processes are slower and not so effectual as paring and burning. In coarse rough pastures, ant-hills frequently abound, which are effectually destroyed by paring and burning. (*Code.*)

SECT. IV. *Moors and their Improvements.*

4537. *Moorlands* are of various descriptions. Sometimes they are in low and mild situations, where the upper soil is thin or scantily supplied with vegetable mould, and where the bottom or under-stratum is impervious and barren: these, in general, may be reclaimed with more or less advantage, according to the proximity of manure or markets, and of other means of improvement. Sometimes, on the contrary, they are in situations much elevated above the level of the sea; where the surface is covered with heath and other coarse plants, and frequently encumbered with stones: such moors are seldom worth the expense of cultivation, and from their height are only calculated for woods or pasturage.

4538. *Moors not placed in high or bleak situations*, where the surface is close-swarded, or covered with plants, and where the subsoil is naturally either not altogether wet, or capable of being made sufficiently dry at a moderate expense, may not only be reclaimed, but can often be highly improved by the common operations of farm culture, by paring and burning, by fallow and liming, or by trenching or deep ploughing.

4539. *Fast improvements on different sorts of moory lands have been made in Yorkshire* where there are immense tracts of moors. It is stated in *The Agricultural Report of the North Riding of Yorkshire*, that an improvement was made upon Lockton Moor, on a quantity of land of about seventy acres, which would not let for more than 1s. per acre before it was enclosed. Of this forty-eight acres were pared and burnt, and sown with rape, except about an acre sown with rye; the produce about sixty quarters. The rye grew very strong, and in height not less than six feet, and was sold, while standing, for five guineas the acre. The land was only once ploughed, otherwise the crop of rape would probably have been much better. One hundred and twenty chaldrons (each thirty-two bushels) of lime were ploughed into the

field; which, for want of more frequent ploughing, was probably not of the service it otherwise might have been. Part of the land was afterwards sown down with oats and grass seeds; the former of which afforded but a moderate crop, the latter a very good one, and has since produced two loads, 120 stones each, per acre. The seeds sown were rye-grass, rib-grass, white clover, and trefoil; of these, the first succeeded amazingly, the others not so well; potatoes thrived very well; turnips not equal to them. A farm-house has been built upon it, which now, along with five acres more of the same kind of land, is let on lease at thirty pounds per annum. The soil consisted, in general, of benty peat, upon red gristone, with a mixture of clay upon limestone; this last is, in some places, at a considerable depth, in others, sufficiently near the surface for lime to be burnt on the premises.

4540. *Finlayson's rid-plough* (§ 2605.) has been found a valuable implement in breaking up heath and moorlands, in Scotland.

SECT. V. Peat Mosses, Bogs, and Morasses, and their Improvement.

4541. *Mossy and boggy surfaces* occupy a very considerable portion of the British Isles. In Ireland alone there are of flat red bog, capable of being converted to the general purposes of agriculture, 1,576,000 acres; and of peat soil, covering mountains, capable of being improved for pasture, or beneficially applied to the purposes of plantation, 1,255,000 acres, making together nearly three millions of acres. Mossy lands, whether on mountains or plains, are of two kinds: the one black and solid; the other spongy, containing a great quantity of water, with a proportion of fibrous materials.

4542. *Black mosses*, though formerly considered irreclaimable, are now found capable of great melioration. By cultivation, they may be completely changed in their quality and appearance; and, from a peaty, become a soft vegetable earth of great fertility. They may be converted into pasture; or, after being thoroughly drained, thriving plantations may be raised upon them; or, under judicious management, they will produce crops of grain and roots; or, they may be formed into meadow-land of considerable value.

4543. *Flow, fluid, or spongy mosses*, abound in various parts of the British Isles. Such mosses are sometimes from ten to twenty feet deep, and even more, but the average may be stated at from four to eight. In high situations, their improvement is attended with so much expense, and the returns are so scanty, that it is advisable to leave them in their original state; but where advantageously situated, it is now proved that they may be profitably converted into arable land, or valuable meadow. If they are not too high above the level of the sea, arable crops may be successfully cultivated. Potatoes, and other green crops, where manure can be obtained, may likewise be raised on them with advantage.

4544. *Peat* is certainly a production capable of administering to the support of many valuable kinds of plants: but to effect this purpose, it must be reduced to such a state, either by the application of fire, or the influence of putrefaction, as may prepare it for their nourishment. In either of these ways, peat may be changed into a soil fit for the production of grass, of herbs, or of roots. The application of a proper quantity of lime, chalk, or marl, prepares it equally well for the production of corn. (*Code.*)

4545. *The fundamental improvement* of all peat soils is drainage, which alone will in a few years change a boggy to a grassy surface. After being drained, the surface may be covered with earthy materials, pared and burned, fallowed, dug, trenched, or rolled. The celebrated Duke of Bridgewater covered a part of Chatmoss with the refuse of coal-pits, a mixture of earths and stones of different qualities and sizes, which were brought in barges out of the interior of a mountain; and, by compressing the surface, enabled it to bear pasturing stock. Its fertility was promoted by the vegetable mould of the morass, which presently rose and mixed with the heavier materials which were spread upon it. (*Marshal on Landed Property*, p. 46.)

4546. *The fenny grounds* of Huntingdonshire are in some cases improved by applying marl to the surface. Where that substance is mixed with the fen soil, the finer grasses flourish beyond what they do on the fen soil unmixed; and when the mixed soil is ploughed, and sown with any sort of grain, the calcareous earth renders the crops less apt to fall down, the produce is greater, and the grain of better quality than on any other part of the land. (*Huntingdonshire Report*, p. 301.)

4547. *Covering the surface of peat bogs with earth* has been practised in several parts of Scotland. Clay, sand, gravel, shells, and sea ooze, two or three inches thick, or more, have been used; and land, originally of no value, has thus been rendered worth from 2*l.* to 3*l.*, and even 4*l.* per acre. The horses upon this land must either be equipped with wooden clogs, or the work performed in frosty weather, when the surface of the moss is hard. Coarse obdurate clay (provincially *hill*) is peculiarly calculated for this process; as, when it is blended with peat and some calcareous matter, it contains all the properties of a fertile soil. (*Clydesdale Report*, p. 150, note.) This is certainly an expensive method of improving land, unless the substance to be laid upon it is within 500 yards' distance; but where it can properly be done, the moss thus obtains solidity, and after it has been supplied with calcareous earth, it may be cultivated, like other soils, in a rotation of white and green crops. In the neighbourhood of populous towns, where the rent of land is high, the covering substance may be conveyed from a greater distance than 500 yards. (*Code.*)

4548. *Rolling peaty surfaces* has been found to improve them. The greatest defect of soft soils is, that the drought easily penetrates them, and they become too open. The roller is an antidote to that evil, and the expense is the only thing that ought to set bounds to the practice of this operation. It also tends to destroy those worms, grubs, and insects, with which light and fenny land is apt to be infested. The roller for such soils ought not to be heavy, nor of a narrow diameter. If it is weighty, and the diameter small, it sinks too much behind the roller, and thus, instead of consolidating, it rends the soil. A gentle pressure consolidates moss, but too much weight has a contrary effect. A roller for moss ought therefore to be formed of wood, the cylinder about four feet diameter, and mounted to be drawn by two or three men. Three small rollers working in one frame, (*fig. 700.*) has sometimes been so drawn. When horses are employed, they ought to have clogs or pattens, if likely to sink. The oftener the rolling is performed, on spongy soils as long as the crops of corn or grass will admit of it, the better, and the more certain is the result.

4549. *An extensive tract of moss in the county of Lancaster* has been recently improved by the celebrated Roscoe of Liverpool, in a very spirit and skilful manner. Chatmoss in that county is well known; its length is about six miles, its greatest breadth about three miles, and its depth may be estimated from ten to upwards of thirty feet. It is entirely composed of the substance well known by the name of peat, being an aggregate of vegetable matter, disorganised and inert, but preserved by certain causes from putrefaction. On the surface it is light and fibrous, but becomes more dense below. On cutting to a considerable depth, it is found to be black, compact, and heavy, and in many respects resembling coal. There is not throughout the whole moss the least intermixture of sand, gravel, or other material, the entire substance being a pure vegetable. About 1796 or 1797, Roscoe began to improve Trafford moss, a tract of three hundred acres, lying two miles east of Chatmoss; and his operations on it seem to have been so successful as to encourage him to proceed with Chatmoss. In the improvement of the latter, he found it unnecessary to incur so heavy an expense for drainage as he had done in the former. From observing that where the moss had been dug for peat, the water had drawn towards it from a distance of fifty to a hundred yards, he conceived that if each drain had to draw the water only twenty-five yards, they would, within a reasonable time, undoubtedly answer the purpose. The whole of the moss was therefore laid out on the following plan:—

4550. *A main road*, Roscoe states, "was first carried nearly from east to west through the middle of my tract of moss. This road is about three miles long and thirty feet wide; it is bounded on each side by a main drain, seven feet wide and six feet deep, from which the water is conveyed, by a considerable fall, to the river. From these two main drains, other drains diverge, at fifty yards distance from each other, and extend from each side of the road to the utmost limits of the moss. Thus, each field contains fifty yards in front to the road, and is of an indefinite length, according as the boundary of the moss varies. These field-drains are four feet wide at the top, one foot at the bottom, and four feet and a half deep. They are kept carefully open, and, as far as my experience hitherto goes, I believe they will sufficiently drain the moss, without having recourse to underdraining, which I have never made use of at Chatmoss, except in a very few instances, when, from the lowness of the surface, the water could not readily be gotten off without open channels, which might obstruct the plough."

4551. *The cultivation of the moss* then proceeds in the following manner:—"After setting fire to the heath and herbage on the moss, and in the lowest part of it, as far as practicable, I plough a thin sod or furrow, with a very sharp horse-plough, which I burn in small heaps and dissipate; considering it of little use but to destroy the tough sods of the *Eriophorum*, *Nardus*

strifeta, and other plants, whose matted roots are almost imperishable. The moss being thus brought to a tolerably dry and level surface, I then plough it in a regular furrow six inches deep; and as soon as possible after it is thus turned up, I set upon it the necessary quantity of marl, not less than 600 hundred cubic yards to the acre. As the marl begins to crumble and fall with the sun or frost, it is spread over the land with considerable exactness, after which I put in a crop as early as possible, sometimes by the plough, and at others with the horse-scuffle or scarifier, according to the nature of the crop, adding, for the first crop, a quantity of manure, which I bring down the navigable river Irwell, to the borders of the moss, setting on about twenty tons to the acre. Moss land thus treated may not only be advantageously cropped the first year with green crops, as potatoes, turnips, &c. but with any kind of grain; and as wheat has, of late, paid better to the farmer than any other, I have hitherto chiefly relied upon it, as my first crop, for reimbursing the expense."

4552. *The expense of the several ploughings, with the burning, sowing, and harrowing, and of the marl and manure, but exclusive of the seed, and also of the previous drainage and general charges, amounts to 18l. 5s. per acre; and in 1812, on one piece of land thus improved, Roscoe had twenty bushels of wheat, then worth a guinea per bushel, and on another piece eighteen bushels; but these were the best crops upon the moss.* "Both lime and marl are generally to be found within a reasonable distance; and the preference given to either of them will usually depend upon the facility of obtaining it. The quantity of lime necessary for this purpose, is so small, in proportion to that of marl, that, where the distance is great, and the carriage high, it is more advisable to make use of it; but where marl is upon the spot, or can be obtained in sufficient quantity at a reasonable expense, it appears to be preferable." Roscoe is thoroughly convinced, after a great many different trials, that all tempering expedients are fallacious; and "that the best method of improving moss land is by the application of a colourless substance, in sufficient quantity to convert the moss into a soil, and by the occasional use of animal or other extraneous manures, such as the course of cultivation, and the nature of the crops, may be found to require."

4553. *Roscoe's contrivance for conveying on the marl seems peculiar.* It would not be practicable, he observes, to effect the marling at so cheap a rate, (10l. per acre,) were it not for the assistance of an iron road or railway, laid out upon boards or sleepers, and moveable at pleasure. Along this road the marl is conveyed in wagons with small iron wheels, each drawn by one man. These wagons, by taking out a pin, turn their sides out on either side; they carry about 15 cwt. each, being as much as could heretofore be conveyed over the moss by a cart with a driver and two horses.

4554. *An anomalous mode of treating peat bogs* was invented and practised by the late Lord Kaimes, which may be applicable in a few cases. This singular mode can be adopted only where there is a command of water, and where the subjacent clay is of a most fertile quality, or consists of alluvial soil. A stream of water is brought into the moss, into which the spongy upper stratum is first thrown, and afterwards the heavier moss, in small quantities at a time; the whole is then conveyed by the stream into the neighbouring river, and thence to the sea. The moss thus got rid of, in the instance of Blair Drummond, in Perthshire, was, on an average, about seven feet deep. Much ingenuity was displayed in constructing the machinery, to supply water for removing the moss, previously to the improvement of the rich soil below. It required both the genius and the perseverance of Lord Kaimes to complete this scheme; but by this singular mode of improvement, about 1000 English acres have been already cleared, a population of above 900 inhabitants furnished with the means of subsistence, and an extensive district, where only snipes and moorfowl were formerly maintained, is now converted, as if by magic, into a rich and fertile *carse*, or tract of alluvial soil. (*Codic.*) In *The General Report of Scotland*, Appendix, vol. ii. p. 38., and at p. 326 of this work, will be found a detailed account of this improvement.

4555. *Moss has been converted into manure* by fermentation with stable dung, and with this article joined with whale oil. In the *Highland Soc. Trans.*, vol. vii., an account is given (p. 147.) of several experiments of this kind by W. Bell, Esq. — A layer of moss a foot thick was formed after the material was tolerably dry, in the month of June; above this layer of stable dung was placed, at least twice the thickness of that of moss; next followed another layer of moss thicker than the first; on this last layer a ton of coarse whale oil was poured, and the whole was completely covered up with moss. In ten days the whole mass came freely into heat; in about eight weeks it was turned, and continued to ferment freely; in a few weeks afterwards the whole mass resembled black garden mould. Out of twenty-five cubic yards of stable dung, and one ton of oil, two hundred and sixty cubic yards of compost were produced.

4556. *Peat may be charred* and rendered fit to be used like charcoal in cookery and other domestic purposes, in the same way as wood or coal is charred, and in much less time. For ordinary purposes, it is charred by some families on the kitchen fire, thus:—Take a dozen or fifteen peats, and put them upon the top of the kitchen fire, upon edge: they will soon draw up the coal fire, and become red in a short time: after being turned about once or twice, and done with smoking, they are charred, and may be removed to the stoves: if more char is wanted, put on another supply of peat, as before mentioned. By following this plan, you keep up the kitchen fire, and have at the same time, with very little trouble, a supply of the best charred peat, perfectly free of smoke; and the vapour is by no means so noxious as charcoal made from wood. Peats charred in this way may be used in a chafin, in any room, or even in a nursery, without any danger arising from the vapour. It would also be found very fit for the warming of beds; and much better than live coals, which are in general used full of sulphur, and smell all over the house. (*Farm. Mag.* vol. xvii.)

SECT. VI. Marshes and their Improvement.

4557. *A tract of land on the borders of the sea or of a large river* is called a marsh: it differs from the fen, bog, and morass, in consisting of a firmer and better soil, and in being occasionally flooded. Marshes are generally divided into fresh-water marshes and salt-water marshes; the latter sometimes called saltings or ings: fresh-water marshes differ from meadows, in being generally soaked with water from the sub-soils or springs.

4558. *Fresh-water marshes* are often found interspersed with arable land, where springs rise, and redundant water has not been carried off; and may be improved by a course of ditching, draining, and ploughing. Where large inland marshes are almost constantly

covered with water, or the soil is extremely wet, they may be drained, as large districts in the fens of Lincolnshire have been, and made highly valuable. The object, in that case, is, by embankments, draining, and other means of improvement, to convert these marshes into pasture or meadow, or even arable lands; and where such improvements cannot be accomplished, the most useful woody aquatics, as willows, osiers, &c., may be grown with advantage.

4559. *Romney marsh* is one of the most extensive and fertile fresh-water marshes in Britain. It contains nearly 24,000 acres; besides which Walland marsh and Dingle marsh, which are comprised within the walls, contain, the former 12,000, and the latter 8,000 acres. Boys informs us that "the internal regulations of these marshes are committed to the superintendance of expeditors. These are appointed by the Commissioners of Sewers, and are to take care that the repairs of the walls are maintained in due order, and that the costs attending the same be levied on each tenant according to the number of acres occupied by him; for which purpose they are to cause assessments to be made out, with the names of the occupiers, and the rateable proportions to be borne by them respectively; and these rates, which must be confirmed by the commissioners, are termed scots; and that when any occupier refuses to pay his scot, the expeditors can obtain a warrant from the commissioners, empowering them to distrain for the same, as for any other tax." These marshes are both appropriated to the purposes of breeding and feeding.

4560. *Salt water marshes* are subject to be overflowed at every spring tide, and at other times, when, from the violence of the wind or the impetuosity of the tide, the water flows beyond its usual limits. Their goodness is in a great measure analogous to the fertility of the adjoining marshes; and their extent differs according to the situation. Embankments, as it is remarked in *The Code of Agriculture*, are perhaps the only means by which they can be effectually improved, especially when they are deficient in pasture. However, where pasture abounds, they are in some cases more valuable than arable lands, the pasture operating as a medicine upon diseased cattle.

4561. *Marshes on the Thames*. In *The Agricultural Survey of Kent* it is asserted, that great profit is made by the renters of marshes bordering on the Thames, in the neighbourhood of London, from the grazing of horses, the pasture being deservedly accounted salubrious to that useful animal. Such horses as have been worn down by hard travel, or long afflicted with the farcy, lameness, &c., have frequently been restored to their pristine health and vigour, by a few months' run in the marshes, especially on the saltings; but as every piece of marsh land in some measure participates of this saline disposition, so do they all of them possess, in a comparative degree, the virtues above mentioned, and for this reason the Londoners are happy to procure a run for their horses, at 4s. or 5s. per week. Another method practised by the graziers in the vicinity of London is, to purchase sheep or bullocks in Smithfield at a hanging market, which, being turned into the marshes, in the lapse of a few weeks are not only much improved in flesh, but go off at a time when the markets, being less crowded, have considerably advanced in price; and thus a twofold gain is made from this traffic. Many of the wealthy butchers of the metropolis are possessed of a tract of this marsh land, and, having from their constant attendance at Smithfield, a perfect knowledge of the rise and fall in the markets, they are consequently enabled to judge with certainty when will be the proper time to buy in their stock, and at what period to dispose of them.

4562. *In various districts of the island* situated on the borders of the sea, or near the mouths of large rivers, there are many very extensive tracts of this description of land, which by proper drainage and enclosure may be rendered highly valuable and productive. This is particularly the case in Somersetshire and Lincolnshire. In the former of these counties, vast improvements have, according to Billingsley, as stated in his able *Survey*, been effected by the cutting of ditches, for the purpose of dividing the property, and the deepening of the general outlets to discharge the superfluous water. Many thousand acres which were formerly overflowed for months together, and consequently of little or no value, are now become fine grazing and dairy lands.

SECT. VII. *Downs and other Shore Lands.*

4563. *Downs* are those undulating smooth surfaces covered with close and fine turf met with in some districts on the sea-shore; the soil is sometimes sandy, and at other times clay or loam. In inland situations there are also down lands, as in Wiltshire, Lincolnshire, and Yorkshire; in the latter two counties they are called wolds.

4564. *Sandy downs on the sea-shore* are often more valuable in their natural state than after cultivation. In a state of nature they frequently afford good pasture for sheep and rabbits, and at other times produce grasses that may be used as food for cattle, or as litter. But the great object should be to raise plants which contribute to fix these soils, and to prevent them from being drifted by the winds, which often occasion incalculable

mischief. The most suitable plants for the purpose are, the *Elymus arenarius*, *Juncus arenarius*, *Arundo Donax*, *Ononis spinosa*, *Galium verum*, *Tussilago Petasites*, and a variety of other creeping-rooted plants and grasses. Of woody plants, the elder is one of the best for resisting the sea breeze, and requires only to be inserted in the sand in large truncheons. Where the sands on sea-shores are mixed with shells, and not very liable to drift, if they can be sheltered by fences or an embankment, and sown with white clover, it will be found both an economical and profitable improvement.

4565. *The drift-sands of the outer*

Hebrides have in some places been consolidated and covered with verdure by "square pieces of turf, cut from solid sward, and laid upon the drifting surface, in steep places nearer to each other, and in less inclined places at a greater distance: on very rapid declivities the turfs are placed in contiguity. These turfs, although separated by intervals of a foot or so of sand, are not liable to be buried, except in very exposed places." (*Quar. Jour. Agr.* vol. i. p. 715.) N. Macleod, Esq. of Harris, has reclaimed and brought into useful permanent pasture above 120 acres of useless drifting sand, by planting it with *Arundo arenaria* (fig. 710.) in 1819. The operation is performed in September, by cutting the plants "about two inches below the surface with a small thin-edged spade, with a short handle, which a man can use in his right hand, at the same time taking hold of the grass with his left; or other persons carrying it to the blowing-sand to be planted in a hole, or rather a cut, made in the sand, about eight or nine inches deep, (and deeper where the sand is very open and much exposed,) by a large narrow-pointed spade. A handful of *Arundo arenaria*, or bent grass, was put into each of these cuts, which were about twelve inches distant, more or less, according to the exposure of the situation. When properly fixed in the blowing-sand, the roots begin to grow and spread under the surface, in the course of a month after planting. This grass is relished by cattle in summer, but it is of greater value, by preserving it on the ground for wintering cattle: it would be injudicious to cut it, because it will stand the winter better than any other grass, and is seldom covered with snow. Neither wind, rain, nor frost will destroy it; but the old grass naturally decays towards the latter end of spring and the beginning of summer, as the new crop grows. White and red clover will grow spontaneously among this grass in the course of a few years, provided it is well secured. (*Trans. Highl. Soc.* vol. vi. p. 265.)

warrens and cultivate corn and turnips; but it frequently happens that, taking the requisite outlay of capital, and the expenses and risk into consideration, they do not pay so well as when stocked with rabbits. Such lands are generally well adapted for planting; but in this, as in every other case where there is a choice, circumstances must direct what line of improvement is to be adopted.

711

4566. *Poor sandy soils in inland districts* are not frequently stocked with rabbits. When the productions of arable lands are high, it is found worth while to break up these warrens and cultivate corn and turnips; but it frequently happens that, taking the requisite outlay of capital, and the expenses and risk into consideration, they do not pay so well as when stocked with rabbits. Such lands are generally well adapted for planting; but in this, as in every other case where there is a choice, circumstances must direct what line of improvement is to be adopted.

4567. *Shores and sea beaches of gravel and shingle*, without either soil or vegetation, are perhaps the most unimprovable spots of any; but something may be done with them by burying the roots of the arenarius grasses along with a little clay or loamy earth. Of these, the best is the *Arundo arenaria* and *Elymus arenarius* (fig. 711. a), already mentioned; and *E. geniculatus* (b) and *sibiricus* (c) would probably succeed equally well. The last grows on the sandy wastes of Siberia, and the preceding is found on the shores of Britain.

CHAP. V.

Improvement of Lands already in a State of Culture.

4568. *A profitable application of many of the practices recommended* in the chapters of this and the foregoing Book may be made to many estates which have been long under cultivation. It is certain, indeed, that the majority of those who study our work will have that object more in view than the laying out or improvement of estates *ab origine*. Few are the estates in Britain in which the farm lands do not admit of increased value,

by rectifying the shape of fields, adjusting their size, improving the fences, draining the soil, or adding to the shelter; and few are the farmeries that may not be rendered more commodious. Of this, we shall give a few examples, after we have stated the general principles and modes of proceeding.

SECT. I. *General Principles and Modes of Procedure, in improving Estates already more or less improved.*

4569. *The groundwork of improvement*, on which a practical man may tread with safety and full effect, is an accurate delineation of the existing state, together with a faithful estimate of the present value, of the lands, and other particulars of an estate to be improved. A general map of the appropriated lands, readily exhibiting the several farms and fields as they lie, and showing the existing watercourses, embankments, fences, and buildings; the woodlands, standing waters, morasses, and moory grounds; the known mines and quarries; together with the commonable lands (if any) belonging to the estate, forms a comprehensive and useful subject of study to the practical improver. It is to him, what the map of a country is to a traveller, or a sea-chart to a navigator. If an estate is large, a faithful delineation of it will enable him in a few hours to set out with advantages, respecting the connections and dependencies of the whole and its several parts, which, were he deprived of such scientific assistance, as many days, weeks, or months could not furnish. If on the same plan appear the rental value of each field or parcel of land, and the annual produce of each mine, quarry, woodland, and productive water, in its present state, the preparatory information which science is capable of supplying may be considered as complete; and it remains with the artist to study with persevering attention the subject itself, in order to discover the species of improvements of which it is susceptible, and the suitable means of carrying them into effect.

4570. *The species of improvements* incident to landed property are numerous. They may, however, be classed under the following heads: — the improvement of the outline, and general consolidation of an estate by purchase, sale, or exchange: the improvement of the roads; of the mines and minerals; of the towns, villages, mills, and manufactories; of the waters; of the woods and plantations; and of the farmeries and farm lands. This last subject is the most common, and to it we shall devote the succeeding section. To discuss the other species of improvement, as applied to old estates, would necessarily include so much of what has already passed in review in the foregoing Book, as to be wearisome to the reader.

SECT. II. *Improvement of Farmeries and Farm Lands.*

4571. *Farm lands are of more or less value according to the means of occupying them.* Arable lands in particular require buildings and other conveniences proportioned to the size of a farm. We frequently see tenants curbed in their operations, and incurring a waste of produce, through the want of sufficient homestalls. On the other hand, we sometimes observe a prodigality of expenditure on farm buildings; thus not only sinking money unnecessarily, but incurring unnecessary expenses in subsequent repairs, by extending homesteads beyond the sizes of farms. In some cases, therefore, it will be found necessary to curtail the extent of farm buildings, as large barns; in others to enlarge the yards, and in many to add and re-arrange the whole. The subject therefore may be considered in regard to design and execution; but as we have already treated fully on laying out new farmeries, we shall here offer only a few general remarks as to alterations.

4572. *In improving the plan of a farmery*, the given intention is first to be maturely considered, and the several requisites to be carefully ascertained. The given site is next to be delineated, so as to show the existing buildings, yards, roadways, and entrances; and then, by maturely studying the plan alternately with the site itself, the improver is to endeavour to trace out the most suitable alterations; all the while keeping in view the perfection of arrangement, the situation and value of the existing buildings, and the expenses of alteration; reconsidering the subject repeatedly, until the judgment be fully satisfied. It is much easier to plan and erect a new farmstead, than to improve one which is already erected. The former requires science and ingenuity only; the latter good sense and judgment also.

4573. *In executing improvements on old farmeries*, some difficulty occurs as to the incorporation of new and old materials. If the situation and plan are likely to be of permanent approval, the new erections may be made in the most substantial manner; keeping it in view that the old, which are repaired at the time, may afterwards be wholly renewed. But if the repairs and improvements are not to extend further than the duration of a lease, or till, by the expiration of various leases, some general plan of improvement can be determined on, then old materials may be used, or less permanent structures may be erected.

4574. As an example of adding part of a newly-enclosed common-field to a small anciently enclosed grass-farm (fig. 712.), we give the following case:

712

4575. The farmery (a) and ancient enclosed fields (b), are separated from the common field by a road, and bounded on the other side by a lake. The soil is a soft black earth on a gravelly subsoil, the surface a gentle slope towards the lake. The farm-house is supposed to be already placed in this ancient part; and the object in view is to unite a large portion of the common field, when enclosed, to each ancient farm, so as to get a fair rent for the lands at the least expense. The soil of this common field is a light poor sand, with nearly a flat surface. The circumstances of the country are favourable to large farms, the climate is dry, and the situation such as to require shelter. The number of acres to be enclosed and added to this farm is 1200. These will be most advantageously cultivated in six shifts of, 1, turnips (c); 2, barley (d); 3, artificial grasses (e); 4 and 5, the same (f, g); 6, wheat or oats (h). Each shift is proposed to be separated by a plantation for shelter, and no inferior divisions are made. In two of the plantations are field-barns, sheds, &c. where the corn grown on one-half of the arable lands is threshed by a moveable threshing-machine, and the straw consumed by cattle. There are cottages at each of these barns for

labourers to attend to the stock, &c. The ridges in each of the breaks or shifts are supposed to extend their whole length; or they may be ploughed as if the whole break were only one ridge, by which means not a moment is lost in turning at the ends, &c. Hereford or Devon oxen are supposed the beasts of labour on this farm.

4576. In place of the above rotation, wheat may be added after the second year of artificial grasses, and one shift kept entirely under saintfoin. This saintfoin division must of course be changed every sixth or seventh year. However, if a proper mixture of artificial grasses is sown, such as red, white, and yellow clover, rib-grass, burnet, saintfoin, timothy, cocksfoot, rye-grass, and soft-grass, the produce will be superior to that from either saintfoin or lucern alone, on a soil such as this, or even perhaps on any soil. Every agriculturist of observation must be aware that the efforts of annual and biennial plants are powerful for a few years at first, and that they uniformly produce a greater bulk than perennials: the latter seem to compensate for this temporary bulk by a steady durable produce.

4577. The old pasture near the house is supposed to be irrigated from the upper part of the lake, by a cut passing near the house. These pastures are particularly advantageous for early lambs, milch cows, &c. and for stock in general in seasons of great drought.

4578. Correcting the outlines of fields is one of the most obvious sources of amelioration on many, perhaps on most, estates. The advantages of proper sized and shaped enclosures have been fully pointed out, when treating of laying out farm lands, and in altering existing fences the same principles must be steadily kept in view; for though, unless by a total eradication of all the existing fences, every requisite may not be attainable, yet such a number may be gained as amply to compensate for the expense. In altering the shape and size of fields, besides the advantages resulting from the improvement in form, it will generally be found that a number of culturable acres may be added to the farm in proportion to the crookedness and width of the fences. Better drainage and roads will also be obtained, and where ornament is an object, a park-like appearance may be produced by leaving a single trees as part of what may have stood in the eradicated hedge-rows.

4579. As an example of improving the shape and size of fields, we shall refer to a farm of 350 acres, situated in Middlesex. (*fig. 713.*) In this case, the fields were larger than usual, but the fences were in

many parts from ten to fifteen yards in width, more resembling strips of copse wood than fences, as they contained hazel, dogwood, black and white thorns, wild roses, brambles, and a variety of native shrubs. The lines of these fences were so ill calculated for carrying off the surface-water, that in one half of the fields there were open gutters for the discharge of the water collected in the hedge-row ditches.

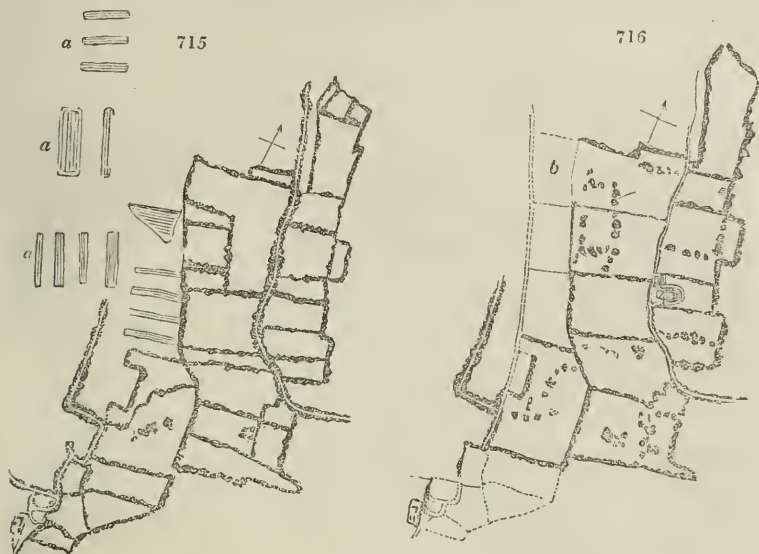

4580. In the centre of one field (25), for example, above an acre was rendered waste by the water from other fields (19, 20, and 21), which water, it is curious to remark, might, if led over the same acre agreeably to the principles of irrigation, have produced annually at least two loads and a half of good hay, in place of annually rendering the produce of this acre unmarketable. The water of some fields (as 16, 18, and part of 19,) ran in a diagonal direction through another (15), two acres of which might have been irrigated by it to advantage.

4581. In the farm, when altered (*fig. 714.*), the fields are more uniform in shape and size; their sides are arc parallel, and better adapted for ploughing the lands in straight ridges. All the surface-water is

carried off by the open fence drains. Access is had to every field by the shortest possible road from the farmery. Only two-thirds of the number of gates formerly required are requisite. Fifty acres are rendered useful which were formerly lost, or pernicious, by occupying space for which rent was paid, and by harbouring insects and noxious weeds; and as much rich vegetable earth is obtained from the old hedge banks as, spread abroad in every direction, may be said to manure at least ten acres. The whole is more open and healthful; and, from the number of single trees thrown into the fields, more elegant, and bearing a greater resemblance to a park. A part near the house (1, 2, 3) is in permanent pasture, and the rest (4, 5, 6, &c.) under a course of fallow, wheat, clover, beans, and wheat.

4582. *As an example of altering the fields and consolidating a farm, we submit the case of a meadow-farm, with the arable lands in a common field state. (fig. 715.)* By an act of enclosure, these scattered arable lands (*a*) were exchanged for others adjoining the meadow grounds (*fig. 716. b*), and the whole ren-

dered more compact and commodious. This farm, being intersected by a public lane, affords an example in which no private roads are wanted. The size and shape of the fields were improved, and the broad fences reduced as in the preceding case, and attended with the same advantages in an agricultural point of view.

4583. *But though in altering broad fences there are obvious and indispensable advantages to the farmer, yet, as justly observed by Loch, gain is not every thing. "The fences on the Marquess of Stafford's estates," he says, "were liable to the same objection which is applicable to a great proportion of the counties of England. They are not composed of quick, at least but in a scanty degree they for the most part consist of bushes, growing from the stump of every sort of forest-tree, intermixed with hazel, birch, hornbeam, maple, alder, willow, &c. They are planted on high and dry mounds, and thus are subject to constant decay. They occupy too much ground, provided agricul-*

ture alone were the occupation of life. But as they give great protection, when they thrive, to the game, they become an important object of preservation, inasmuch as every thing must be of consequence which contributes to the sport, and has the effect of retaining the gentry of England much upon their estates. For this reason, it may occasionally be proper to consider of the best way to preserve these hedges at the least expense, in place of substituting more perfect ones in their stead; nor should one object exclusively be attended to in the agricultural improvements of so great and so wealthy a country." Such are Mr. Loch's ideas on game and hedges.

4584. *When farm-lands are exposed to high winds, interspersing them with strips or masses of plantation is attended with obviously important advantages. Not only are such lands rendered more congenial to the growth of grass, and corn, and the health of pasturing animals, but the local climate is improved. The fact, that the climate may be thus improved, has, in very many instances, been sufficiently established. It is, indeed, astonishing how much better cattle thrive in fields even but moderately sheltered than they do in an open exposed country. In the breeding of cattle, a sheltered farm, or a sheltered corner in a farm, is a thing much prized; and, in instances where fields are taken by the season for the purpose of fattening, those most sheltered never fail to bring the highest rents, provided the soil is equal to that of the neighbouring fields which are not sheltered by trees. If we enquire into the cause, we shall find, that it does not altogether depend on an early rise of grass, on account of the shelter afforded to the lands by the plantations; but likewise that cattle, which have it in their power, in cold seasons, to indulge in the kindly shelter afforded them by the trees, feed better; because their bodies are not pierced by the keen winds of spring and autumn, neither is the tender grass destroyed by the frosty blasts of March and April. (Plant. Kal. p. 121.)*

4585. *The operation of screen plantations, in exposed situations, Marshal observes, is not merely that of giving shelter to the animals lodging immediately beneath them; but likewise that of breaking the uniform current of the wind,—shattering the cutting blasts, and throwing them into eddies; thus meliorating the air to some distance from them. Living trees communicate a degree of actual warmth to the air which envelopes them. Where there is life there is warmth, not only in animal but in vegetable nature. The severest frost rarely affects the sap of trees. Hence it appears, that trees and shrubs properly disposed, in a bleak situation, tend to improve the lands so situated, in a threefold way, for the purposes of agriculture; namely, by giving shelter to stock; by breaking the currents of winds; and by communicating a degree of warmth or softness to the air, in calmer weather.*

4586. *The proper disposal of screen plantations for this purpose is in lines across the most offensive winds, and in situations best calculated to break their force. Placed across valleys, dips, or more open plains, in bleak exposures, they may be of singular use; also on the ridges, as well as on the points and hangs, of hills.*

4587. *The width of skreen plantations* ought generally to be regulated by the value of the land for agricultural uses, and the advantages of the situation for the sale and delivery of timber. In ordinary cases, from two to four statute poles may be considered as an eligible width.

4588. *The form of plantations* for shelter, however, will not in every case be that of a stripe or belt of uniform width. In hilly, rocky, and other situations, different forms will suggest themselves, according to the situation and the objects in view. In rocky abrupt sites (fig. 717.) the plantation will consist of a

717

number of masses (*a, b, c*), of forms determined by the rocks and precipices, among which some of the most valuable pasture may be left as glades (*d, e*), for use, effect, and for the sake of game. Strips and hedges for sheltering, or separating arable lands, should be formed as much as possible in straight and parallel lines, in order not to increase the expense of tillage by short and irregular turnings. Straight parallel strips, on irregular surfaces, have a more varied appearance at a distance, than strips ever so much varied on a flat surface; for, in the former case, the outline against the sky is varied as much as that on the earth. In extensive hilly pastures, in which it is often desirable to produce shelter, and at the same time to plant only the most rocky and unproductive spots, the forms may be of the most irregular description; and by planting chiefly on the eminences and slopes (fig. 718.), shelter will be most effectually produced, the pasture improved, the least valuable ground rendered productive in copse or timber, and the greatest richness and picturesque beauty conferred on the landscape. There are some fine examples of this in the hilly districts of Fifeshire: there, on many estates where nothing was sought for but profit and shelter, the greatest beauty has been produced; and the picturesque tourist now passes through glades and valleys, pastured by well-fed cattle and sheep, enlivened by rocks, thickets, hanging-woods, and occasional rills and lakes. Fifty years ago scarcely a tree was to be seen, and only the most inferior descriptions of live stock.

718

beneficial; not only the blast acquiring additional current, but snow being liable to be blown through, and to be lodged in drifts on the leeward side, to the annoyance and danger of sheep that have repaired to it for shelter. A larch plantation margined with spruce firs, and these headed at twelve or fifteen feet high, would afford the required shelter for a length of years. The firs, or pines, thus treated, would be induced to throw out lateral boughs, and feather to the ground: while the larches, in their more advanced state of growth, would, by permitting the winter's winds to pass through the upper parts of the skreen, break the current and mellow the blast.

4591. In *more genial situations*, the beech, by retaining its leaves in winter, especially while it is young, forms a valuable skreen. If the outer margins were kept in a state of coppice wood, and cut alternately, and the middle ranks suffered to rise as timber trees, the triple purpose of skreen plantations might be attained in an eminent degree, and almost in perpetuity.

4592. In *deep-soiled vale districts*, which not unfrequently want shelter, skreens of oak might be managed in a similar way. Hollies, or other hardy evergreens, planted as underwood, in groves of either of the above descriptions, would, if suitable situations were assigned them, assist much in this intention.

4593. *A tall impervious fence* is, for the purpose of shelter to pasturing stock, nearly equal to a depth of coppice wood, and infinitely preferable to an open grove of timber trees; beside its additional use as a fence. There appears one species of fence which is peculiarly adapted to this purpose. This is the coppice mound hedge of Devonshire and South Wales; namely, a high wide bank or mound of earth, planted with coppice woods. This becomes, immediately on its erection, a shelter and a guard to pasture grounds.

4594. *The method of forming fences of this kind* is to carry up a stratum of earth, between two sod facings, "battering," or leaning somewhat inward, to the required height; and to plant on the top the roots and lower stems of coppice plants, gathered in woods or on waste grounds; or nursery plants adapted to the given situation. If the mound be carried to a full height, as five or six feet, and about that width at the top, and this be planted with strong plants, with stems cut off about two feet above the roots (in the usual practice of Devonshire), a suf-

ficient fence is thus immediately formed against ordinary stock. But if the bank be lower, or if nursery plants be put in, a slight guard run along the outer brink on either side, and leaning outward over the face of the mound, is required (especially against sheep) until the plants get up. If a hedge of this kind be raised as a *plantation fence* (especially on the lower side of a slope), the outer side only requires to be faced with sods; the hedge plants being set in a rough shelving bank, on the inner side.

4595. *The species of hedge woods*, proper for mound fences, depends entirely on the soil and situation. On mounds of bad soil, in a bleak situation, the furze alone affords much shelter, and a good fence. The sides being kept pruned, so as to show a close firm face rising above the top of the bank, it is a secure barrier, even against the wider breeds of Welsh sheep. The beech is commonly planted in high exposed situations; and in places more genial to the growth of wood, the hazel, the ash,

and the oak are the ordinary plants of hedge mounds. The willow tribe have a quality which recommends them, in situations where they will flourish; they grow freely from cuttings, or truncheons set in the ground; whereas, to secure the growth of ordinary coppice woods, rooted plants are required. The rock-willow (*Salix caprea*) will grow in high and dry situations.

4596. *On thin-soiled stony surfaces*, tall mounds are difficult to raise; and there *stone walls* are not only built at a small expense, but are convenient receptacles for the stones with which the soil is encumbered. But a stone wall, unless it be carried up to an inordinate height, at a great expense, is useless as a skreen; and may be said to be dangerous as such, in a bleak exposed situation, for as soon as the drifting snow has reached the top of the wall, on the windward side, it pours over it, and inevitably buries the sheep which may be seeking for shelter on the leeward side. Hence, in a situation where shelter is required, it is necessary that a stone fence should be backed with a skreen plantation.

4597. *To plant trees for shade* may in some cases be requisite for agricultural purposes. Where this is the case, close plantations are seldom desirable, a free circulation of air being necessary to coolness; therefore trees with lofty stems, and large heads pruned to single stems, are preferable: the oak, elm, chestnut, and beech, for thick shade; the plane, acacia, and poplar, for shade of a lighter degree.

4598. *An example of sheltering a hill farm by plantation*, and at the same time improving the shape and size of fields, shall next be given. No farming subject affords better opportunities of introducing hedge-rows, and strips of planting, than hill-farms. The one under consideration (*fig. 719*) is a small estate farmed by its owner: it consists of nearly 370 acres; and is situated in an elevated, picturesque part of a central English county. The soil is partly a flinty loam or chalk, and partly a strong rich soil, incumbent on clay. The fields are very irregular, bounded by strips of timber and copse. By the alterations and additions proposed (*fig. 720.*), all the most hilly and distant spots will be kept in permanent pasture; and the exposed and abrupt places, angles, &c. planted chiefly with oaks for copse, and beech for timber and shelter.

4599. *On hill farms in Scotland*, where shelter cannot be given to grass and stock by plantations, small circular inclosures have been adopted for that purpose. The diameter of these circles is from 10 to 30

feet, the height of the wall six or eight feet, and a conical roof is placed on them, and covered with turf; but many inclosures of this kind are formed without roofs. They are called in Selkirkshire stells, and were brought into notice, in 1822, by Captain, now Lord Napier, in his Treatise on Store Farming, a work to which we shall have recourse in a subsequent section.

CHAP. VI.

Execution of Improvements.

4600. *The mode in which improvements are executed* is a point of very considerable importance, and may materially affect their success as well as their expense. We shall first consider the different modes of execution, and next offer some general cautions to be kept in view in undertaking extensive works.

SECT. I. *Different Modes of procuring the Execution of Improvements on Estates.*

4601. *The necessary preliminary to the execution of an improvement*, is a calculation of the advantages to arise from it, and an estimate of the expense of carrying it into effect. If the former, taken in their full extent, do not exceed the latter, the proposed alteration cannot, in a private view, be considered as an improvement. The next point to be ascertained is the practicability, under the given circumstances of a case, of executing the plan under consideration. There are three things essential to the due execution of an improvement. 1st, an undertaker, or a person of skill, leisure, and activity, to direct the undertaking; 2d, men and animals with which to prosecute the work; 3d, money, or other means of answering the required expenditure. A deficiency in any one of these may, by frustrating a well-planned work after its commencement, be the cause not only of its failure, but of time, money, and credit being lost. — Improvements may be executed by the proprietor, either directly; gradually, by economical arrangements; or remotely, to a certain extent, by moral and intellectual means.

4602. *To execute improvements directly*, all that is necessary is to employ a steward or manager of adequate abilities and integrity, and supply him with the requisite plans, men, and money. This will generally be found the best mode of forming new roads, new plantations, opening new quarries or mineral pits, altering the course of waters, and all such creations or alterations as are not included in the improvement of farm lands.

4603. *To procure the gradual execution of improvements on farm lands*, various arrangements may be made with the tenants: for example, by granting long leases; letting them find the requisites of improvement, and take the advantages during their terms; by granting shorter leases, with a covenant of remuneration for the remainder of such improvements as they have made, at the time of quitting; by granting leases, at a low rent, for the first years of the term, to give the tenants time and ability to improve at their own expense; by advancing money to tenants at will, or, which is the same, making allowances of rent for specified improvements, to be executed by them under the inspection and control of the manager, they paying interest for the money advanced or allowed; by employing workmen on tenanted farms; the tenants in like manner paying interest on the money expended. The usual interest, till lately, was six per cent.; thus estimating the value of the improvement at sixteen years' purchase.

4604. *The moral and intellectual means of improving farm lands* consists, as Marshal has observed, in enlightening the minds of tenants. Though this mode is but of slow operation, and respects improvements in modes of culture, rather than such as require great outlay; yet it deserves notice in this place, as necessary to second the efforts of the landlord.

4605. *Farmers, as moral and intellectual agents*, may be divided into reading men, and illiterate beings; the first class derive hints for improvement from books; but the second can only, if at all, derive benefit from example.

4606. With respect to *improving farmers by books*, — agricultural newspapers, magazines, and county surveys, are probably what would be read with most eagerness; and as such works abound in statements of what actually has taken place in different situations, by farmers like themselves, perhaps they are the most likely to stimulate to exertion. Historical relations of the agriculture of other countries are also generally interesting to agriculturists; and though no great professional benefit is to be derived from them, yet they tend to enlarge and liberalise the mind, and promote a taste for knowledge. Under these circumstances, it may be worthy of consideration whether an agricultural library might not be established in the steward's office, on very extensive estates, for the use of tenants and all other persons belonging to the estate who chose to read from it. Itinerating libraries for the use both of farmers and their servants, or, indeed, of whoever chooses to use them, have for some time been established, and extensively used in East Lothian, and they are gradually being adopted in other counties both in Scotland and England. (*Gard. Mag.* vol. ii. p. 376.)

4607. *The establishment of schools* for the children of the lower class of tenants, and of cottagers of every description, is an obvious and important source of moral and intellectual improvement; and considering it as decided by experience and the most competent judges, that the education of the lower classes will tend greatly to their amelioration and the benefit of society at large, we are of opinion that, wherever they are not already established, they should be introduced. Working schools, somewhat in the German manner, both for boys and girls, would also be a material improvement in such districts as are behind in a taste for cleanliness, fireside comforts, cookery, and dress.

4608. *Examples as stimuli to improvement* may be exhibited in various ways: by letting a farm to a tenant of superior energy, or from a more improved district; by exhibiting improved implements and operations on one particular farm; by an itinerant ploughman of abilities, accompanied by a smith and carpenter, and with some implements, to go round the estate and instruct each tenant on his own farm; and finally, and perhaps preferably, by inducing every farmer to make a tour into some other district once a year.

4609. *In addition to these modes*, appropriate as we consider for two different classes of tenants, Marshal suggests the following as calculated to insure a spirit of improvement among all farmers not of sufficient energy and intelligence. They are to be adopted in various ways, by a proprietor, or by the manager of an estate, who has a knowledge of rural affairs, and who possesses the good will and confidence of its tenantry.

4610. *By personal attention alone* much is to be done. By reviewing an estate, once or twice a year; by conversing with each tenant in looking over his farm; and by duly noticing the instances of good management which rise to the eye, and condemning those which are bad; vanity and fear, two powerful stimulants of the human mind, will be roused, and an emulation be created among superior managers; while shame will scarcely fail to bring up the more deserving of the inferior ranks. If, after repeated exhortations, an irreclaimable sloven be discharged as such, and his farm given to another, professedly for his superior qualifications as a husbandman, an alarm will presently be spread over the estate, and none, but those who deserve to be discharged, will long remain in the field of bad management.

4611. *Even by conversation*, well directed, something may be done. If, instead of, on the one hand, collecting tenants to the audit, as sheep to the shearing, and sending them away, as sheep that are shorn; or, on the other, providing for them a sumptuous entertainment, and committing them to their fate in a state of intoxication; a repast suited to their conditions and habits of life were set before them; and, after this, the conversation bent towards agriculture, by distributing presents to superior managers, and specifying the particulars of excellence for which the rewards or acknowledgments were severally bestowed; a spirit of emulation could not fail to arise among the higher classes; while the minds of the lower order of tenants, and of the whole, would be stimulated and improved by the conversation.

4612. *By encouraging leading men* in different parts of a large estate, men who are looked up to by ordinary tenants; by holding out these as patterns to the rest; by furnishing them with the means of improving their breeds of stock; by supplying them with superior varieties of crops, and with implements of improved constructions: and, in reclude and backward districts, much may be done by tempting good husbandmen, and expert workmen, from districts of a kindred nature, but under a better system of cultivation, to settle upon an estate.

4613. *By an experimental farm*, to try new breeds of stock, new crops, new implements, new operations, and new plans of management; such as ordinary tenants ought not to attempt, before they have seen them tried. To this important end, let the demesne lands of a large estate, or a sufficient portion of them, be appropriated to a nursery of improvements, for the use of the estate; to be professedly held out as such, and be constantly open to the tenants; more particularly to the exemplary practitioners, the leading men of the estate, just mentioned; who, alone, can introduce improvements among the lower classes of an ignorant and prejudiced tenantry: it is in vain for a proprietor to attempt it. On the contrary, the attempt seldom fails to alarm, disgust, and prevent the growth of spontaneous improvements.

4614. *Under the present plan of demesne farming*, the tenants see expensive works going forward, which they know they cannot copy, and hear of extraordinary profits, by particular articles, which they are certain cannot be obtained by any regular course of business. They therefore conclude that the whole is mere deception, to gain a pretext for raising the rents of their farms above their value. Whereas, if the demesne lands were held out, as trial grounds, for their immediate benefit, and conducted, as such, in a manner intelligible to them, they would not fail to visit them. Instead of large proprietors attempting to rival the meanness of their tenants, in farming for pecuniary profit, which, on a fair calculation, they rarely, if ever, obtain; let their views in agriculture be professedly and effectually directed toward the pecuniary advantages of their tenants; for from these alone can their own arise, in any degree that is entitled to the attentions of men of fortune. Instead of boasting of the price of a bullock, or the produce of a field, let it be the pride of him who possesses an extent of landed property, to speak of the flourishing condition of his estates at large, the number of superior managers that he can count upon them, and the value of the improvements which he has been the happy means of diffusing among them. Leave it to professional men, to yomanry and the higher class of tenants, to carry on the improvements, and incorporate them with established practices; to prosecute pecuniary agriculture in a superior manner, and set examples to inferior tenantry. This is strictly their province; and their highest and best view in life. It has been through this order of men, chiefly or wholly, that valuable improvements in agriculture have been brought into practice, and rendered of general use.

4615. *The possessor of an extent of territory has higher objects in view*, and a more elevated station to fill. As a superior member of society, it may be said, he has still higher views than those of aggrandising his own income. But how can a man of fortune fill what may well be termed his legitimate station in life, with higher advantage to his country, than by promoting the prosperity of his share of its territory; by rendering not one field, or one farm, but every farm upon it productive? This is, indeed, being faithfully at his post: and it is a good office in society, which is the more incumbent upon him, as no other man on earth can of right perform it, valuable as it is to the public.

SECT. II. General Cautions on the Subject of executing Improvements.

4616. *No work can be prudently commenced until the plan be fully matured*, not in idea only, but in diagrams, and in models, if the subject requires them; in order that every bearing and every hinge may be sufficiently foreknown: the site of improvement being reverted to, again and again, with the draught or the model in hand, until the judgment be satisfied and the mind be inspired with confidence. If a proprietor have not yet acquired sufficient judgment within himself, let him consult some one man, or one council of men, in whose knowledge and judgment he can confide; and thus fix a rallying point. Having brought his plan to a degree of maturity, in this private manner, he may then venture to publish it; and endeavour to improve it, by the advice of its friends, and the animadversions of its enemies.

4617. *If a proprietor wants judgment himself, and a friend to supply it*, let him not attempt the more difficult works of improvement. Yet how often we see, both in public and private life, men engaged in arduous undertakings, embarked on the wide ocean of business, without rudder or compass to guide them, depending on casual information, to help them on their way! They are consequently ever of opinion with the last persons they converse with. Such men's decisions and operations are always wrong; and for

an obvious reason. They consult those who are best able to inform them, first; and receive their last impressions from those who are least capable to give them. Men who have neither judgment in themselves, nor any standard of practice to rally at, are liable to be led astray by the plausible schemes of theorists, the greater part of whom know nothing of the practical part of business, and who, by their calculations, both of expense in the outlay and of profit in the return, deceive both themselves and their friends or employers: some also may have sinister designs in view; though we believe the errors of speculative men are in most cases owing to their being endowed with more imagination than judgment.

4618. *The execution of the different improvements* of which an estate has been found susceptible being determined on, it is always advisable to begin with one which is obvious; which may be effected with the greatest certainty; which will repay most amply the expenses of carrying it into effect; or which leads to other improvements, as embankment, drainage, &c. To attempt a doubtful project, while plans which are obvious and certain remain unexecuted; to try experiments before the list of known improvements has been gone through; is seldom to be recommended, though it might sometimes turn out to be right.

4619. *All rural operations are more or less public*, and as it were performed on a stage; and spectators fail not to criticise. If an experiment should prove abortive, or a proposed improvement turn out to be false, the ardour of the improver will be liable to be damped, his people to be discontented (as partaking in the discredit), and the expecting public around him to be disappointed. A few miscarriages, in the outset, might frustrate the best intentions and the most profitable schemes. But if, by prosecuting plain and certain improvements, a man once gain his own confidence, as well as that of the people about him, he may then venture to explore less beaten paths; and this he will be able to do with greater caution, and more probability of success, by the experience already gained; this being a further motive for pursuing the line of conduct here suggested.

4620. *All works of improvement should be executed with vigour*. Many falter in the midst of well-planned works, either, through the want of foresight or of business-like exertion; in consequence, the money already expended lies dead, and the works are injured by the delay. Some works, as embankments and drainages, may be ruined by the slightest neglect or relaxation; and, indeed, as Marshal observes, we see, in every department of the kingdom, these and other works deserted, and left to moulder into nuisances or disreputable eyesores.

4621. *In carrying on a work, execute every thing substantially, and in a workman-like manner*. Too often a false economy leads to the subversion of this principle. To save a few pounds in the first cost, materials of an inferior quality are laid in, or a quantity used insufficient to give the required substance and strength to the work. By either of these imprudences, its duration is abridged; and the eventual loss, by repairs and renewal, may be ten times greater than the sum injudiciously saved in the original erection. Nevertheless, to increase the evil of these ill-judged savings, inferior workmen are employed; or sufficient workmen at inferior prices, at which they cannot afford to make good work, nor can a superintendent urge them to make it under such circumstances. Consequently the work is ill performed, its duration is still more abridged, and a further loss is incurred by injudicious saving.

4622. *There are cases in which temporary works only are required*. A lease-tenant, for instance, wants to make an improvement which will last as long as his lease, without caring about its further duration. In such a case, it may be well-judged frugality and admissible "cleverness in business," to work up cheap materials in a cheap way: but it seldom can be right in the proprietor of a hereditary estate, whose interest in it may be said to be perpetual, to proceed in the same manner. His best policy is to take favourable opportunities of laying in good materials at moderate prices; to use them when duly seasoned; and to employ good workmen at such prices as cannot furnish an excuse for bad workmanship, and will warrant him to enforce good.

4623. *Accomplish one work before another is commenced*. A work may be considered as accomplished when the chief difficulties are surmounted, and the chief cost expended; and, till this is the case, it cannot be prudent to embark in another. By avoiding embarrassments, the execution of improvements becomes a present pleasure, as well as a source of future profit; no half-finished works are left as monuments of disgrace to an estate and its owner; no time nor interest of money is lost; every work is brought into action and profit as it is finished; and if, as it frequently will happen with the most prudent calculators, the estimated sum has been exceeded, due time may be taken to let the fund of improvement accumulate, so as to enable it to discharge the arrear, and to furnish, as wanted, the estimated sums requisite for the succeeding work.

BOOK IV.

MANAGEMENT OF LANDED PROPERTY.

4624. *The management of an extensive landed estate*, like that of every other great property, is a business both of talent and integrity. In former times, when every proprietor may be said to have cultivated the whole of his agricultural territory, it constituted his whole occupation, when not engaged in war; or required a host of managers, if he was a man of the first rank. On the continent, and especially in Russia and Hungary, where estates are of enormous extent, and wholly farmed by the proprietor, the largest estates, as we have seen (621.), are managed by a court of directors, and an executive department, with a numerous body of superintendent officers, artists, and artisans. A better system is now adopted in this country, in consequence of the creation of professional farmers, who, taking large portions of territory from the owner for a certain number of years at a fixed rent, and on certain stipulations for mutual security, occasion little more trouble to the proprietor, during that period, than receiving payments. Hence it is that the management of estates in Britain, though important, is a more simple business than in any other country.

4625. *Where there are only tenanted holdings*, the business of management is very simple; where there are woodlands, it requires a person to look after that department; and where there are waters, quarries, and mines, a greater number of subordinate officers are requisite. But what often occasions most expense, and at the same time is attended with the least profit, is the management of the abstract rights belonging to an estate; such as manorial rights, quit-rents, and other feudal or antiquated trifles or absurdities, which require courts to be holden, and lawyers and other officers to be called in to assist. The only British author who has digested the business of managing estates into a regular system is Marshal, and we shall follow him in considering this subject: — 1st, as to the superintendents on the executive establishment of an estate; and, 2dly, as to the general business of management.

 CHAP. I.
Superintendents, or Executive Establishment of an Estate.

4626. *Though every man who cannot manage his own estate in all important matters, deserves to lose it*, yet, as extensive proprietors generally have their properties situated in different parts of the country, and have, besides, public duties to attend to, certain subordinate managers become necessary. In *The Code of Agriculture* it is stated, that no individual having a large estate is equal to the task of managing it, unless he is in the prime of life, dedicates his whole time to the business, and gives up every other occupation. It is there stated to have been found expedient, by the proprietor of an estate of great extent, to nominate two or three commissioners to assist him in its management. Under the superintendence of such commissioners, it is said, the affairs of a great property would be as well conducted as on the best managed small or moderate-sized estates; while the duties of the proprietor would principally be to carry the exercise of true benevolence into effect, which would consist in softening severe decisions; or in granting those marks of approbation and reward which, when bestowed by the proprietor himself, are the most likely to produce beneficial consequences. (*Code, &c. App. 58.*) Such may be the case on a few estates in the British isles not yet brought into a regular system of improvement, and about to be remodelled, of which a grand example occurs in the immense property of the Marquess of Stafford; but, in the great majority of cases, to each estate a manager of qualifications suited to its extent and duties, and a general receiver and controller in the capital or metropolis (if the proprietor and his banker cannot effect these duties between them) are all that is requisite. We shall first offer a few remarks on the qualifications and duties of managers, and next on the place of business and its requisites.

SECT. I. *Steward or Manager of an Estate, and his Assistants.*

4627. *The head manager of an estate* ought unquestionably to be the proprietor himself, or his representative, if a minor or otherwise incompetent. Next to the proprietor is his acting man of business, with proper assistants; together with such professional men as advisers as the circumstances of business may render necessary. A tenanted estate differs widely from other species of property; as giving power and authority over persons as well as things. It has, therefore, a dignity and a set of duties attached to it,

which are peculiar to itself. A man who receives ten thousand pounds a year from the public funds, for instance, is an insulated being, compared with him who receives the same income from landed property, and who is one of society's best members, provided his affairs are judiciously conducted. On the contrary, if, regardless of the dignity and the duties of his station, he lives but to dissipate his income, leaving the government of his estates and their inhabitants to those whose interest and honour are unconcerned in their welfare, or to those whose best interests lie in their derangement, he becomes at once an enemy to himself, to his family, and to the community. As unpardonable it would be in the possessor of a kingdom to be ignorant of state affairs, and unmindful of the ministers who reside about his court; or in the commanding officer of a regiment to be a stranger to his men, a priest to his parishioners, or a shepherd to his flock; as for the possessor of a tenanted estate to be ignorant of territorial concerns, and a stranger to his lands and their occupiers.

4628. Though it be an *essential part of the duty of a man of fortune to be intimately acquainted with his own affairs*, it does not follow that he should be absorbed in them, and neglect his duties as a superior member of society. In all matters of government and command, subordination is essential to good order and success. A commander in chief does not act as pioneer, nor does a naval commander reef his sails, or heave his anchor. Each has his subordinate officers to convey his commands, and men to execute them. But it is essentially necessary that the former should be well acquainted with military, the latter with naval, affairs. Every heir apparent, therefore, to a large landed property, should be regularly, or at least more or less, bred up in the knowledge of rural affairs, so as to fill with honour and profit the high station he has in view. But if the possessor of an estate has not been fortunately initiated in the knowledge which belongs to his station, the task of acquiring it is far from great.

4629. *On a large estate we generally find a resident manager*, a land steward, a man who has some knowledge of what is termed country business, and who acts under the control of his employer, or of a confidential friend, who is more conversant in rural concerns; or perhaps of a law agent, who knows less of them; or such residing steward, especially of a detached estate which lies at some distance from the residence of its proprietor, acts without control. In the last case, if he is a man of judgment, it is fortunate both for the landlord and tenant: but, on the contrary, if such possessory manager wants those requisite qualifications, the consequence becomes mischievous to the lands, their occupiers, their proprietors, and the community.

4630. *The requisite acquirements of an acting manager*, according to Marshal, are, a knowledge of agriculture, surveying, planting, some knowledge of mechanics, natural history, and skill in accounts. Agriculture is the only firm foundation on which the other required attainments can be securely reposed. It is not more essentially valuable in the superintendance than in the improvement of an estate. It is difficult to become an accurate judge of the value of lands without a practical knowledge of their uses; nor can any man without it properly appreciate the management of occupiers, much less assist them in correcting their errors, and improving their practice.

4631. *Land-surveying* is a requisite qualification. Not so much, however, for the purpose of measuring and mapping an estate at large, as for checking and correcting the works of professional men, as well as to assist in laying out its lands to advantage.

4632. *Planting*, and the management of woodlands, are acquirements that cannot be dispensed with. Nor should his knowledge and attention be confined to the surface of the estate entrusted to his care; he ought to have some acquaintance with natural history, chemistry, and experimental philosophy, to enable him to form just notions on the subject of the subterrene productions which it may contain.

4633. *Some knowledge of mechanics*, and other sciences that are requisite to the business of an engineer, may be highly useful in prosecuting the improvements incident to landed property.

4634. A competent knowledge of *rural architecture*, the doctrine of the strength of materials, and the superintendance of artificers, may be said to be of daily use.

4635. *A thorough knowledge of accounts* is essentially requisite to the manager of a landed estate.

4636. He should be a *man of good character, of upright principles, and conciliatory manners*; to set an example of good conduct to the tenants, and to become their common counsellor and peace-maker, in those trifling disputes which never fail to arise among the occupiers of adjoining land; and which too frequently bring on serious quarrels and lawsuits, that end in the ruin, not only of themselves, but of the tenements they occupy. A proprietor has, therefore, an interest in checking such disputes in the bud; and no man can do this with so much effect as a manager in whom they have a proper confidence, and who possesses a due share of popularity on the estate.

4637. *The acting manager requires certain assistants* on a large estate; especially if it lies in detached and scattered parts. Those in general use are a ground officer and clerk.

4638. *A land-reeve, woodward, or ground officer*, is required on each district or department of a large estate; to attend not only to the woods and hedge-timber, but to the state of the fences, gates, buildings, private roads, driftways, and watercourses; also to the stocking of commons (if any), and encroachments of every kind; as well as to prevent or detect waste and spoil in general, whether by the tenants of the estate, or others; and to report the same to the manager.

4639. *The office-clerk, book-keeper, or under steward*, is employed to form registers,

make out rentals, &c. and keep the accounts of the estate; as well as to assist the manager in his more active employments; also to act as his substitute in case of sickness, or absence; and to become his successor in the event of his death, or other termination of his stewardship.

4640. *A law assistant, solicitor, or attorney, may next be considered as requisite to the good management of a landed estate.* For although much is to be done by judicious regulations, and the timely interposition and advice of a resident manager, such are the frailties of human nature, that, in a state of civilised society, and of property, legal assistance will sometimes be necessary. The error of country gentlemen consists, not in employing lawyers, but in committing the management of their landed estates to them. The employment of law agents as land stewards, however, is not without some reason. Farmers are not for the most part sufficiently skilled in accounts for taking the charge of a large estate; and such of them as are capable, are commonly men of capital, and would not exchange their situation for the less independent one of a land steward. The division of labour, in the case of large estates, is not without its use, and is recognised in practice. A law agent collects the rents and keeps the accounts, often on a very small salary; and in questions of a practical nature, such as the valuation of new leases, the modes of cropping, &c. he advises with a surveyor or land valuer. After all, however, a well chosen land-steward to reside upon the estate, and to consult, when necessary, with a lawyer, must be the best plan, even though his salary be higher than that of the law agent, who commonly acts for several proprietors, does not reside on any of their estates, and very likely, as we think, cannot do them justice.

4641. *In the feudal system, under which every manor court was a court of law, we may perceive the origin of law land-stewards.* It is allowed by the best agricultural writers in Europe (Chateauvieux, Thaer, Thouin, Mathieu de Dombasle, Sigismondi, Jovellanos, Young, Marshal, Brown, Coventry, &c.), that these men by their rigid adherence to precedent in the clauses of leases, have contributed most materially to retard the progress of agricultural improvement.

4642. *The land-surveyor is another professional man, whom the superintendent of an estate may want to call in occasionally.* Not merely to measure and map the whole or parts of the estate, but to assist in matters of arbitration, and the amicable settlement of disputes; or to act himself, as valuer or referee.

SECT. II. *Land Steward's Place of Business, and what belongs to it.*

4643. *A manager's place of business may be considered in regard to its situation, accommodations, and appropriate professional furniture.*

4644. *The situation of the place of business should be under the roof of the proprietor's principal residence; round which, and in its neighbourhood, some considerable parts of his estates may be supposed (as they ever ought) to lie.* If a large bulk of his property lie at too great a distance for tenants to attend at the principal office, and if on this he has a secondary residence, an inferior office is there required for such detached part. And it may be laid down as a rule, in the management of landed property, Marshal observes, that every distant part of an estate ought to have a place upon it (be it ever so humble) in which its possessor may spend a few days comfortably; to diffuse over it a spirit of good order and emulation. He has known the most neglected and almost savage spot, such as are many landed estates in Ireland, reclaimed and put in a train of improvement by this easy method.

4645. *The accommodations requisite for a principal office are, a commodious business room, a small ante-room; and a safe-keep, or strong room, fire proof, for the more valuable documents.*

4646. *The professional furniture with which an office of this description requires to be supplied are maps, rental-books, books of valuation, register, legal papers, and some others.*

4647. *A general map of the whole estate on a large scale is an obvious requisite; and portable separate maps, with accompanying registers and other descriptive particulars, are useful in proportion as improvements may be in contemplation.*

4648. *Books of valuation are essential, especially where there are numerous small holdings on short terms.* In these registers are contained the number, name, admeasurements, and estimated value of each field, and of every parcel of land, as well as of each cottage or other building not being part of a farmstead, on the several distinct parts or districts of the estate. The valuations being inserted in columns, as they arise, whether by general surveys, or incidentally, headed with the names of their respective valuers, so that whenever a farm is to be relet, these columns may be consulted, and its real value fixed in a resurvey with the greater exactness.

4649. *A general register of timber trees, copsewood, and young plantations is particularly wanted where there is much hedgerow timber.* Marshal directs to specify in this register the number of timber trees in each wood, grove, hedgerow, and area, with the species, number, and admeasurements of each tree. He also recommends separate pocketbooks, containing the particulars of each division, or of a number of contiguous divisions, for the occasional use of the manager and woodreeve.

4650. *Contracts, agreements, accounts, letters on business, and other documents, should be intelligibly endorsed, dated or numbered, and arranged so as to be easily referred to.* A book of abstracts, or heads of papers of greater importance, should be made out to be referred to on ordinary occasions, and likewise

to serve as an index to the originals, which require a more secure repository than a common business-room.

4651. *Legal documents*, such as title deeds, legal decisions, awards of arbitration, counterparts of leases, securities, cash, bills, passed accounts, &c., as being the most important objects, should be carefully deposited in the safety-chest or strong room.

4652. *Portable registers* of the tenanted lands, in convenient pocket volumes, with maps on a small scale heading every farm, are, according to Marshal, who seems to have looked upon tenants as placed in a state of continual hostility with their landlords, a most invaluable description of books both for the manager and his employer. Two opposite pages being appropriated to each farm with its map, the following information should be given:—

Name of the farm and its number of acres.
The name of the tenant and the existing rent.
The tenancy; if on lease, the term of expiring.
Any extraordinary covenant of the lease.
The number of cottages let with the farm.
The number of timber trees growing on it.
The number of orchard trees growing on it.

The eligibility of the plan and circumstances of the farm.

The eligibility of the occupier.

The eligibility of the present rent.

The state of the buildings, fences, and gates, roads, and watercourses.

The state of cultivation, and condition of the live stock.

4653. *Add*, among other things, the following, viz.:—

The repairs more immediately wanted.
The improvements of which the whole is susceptible.

The agreements entered into with the tenant.

The permissions granted him.

The injunctions delivered to him.

With a hint as to his personal character, and the number and general character of his family.

With any other incident or occurrence respecting the farm or its occupier, that requires to be remembered; and with references to the books and papers which may pertain to the several particulars; thus having at one view a complete abstract of the history and present state of every farm, together with the particulars of attention which each will require.

4654. *The trouble of forming an abstract of this kind*, or of renewing it when filled, or in order to adapt it to the varying circumstances of the several farms, is inconsiderable, compared with its uses, which are not only obvious in theory, but are fully established in practice. On returning to an estate, after twelve months' absence, Marshal has generally found, that, by consulting a register of this sort, and, through its means, making systematic enquiries respecting the incidents that have occurred on the several farms during his absence; he, in this summary way, and before he entered upon a fresh view, became better acquainted not only with the general interests, but with the more ordinary business, of the estate, than the acting manager, who had constantly resided upon it, without such a remembrancer. This abstract or remembrancer, he says, ought not to comprehend tenanted farms only; but should comprise woodlands, quarries, the demesne, &c. in hand; as well as the more important improvements going on: each of which ought to have its separate folio assigned it. To a proprietor, or his confidential friend, who only goes over his estate occasionally, such an intelligent companion is essentially serviceable. He cannot profitably direct, nor safely advise with, an acting manager, or other agent or officer of the estate, until he has consulted so infallible an oracle. The utility of such a register, while a proprietor is absent from his estate, if he can be said to be so, with such a faithful mirror in his possession, is too obvious to require explanation.

4655. *Among the instruments necessary for a manager's office*, may be included those requisite for surveying, mapping, levelling, measuring timber, and every description of country work, together with boring machines, draught measurers, weighing scales, some chemical tests, models, and such other articles as may be required or rendered useful by particular circumstances.

4656. *An agricultural library* may be considered an essential requisite; including works on rural architecture, the prices and measuring of work, and other fluctuating matters; and one of the best encyclopedias of universal knowledge. We have already suggested an important use to which such a library might be applied.

4657. *Such an establishment and place of business as has been described*, we agree with Marshal in thinking, many will consider as in some degree superfluous or extravagant. In many cases we admit it would be so; but it is impossible to determine what things can be done without, unless a particular case were given. Such a minute register of farms, for example, would be quite ridiculous on an estate in East Lothian, where tenants are of sufficient wealth and respectability of manners to be treated as men; and not watched and schooled like those which Marshal seems generally to have in view. As tenants of land become enlightened, they will be very differently treated from what in many places they are at present. As a proof of this, we have only to compare one district of country with another. In East Lothian, Berwickshire, and some other parts of Scotland, the farmers are as intelligent as their landlords; and the transactions which take place between them resemble the transactions which take place between one mercantile man and another. In districts where the tenant has little capital, and where he is sunk in ignorance, he ranks with the labourer, and occupies his farm by a sort of sufferance. It is a pity that the ignorance and seclusion of such men do not admit of their comparing their state with that of others possessing no greater capital, but more knowledge and skill: it is a pity, we say, for the sake of their children, whom they might thus be induced to educate.

CHAP. II.

Duties of Managers of Estates.

4658. *The various duties of the manager*, or the proprietor, of a landed estate, may be considered under the heads of general business, business with tenants, and auditing accounts.

SECT. I. *General Principles of Business considered relatively to Land-Stewardship.*

4659. *The first and most general principle*, in this and every other department of business, is to embrace readily the several matters as they occur; and not to put them off from time to time, until they accumulate, and render the task difficult and irksome. The only artifice, it may be said, which a man of character can well employ in business is that of endeavouring to render it pleasurable; and, by meeting it cheerfully, as it rises, or as it becomes ripe for despatch, this desirable end will generally be attained: for, in that state a man not only enters upon it with pleasure himself, but he will generally find his opponent in the same temper of mind. Whereas, through delay, misunderstandings, idle tales, and groundless surmises are liable to intervene; the minds of both to be soured; a distant coolness to take place between them; and a barrier to be raised, which, though altogether imaginary, nothing but the mystic wand of the law may be able to remove.

4660. *There are three distinct methods of conducting business.* The first is that in which the parties meet, with fair intentions, to find out the point of equity, and there to close. In the second, they enter upon business, guarded with cunning, and armed with trick and artifice, as gamblers draw round a table, to take every advantage, fair or otherwise, which they can effect with impunity. The last method lies in the courts of law and equity.

4661. *A business founded on honourable intentions* is the only one in which a man of honour can voluntarily appear. Here honest men come, as indifferent persons, to arbitrate the matter in reference. In every settlement between man and man, there is a point of equity and right, which all good men are desirous to find; and when men of liberal minds fortunately meet and join in the search, it is seldom difficult to be discovered. Should some little difference of opinion arise, let them call in an umpire to decide between them; or leave the whole to the decision of three capable and disinterested men.

4662. *A man of strict integrity may become entangled in business with a man of looser principles.* In this case, it behoves him to be upon his guard; but still to enter into the negotiation with temper and civility. There is even a politeness in affairs of business which cannot be departed from on any occasion. Interruptions and schisms frequently arise, especially between men who are of keen sensibility, and who (though passably honest) are tenacious of their own interests, from mere matter of punctilio. The mind of either being once soured by neglect, or ruffled by disrespectful behaviour, the smooth path of peaceful negotiation is broken up, a spirit of warfare is roused, and advantages are taken, or attempted, which calm reason would not have suggested. Hence, when men of unequal degree are brought together in business, it is incumbent on the superior to set the example of liberality and civility of demeanour.

4663. *In extreme cases there is no resource but the law;* and here the most that an honest man can do is to procure, without loss of time, the best advice; and to spare no exertion or useful expense in bringing the dangerous and tormenting business to a speedy conclusion. Not only is a man's property endangered, while it is tossed on the troubled sea of the law; but his time and attention are led astray, and his peace of mind is liable to be broken in upon, thus deranging his ordinary concerns, and disturbing the stream of life. How much legal disputation might be prevented by a timely attention to business!

4664. *In forming connections in business, select the man who has a character to lose.* This principle should be invariably acted on: for if a man of established good character be properly treated, and determinately closed in with in case he demur or swerve from the right line of conduct, he will not forfeit his good name by doing a disreputable action; and must therefore come forward to the point of equity and justice.

SECT. II. *Management of Tenants.*

4665. *The general treatment of tenants and cottagers* may be considered as the most important part of every land-steward's occupation: it includes the mode and conditions of letting lands, and the time and manner of receiving rents. The idea of a landlord or his agents managing his tenants does certainly on the face of it appear an absurdity. The tenant is not more obliged to the landlord than the landlord is to the tenant; and therefore both parties being on an equality in point of obligation, the one ought not to require or have the power to manage the other. This power is given, however, by the ignorance of one of the parties, and the existing monopoly in favour of the other; and till these are done away with, by education and political changes, the ignorant part of farmers will always be managed by their landlords.

SUBSECT. 1. *Proper Treatment of Tenants.*

4666. *On every large hereditary estate, there are established customs and usages*, to which the proprietor and the occupiers consider themselves mutually amenable, though no legal contracts may subsist between them. Even where imperfect leases, or other legal agreements exist, still there is generally much left for custom and usage to determine. Though some of these may be improper, yet they ought to be strictly observed by its superintendent, until better can be placed in their stead; not merely on the score of moral justice, but, in the same observance, to set an example of integrity and good faith to the tenants. If a superintendent imprudently break through a custom or a covenant, what can he say to a tenant who follows his example?

4667. *A manager ought to set an example to the tenants* under his care of liberality and kindness. This is more especially applicable to the case of cottagers and others who rent small holdings. There are numberless small favours which he can bestow upon them without loss, and many with eventual advantage to the estate. A spirited improv-

ing tenant should be refused nothing that he can reasonably ask ; should have favours voluntarily conferred upon him, not merely as a reward for the services which he individually is rendering the estate, but to induce its other tenants to follow his example, and to make known to the whole that their conduct is observed, and distinctions made between good and bad managers.

4668. *Estates, like men, have their good and bad characters.* No skilful farmer who has a capital to lose, will take up his residence on an estate of known bad character. On the contrary, when once an estate has acquired the character of good faith and proper treatment of its tenantry, men of money and spirit will ever be anxious to gain a footing there. Besides, the character of an estate will ever involve that of its possessor : and, setting income at naught, it surely behoves a man of property to pay some attention to the character of his estates ; for what can well add more to the permanent respectability of a family of rank or fortune, than having its estates occupied by a wealthy and respectable tenantry ?

4669. *In a state of civilised society and property, one of the great arts of life is to teach character and interest to go hand in hand,* and on ordinary occasions to endeavour to turn every incident, as it fortuitously occurs, to their mutual advantage. If a tenant of capital and an improving spirit be found upon an estate, give him due encouragement, for the purposes already explained. On the contrary, if another is found to possess refractory habits, to swerve from his engagements, or to injure the lands in his occupation, it is but common prudence to take the first legal and fair opportunity of dismissing him, and supplying his place with another who is better qualified to fill it ; not more with a view of rescuing his particular farm from further injury, and of making an example of him in terror to others of similar habits, than to preserve and heighten the character of the estate.

4670. *These remarks may be considered as applicable chiefly to small tenants,* or such as from ignorance and want of leases may be considered in a state of bondage. It ought never to be in the power of a landlord to make “an example of a tenant in terror to others ;” it is enough if this power be left to the laws. A tenant who rents a farm on certain conditions, and fulfils them, is, in point of obligation, on an equality with his landlord ; neither is obliged to the other : and while the one does not require those acts of kindness and liberality which Marshal inculcates, the other is not entitled to that submission and slavish deference so common among tenants at will, and indeed most others in England. It is justly observed by Brown (*Treat. on Rur. Aff.*) that the moral excitement, or degree of encouragement, given to the tenant for improving the ground put under his occupation, is regulated entirely by the terms or conditions of the lease under which he holds possession. If the conditions be liberal and judicious, and accommodated to the soil and situation of the land thereby demised to the tenant, all that is obligatory upon the proprietor is faithfully discharged. But when matters are otherwise, when the tenant possesses under a short lease, when the covenants or obligations are severe in the first instance and ultimately of little avail towards forwarding improvement, it may reasonably be inferred that the connection is improperly constituted, and that little benefit will thence follow either to the public or to the parties concerned. The proper view of a lease is, that it is merely a mercantile transaction reduced to writing, in which both parties are on an equal footing.

SUBJECT. 2. *Business of letting Farms.*

4671. *There are three methods of letting a farm :* putting it up to public auction, and taking the highest bidder for a tenant ; receiving written proposals, and accepting the highest offer ; and asking more rent for it than it is worth, haggling with different chappmen, and closing with him who promises to give the most money, without regard to his eligibility as a tenant. After a variety of obvious remarks, Marshal concludes, that “seeing in every situation, there is at all times a fair rental value, or market price of lands, as of their products, there appears to be only one rational, and eventually profitable, method of letting a farm ; and this is, to fix the rent, and choose the tenant. In the choice of a tenant every body knows the requisite qualifications to be, capital, skill, industry, and character. The respective advantages of these qualities are amply developed in *The Treatise on Landed Property.*”

SUBJECT. 3. *Different Species of Tenancy.*

4672. *The different holdings in use in Britain are at will, from year to year, for a term of years, or for a life or lives.*

4673. *The tenant holding at will, or until the customary notice be given by either party to the other, is without any legal contract, or written agreement ; the only tie between the owner and the occupier being the custom of the estate or of the country in which it lies, and the common law of the land.* This may be considered as the simple holding which succeeded the feudal or copyhold tenure ; but which is now fast going into disuse.

4674. *Holding from year to year, under a written agreement, with specified covenants, is a more modern*

usage, and becoming more and more prevalent in some parts of England, and among small tenants, even where leases for a term of years were formerly granted.

4675. *Leases for a term of years*, as seven, fourteen, twenty-one, or a greater number of years, certain; but without the power of assignment, unless with the consent of the lessor.

4676. *Leases for lives*; as, one, two, three, or more, without the power of assignment. In Britain, life leases of this description are now rarely granted. In Wales and Ireland they are still prevalent; the rent being there settled according to the value of the land at the time of letting; as on granting a lease for a term. In the western extreme of England, what are termed life leases are still common: but they are rather pledges for money taken up, or deeds of sale for lives, than leases; for nearly the whole of the estimated sale value of the land, during the life term, is paid down at the time of purchase, the seller reserving only a quit rent, or annual acknowledgment.

4677. *A lease for a term of years*, or for two or more lives, can alone be favourable for the progress of agriculture. A farmer holding at will, or from year to year, may plough, sow, and reap; but he will, if a prudent man, be very careful not to make improvements, well knowing that the first effect would be a rise of rent or a notice to quit. Leases for a single life have the great disadvantage of uncertainty in duration, both as to landlord and tenant; and though the latter may insure a certain sum on his life for the benefit of his family, yet it were better that he should lay out that money in improving the farm. Leases on lives, renewable, are for all purposes of culture as good as freehold; but they have this disadvantage to a tenant, that they require a considerable part of his capital paid down, and a further draught on his capital on the falling in of any of the lives. Even the first of these payments would embarrass the great majority of professional farmers, and disable them from bestowing proper cultivation on the soil; but to a farmer with a surplus capital no description of lease can be better, as he lays out his surplus capital at the market rate of interest, and is, as it were, his own annuitant. To the landlord such leases cannot be advantageous; because, there being fewer who can compete for them, lands let on these conditions do not fetch their full price.

4678. *The fundamental principle* on which both the duration and conditions of leases are established is evidently this:—A agrees to lend to B a certain article for his use for an equivalent in money; but such is the nature of this article, that, in order to use it with advantage, B must possess it during a considerable time: he, therefore, requires a security from A to that effect; and A on his part requires a security from B that he will return the article at least in as good condition as when it was lent to him. The term of years for which the article is to be lent, and the precautions taken to insure its return without deterioration, are founded on experience, and vary according to the peculiar circumstances of lender and borrower. In general, however, this is obvious, that where the period of lending is not sufficient for profitable use, or the conditions required for ensuring the lender an undeteriorated return of the article unreasonable, the value of the loan or rent will be proportionably diminished. (*Sup. Enc. Brit. art. Agr.*)

4679. *In recurring to what actually exists in the best cultivated districts*, we shall quote the excellent observations of an experienced farmer and approved public writer:—"The general principle which should regulate the connection between landlord and tenant seems to be, that while the farm ought to be restored to the owner at the expiration of the tenant's interest, at least without deterioration, the tenant should be encouraged to render it as productive as possible during his possession. In both of these views, a lease for a term of years is scarcely less necessary for the landlord than for the tenant; and so much is the public interested in this measure, that it has been proposed by intelligent men, to impose a penal tax on the rent of lands held by tenants at will.

4680. *That the value of the property is enhanced by the security which such a lease confers on the tenant* will be put beyond all doubt, if the rents of two estates for half a century back are compared; the one occupied by tenants at will, and the other by tenants on leases for a moderate term, and where the soil and situation are nearly alike in every respect. If the comparison be made between two tracts originally very different in point of value, the advantages of leases will be still more striking; while that which is held by tenants at will remains nearly stationary, the other is gradually, yet effectually, improved, under the security of leases, by the tenants' capital; and, in no long period, the latter takes the lead of the former, both in the amount of the revenue which it yields to the proprietor, and in the quantity of produce which it furnishes for the general consumption. The higher rents and greater produce of some parts of Scotland than of many of the English counties, where the soil, climate, and markets are much more favourable, must be ascribed to the almost universal practice of holding on leases in the former country, in a much greater degree than to any of the causes which have been frequently assigned. Less than a century ago, what are now the best cultivated districts of Scotland were very far behind the greater part of England; and, indeed, had made very little progress from the time of the feudal system. It is not fifty years since the farmers of Scotland were in the practice of going to learn of their southern neighbours an art, which was then very imperfectly known in their own country. But in several parts of England there has been little or no improvement since, while the southern counties of Scotland have uniformly advanced; and at present exhibit very generally, a happy contrast to their condition in the middle of the last century.

4681. *In respect to farmers themselves*, it cannot be necessary to point out the advantages of leases. It may be true, that, under the security of the honour of an English landlord, tenants at will have been continued in possession from generation to generation, and acquired wealth which he has never, like the landholders of some other countries, attempted to wrest from them. But there are few individuals in any rank of life, who continue for a length of time to sacrifice their just claims on the altar of pure generosity. Something is almost always expected in return. A portion of revenue in this case is exchanged for power, and that power is displayed not only in the habitual degradation of the tenantry, but in the control over them, which the landlord never fails to exert at the election of members of parliament, and on all other political emergencies. No prudent man will ever invest his fortune in the improvement of another person's property, unless, from the length of his lease, he has a reasonable prospect of being reimbursed

with profit; and the servility which holding at will necessarily exacts is altogether incompatible with that spirit of enterprise which belongs to an enlightened and independent mind.

4682. *Every measure which has a tendency to fetter the productive powers of the soil, must deeply affect the public at large, as well as depress one of the largest and most valuable classes.* It is clearly their interest, that corn and other provisions should be supplied in abundance, and the people of England may justly complain of the want of leases, as one of the principal causes which check the improvement of their own territory.

4683. *What ought to be the term of a lease can only be determined by a reference to the circumstances of each particular case.* Lands naturally rich, or such as have already been brought to a high degree of fertility, requiring no great investment of capital, and returning all or nearly all the necessary output within the year, may be advantageously held upon short leases, such as perhaps give time for two, or at most three of the rotations or courses of crops to which the quality of the soil is best adapted. The practice of England in this respect is extremely various, almost every term, from twenty years downwards, being found in different parts of it. In Scotland, by far the most common period is nineteen years, to which it was formerly the practice, in some places, to add the life of the tenant. In that country, even when it is thought expedient to agree for a much longer term, this is still expressed in periods of nineteen years, a sort of mysterious cycle, which seems to be no less a favourite with the courts of law than with landholders and farmers. Yet this term is somewhat inconvenient, as it can never correspond with any number of the recognised rotations of arable land.

4684. *A lease for twenty years, it has been maintained by several writers, is not sufficient to reimburse a tenant for any considerable improvements, and landholders have often been urged to agree to a much longer term, which, it is alleged, would be not less for their own interest than for that of the tenant.* This is a question which our limits do not permit us to discuss; but, after viewing it in different lights, assisted by the experience of long leases in different parts of Scotland, we cannot help expressing some doubts of their utility, even in so far only as it regards the parties themselves; and we are decidedly of opinion, that a greater produce will be brought to market, from any given extent of land held on successive leases of twenty years, for half a century, than if held on one lease of that duration, whether the term be specified, or indefinite as is the case of a lease for life. As a general mode of tenure, leases for lives seem to us particularly objectionable.

4685. *The great advantages of a lease are so well known in Scotland, that one of her best agricultural writers, himself a landed proprietor, has suggested a method of conferring on it the character of perpetuity, to such an extent as, he thinks, would give ample security to the tenant for every profitable improvement, without preventing the landlord from resuming possession upon equitable terms, at the expiration of every specified period.* But the author of this plan (Lord Kaimes), in his ardent wishes for the advancement of agriculture, at that time in a very backward state in his native country, seems to have overlooked the difficulties that stood in the way of its adoption; and the great advance in the price of produce, and consequently in the rate of rents, since his lordship wrote, have long since put an end to the discussion which his proposal excited. For a form of a lease on his plan, the reader may consult Bell's *Treatise on Leases*; and the objections to the plan itself are shortly stated in the supplement to the sixth edition of *The Gentleman Farmer*, recently published.

4686. *Long leases granted upon condition of receiving an advance of rent at the end of a certain number of years have been granted; but covenants of this kind, meant to apply to the circumstances of a distant period, cannot possibly be framed in such a manner as to do equal justice to both parties; and it ought not to be concealed, that, in every case of a very long lease, the chances are rather more unfavourable to the landholder than to the farmer.* If the price of produce shall continue to rise as it has done, till very lately, for the last forty years, no improvements which a tenant can be expected to execute will compensate the landlord's loss; and if, on the other hand, prices shall decline, the capital of most tenants must be exhausted in a few years, and the lands will necessarily revert to the proprietor, as has been the case of late in many instances. Hence a landholder, in agreeing to a long lease, can hardly ever assure himself that the obligations on the part of the tenant will be fully discharged throughout its whole term, while the obligations he incurs himself may always be easily enforced. He runs the risk of great loss from a depreciation of money, but can look forward to very little benefit from a depreciation of produce, except for a few years at most. Of this advantage a generous man would seldom avail himself; and, indeed, in most instances, the advantage must be only imaginary, for it would be over-balanced by the deterioration of his property." (*Sup. Encyc. Brit. art. Agr.*)

4687. *There are various objections made to leases of nineteen or twenty-one years.* Some of these are of a feudal and aristocratical nature; such as the independence it gives the tenants, who may become purse-proud and sancy under the nose of their landlord, &c. A greater objection has arisen from the depreciation of British currency during the last ten years of the eighteenth, and first ten of the nineteenth centuries. Various schemes have been suggested to counteract this evil; but the whole of them are liable to objections, and it may be doubted if it admits of any remedy, except a compromise between the parties.

SUBJECT. 4. *Rent and Covenants of a Lease.*

4688. *To avert the evils of fixed money rents, and long leases, both to landlords and tenants, the best mode known at present is the old plan of corn rents.* This plan was first revived in 1811, by a pamphlet published in Cupar, which attracted considerable attention, and has led to the adoption in various parts of Scotland, of a mixed mode of paying rents, partly in corn or the price of corn, and partly in money. In hilly districts, wool, or the price of wool for an average of years, is sometimes fixed on instead of corn. We shall quote from the same intelligent writer on the duration of leases, his sentiments on corn rents, and subjoin his observations on covenants.

4689. *Though the most equitable mode of determining the rent of lands on lease, would be to make it rise and fall with the price of corn; yet a rent paid in corn is liable to serious objections, and can seldom be advisable in a commercial country.* It necessarily bears hardest on a tenant when he least able to discharge it. In very bad seasons, his crop may be so scanty, as scarcely to return seed and the expenses of cultivation, and the share which he ought to receive himself, as the profits of his capital, as well as the quantity allotted to the landlord, may not exist at all. Though, in this case, if he pays a money rent, his loss may be considerable, it may be twice or three times greater if the rent is to be paid in corn, or according to the high price of such seasons. In less favourable years, which often occur in the variable climate of Britain, a corn rent would, in numerous instances, absorb nearly the whole free or disposable produce, as it is by no means uncommon to find the gross produce of even good land reduced from twenty to fifty per cent. below an average in particular seasons. And it ought to be considered, in regard to the landlord himself, that his income would thus be doubled or trebled, at a time when all other classes were suffering from scarcity and consequent dearth; while, in times of plenty and cheapness, he might find it difficult to make his expenses correspond with the great diminution of his receipts. It is of much importance to both parties, that the amount of the rent should vary as little as possible from any unforeseen causes, though tenants in general would be perhaps the most injured by such fluctuations.

4590. *To obviate these and other objections to a corn rent, and to do equal justice at all times to both landlord and tenant, a plan has been lately suggested for converting the corn into money, adopting for its price, not the price of the year for which the rent is payable, but the average price of a certain number of years. The rent, according to this plan, may be calculated every year, by omitting the first year of the series, and adding a new one; or, it may continue the same for a certain number of years, and then be fixed according to a new average. Let us suppose the lease to be for twenty-one years, and the average agreed on being seven years, and the first year's rent, that is, the price of so many quarters of corn, will be calculated from the average price of the crop of that year, and of the six years preceding. If it be meant to take a new average for the second and every succeeding year's rent, all that is necessary is, to strike off the first of these seven years, adding the year for which the rent is payable, and so on, during all the years of the lease. But this labour, slight as it is, may be dispensed with, by continuing the rent without variation for the first seven years of the lease according to the average price of the seven years immediately preceding its commencement, and, at the end of this period, fixing a new rent, according to the average price of the seven years just expired, to continue for the next seven years. Thus, in the course of twenty-one years, the rent would be calculated only three times; and for whatever quantity of corn the parties had agreed, the money payments would be equal to the average price of four teen years of the lease itself, and of the seven years preceding it; and the price of the last seven years of the old lease would determine the rent during the first seven years of the new one.*

4591. *The landlord and tenant could not suffer, it has been thought, either from bad seasons, or any change in the value of the currency, should such a lease as this be extended to several periods of twenty-one years. The quantity of corn to be taken as rent, is the only point that would require to be settled at the commencement of each of those periods; and though this would no doubt be greater or less, according to the state of the lands at the time, yet it may be expected, that in the twenty-one years preceding, all the tenant's judicious expenditure had been fully replaced. Instead of the twofold difficulty in fixing a rent for a long lease, arising from uncertainty as to the quantity of produce, which must depend on the state of improvement, and still more, perhaps, from the variations in the price of that produce; the latter objection is entirely removed by this plan; and in all cases where land is already brought to a high degree of fertility, the question about the quantity of produce may likewise be dispensed with.*

4592. *If the corn-rent plan be applied to leases of nineteen or twenty-one years, the inconvenience resulting from uncertainty as to the amount of rent, as well as other difficulties which must necessarily attend it, would be as great, perhaps, as any advantages which it holds out to either of the parties. If it be said that a rent, determined by a seven years' average, could not suddenly nor materially alter, this is at once to admit the inutility of the contrivance. The first thing which must strike every practical man is, that corn is not the only produce of a farm, and in most parts of Britain, perhaps not the principal source from which rent is paid; and there is no authentic record of the prices of butcher meat, wool, cheese, butter, and other articles in every county to refer to, as there is of corn. This is not the place to enquire whether the price of corn regulates the price of all the other products of land, in a country whose statute books are full of duties, bounties, drawbacks, &c., to say nothing of its internal regulations; but it is sufficiently evident that, if corn does possess this power, its price operates too slowly on that of other products to serve as a just criterion for determining rent on a lease of this duration. Besides, in the progress of agriculture, new species or varieties of the cerealia themselves are established even in so short a period as twenty-one years, the prices of which may be very different from that of the corn specified in the lease. What security for a full rent, for instance, would it give to a landlord, to make the rent payable according to the price of barley, when the tenant might find it more for his interest to cultivate some of the varieties of summer wheat, lately brought from the Continent? or, according to the price of a particular variety of winter wheat, when, within a few years, we have seen all the old varieties superseded, throughout extensive districts, by the introduction of a new one, the potato-oat, which may not be more permanent than those that preceded it? There can be no impropriety, indeed, in adopting this plan, for ascertaining the rent of land kept always in tillage; but it would be idle to expect any important benefits from it, during such a lease as we have mentioned.*

4593. *The corn-rent plan, in the case of much longer leases, will no doubt diminish the evils which we think are inseparable from them, but it cannot possibly reach some of the most considerable. Its utmost effect is to secure to the landholder a rent which shall in all time to come be an adequate rent, according to the state of the lands and the mode of cultivation known at the date of the lease. But it can make no provision that will apply to the enlargement of the gross produce from the future improvement of the lands themselves, or of the disposable produce from the invention of machinery and other plans for economising labour. And the objections just stated, in reference to a lease of twenty-one years, evidently apply much more forcibly to one of two or three times that length. Old corn-rents, though much higher at present than old money-rents, are seldom or never so high as the rents that could now be paid on a lease of twenty-one years. But, independently of these considerations, which more immediately bear upon the interests of the parties themselves; one insuperable objection to all such leases is, that they partake too much of the nature of entails, and depart too far from that commercial character which is most favourable to the investment of capital, and consequently to the greatest increase of land produce.*

4594. *The most recent opinions on this subject are in favour of a money rent, or of a rent formed partly from the average prices of produce, and partly of money, but somewhat complicated in its arrangement, and therefore not likely to come into general use. There seems, indeed, no essential reason why rents in agriculture should not be regulated on the same general principle as rents in commerce; and were it not for the extraordinary fluctuation that has taken place in the currency of the country within the last forty years, it is more than probable no such alteration of principle would ever have been thought of. The reader who wishes to enter more at length into this subject, may consult the most recent works on political economy, and especially *M'Culloch's Principles*. He will also find a paper on the subject, of some practical value, in the *Quarterly Journal of Agriculture*, vol. i. p. 809. and vol. ii. p. 126.*

4595. *Mr. M'Culloch, in the second edition of his *Principles of Political Economy*, with reference to corn rents, observes, that the disturbing effects of changes in the value of money are averted, at the same time that the effect of those which occur in the cost of producing corn are mitigated. This plan, he adds, is, however, defective, inasmuch as it obliges the tenant to pay more than the fair value of his farm in scarce years; while, on the other hand, it has the effect of improperly reducing the landlord's rents in years of unusual plenty. A simple device has, however, been fallen upon, which has gone far to reduce these defects: this consists in fixing a *maximum* and a *minimum* price, it being declared in the lease that the produce to be paid to the landlord shall be converted into money, according to the current prices of the year; but that, to whatever extent prices may rise above the maximum price fixed in the lease, the landlord shall have no claim for such excess of price. By means of this check, the tenant is prevented from paying any great excess of rent in scarce years. And to prevent, on the other hand, the rent from being improperly reduced in very plentiful years, a minimum price is agreed on by the parties; and it is stipulated that, to whatever extent prices may sink below this limit, the landlord shall be entitled to receive this minimum price for the fixed quantity of produce payable to him. This plan has been introduced into some of the best cultivated districts in the empire, particularly East Lothian and Berwickshire; and the experience of the estates in which it has been adopted shows that it is as effectual as can well be desired, for the protection of the just rights of both parties, and for securing the progress of agriculture.*

4596. *The terms of payment of rent differ a little in different districts and countries. Rents, in Scotland, are paid either previously to the first crop being reaped, when they are called *forc-rents*; or they are paid*

subsequently to the reaping, when they are termed *back-rents*. In England, it is believed that, with a few exceptions in the border counties, back-rents are not in use. The effect of these rents is, to afford a long credit to the tenant; it is assumed that his means of paying any year's rent are chiefly derived from the sale of the crop of that year, and hence he is allowed to reap and sell the crop, in order to pay the rent: thus, if he enters at Whitsunday, 1829, and at separation of crop 1829 from the ground, his first year's crop is that of 1830, and his first year's payment is usually made at Martinmas 1830, and Whitsunday 1831. Were he to pay what is termed fore-rent, his first term's payment would be at Martinmas 1829, and his second at Whitsunday 1830; thus completing his first year's rent before his crop had been reaped. Wherever custom has established the system of back-rents, it should not be disturbed; by means of the credit afforded, tenants are enabled to take land with a smaller capital, and to expend those funds in the improvement of the farm, of which they must otherwise have been deprived. It must be thus attended with one or other of two advantages to the landlord; first, by bringing farms more within the reach of the funds of takers, it excites greater competition; or, secondly, it leaves a fund in hand to the lessee, for the immediate cultivation of his land. In Scotland this system is attended with no hazard, since landlords have always, in that country, a security, by means of their legal rights of hypothec, on the crop of the tenant. In the case of farms merely pastoral, indeed, the landlord's claims will not be well secured, because a tenant removing at Whitsunday will have left no crop behind to answer for the rent: in farms of this nature, accordingly, rents are stipulated to be paid in advance. (*Quar. Jour. Agr.* vol. ii. p. 134.)

4697. *A lease for a term of years is not, in all cases, a sufficient encouragement to spirited cultivation; its covenants in respect to the management of the lands may be injudicious; the tenant may be so strictly confined to a particular mode of culture, or a particular course of crops, as not to be able to avail himself of the beneficial discoveries which a progressive state of agriculture never fails to introduce. Or, on the other hand, though this is much more rare, the tenant may be left so entirely at liberty, that either the necessity of his circumstances, during the currency of the lease, or his interest towards its expiration, may lead him to exhaust the soil, instead of rendering it more productive. When a lease therefore is either redundant, or deficient in this respect, where it either permits the lands to be deteriorated, or prevents their improvement; the connection between landlord and tenant is formed upon other views, and regulated by some other principle, than the general one on which we think it should be founded.*

4698. *Restrictive covenants are always necessary to the security of the landlord, notwithstanding the high authority of Dr. Smith to the contrary, and in some cases beneficial to the tenant. Their expediency cannot well be questioned in those parts of the country where an improved system of agriculture has made little progress. A landholder, assisted by the advice of men experienced in framing these covenants, cannot adopt any easier or less offensive plan for the improvement of his property, and the ultimate advantages of his tenantry. Even in the best cultivated districts, while farms continue to be let to the highest responsible offerers, a few restrictive covenants cannot be dispensed with. The supposed interest of the tenant is too feeble a security for correct management, even during the earlier part of a lease; and in the latter part of it, it is thought to be his interest, in most cases, to exhaust the soil as much as possible, not only for the sake of immediate profit, but frequently in order to deter competitors, and thus to obtain a renewal of his lease at a rent somewhat less than the lands would otherwise bring. (*Sup. Encyc. Brit.* art. *Agr.*) In England the tenant is generally bound down by a mass of cumbersome and useless covenants, not only depriving him of the power of exercising all judgment, but often tying him to a course at variance with the interest of both the contracting parties. A few simple, but precise stipulations, will, for the most part, be sufficient to restrain the lessee from an injurious course of cultivation, and supersede the necessity of those vexatious covenants which are often too heedlessly imposed upon him. (*Quar. Jour. Agr.* vol. i. p. 798.)*

4699. *With tenants at will, and such as hold on short leases, restrictive covenants are more necessary than with tenants on leases of nineteen or twenty years; but in many instances, they are too numerous and complicated, and sometimes even inconsistent with the best courses of modern husbandry. The great error lies, in prescribing rules by which a tenant is positively required to act, not in prohibiting such practices and such crops as experience has not sanctioned. The improved knowledge, and the liberality of the age, have now expunged the most objectionable of these covenants; and throughout whole counties, almost the only restriction in reference to the course of crops is, that the tenant shall not take two culmiferous crops, ripening their seeds in close succession. This single stipulation, combined with the obligation to consume the straw upon the farm, and to apply to it all the manure made from its produce, is sufficient not only to protect the land from exhaustion, but to insure, in a great measure, its regular cultivation; for half the farm, at least, must, in this case, be always under either fallow or green crops. The only other necessary covenant, when the soil is naturally too weak for carrying annual crops without intermission, is, that a certain portion of the land shall be always in grass. According to the extent of this, will be the interval between the succession of corn crops on the same fields; if it be agreed that half the farm, for instance, shall always be under grass, there can be only two crops of corn from the same field in six years. In this case, not more than two sixths being in corn, one sixth in green crops or fallow, and three sixths in clover or grasses, it becomes almost impossible to exhaust any soil at all fitted for tillage. There are few indeed that do not gradually become more fertile under this course of cropping. It is sufficiently evident, that other covenants are necessary in particular circumstances; such as permission to dispose of straw, hay, and other crops from which manure is made, when a quantity of manure equal to what they would have furnished is got from other places; and a prohibition against converting rich old grazing lands or meadows into corn lands. In this place we speak only of general rules, such as are applicable to, perhaps, nine tenths of all the arable land of Britain, and such as are actually observed in our best cultivated counties.*

4700. *For the last four years of a lease, the same covenants are generally sufficient, only they require to be applied with more precision. Instead of taking for granted, that the proportion of the farm that cannot be under corn, will be properly cultivated, from the tenant's regard to his own interest, it becomes necessary to take him bound to this effect in express terms; the object generally being to enable the tenant, upon a new lease, to carry on the cultivation of the lands, as if the former lease had not terminated. What these additional stipulations should be, must depend in part on the season of the year at which the new lease commences, and in part on the course of crops best adapted to the soil, and the particular circumstances of every farm.*

4701. *With respect to the form of a lease, as no one form would suit every district, nothing specific can be laid down with advantage. The lawyers of every estate have particular forms, and it is easy for them, in concert with the proprietor or manager, to obliterate useless or injurious restrictions, and substitute such as may be deemed best for the estate, or in harmony with the progress of the age. (*Sup. Encyc. Brit.* art. *Agr.*)*

SUBJECT. 5. *Receiving Rents.*

4702. *The business of receiving the rents and profits of a landed estate, simple as it may seem, is subject to analysis, and entitled to consideration. Indeed, on large properties, on which not farm rents only, but various other profits, are to be received, as cottage rents, tithes compositions, chief rents, and, perhaps, quit rents of copyhold lands; the business becomes so complex as to require to be methodised and simplified, in order to obtain the requisite facility and despatch. This is generally best effected by appointing*

distinct days, or distinct parts of the day, for each receipt, so that the different tenants and suitors may know their hours of attendance.

4703. *The business of holding manor courts* depends on whether they are held of right, or merely by custom. If the copyhold tenure is so far worn out in any manor, that there are not two ancient or feudal tenants remaining within it, the court has lost its legal power; it cannot by right take cognizance of crimes, nor enforce amerçiements. Nevertheless, manorial courts have their uses, in regulating farm roads, driftways, and water-courses, and in preventing nuisances of different kinds within a manor; and it is generally right to preserve the custom of holding them for these purposes.

4704. *Where copyhold courts remain in force*, and where legal forms are to be observed, a law "steward of the manor" is proper to hold them. It is not necessary, however, that courts of this kind should interfere with the receipt of farm rents; or that a business of this nature should in any way clash with the general receivership of the estate. Employ an attorney to hold courts, as a surveyor to arbitrate disputes, or an engineer to plan works of improvement.

4705. *The propriety of having fixed days for receiving the rents of farms* is evident; and some consideration is required to determine on the season of the year for holding them, so as not to oblige the farmer to forced sales of his produce. In England and Ireland, farm rents are generally due at Lady-day and Michaelmas, and in Scotland at Candlemas and Lammas. But the proper times of paying them depend on the marketable produce of an estate, and on the season of the year at which it goes in common course, and with the best advantage, to market. A tenant should never be forced to sell his produce with disadvantage; nor, when he has received his money for it, ought he to be at a loss for an opportunity of discharging his debt to his landlord. On corn-farm estates, or those whose lands are kept in a state of mixed cultivation, which comprise the great mass of farm lands in this kingdom, Michaelmas may be considered as one of the worst times of the year, at which to call upon tenants for their rents. It is at the close (or, in the northern provinces, perhaps at the height) of harvest, when the farmers' pockets are drained by extra labour, and when they have not yet had time to thresh out their crops to replenish them; nor is the summer's grass at that season yet consumed, nor off-going stock, perhaps, yet ready for market. In Norfolk, Marshal found the end of February, or beginning of March, a very fit time to pay the half year's rent due at Michaelmas; and June for paying those due at Ladyday. In some districts of the north it used to be the custom not to demand the first half year's rent, till the tenant was a year in his farm, by which means he had the use during his lease of nearly a year's rent in addition to his actual capital. But farmers there being now considered as possessed of more wealth than formerly, the first half year's rent of the lease is paid nine months after possession, and the last half year's rent of the term on or immediately before its expiration.

4706. *The proper days for receiving rents* are to be determined by the local circumstances of an estate and the district in which it lies; more especially by the fairs of the neighbourhood at that season, and by other stated times at which the tenants are accustomed, in conformity with the practice of the country, to receive for their dairy produce or other articles delivered in to dealers; and should be fixed immediately after these days of embursement.

4707. *On the subject of arrears*, a good deal has been said by Marshal; but it is one of those which may very safely be left to the good sense and discretion of the proprietor or his manager.

SECT. III. *Keeping and Auditing Accounts.*

4708. *Clearness and brevity* constitute the excellence of accounts, and these excellencies are only to be obtained by simplicity of method. Where lands lie in detached estates so as to require different receivers, a separate account is necessarily required for each receivership; but to preserve this simplicity and clearness, it is necessary that the several sets should be in precisely the same form.

4709. *The groundwork of the accounts peculiar to a landed estate* is the rent-roll: from this receiving rentals are to be taken, and with these and the miscellaneous receipts and disbursements incident to the estate, an account current is to be annually made out.

4710. *In the receiving rental* the particulars which a receiver wants to see at one view, when receiving the rents of an estate under judicious management, where rents are regularly received, and where occupiers pay taxes and do ordinary repairs, are few; the name of the farm, the name of the tenant, and the amount of his half year's rent, only are required: but upon an estate, on which arrears are suffered to remain, and on which matters of account are liable to take place, a greater number of particulars are necessary; as the name of the farm, of the tenant, his arrears, his half year's rent, any other charge

against him, any allowance to be made him, and the nett sum receivable, leaving a blank for the sum received and another for the arrear left.

4711. *Accounts current* are required to be delivered in annually by the acting manager, who ought generally to be the receiver. If the current receipts and disbursements are numerous, as where extensive improvements are going on, and woods, mines, quarries, &c., in hand, such accounts may be given in monthly, which will show the progress of the several concerns, and simplify the business at the end of the year.

4712. *On the best managed estates* it is usual, besides the books which have been mentioned, to keep a ledger; opening separate accounts for farm lands, woods, mines, quarries, waters, houses and their appurtenances, public works, &c.: and where a proprietor has several detached estates, besides such accounts being kept on each, one master ledger contains accounts for the whole property. This, indeed, is nothing but an obvious application of mercantile book-keeping to territorial property, the advantages of which cannot but be as great in the one case as in the other.

4713. *In auditing estate accounts*, the rent accounts are to be checked with the arrears of the preceding year; the column of rents with the rent-roll, corrected up to the last term of entry in order to comprise the fresh lettings; and the columns of account with the particulars, those of allowances being signed by the respective tenants.

4714. *The monthly accounts of receipts and disbursements*, as well as the annual payments, are to be compared with vouchers. The receipts are checked by deeds of sale, contracts, and other written agreements, the awards of referees, or the estimates of surveyors, the market prices of produce, &c.; the receiver, in every case, identifying the person from whom each sum was received. Each disbursement requires a direct and sufficient voucher, endorsed and numbered, with a corresponding number affixed to the charge in the account, so that they may be readily compared.

4715. *The most essential part of the office of an auditor* is that of entering into the merits of each receipt and payment; and considering whether the charges correspond with the purposes for which they are made; and whether the several sums received are adequate to the respective matters disposed of; by these means detecting, and thenceforward preventing, imposition and connivance. This, however, is an office which no one but a proprietor, or other person, who has been conversant with the transactions that have taken place upon the estate, and who has a competent knowledge of rural concerns, can properly perform. It may therefore be right to repeat, that if a proprietor has not yet acquired a competent knowledge of his own territorial concerns, to form an adequate judgment of the different entries in his manager's account, he should call in the assistance of those who are conversant in rural affairs, to enable him to judge of any particular parts that may seem to require it; and should not set his hand to an account which he does not clearly understand, nor authorise another to sign it, who may have less knowledge than himself of its merits.

BOOK V.

SELECTION, HIRING, AND STOCKING OF FARMS.

4716. *FARMS or lands let out to men who cultivate it as a business or profession* exist in all highly civilised countries. Sometimes the farmer or tenant pays to the proprietor or landlord a proportion of the produce, determined yearly, or as the crops ripen; and sometimes he pays a fixed quantity of produce, or labour, or money, or part of each of these. In Britain, where farming, as a profession, is carried to a higher degree of perfection than in any other country, the connection between landlord and tenant is regularly defined by particular agreements and general laws; and the latter, on entering on a farm, engages to pay a fixed sum for its use for a certain number of years. This sum is fixed according to the estimated value of the land; but being fixed, and for a certain time, it admits of no abatement in proportion to the quantity or value of the produce, as in the proportional or metayer system general in most countries (265. and 596.); and hence the necessity of a farmer maturely considering every circumstance connected with a farm before he becomes its tenant. The subjects of consideration form the business of this Book, and naturally divide themselves into such as relate to the farm, to the farmer, and to the landlord. Some of the subjects, being treated of in the preceding Book, will be but slightly noticed, though, as connected with the object of the present, they could not be altogether omitted.

CHAP. I.

Circumstances of a Farm necessary to be considered by a proposed Tenant.

4717. *Whoever intends to become a professional or rent-paying farmer will, in searching for a farm, find it necessary to attend to a great variety of considerations. Those of the greatest importance may be included under climate, soil, and subsoil, character of surface, topographical position, extent, buildings, roads, fields, tenure, rent, and outgoings. In The Code of Agriculture, a more valuable collection of facts as to these points is brought together than in any other work, and from it, therefore, we shall select the greater part of the following sections.*

SECT. I. *Climate, in respect to farming Lands.*

4718. *The climate of a farm is one of the circumstances over which human art has less control than over any other; and a farmer who has but a temporary interest in his possession may be considered as incapable of exercising any influence over it. He may improve the soil and subsoil by draining and culture; and the buildings, roads, and fences by additions and alterations; but it is for the landlord to attempt improving the climate by planting, and for a future generation to enjoy the effects.*

4719. *Sufficient attention, it is said in The Code of Agriculture, "is rarely paid by the farmer to the nature of the climate in which his operations are carried on. Unless the system he adopts be calculated for the weather his crops are likely to experience, every exertion will often terminate in disappointment. The system that is proper for warm and dry situations is not suitable for cold and wet ones; and in a bleak and backward climate, the nature of the soil ought not only to be attended to, but the utmost care ought to be paid to the early sowing of the earliest varieties of seed. Even the species of stock to be bred or kept on a farm should, in a great measure, be regulated by the climate. Hence, this is a subject which the diligent farmer will invariably study with the greatest solicitude. Climate and soil, Curwen justly remarks, are, above all other considerations, those which the farmer ought constantly to keep in view." (Report to the Workington Society.)*

4720. *In considering the climate of a country, the following points are of peculiar importance:—Its general character, and the means of its improvement; its local heat; the light it furnishes; the quantity of its moisture; the prevailing winds; its position, whether maritime or inland; the regularity of the seasons; the phenomena to which it is liable; the productions best suited to it; the expenses it may occasion in cultivation; and its suitability for the introduction of exotic plants and animals.*

4721. *The general character of a climate not only depends on position or latitude, but likewise on the elevation of a country above the level of the sea; its general aspect; the vicinity to mountains, forests, bogs, marshes, lakes, and seas; the nature of the soil and subsoil, and the power which the former possesses of retaining heat and moisture; the direction of the winds; the length of time the sun continues above the horizon; the difference of temperature between the day and the night; and the extent of dry surface in the neighbourhood. The result of these particulars combined form what may be called the general character of climate. Some of the causes of an unfavourable climate cannot be remedied by any human effort; in other cases, art may effect much; but that art is generally such as the farmer can seldom undertake, unless with a very long lease. Ameliorations of this sort, therefore, belong to the landlord.*

4722. *The importance of heat, as a stimulus to vegetation, cannot be doubted. It is at a certain degree of heat that vegetation commences, and it becomes nearly stationary when the temperature falls below it. There are, comparatively speaking, but few plants calculated for very cold countries, and these are seldom valuable; whereas, in warm and temperate regions, the variety is great, and their value unquestionable. Indeed, such is the effect of cold, that, while the thermometer is below forty degrees of heat, the strongest plants become torpid, and remain in that state while it continues. Revived by the warmth of spring, and strengthened by the heat of summer, they acquire fresh life and vigour, and are thus better enabled to withstand the rigours of the succeeding winter.*

4723. *An increased temperature, when not carried to excess, will augment the quantity of nutritive matter in a plant, or improve the quality of fruit grown under its influence. Thus, English barley, of equal weight, is more valuable than the Scotch, because, from growing in a warmer climate, and enjoying the advantage of a greater quantity of heat and light, it is more fully ripened. It thence acquires more saccharine matter, and produces a greater quantity of spirits, or of malt liquor. It is also proved, by the experiments of Sir Humphry Davy, that wheat, ripened in a more regular and warmer climate, contains more of that valuable article called gluten, than the same species of grain when raised in England.*

4724. *The average heat of the year is not, however, of so much importance to the growth of plants, as its duration, and its steadiness at a certain degree, during the season when the grain is ripening. This gives the uniform climates of the Continent a great advantage over our variable seasons, in the production of the more delicate sorts of fruit; which, in this island, are often injured by the frosts in spring, and seldom ripen in a northern climate, where the greatest summer heat is both unsteady and of short duration.*

4725. *The quantity of solar light which a climate furnishes, is likewise an important object of enquiry. Light is essential to increase the proportion of starch or farina; to complete the formation of oils in plants; and to give to fruits their proper colour and flavour. It has also the effect of augmenting saccharine matter, inasmuch that those sugar-canes which are exposed to the sun have more of that important ingredient than when they grow under shade. Nor ought the observation to be omitted, that darkness and light have effects directly opposite upon vegetables. Darkness favours the length of the growth, by keeping up the pliancy of their parts; light consolidates them, and stops growth, by favouring maturation. Hence, in the northernmost regions, plants go through all their stages of growth at a time when the sun no longer quits the horizon; and the light, of which they thus experience the unremitting effect, hardens them before they have time to lengthen. Their growth is therefore quick, but of short duration. They are robust, but undersized. (Mirbel.) It has been remarked also, that a soil, not reten-*

time, will be more productive in a wet climate than in a dry one. Hence, in the western coasts of England, as in Lancashire, where the quantity of rain that falls annually varies from forty to sixty inches, a siliceous sandy soil is much more productive than the same species of soil in the eastern districts, where seldom more than from twenty-five to thirty-five inches of rain fall in a year. In wet climates, also, even wheat and beans will require a less coherent and absorbent soil than in drier situations. At the same time, weather moderately dry is the most favourable to a great produce of corn; and the blossoms of wheat, in particular, set best if no rain falls in the flowering season.

4726. *The importance of moisture to vegetation is obvious to every one.* Water constitutes a large proportion of every plant, and is the vehicle of the food of plants held in solution. Hence, without so essential an ingredient, they must either become stunted in their growth or perish. In dry weather, when vegetation seems at a stand, no sooner do showers of rain fall, than a rapid growth of every kind of herbage immediately succeeds, even on poor dry soils, where otherwise, however well manured, vegetation would make but slow progress.

4727. *The quantity of rain that falls annually in any country is a very inferior consideration, when compared with that of the general and equable distribution of that quantity throughout the several days and months of the year.* A great quantity, at the same time, is rather hurtful than beneficial; whereas those moderate, but golden showers, which regularly fall on a soil calculated to receive them, are real sources of fertility. It is by this that the character of a climate, whether wet or dry, is chiefly determined, and the operations of agriculture are principally influenced.

4728. *The utility of a moist atmosphere, with a view to vegetation, is, in some respects, peculiarly remarkable.* Thus, in wet climates, as on the western coasts of England, Scotland, and Ireland, crops of grain and potatoes are found to exhaust the soil less than in dry situations. Oats in particular are impoverishing in a greater degree in dry climates, than in moist ones; and in the former, should be sown much earlier than in the latter.

4729. *The disadvantages of a wet climate to a farmer, more especially if accompanied with a retentive soil, are very great.* It is calculated, that in the richest district in Scotland, the Carse of Gowrie, there are only about twenty weeks in the year fit for ploughing; whereas in several parts of England, they have thirty weeks, and in many cases more, during which this essential operation can be performed. Hence ploughing must be much more expensive in the one case than in the other.

4730. *The season of the year in which rain abounds is likewise of much importance.* An excess is prejudicial in any season, but is peculiarly so in autumn, when it often lodges the grain by its violence, or by its long continuance prevents the corn from being properly harvested. The hopes of the husbandman are thus blasted, and the fruits of his toil and industry are frequently diminished, and sometimes entirely lost.

4731. *Dews have a great effect in furnishing plants with moisture; and, indeed, without their aid, vegetation, in warm and dry climates, could not go on.* Even in temperate regions dews are beneficial. In Guernsey, on the coast of Normandy, the autumnal dews are singularly heavy, so much so that, in the middle of a hot day, the dew-drops are not quite exhaled from the grass. From this moisture the after-grass receives great benefit. Dr. Hales estimated the quantity of dew that falls in one year at three and a half inches; Dalton, at nearly five inches. In this matter, however, it is not easy to be correct.

4732. *The prevailing winds have a great influence on the character of a climate, and a powerful effect on vegetation.* When they pass over a large expanse of water, they are usually of a warmer or higher temperature in winter, than those which blow over high lands; more especially if such come from countries covered with snow. Hence the east and north-east winds, which have passed over the coldest regions of Europe, are much colder than the west and south-west winds, which blow over the Atlantic Ocean, and they oftener occasion blights. The former are comparatively drier, unless when accompanied by those thick mists, called haars, arising from the copious evaporation of the German Ocean. The latter are loaded with the vapours of the Atlantic, and often, from excess of moisture, are rendered prejudicial. The strength of the prevailing winds, or the violence with which they act, more especially during harvest, ought likewise to be considered. If they are very violent, they are apt to affect the crops, and of course it becomes an object to suit the produce to them; and to form fences, enclosures, and plantations accordingly.

4733. *A maritime position occasions a more equal temperature in a climate.* Where a great body of land is exposed to the heating rays of the sun, the air becomes much warmer than it would if resting upon a small body of land, contiguous to, or surrounded by, the ocean. On the other hand, as the sea always preserves nearly the same temperature, and, except in the most northern regions, is never frozen, it communicates warmth, in the cold seasons of the year, to the air passing over it, which had been cooled in its passage over continents covered with ice and snow. Hence islands are more temperate than continents. It appears, indeed, that the thermometer has not so great a range on the sea coast, as in the more inland parts of Great Britain, even at an elevation of 400 feet above the level of the sea. Of the influence of proximity to the sea many proofs might be brought forward. It is in consequence of this circumstance, that the city of Moscow, which is situated somewhat farther south than Edinburgh, experiences winters much more severe. Another effect of a maritime position is, that strong winds which blow from the sea are sometimes accompanied by salt spray or vapour, which is injurious to crops of grain, and the leaves of trees; but when it comes in moderation, those saline particles, with which the westerly winds are loaded, contribute to the verdure of the fields in pasture.

4734. *The nature of the inland position is also of much importance.* The relative position of the neighbouring hills occasions a material difference of climate, exposing some districts to great severity of weather, and, by protecting others from that disadvantage, greatly promoting their fertility.

4735. *In many countries the seasons are regular.* In others, as in Great Britain, they are extremely variable, and often change, in the space of a few hours, from dry to moist, from hot to cold, from clear to cloudy, and from a pleasant serenity to all the violence of a tempest. But such irregularities of climate, however uncomfortable, are often favourable to vegetation, and compensated by the advantages they produce. It is not in countries where the seasons of heat and cold, wind and rain, are periodical, or where the greatest regularity of climate takes place, that mankind are the most healthy or vigorous, or the useful productions of the soil most perfect. Perhaps a sameness of climate, as well as of other things, is prejudicial rather than useful. Where a climate is inconstant, the air is refined and purified by the frequent changes it undergoes; and the disadvantages which originate from that source are often counteracted, or at least essentially mitigated, by judicious management, and persevering exertions.

4736. *The climate of a country is likewise affected by atmospheric and natural phenomena; by earthquakes, volcanos, violent thunder storms, lightning, hail storms in summer, early frosts, whirlwinds and hurricanes, water-spouts, and by that atmospheric appearance, known under the name of the aurora borealis, so frequently to be seen in northern, and sometimes even in southern, regions; but these phenomena, for the most part only occasional, sometimes prevent greater calamities, and, in this country, are rarely attended with permanent evils.*

4737. *Frosts late in spring are highly injurious to the blossoms of fruit trees; and autumnal frosts creep along the banks of rivers, destroying the corn in the flowering season, and blasting the stems of potatoes in low situations.* Winter frosts are ultimately rather favourable to vegetation; and snow, particularly when it covers the ground for some time, and gradually melts away.

4738. *The size, and, in many cases, the value, of the productions of a country, depend upon its climate, by whose influence their growth may either be advanced or retarded.* The same species of tree, which, in a temperate climate, will rise to a great height, and swell to an immense size, in an exposed situation will remain small and stunted. By a favourable climate, also, the most barren spots, which in a cold country

must remain completely waste, in a warm one may be rendered productive. Thus, where the climate is adapted to the culture of the vine, rocks, which in Great Britain, and in colder countries, would in general be of little or no worth, in the southern provinces of France may yield as much in valuable produce as the cultivated land in their neighbourhood. The real excellence of a climate, however, depends on its yielding, in perfection and abundance, the necessaries of life, or those which constitute the principal articles of food for man, and for the domestic animals kept for his use. In this point of view, a meadow is much more productive, and in some respects more valuable, than either a vineyard or a grove of oranges; though the one may be situated in a cold and variable climate, and the other in a country celebrated both for its regularity and warmth of temperature.

4739. *Even the nature of the articles raised depends upon the climate.* Thus, in many elevated parts, both of England and Scotland, wheat cannot be grown to advantage, and in some of the high-lying districts of the latter, it has never been attempted. In several of the northern counties, it has been found necessary to sow, instead of the two-rowed barley, the inferior sort called bear or big; and oats, from the hardy quality of the grain, are found to be a more certain and more profitable species of corn than any other; while in humid districts peas or beans cannot be safely cultivated, from the periodical wetness of the autumn. On the whole, without great attention to the nature of the climate, no profitable system can be laid down by any occupier of land.

4740. *An inferior climate greatly augments the expenses of cultivation;* because a number of horses are required for labour during the short period of the year, when the weather will admit of it, which, at other seasons, are a useless burden upon the farm. When to this are joined an uneven surface and an inferior quality of soil, arable land is of little value, and yields but a trifling rent.

4741. *Exotic plants or animals can only be naturalised in climates with success by paying attention to that whence they were brought, and by endeavouring either to render the one as similar to the other as circumstances will admit of, or to counteract, by judicious management, the deficiencies of the new one.*

4742. *In order to ascertain the nature of a climate,* the farmer, in modern times, has many advantages which his predecessors wished for in vain. The progress of science has given rise to many new instruments, which ascertain natural phenomena with a considerable degree of accuracy. It may still be proper to study the appearance of the heavens, and not to despise old proverbs, which often contain much local truth; but the vane now points out the quarters whence the winds blow, with all their variations; the barometer often enables us to foretell the state of the weather that may be expected; the thermometer ascertains the degree of heat; the hygrometer, the degree of moisture; the pluviometer, or rain-gauge, the quantity of rain that has fallen during any given period; and, by keeping exact registers of all these particulars, much useful information may be derived. The influence of different degrees of temperature and humidity, occurring at different times, may likewise be observed, by comparing the leafing, flowering, and after-progress of the most common sorts of trees and plants, in different seasons, with the period when the several crops of grain are sown and reaped each year.

SECT. II. Soil in respect to farming Lands.

4743. *The necessity of paying attention to the nature and quality of the soil need not be dwelt upon.* By ascertaining the qualities it possesses, or by removing its defects, the profits of a farmer may be greatly increased. He must, in general, regulate his measures accordingly, in regard to the rent he is to offer; the capital he is to lay out; and the stock he is to keep; the crops he is to raise; and the improvements he is to execute. Indeed, such is the importance of the soil, and the necessity of adapting his system to its peculiar properties, that no general system of cultivation can be laid down, unless all the circumstances regarding the nature and situation of the soil and subsoil be known; and such is the force of habit, that it rarely happens that a farmer who has been long accustomed to one species of soil will be equally successful in the management of another. From inattention to the nature of soils, many foolish, fruitless, and expensive attempts have been made to introduce different kinds of plants, not at all suited to them; and manures have often been improperly applied. This ignorance has likewise prevented many from employing the means of improvement, though the expense was trifling, and within their reach. From ignorance also of the means calculated for the proper cultivation of the different soils, many unsuccessful and pernicious practices have been adopted. Soils may be considered under the following general heads: — Sandy; gravelly; clayey; stoney; chalky; peaty; alluvial; and loamy, or that species of artificial soil into which the others are generally brought by the effects of manure, and of earthy applications, in the course of long cultivation.

4744. *Though sandy soils are not naturally valuable,* yet being easily cultivated, and well calculated for sheep, that most profitable species of stock, they are often farmed with considerable advantage; and when of a good quality, and under a regular course of husbandry, they are invaluable. They are easily worked, and at all seasons; they are cultivated at a moderate expense; are not so liable to injury from the vicissitudes of the weather; and in general they are deep and retentive of moisture, which secures excellent crops even in the driest summers. The crops raised on sandy soils are numerous, such as turnips, potatoes, carrots, barley, rye, buck-wheat, peas, clover, sainfoin, and other grasses. This species of soil, in general, has not strength enough for the production of Swedish turnips, beans, wheat, flax, or hemp, in any degree of perfection, without much improvement in its texture, the addition of great quantities of enriching manure, and the most skillful management. In Norfolk and Suffolk it is found, that poor sandy soils, unfit for any other purpose, will, under sainfoin, produce, after the first year, about two tons per acre of excellent hay; for several years; with an after-grass, extremely valuable for weaning and keeping lambs. How much more beneficial than any crops of grain that such soils usually yield! (*Young's Kalendar*, 123.)

4745. *The fertility of sandy soils is in proportion to the quantity of rain that falls, combined with the frequency of its recurrence.* As a proof of this, in the rainy climate of Turin, the most prolific soil has from seventy-seven to eighty per cent. of siliceous earth, and from nine to fourteen of calcareous; whereas in the neighbourhood of Paris, where there is much less rain, the silex is only in the proportion of from twenty-six to fifty per cent. in the most fertile parts.

4746. *Gravelly soils differ materially from sandy, both in their texture and modes of management.* They are frequently composed of small soft stones, sometimes of flinty ones; but they often contain granite, limestone, and other rocky substances, partially, but not very minutely decomposed. Gravel, being more porous than even sand, is generally a poor, and what is called, a hungry soil, more especially when the parts of which it consists are hard in substance, and rounded in form. Gravelly soils are easily exhausted; for the animal and vegetable matters they contain, not being thoroughly incorporated with the earthy constituent parts of the soil (which are seldom sufficiently abundant for that purpose), are more liable to be decomposed by the action of the atmosphere, and carried off by water.

4747. *A gravelly soil, free from stagnant water, gives such an additional warmth to the climate, that vegetation is nearly a fortnight earlier than where other soils predominate.* About Dartford and Blackheath, in Kent, such soils produce early green peas, winter tares, rye, autumnal peas, and occasionally wheat, in great perfection.

4748. *Gravelly soils, in a wet climate, answer well for potatoes; in Cornwall, in a sheltered situation, with a command of sea-sand, and of sea-weed, they raise two crops of potatoes in the same year.*

4749. *Poor gravelly soils full of springs, and those sulphureous, are very unfriendly to vegetation; and are better calculated for wood than for arable culture.*

4750. *The stony, shaley, or stone-brash soils of Gloucestershire, and the midland counties of England, are much mixed with small stones, but have more frequently sand, or clay, or calcareous loam, in their composition than gravelly soils, and are therefore generally preferable.*

4751. *A clayey soil is often of so adhesive a nature that it will hold water like a dish. In a dry summer, the plough turns it up in great clods, scarcely to be broken or separated by the heaviest roller. It requires, therefore, much labour to put it in a state fit for producing either corn or grass, and it can only be cultivated when in a particular state, and in favourable weather. Though it will yield great crops under a proper system of management, yet, being cultivated at a heavy expense, requiring stronger instruments and stouter horses, it is seldom that much profit is obtained, unless when occupied by a judicious and attentive farmer. The best management of clay soils is that of the Lothians. There they are found well calculated for growing crops of beans, wheat, oats, clover, and winter tares: but are not adapted for barley, unless immediately after a fallow; nor for potatoes, unless under very peculiar management. In regard to turnips, they do not usually thrive so well in clays, as in soils which are more free and open: but it is now ascertained, that the Swedish, and above all the yellow, turnip may be raised in them with advantage; that the quality is superior; that if they are taken up early, the soil is not injured; and that there is no difficulty in preserving them. Clays become good meadow-lands, and answer well for hay, or soiling, when in grass; but from their aptitude to be poached, they are, in general, unfit to be fed by heavy cattle in wet weather. In dry seasons the after-grass may be used to feed neat cattle till October, and sheep till March. A stiff clay, when not cold or wet, with a strong marl under it, is preferred in Cheshire and Derbyshire for the dairy.*

4752. *On reclaimed peat-bogs, oats, rye, beans, potatoes, turnips, carrots, cole-seed, and white and red clover, may be cultivated. Wheat and barley have succeeded on such lands, after they have been supplied with abundance of calcareous earth; and the foin grass (*Agrostis stolonifera*) seems likewise to be well adapted to that description of soil in a warm climate. In Leicestershire, and other counties, they have great tracts of meadow-land; these are, in many instances, the sites of lakes filled up, and the soil is composed of peat and sediment; the peat originally formed by aquatic vegetation, and the sediment brought down by rains and streams from the upland. This soil is admirably calculated for grass.*

4753. *The fens in Cambridgeshire, Lincolnshire, and several other districts in England, consist of peat and sediment.*

4754. *Chalky soils principally consist of calcareous matter mixed with various substances, in greater or less proportions. Where clayey or earthy substances are to be found in such soils in considerable quantities, the composition is heavy and productive; where sand or gravel abounds, it is slight, and rather unfruitful. The crops chiefly cultivated on chalky soils are peas, turnips, barley, clover, and wheat; and, however much the soil is exhausted, it will produce saintfoin.*

4755. *Chalky soils are in general fitter for tillage than for grazing; for, without the plough, the peculiar advantages derived from this soil by saintfoin could not be obtained. The plough, however, ought not to extend to those fine chalky downs (called ewe leases in Dorsetshire), which, by a very attentive management during a number of years, have been brought to a considerable degree of fertility as grazing land, and which are so useful to sheep in the winter season. A chalky soil that has been in tillage permits water to pass through it so freely in winter, and is so pervious to the sun's rays in summer, that it is the work of an age to make it a good pasture of natural grasses, more especially when the chalk lies near the surface. Hence, in the western counties of England, several thousands of acres of this soil, though not ploughed for thirty years, have scarcely any grass of tolerable quality upon them, and are literally worth nothing. Such soils ought to be laid down with saintfoin.*

4756. *Alluvial soils are of two sorts; one derived from the sediment of fresh, and the other from that of salt water. Along the sides of rivers, and other considerable streams, water-formed soils are to be met with, consisting of the decomposed matter of decayed vegetables, with the sediment of streams. They are in general deep and fertile, and not apt to be injured by rain, as they usually lie on a bed of open gravel. They are commonly employed as meadows, from the hazard of crops of grain being injured or carried off by floods.*

4757. *Alluvial soils, arising from the operations of salt water, called salt marshes in England, corses in Scotland, and polders in Holland and Flanders, are composed of the finest parts of natural clay, washed off by running water, and deposited on flat ground, on the shores of estuaries, where they are formed by the reflux of the tide, and enriched with marine productions. They generally have a rich level surface, and being deep in the staple, they are well adapted for the culture of the most valuable crops. Hence wheat, barley, oats, and clover are all of them productive on this species of soil; which is likewise peculiarly well calculated for beans, as the tap-root pushes vigorously through it, and finds its nourishment at a great depth. From the great mass of excellent soil, the fertility of these tracts is nearly inexhaustible; but, from their low and damp situations, they are not easily managed. Lime, in considerable quantities, is found to answer well upon this species of soil.*

4758. *The term loamy soil is applied to such as are moderately cohesive, less tenacious than clay, and more so than sand. Loams are the most desirable of all soils to occupy. They are triable; can in general be cultivated at almost any season of the year; are ploughed with greater facility, and less strength than clay; bear better the vicissitudes of the seasons; and seldom require any change in the rotation adopted. Above all, they are peculiarly well adapted for the convertible husbandry; for they can be changed, not only without injury, but generally with benefit, from grass to tillage, and from tillage to grass.*

4759. *As to the comparative value of soil, it has been justly remarked, that too much can hardly be paid for a good soil, and that even a low rent will not make a poor one profitable. The labour of cultivating a rich and a poor soil is nearly the same; while the latter requires more manure, and consequently is more expensive. Poor soils, at the same time, may have such a command of lasting manures, as lime or marl, or even of temporary sorts, like sea-weed, or the refuse of fish, as may render them profitable to cultivate. It is a wise maxim in husbandry, that the soil, like the cattle by which it is cultivated, should always be kept up in good condition, and never suffered to fall below the work it may be expected to perform.*

SECT. III. Subsoil relatively to the Choice of a Farm.

4760. *On the nature of the under-stratum depends much of the value of the surface soil. On various accounts its properties merit particular attention. By examining the*

subsoil, information may be obtained in regard to the soil itself; for the materials of the latter are often similar to those which enter largely into the composition of the former, though the substances in the soil are necessarily altered, by various mixtures, in the course of cultivation. The subsoil may be of use to the soil, by supplying its deficiencies and correcting its defects. The hazard and expense of cultivating the surface are often considerably augmented by defects in the under-stratum, but which, in some cases, may be remedied. Disorders in the roots of plants are generally owing to a wet or noxious subsoil. Subsoils are retentive or porous.

4761. *Retentive subsoils* consist of clay, or marl, or of stone beds of various kinds. A retentive clayey subsoil is in general found to be highly injurious. The surface soil is soaked with water, is ploughed with difficulty, and is usually in a bad condition for the exertion of its vegetative powers, until the cold sluggish moisture of the winter be exhaled. By the water being retained in the upper soil, the putrefactive process is interrupted, and manures are restrained from operating, consequently the plants make but little progress. Hence, its grain is of inferior quality, and when in grass its herbage is coarse.

4762. *A stony subsoil*, when in a position approaching to the horizontal, is in general prejudicial, and, if the surface-soil be thin, usually occasions barrenness, unless the rock should be limestone; and then the soil, though thin, can easily be converted into healthy pastures, and, in favourable seasons, will feed a heavy stock. They will also produce good crops of corn, though subject to the wire-worm, also produce good crops of corn, though subject to the wire-worm.

4763. *A porous subsoil* is uniformly attended with this advantage, that by its means all superfluous moisture may be absorbed. Below clay, and all the variety of loams, an open subsoil is particularly desirable. It is favourable to all the operations of husbandry; it tends to correct the imperfections of too great a degree of absorbent power in the soil above; it promotes the beneficial effects of manures; it contributes to the preservation and growth of the seeds; and ensures the future prosperity of the plants. Hence it is, that a thinner soil, with a favourable subsoil, will produce better crops than a more fertile one incumbent on wet clay, or on cold and non-absorbent rock. Lands whose substratum consists of clean gravel or sand can bear little sun, owing to their not having the capacity of retaining moisture, and their generally possessing only a shallow surface of vegetable mould. In England this soil was formerly called rye-land, being more generally cropped with that species of grain than any other. When such soils are cultivated for barley, they should be sown early and thick, with seed soaked forty-eight hours in water or in the exudation from a dung-heap. Thus its simultaneous germination and its simultaneous ripening may be secured.

SECT. IV. *Elevation of Lands relatively to Farming.*

4764. *The elevation of lands above the level of the sea* has a material influence on the kind and quality of their produce. Land in the same parallel of latitude, other circumstance being nearly similar, is always more valuable in proportion to the comparative lowness of its situation.

4765. *In the higher districts* the herbage is less succulent and nourishing, and the reproduction slower when the land is in grass; while the grain is less plump, runs more to straw, is less perfectly ripened, and the harvest is also later when the produce is corn. It has been calculated that in Great Britain sixty yards of elevation in the land are equal to a degree of latitude; or, in other words, that sixty yards perpendicularly higher, are, in respect of climate, equal to a degree more to the north. In considering the crops to be raised in any particular farm, attention ought therefore to be paid to its height above the level of the sea, as well as to its latitude. In latitude 54° and 55°, an elevation of 500 feet above that level is the greatest height at which wheat can be cultivated with any probable chance of profit; and even there the grain will prove very light, and will often be a month later in ripening than if sown at the foot of the hills.

4766. *The usual maximum of elevation* may be reckoned between 600 and 800 feet for the more common sorts of grain; and in backward seasons the produce will be of small value, and sometimes will yield nothing but straw. It is proper, at the same time, to remark, that in the second class of mountains in the county of Wicklow, in Ireland, where no other grain is considered to be a safe crop, rye is cultivated with success. Where the soil is calcareous, however, as on the Gloucestershire and Yorkshire wolds, from the superior warmth of that species of soil, compared to cold clays or peat, barley grows in great perfection at an elevation of 800 feet above the level of the sea. Some experiments have been made to raise corn crops, at even a higher elevation, on the celebrated mountain Skiddaw, in Cumberland, but unsuccessfully.

4767. *The greatest height at which corn will grow*, in the more remote parts of Scotland, so as to yield any profit to the husbandman, is stated to be at 500 feet above the level of the sea. At the same time corn has been produced, in other districts of that country, at still higher elevations, in particular at the following places:—

	Feet above the Level of the Sea.		Feet above the Level of the Sea.
Parish of Hume, in Roxburghshire	600	Doubruch, in Braemar, Aberdeenshire	1294
Upper Ward of Lanarkshire	760	Lead-hills, in Lanarkshire	1564

4768. *These and other instances* of land being cultivated on high elevations, however, are merely small spots, richly manured, and, after all, producing nothing but crops of inferior barley and oats, and seldom fully ripe or successfully-harvested. It is chiefly where the soil is sandy or gravelly, that corn will answer in Scotland on such elevated situations; and even then, only when the seasons are propitious, and when there are local advantages, favourable to warmth and shelter, in the situation of the lands.

SECT. V. *Character of Surface in regard to farming Lands.*

4769. *A hilly irregular surface*, whether at a high or low elevation above the sea, is unfavourable to farming. The labour of ploughing, carrying home produce, and carrying out manure, is greatly increased; while the soil on the summit of steep hills, mounts, or declivities, is unavoidably deteriorated. On the sides of slopes the finer parts of the clay and mould are washed away, while the sand and gravel remain. Hence the soil in such

districts often wants a proper degree of tenacity for supporting corn crops. A great part of the manure that is applied in such situations is likewise soon lost. From various causes, also, they are colder than the plains.

4770. *Many extensive countries have no perceptible rise.* These have their advantages from uniformity of soil, where it is rich. In other districts, the surface is of a waving description, an inequality which contributes much to the ornament of the country, by the agreeable relief which the eye constantly meets with in the change of objects; while the universal declivity which prevails more or less in every field is favourable to the culture of the land, by allowing a ready descent to any water with which the surface may be encumbered.

SECT. VI. *Aspect in regard to farming Lands.*

4771. *Aspect, in hilly or mountainous districts,* is an important subject of attention to the farmer; more especially where the climate is unfavourable. It is proved in a variety of instances, both in the central highlands of Scotland, and in other parts of the kingdom, that where the aspect of a hill is towards the north, the soil is more fertile than when it lies with a southern exposure. This is attributed to the variations from frost to thaw in the spring months, which are greater in a southern than in a northern aspect. Hence, while the soil to the north remains locked fast, and secured from waste, the other is loosened by the sun, and carried off by showers falling in the intervals of thaw.

4772. *Soils which face the south* are more liable to have their substance carried away by heavy rains, which are generally impelled from the south and south-west. But though the soil to the north often produces the heaviest crops of grass and hay, yet from possessing a more genial climate, and from the earlier and more powerful action of the sun, both corn and grass are harvested earlier on land which has a southern than on that which has a northern aspect; and superiority of quality thus compensates for any inferiority in the quantity of the produce.

SECT. VII. *Situation of Farm Lands in regard to Markets.*

4773. *No farming can go on without markets.* The system of farming to be adopted on any particular farm, and the expense attending it, must materially depend on its situation in regard to markets; to the facility with which its produce can be conveyed, where a contiguous market is wanting; to vicinity to manure, to fuel, and to water.

4774. *The advantages resulting from vicinity to a market,* or to a large town, by which that is insured, are very great. Some crops, as those of potatoes, turnips, and clover, are frequently sold on the ground, without any farther trouble or expense to the farmer; and great quantities of manure may be purchased at a moderate expense. In such situations also there is a ready sale for every article the farm can produce; and the articles sold are not only brought to market at a small expense, but the payment is immediate. For all these reasons, it is contended, and apparently with justice, that the neighbourhood of a capital is the most profitable spot to farm in, notwithstanding the high rent of land, and the great expense of labour.

4775. *Where markets are not at hand,* the farmer ought to take into consideration what articles will best suit those at a distance to which his produce must be sent. In such a situation, unless there are facilities for the conveyance of so bulky an article as corn by good roads, or by water-carriage, it is advisable, instead of cultivating grain, to attend either to the dairy husbandry, or to the breeding of stock which can be fattened in other districts where good markets are more numerous. This plan, by which the dairy, the breeding, and the fattening of stock, are made distinct professions, is highly beneficial to the country at large. Stock can be reared cheaper in remote districts than where land is dear and labour high. On the other hand, the purchaser of lean stock avoids the expense and risk of breeding great numbers of animals. His attention is not distracted by a multiplicity of objects; he can alter his system from cattle to sheep, or from sheep to cattle, as is likely to be most profitable; his business is simplified, and the capital he lays out is speedily returned. The division of professions between breeding and feeding (though they may be united in circumstances peculiarly favourable), is on the whole a most important link in the progress of agricultural prosperity.

4776. *In regard to facility of conveyance,* the state of public roads, bridges, iron rail-ways, canals, rivers rendered navigable, and harbours, deserves the consideration of the farmer, and will most materially influence the value of produce.

4777. *The situation of the farm in regard to manures,* for an easy access to lime, chalk, marl, sea-weed, &c. is of essential advantage to cultivation. The price at which these articles can be purchased, their quality, their distance, and expense of conveyance, are likewise of importance. Farms, for example, possessing the advantage of sea-weed contiguous and in abundance, can pay from fifteen to twenty per cent. more rent per acre than otherwise could be afforded.

4778. *Vicinity to fuel* in the cold and moist regions of Europe are important considerations to the farmer. In the same county, even in England, the difference of expense is often material. In the Hebrides, from the moistness of the climate, the expense of fuel is reckoned equal to a third part of the rent of the land; and farmers who pay, in some cases, 150*l.* per annum, would give 200*l.* if the landlord would supply them and their servants with fuel.

4779. *Where a farmer is under the necessity of using peat,* from the labour attending the cutting, spreading, drying, and conveying it from a distance, several weeks of his horses and servants are devoted to that sole purpose; and much valuable time is lost, which ought to have been employed in the cultivation of his farm. It has been well remarked, that many farmers, to save five guineas on coal, often expend twenty, in thus misapplying the labour of their horses.

4780. *Where wood is used,* it occupies a great deal of ground that might often be cultivated to advantage, and it is not of a lasting quality. Coal is preferable, for general purposes, to every other species of fuel; and besides its domestic application, its superiority for burning lime, that important source of fertility, or calcareous clay, also of much value to the farmer, is an object of great moment. The tenant, therefore, who resides in the neighbourhood of coal, more especially if limestone or calcareous substances are at no great distance, farms at less expense, can afford to pay a higher rent, and may derive more profit from the land he cultivates, than if in these respects he were differently circumstanced.

SECT. VIII. *Extent of Land suitable for a Farm.*

4781. *The extent of ground which a farmer proposes to occupy demands due consideration.* If it be beyond his capital to cultivate or improve, he can derive no profit by taking it. On the other hand, a small occupation may not be worthy of his attention.

4782. *Farms as to size may be divided into three sorts* : small farms under 100 acres ; moderate-sized farms, from 100 to 200 acres ; large farms, from 200 to 1000 acres, and upwards, of land fit for cultivation. The expense of labour is now so great, and the rent of land so high, that the profits of a small farm are not sufficient, with the utmost frugality, or even parsimony, to maintain a family with comfort.

4783. *Moderate-sized farms* are well calculated for the dairy system, for the neighbourhood of large towns, and where capital is not abundant. There are few trades in which a small capital can be employed to a greater advantage than in a dairy farm, yet there is no branch of agriculture where such constant and unremitting attention is required. That is not to be expected from hired servants ; but it is in the power of the wife and daughters of the farmer to perform, or at any rate to superintend, the whole business, and without their aid it cannot be rendered productive.

4784. *Moderate-sized farms* are general in the neighbourhood of towns. This necessarily results from the high rents paid in such situations ; the shortness of the leases usually granted of land near towns ; and the necessity the farmer is under of selling, in small quantities, the articles produced on his farm. On this subject it has been remarked, that farmers in the vicinity of large towns resemble retail shopkeepers, whose attention must be directed to small objects, by which a great deal of money is got, the greater part of which would be lost, without the most unremitting attention. The farmer at a distance from markets, who cultivates on a great scale, may be compared, on the other hand, to a wholesale trader, who, as his profits are less, requires a greater extent of land, for the purpose both of engaging his attention, and of enabling him to support that station of life in which he is placed. There is this difference also between farmers in the neighbourhood of towns, and those who reside at a distance from them, that the former find it more profitable to sell their produce, even such bulky articles as turnips, potatoes, clover, hay, and straw, than to fatten cattle for the butcher ; and they are enabled to do so, without injury to their farms, as they can procure dung in return.

4785. *Farms of the largest size* differ in respect to the capital required. A mountain breeding farm of 5000 acres will not require more to stock it than an arable farm of 500 acres, and much less expense of labour to carry it on. In all cases the safe side for the farmer to lean to, is to prefer a farm rather under than exceeding his capital : and let him consider well beforehand whether he is going to commence a retail farmer for daily markets, or a manufacturer of produce on a large and ample scale ; for the spirit, attention, and style of living of the one differs materially from that of the other. — The subject of this section and the two following having been treated in a general way as between landlord and tenant in the preceding chapter, will be here only briefly noticed as on the part of the tenant.

SECT. IX. *Tenure on which Lands are held for Farming.*

4786. *Perpetual tenures*, or absolute property in land, can never come into consideration with a farmer looking out for a farm. A proprietor cultivating his own property cannot, in correct language, be said to be a farmer ; for to constitute the latter an essential requisite is the payment of rent.

4787. *The leases* on which lands are let for farming are for various terms, and with very different covenants. The shortest lease is from year to year, which, unless in the case of grass lands in the highest order, and of the richest quality, or under some other very peculiar circumstances, no prudent man, whose object was to make the most of his skill and capital, would accept of. Even leases for seven or ten years are too short for general purposes ; a period of fourteen or fifteen years seems to be the shortest for arable lands, so as to admit of the tenant paying a full rent ; but fourteen years, when the lands to be entered on are in bad condition, are too few, and twenty-one years much better for the true interests of both parties. In farming, however, as in every other occupation where there are more skill and capital in want of employment than can find subjects to work on, farms will be taken under circumstances, both in regard to leases and rent, that are highly unfavourable to the farmer ; and if they do not end in his ruin will keep him always poor, and probably not only pay less interest for his capital than any other way in which he could have employed it, but also infringe on its amount. The rapid depreciation of currency which took place in Britain during the wars against the French deceived many farmers, and flattered them for a time with the gradual rise of markets year after year. However high land might be taken at the commencement of a lease, it was always considered a consolation that it would be a bargain by the time it was half done ; and that the farmer's fortune would be made during the last few years of its endurance. When the currency of Britain was permitted to find its level with that of other countries, the delusion ceased, and the majority of farmers were partially or wholly ruined.

4788. *In regard to the covenants of a lease*, it is necessary that there should be such in every one as shall protect both landlord and tenant. Certain general covenants in regard to repairs, renewals if necessary, timber, minerals, entry and exit crops, are common to all leases. Regulations as to manure are required where hay and straw, and other crops, are sold not to be consumed on the farm. Water meadows, rich old grass lands, copse woods, hop grounds, orchards, &c. require special covenants. Fewest covenants are required for a mountain breeding farm ; and in all cases there should be a clause entitling the tenant to an appeal, &c., and a hearing from the landlord, and perhaps a jury of landlords or agents and farmers, against covenants as to cropping, repair, or renewals, which may, from extraordinary circumstances, press particularly heavy on the tenant.

4789. *The power of the landlord to grant a lease*, with liberal conditions, may in some cases be required to be ascertained by the tenant ; and in Scotland, where it is illegal to sublet a farm unless a clause to that effect has been inserted in the original lease, a farmer may cease to be the master of his own property, unless he has taken care to see that clause inserted. In England, for the most part, subletting a farm is no more prohibited than subletting a dwelling-house or a shop. When the laws of countries shall come to be founded on equity, this will be the case every where. At present they almost every where lean to the side of the powerful party, the landlord. In the progress of things it could not be otherwise.

SECT. X. *Rent.*

4790. *The rent of land*, in a general point of view, must always depend on a variety of circumstances ; as the wealth of the country ; its population ; the price of produce ; the amount of public and other burdens ; the distance from markets ; the means of conveyance ; the competition among farmers ; and other less important considerations : but the rent of any particular farm must be regulated by the nature of the soil ; the duration

of the tenure, and the covenants contained in the lease ; the capital to be invested by the farmer in its culture ; and the expenses to which he is liable.

4791. *The rent of poor land* cannot possibly be the same as in the case of fertile lands. The labour of ploughing, harrowing, sowing, &c., when the land is in cultivation, is nearly the same, and yet the produce is greatly inferior, not only in quantity, but in quality. Indeed, where the produce is inconsiderable, or the quality much inferior, the whole, or nearly the whole, may be swallowed up by the expense of labour, and no rent whatever can be afforded, more especially in adverse seasons.

4792. *The duration of the tenure* must have a considerable effect in fixing the rent. No farmer can afford to pay the same sum for land on a short as if he held it on a long lease. The covenants, also, which are in fact a species of rent, must influence the money payments.

4793. *Rent must also depend on the capital invested in the cultivation of the farm.* Thus, if a farmer can lay out only 4*l.* of capital per acre, he may not be able to afford for it a higher rent than 10*s.* per acre ; if he lays out 7*l.* he may pay 14*s.* ; and with a capital of 10*l.* per acre, he may be enabled to pay 18*s.* or 20*s.* of rent.

4794. *The proportion of produce which should be paid as rent*, is a question that has long been considered as abstruse, mysterious, and very difficult to resolve. Some have supposed that one fifth was a reasonable proportion, while others contend for a fourth, or even a third part of the produce of arable land. But all former calculations on this subject are rendered fallacious by the effects of modern improvements. The rent ought certainly to depend upon the amount of the disposable produce ; and that produce in grain is greatly augmented, both by a diminution of the consumption on the farm, effected by improved implements, and a more correct arrangement of labour, and likewise a better cultivation of the land in tillage. Hence, while the price of wheat has greatly advanced during the last twenty years, above the average price of the preceding twenty, the rent of land has not only risen, but in a higher proportion. More grain, and that of a better quality, has been produced on the same extent of land, and a greater amount of disposable surplus has gone to market. Out of this surplus disposable produce, it is evident that the rent must be paid. But it is difficult to divide its amount between the landlord and tenant, as so much depends upon the seasons, and on the prices of the different articles which the farm produces. In had seasons also, every deficiency of produce, in the acres set apart for supporting home population, must be made up from the disposable surplus ; nor is it possible to apply the same rules to all situations, soils, and climates, in all the various districts of an extensive country. It may be proper, however, to give some general idea of the proportion of produce paid as rent in Scotland and in England.

4795. *In Scotland*, the following table states what is considered to be a fair proportion, where the land is cultivated. One of the most scientific agricultural writers, and, at the same time, one who has had much experience in farming, informs us that "this table is a statement of Sir John Sinclair, who wishes to subject every thing to petty regulation ; and that there is no such proportion recognised in Scotland :"—

	<i>Per acre.</i>
Where land produces 10 <i>l.</i> 10 <i>s.</i> per acre per annum, one third, or	£3 11 0
Where land produces 6 <i>l.</i> 12 <i>s.</i> per acre per annum, one fourth, or	£2 13 0
Where land produces only 4 <i>l.</i> 5 <i>s.</i> per acre per annum, one fifth, or	£1 7 0

4796. *In regard to grazing farms*, they are let on principles totally different from the arable ; namely, according to the quantity of stock they can maintain ; and as they are not liable to the same expense of management, both the landlord and the tenant receive larger shares of the produce than in the case of arable farms.

4797. *In England*, the tenant is allowed, on arable land, what is considered to be one moiety of the surplus, after defraying the expenses of cultivation, the taxes to which he is liable, and every other outgoing. Hay land requires much less of his attention ; and for this he only obtains one third of the surplus. But the profits of grazing depending much on superior judgment in buying and selling stock, as well as skill in preventing or curing their diseases, the grazier is entitled to a share of the surplus, fully equal to that of his landlord. It has been contended, as a general principle, that as both the expense of cultivating land, and the value of its produce, are infinitely various, a farmer ought to calculate what profit he can make on his whole farm, without entering into details ; it being of little consequence to him whether he pays at the rate of 10*l.* or 10*s.* per acre, provided he makes an adequate interest on the capital invested. That is certainly a fair criterion on which a tenant may calculate what he ought to offer ; but a landlord, in estimating the rent he ought to insist on, will necessarily take into his consideration the produce that his land is capable of yielding, and what proportion of it, or of its value, at a fair average, he has reason to expect, under all the circumstances of the case.

4798. *Tithe.* In Scotland there is no tithe. In England, compositions for tithes are computed as six is to twenty-two ; so is the composition for tithe to the rent ; so that land averaging 10*l.* 10*s.* per acre would, according to Sir John Sinclair's calculation, be charged for

Rent	£2 11 7½
Composition for tithe	19 4½
	£3 11 0

4799. *What the profits are to which a farmer is entitled*, is a question much disputed. The proper answer is simply this :—The common profits of capital invested in other commercial undertakings. As the subject, however, will bear talking about, let us hear what is said in the *Code* on this subject. On the one hand it is contended, that the produce of land is of such universal and absolute necessity to the existence of mankind, that it is not reasonable it should yield to him who raises it more than a fair profit. On the other hand it is urged, that a farmer is entitled to be fully recompensed for the application of a considerable capital, exposed to the uncertainty of the seasons, when it is managed with economy, and conducted with industry and skill ; and it has also been observed, that it is seldom more money is got by farming than an adequate interest for the capital invested. This is owing to competition, the articles produced being in numberless hands, who must bring them to market ; and necessity, the goods of the farmer being in general of a perishable nature, on the sale of which he depends for the payments he has to make, and the subsistence of his family. To prove how moderate the profits of farming in general are, it appears from the most careful enquiries, that on arable farms they rarely exceed from ten to fifteen per cent. on the capital invested, which is little enough, considering that few employments are more subject to casualties than farming, or require more uniform attention. Some arable farmers, possessed of superior skill and energy, and who have got leases on reasonable terms, may clear from fifteen to twenty per cent. ; while others, who are deficient in these qualities, or pay too high rents, frequently become insolvent. Certain it is, that the great majority of farmers merely contrive to live and bring up their families ; adding little or nothing to their capital, but that nominal addition which takes place in consequence of the depreciation of the currency.

4800. *In grazing farms* the case is different ; as they are attended with less expense of labour, and produce articles of a more luxurious description, for which a higher price will be given. Hence, in such farms, fifteen per cent. and upwards is not unusual. Besides, the grazier is more of a trader than the mere arable farmer ; is frequently buying as well as selling stock ; and sometimes makes money by judicious speculations, though occasionally, from a sudden fall of stock, his losses are considerable. The grazier who breeds superior stock, and thence incurs great expense, is certainly well entitled to more than common profit for his skill and attention.

4801. *For the mode in which rent should be paid, and the terms of payment, we refer to the succeeding Book.*

SECT. XI. *Taxes and other Burdens which affect the Farmer.*

4802. *Farmers are subjected to the payment of various taxes besides the rent paid to the landlord; some of them imposed for local purposes, and others for the general expenses of the state. The real amount of such burdens every careful tenant ought accurately to know before he bargains for his lease. They may be classed under the following heads: parochial, national, and miscellaneous.*

4803. *Parochial taxes* are for the support of the clergyman, for the maintenance of the poor, and, in Scotland, for providing a parochial schoolmaster. The mode of supporting the clergy in England, by paying them a tenth part of the produce of the land in kind, is highly injurious to agriculture, and a bar to improvement. It is a great bar to improvement, because an improving farmer, one more enlightened or more spirited than his neighbours, would pay more tithe by means of his outlay and his exertions, but it is not certain that he would likewise receive more profit. The produce would be more, but the expense would be greater. Nothing can be more obnoxious than a law by which, when a person expends a large sum, either in reclaiming wastes, or augmenting the fertility of land already cultivated, he should be under the necessity of yielding up one tenth of its produce to a person who has been liable to no share of the expense, who has run none of the risk, and who has sustained none of the labour attending the improvement. A commutation of tithe, therefore, instead of its being exacted in kind, would be one of the greatest benefits that could be conferred on agriculture; and there is not the least difficulty in effecting it, by giving to the tithe-owner either a proportion of the land; or by converting the tithe into a perpetual corn rent. Both these plans have been adopted in a variety of cases, by local acts in England, and they ought now to be enforced as a general system.

4804. *An assessment for the maintenance of the poor* is another parochial burden, which is annually increasing, and which, if not speedily regulated upon proper principles, will inevitably absorb a very large proportion of rent in England. Indeed, there are instances where, between the years 1815 and 1822, it has absorbed the whole. This tax is the most dangerous of all for the farmer, on account of its fluctuation; and, indeed, it may be said that it never falls, but continually rises. During infancy, in sickness, and in old age, assistance may be necessary; but, as Malthus justly observes, the poor-laws hold out support to the vicious and idle, at the expense of the prudent and the industrious. These payments also destroy the spirit of independence, and those ideas of honest pride which stimulate a man to use his utmost exertions in support of himself and his family; and, on its present footing, the boon is administered by the parish officers with caution and reluctance, and received by the poor with dissatisfaction and ingratitude.

4805. *The tithes and the poor-rates* are charges upon the land, and in fact come from the landlord's pocket rather than from the tenant's; but in their operation are often oppressive to the tenant, by rising in the course of the lease much higher than they were at the commencement; and as a farmer's rent is always considered by the overseer to be his income, he is charged on that; while the tradesman, who realises three times the amount, is only charged to the poor on the amount of rent of his house.

4806. *In Scotland, the poor are in general maintained by voluntary contributions;* but when these are not found to be sufficient, the proprietors of the parish, with the clergyman and vestry, or kirk-session, are directed to make a list of the indigent persons in the parish, and then to impose an assessment for their relief, one half to be paid by the proprietors, and the other half by the tenant.

4807. *The national burdens in general,* as the duties on houses and windows, and other assessed taxes, or assessments for the support of militia-men's wives and families, for the conveyance of vagrants, or the prosecution of felons, fall no heavier upon the farmer than upon other classes of the community.

4808. *There are various miscellaneous burdens* affecting the farmer, as statute assessments for bridges, which are of such public utility, that moderate rates for their maintenance, properly applied, cannot be objected to: statute labour on the highways; constable dues, which are seldom of much moment; charges of the churchwardens, including the repairs of the church; and in some populous parishes, there is sometimes a burial-ground tax. All these are paid by the occupiers. In some places, also, there is a sewer tax, chargeable on the landlords, where it is not otherwise settled by express contract.

4809. *The vexations* to which farmers in England are subjected, from various uncertain burdens, operate as a premium to Scottish agriculture. It is ingeniously and justly remarked, that physical circumstances are much more favourable to agriculture in England than in her sister country; but these advantages are counteracted by the accumulation of moral evils, which might be removed if the legislature were to bestow on matters connected with the internal improvement of the country, and the means for promoting it, a portion of that attention which it so frequently gives to the amelioration or improvement of our foreign possessions. It ought to have been the business of the late Board of Agriculture to endeavour to prevail on the legislature to relieve agriculture from its moral and political evils; but, instead of this, they set about procuring and distributing statistical and professional information, comparatively of very inferior utility; and after receiving from government nearly 50,000*l.*, or, for any thing we know, more, left agriculture where they found it. Even in the particular line which the Board adopted, Marshall was a much more effectual instrument of agricultural improvement.

SECT. XII. *Other Particulars requiring a Farmer's Attention, with a View to the Renting of Land.*

4810. *A variety of miscellaneous particulars* require consideration before a prudent farmer will finally resolve to undertake the cultivation of a farm; as, the nature of the property on which the farm is situated; in particular, whether the estate is entailed, and to what extent the possessor of the estate is authorised to grant a lease; the character of the landlord, and, in case of his decease, that of his family, and of those whom they are likely to consult; the real condition of the farm in regard to the enclosures, drainage, buildings, &c.; the crops it has usually produced, and the manner in which it has been managed for some years preceding; the general state of the district, in regard to the price of labour, and the expense of living; the character of its inhabitants, in particular of the neighbouring farmers and labourers, and whether they are likely to promote or to discourage a spirit of improvement; the probability of subletting to advantage in case of not liking the situation, of finding a better bargain, or of death. The chances of settling one's family; as of marrying daughters, or of sons' making good marriages. The social state of the farmers, or those that would be considered one's neighbours; the number and

tone of clergy, and lawyers; the game, and the chances of disputes concerning it; the morals of the serving class; schools, places of worship, &c. It is evident, that in hardly any one instance can all the circumstances above enumerated be favourably combined. But the active and intelligent farmer will not be discouraged by the obstacles he may have to surmount; but will strenuously endeavour, by exertion, industry, and perseverance, to overcome the difficulties he must unavoidably encounter. These are vague generalities, and may be thought too commonplace for a work of this description; but the young farmer on the look-out for a farm may not be the worse for having his memory refreshed by them.

CHAP. II.

Considerations respecting Himself, which a Farmer ought to keep in view in selecting and hiring a Farm.

4811. *Whoever intends to embrace farming as a profession, will be less likely to meet with disappointment, if he previously examines a little into his own disposition and talents; and weighs his expectations against ordinary results. Nor is it less essential that he should estimate justly the extent to which his capital may be adequate, and keep regular accounts.*

SECT. I. *Personal Character and Expectations of a professional Farmer.*

4812. *Every one who proposes to farm with success, Professor Thaer observes, ought to unite energy and activity, to reflection, to experience, and to all necessary knowledge. It is true, he says, farming has long been considered as an occupation fit for a young man incapable for any other, and such have sometimes succeeded; but this has always been chiefly owing to a fortunate concurrence of circumstances, which it is not now very easy to meet with.*

4813. *The practice of agriculture consists of an infinite number of particular operations, each of which appears easy in itself, but is often for that very reason the more difficult to execute to the precise extent required; one operation so often interferes with another. To regulate them according to the given time and strength, and in such a way that none is neglected, or causes the neglect of others, requires at once a great deal of attention and activity, without inquietude; of promptitude without precipitation; of general views, and yet with an extreme attention to details.*

4814. *To casualties and accidents no business is so much exposed as farming; and therefore, to enjoy an ordinary degree of happiness, Professor Thaer considers it essential that the farmer possess a certain tranquility of mind. This, he says, may either be the result of a naturally phlegmatic habit of body, or of elevated views in religion or philosophy. These will enable him to bear with every misfortune arising from adverse seasons, or the death of live stock; and only permit him to regret accidents which result from his own neglect.*

4815. *The expectations of profit and happiness which a young farmer has formed ought to be well weighed against the profits and happiness of farmers in general. However superior a farmer may consider his own talents and abilities, he may rest assured there are a number as skilful and adroit as himself, and just as likely to realise extraordinary advantages. Let none therefore engage in farming, thinking to make more money than other farmers similarly circumstanced with himself. If from a happy concurrence of circumstances he is more than usually successful, so much the better, and let him consider it as partly owing to good fortune as well as good farming; but never let him set out on the supposition of gaining extraordinary advantages with only ordinary means.*

4816. *The profits of farming are much exaggerated by people in general; but it may be asserted as an unquestionable fact, that no capital affords less profit than that employed in farming, except that sunk in landed property. This is the natural result both of the universality of the business and of its nature. Farming is every where practised, and every one thinks he may easily become a farmer; hence high rents, which necessarily lessen the profits on capital. From the nature of farming, the capital employed is returned seldom. A tradesman may lay out and return his capital several times a year; but a farmer can never, generally speaking, grow more than one crop per annum. Suppose he succeeds in raising the best possible crops in his given circumstances, still his profits have an absolute limit: for if an ordinary crop be as five, and the best that can be grown be as seven, all that the most fortunate concurrence of circumstances will give is not great, and is easily foreseen. It is hardly possible for a farmer, paying the market price for his land, to make much more than a living for himself and family. Those few who have exceeded this, will be found to have had leases at low rents; indulgent landlords; to have profited by accidental rises in the market, or depreciation of currency; or to have become dealers in corn and cattle; and rarely indeed to have realised any thing considerable by mere good culture of a farm at the market price. Very different is the case of a tradesman, who, with the properties which we have mentioned as requisite for a good farmer, seldom fails of realising an independency.*

4817. *Many persons, chagrined with a city life, or tired of their profession, fancy they will find profit and happiness by retiring to the country and commencing farming. Independently of the pecuniary losses attending such a change, none is more certain of being attended with disappointment to the generality of men. The activity required, and the privations that must be endured, are too painful to be submitted to; whilst the dull uniformity of a farmer's life to one accustomed to the bustle of cities, becomes intolerable to such as do not find resources in their fire-sides, their own minds, or, as Professor Thaer observes, in the study of nature.*

4818. *The most likely persons to engage in farming with success are the sons of farmers, or such others as have been regularly brought up to the practice of every part of agriculture. They must also have an inclination for the profession, as well as a competent understanding of its theory or principles. Books are to be found every where, from which the science of the art is to be obtained; and there are eminent farmers in the improved districts who take apprentices as pupils.*

4819. *In The Husbandry of Scotland, the case is mentioned of Walker, of Mellendean, an eminent*

farmer of Roxburghshire, renting about 2866 acres of arable land, and distinguished for his skill in agriculture, who takes young men under him as apprentices, and these, instead of receiving wages, have uniformly paid him ten pounds each. Some of them remain with him two years, but the greater number only one. They eat in his kitchen, where they have always plenty of plain wholesome food. He takes none who are above living in that way, or who will not put their hands to every thing going forward on the farm. He has sometimes been offered ten times the above sum, to take in young gentlemen to eat and associate with his own family; but that he has uniformly declined. These young men have an opportunity of attending to every operation of husbandry, as practised on Walker's farm; and are taught to hold the plough, to sow, to build stacks, &c.

SECT. II. *Capital required by the Farmer.*

4820. *The importance of capital* in every branch of industry is universally acknowledged, and in none is it more requisite than in farming. When there is any deficiency in that important particular, the farmer cannot derive an adequate profit from his exertions, as he would necessarily be frequently obliged to dispose of his crops for less than their value, to procure ready money; and it would restrain him from making advantageous purchases, when even the most favourable opportunities occurred. An industrious, frugal, and intelligent farmer, who is punctual in his payments, and hence in good credit, will strive with many difficulties, and get on with less money than a man of a different character. But if he has not sufficient live stock to work his lands in the best manner, as well as to raise a sufficient quantity of manure; nor money to purchase the articles required for the farm; he must, under ordinary circumstances, live in a state of penury and hard labour; and the first unfavourable season, or other incidental misfortune, will probably sink him under the weight of his accumulated burdens. Farmers are too generally disposed to engage in larger farms than they have capital to stock and cultivate. This is a great error; for it makes many a person poor upon a large farm, who might live in comfort and acquire property upon one of less extent. No tenant can be secure without a surplus at command, not only for defraying the common expenses of labour, but those which may happen from any unexpected circumstance. When a farmer farms within his capital, he is enabled to embrace every favourable opportunity of buying when prices are low, and of selling when they are high.

4821. *The amount of capital* required must depend upon a variety of circumstances; as whether it is necessary for the farmer to expend any sum in the erection, or in the repair, of his farm-house and offices; what sum an in-coming tenant has to pay to his predecessor, for the straw of the crop, the dung left upon the farm, and other articles of similar nature; the condition of the farm at the commencement of the lease, and whether any sums must be laid out in drainage, enclosure, irrigation, levelling ridges, &c.; whether it is necessary to purchase lime, or other extraneous manures, and to what extent; on the period of entry, and the time at which the rent becomes payable, as this is sometimes exacted before there is any return from the lands, out of the actual produce of which it ought to be paid; and, lastly, on its being a grazing or an arable farm, or a mixture of both.

4822. *In pasture districts*, the common mode of estimating the amount of capital necessary is according to the amount of the rent; and it is calculated that, in ordinary pastures, every farmer ought to have at his command from three to five times the rent he has agreed to pay. But in the more fertile grazing districts, carrying stock worth from 20*l.* to 30*l.* and even upwards, per acre (as is the case in many parts of England), five rents are evidently insufficient. When prices are high, ten rents will frequently be required by those who breed superior stock, and enter with spirit into that new field of speculation and enterprise.

4823. *The capital required by an arable farmer* varies, according to circumstances, from 5*l.* to 10*l.* or even 15*l.* per acre. An ignorant, timid, and penurious farmer lays out the least sum he can possibly contrive; and consequently he obtains the smallest produce or profit from his farm. The profit, however, will always increase, when accompanied by spirit and industry, in proportion to the capital employed, if judiciously expended. At the same time, attention and economy cannot be dispensed with. It is ill-judged to purchase a horse at forty guineas, if one worth thirty can execute the labour of the farm; or to lay out sums unnecessarily upon expensive harness, loaded with useless ornaments. Prudent farmers also, who have not a large capital at command, when they commence business, often purchase some horses still fit for labour, though past their prime, and some breeding mares, or colts; and in five or six years, they are fully supplied with good stock, and can sometimes sell their old horses without much loss. In every case, such shifts must be resorted to, where there is any deficiency of capital.

4824. *A mixture of arable and grass farming* is, on the whole, the most profitable method of farming. Independently of the advantages to be derived from the alternate husbandry (which are always considerable), the chances of profit are much more numerous from a varied system than where one object is exclusively followed. Where this mixed mode of farming is practised, the farmer will frequently rely on the purchase of lean stock, instead of breeding his own; and derives great advantage from the quickness with which capital thus employed is returned. But, in that case, much must depend upon judicious selection. In general it may be said, that to stock a turnip-land arable farm, will require, at this time (1830), 5*l.* or 6*l.* and a clay-land farm from 7*l.* or 8*l.* per acre, according to circumstances.

4825. *This capital is necessarily divided into two parts.* The one is partly expended on implements, or stock of a more or less perishable nature, and partly vested in the soil; for this the farmer is entitled to a certain annual gain, adequate to replace, within a given number of years, the sum thus laid out. The other is employed in defraying the charges of labour, &c. as they occur throughout the year; the whole of which, with the interest, should be replaced by the yearly produce. These two branches of expense on a farm are the first to be attended to, both in order of time, and in magnitude of amount.

CHAP. III.

Choice of Stock for a Farm.

4826. *The stocking of a farm* may be considered as including live stock, implements, servants, and seed. A considerable portion of a farmer's capital is employed in manures, tillages, labour, &c. ; but a farm being once engaged, the above are the only descriptions of stock which admit of a choice.

SECT. I. *Choice of Live Stock.*

4827. *The animals required by a farmer* are of two kinds ; such as are employed to assist in labour ; and such as are used to convert the produce of the farm into food, or other disposable commodities.

SUBSECT. 1. *Live Stock for the Purposes of Labour.*

4828. *The animals of labour used in British farming* are exclusively the horse and the ox. Much difference of opinion formerly prevailed, as to which of these two animals should be preferred ; and the preference has generally been given by speculative writers to the ox, and by practical farmers to the horse. Lord Kaimes in the last century, and Lord Somerville in the present, may be considered the principal advocates for the ox. To their arguments, and to all others, the following objections have been stated by the able author of the supplement to the 6th edition of *The Gentleman Farmer* ; and they may be considered as conveying the sentiments, and according with the practice, of all the best informed and most extensive British farmers.

4829. *The first objection to oxen* is, that they are unfit for the various labours of modern husbandry, — for travelling on hard roads in particular, — for all distant carriages, — and generally for every kind of work which requires despatch : and what sort of work often does not in this variable climate ? A great part of a farmer's work is indeed carried on at home ; and it may still be thought that this may be done by oxen, while one or more horse teams are employed in carrying the produce to market, and bringing home manure and fuel. But it is unnecessary to appeal to the author of *The Wealth of Nations*, to prove the impracticability of this division of labour, unless upon very large farms ; and even on these the advantages of such an arrangement are at best extremely problematical. The different kinds of farm-work do not proceed at the same time ; but every season, and even every change of weather, demands the farmer's attention to some particular employment, rather than to others. When his teams are capable of performing every sort of work, he brings them all to bear for a time upon the most important labours of every season ; and when that is despatched, or interrupted by unfavourable weather, the less urgent branches are speedily executed by the same means. This is one cause, more important perhaps than any other, why oxen have ceased to be employed ; for even ploughing, which they can perform better than any other kind of work, is scarcely ever going forward all the year ; and for some months in winter, the weather often prevents it altogether.

4830. *Another objection* is, that an ox team capable of performing the work of two horses, even such kind of work as they can perform, consumes the produce of considerably more land than the horses. If this be the case, it is of no great importance, either to the farmer or the community, whether the land be under oats, or under herbage and roots. The only circumstance to be attended to here is, the carcass of the ox : the value of this, in starting the consumption of produce, must be added to the value of his labour. He consumes, from his birth till he goes to the shambles, the produce of a certain number of acres of land ; the return he makes for this is so much beef, and so many years' labour. The consumption of produce must therefore be divided between these two articles. To find the share that should be allotted to each, the first thing is to ascertain how many acres of grass and roots would produce the same weight of beef from an ox, bred and reared for beef alone, and slaughtered at three or four years old. What remains has been consumed in producing labour. The next thing is to compare this consumption with that of the horse, which produces nothing but labour. By this simple test, the question, viewing it upon a broad national ground, must evidently be determined. Every one may easily make such a calculation suited to the circumstances of his farm ; none that could be offered would apply to every situation. But it will be found, that if even three oxen were able to do the work of two horses, the advantages in this point of view would still be on the side of the horses ; and the first objection applies with undiminished force besides.

4831. *The money-price of the horse and ox*, it is evident, is merely a temporary and incidental circumstance, which depends upon the demand. A work ox may be got for less than half the price of a horse, because there is little or no demand for working oxen ; while the demand for horses by manufactures, commerce, pleasure, and war, enhances the price of farm-horses, as well as of the food they consume. Those who wish to see horses banished from all sorts of agricultural labour, would do well to consider where they are to be reared for the numerous wants of the other classes of society. Besides, if two oxen must be kept for doing the work of one horse, it ought to be foreseen, that though beef may be more abundant than at present, there will be a corresponding deficiency in the production of mutton and wool. A greater portion of the arable land of the country must be withdrawn from yielding the food of man directly, and kept under cattle crops, which, however necessary to a certain extent for preserving the fertility of the soil, do not return human food, on a comparison with corn crops, in so great a proportion as that of one to six from any given extent of land of the same quality.

4832. *The demand for oxen is confined almost every where to the shambles* ; and by the improvements of modern husbandry, they are brought to a state of profitable maturity at an early age. No difference in price at setting to work, — no increase of weight while working, — no saving on the value of the food consumed, can ever make it the interest of tillage farmers generally to keep oxen as formerly, till they are eight or ten years old. They judiciously obtain the two products from different kinds of animals, each of them from the kind which is best fitted by nature to afford it, — the labour from the horse, and the beef alone from the ox. And though the price of the horse is almost wholly sunk at last, during the period of his labour he has been paying a part of it every year to a fund, which, before his usual term expires, becomes sufficiently large to indemnify his owner. The ox, on the other hand, is changed three or four times during the same

period; and each of them gives nearly as large a carcase for the food of man as if his days had been unprofitably prolonged in executing labour, from which he has been gradually exempted in Britain, in France, and in other countries, very nearly in proportion to the progress of correct systems of husbandry.

4833. *The description of horse* which a farmer ought to choose will depend chiefly on the soil of the farm, and partly also on the quantity of road-work. Stiff lands require obviously a heavier and more powerful breed than such as are light and hilly. In the latter case, two of the best breeds are the Clevelands and Clydesdale, or some local cross with these breeds. In general, it is not advisable to procure horses from a climate materially different from that where they are to remain; and therefore, for various reasons, a prudent farmer will look out for the best in his neighbourhood. Often, however, he is obliged to take the stock of his predecessor; and this he can only get rid of or improve to his mind by degrees. The farm-horses in most parts of England are much too cumbersome and heavy, and are more fitted for drawing heavy drays or waggons in towns than for the quick step required in the operations of agriculture.

4834. *The objections of Davis of Longleat to the using of large heavy-heeled horses*, in preference to the smart, the active, and the really useful breeds, merit particular attention. In some situations, the steepness of the hills and the heaviness of the soil require more than ordinary strength; but, in such cases, he maintains that it would be better to add to the number of horses than to increase their size. Great horses not only cost proportionably more at first than small ones, but require much more food, and of a better quality, to keep up their flesh. The Wiltshire carter also takes a pride in keeping them as fat as possible; and their food (which is generally barley) is given without stint. In many instances, indeed, the expense of keeping a fine team of horses amounts nearly to the rent of the farm on which they are worked. They are purchased young when two years' old colts, and sold at five or six years of age for the London drays and waggons. The expense of their maintenance is very seldom counterbalanced by the difference of price, more especially as such horses are gently worked when young, that they may attain their full size and beauty. In ploughing light soils, the strength of a dray-horse is not wanted; and in heavy soils, the weight of the animal does injury to the land.

SUBJECT. 2. *Choice of Live Stock for the Purposes of breeding or feeding.*

4835. *The most desirable properties of live stock destined for food* are considered in *The Code of Agriculture*, in respect to size, form, a tendency to grow, early maturity, hardiness of constitution, prolific properties, quality of flesh, a disposition to fatten, and lightness of offal.

4836. *The bulk of an animal* was the sole criterion of its value before the improvements introduced by Bakewell; and if a great size could be obtained, more regard was paid to the price the animal ultimately fetched than to the cost of its food. Of late, since breeders began to calculate with more precision, small or moderate-sized animals have been generally preferred, for the following reasons:—

4837. *Small-sized animals* are more easily kept, they thrive on shorter herbage, they collect food where a large animal could hardly exist, and thence are more profitable. Their meat is finer grained, produces richer gravy, has often a superior flavour, and is commonly more nicely marbled, or veined with fat, especially when they have been fed for two years. Large animals are not so well calculated for general consumption as the moderate-sized, particularly in hot weather; large animals poach pastures more than small ones; they are not so active, require more rest, collect their food with more labour, and will only consume the nicer and more delicate sorts of plants. Small cows of the true dairy breeds give proportionably more milk than large ones. Small cattle may be fattened solely on grass of even moderate quality; whereas the large require the richest pastures, or to be stall-fed, the expense of which exhausts the profit of the farmer. It is much easier to procure well-shaped and kindly-feeding stock of a small size than of a large one. Small-sized cattle may be kept by many persons who cannot afford either to purchase or to maintain large ones, and their loss, if any accident should happen to them, can be more easily borne. The small-sized sell better; for a butcher, from a conviction that, in proportion to their respective dimensions, there is a greater superfluity of valuable parts in a small than a large animal, will give more money for two oxen of twelve stone each per quarter than for one of twenty-four stone.

4838. *In favour of the large-sized* it is, on the other hand, contended, that without debating whether from their birth till they are slaughtered the large or the small one eats most for its size, yet on the whole the large one will pay the grazier or the farmer who fattens him as well for his food; that though some large oxen are coarse-grained, yet where attention is paid to the breed (as is the case with the Herefordshire), the large ox is as delicate food as the small one; that if the small-sized are better calculated for the consumption of private families, of villages, or of small towns, yet that large cattle are fitter for the markets of great towns, and in particular of the metropolis; that were the flesh of the small-sized ox better when fresh, yet the meat of the large-sized is unquestionably more calculated for salting, a most essential object in a maritime and commercial country,—for the thicker the beef, the better it will retain its juices when salted, and the fitter it is for long voyages; that the hide of the large ox is of very great consequence in various manufactures; that large stock are in general distinguished by a greater quietness of disposition; that where the pastures are good, cattle and sheep will increase in size, without any particular attention on the part of the breeder; large animals are therefore naturally the proper stock for such pastures; that the art of fattening cattle, and even sheep, with oil-cake, being much improved and extended, the advantage of that practice would be of less consequence, unless large oxen were bred, as small oxen can be fattened with grass and turnips as well as oil-cake; and, lastly, that large oxen are better calculated for working than small ones, two large oxen being equal to four small ones in the plough or the cart.

4839. *Such are the arguments generally made use of on both sides of the question*; from which it appears that much must depend upon pastures, taste, mode of consumption, markets, &c. and that both sides have their advantages. The intelligent breeder, however, (unless his pastures are of a nature peculiarly forcing,) will naturally prefer a moderate size in the stock he rears. Davis of Longleat, one of the ablest agriculturists England has produced, has given some useful observations on the subject of size. He laments that the attempts which have been made to improve the breeds of cows, horses, and sheep, have proceeded too much upon the principle of enlarging the size of the animal; whereas, in general, the only real improvement has been made in the pig, and that was by reducing its size, and introducing a kind that will live harder, and come to greater perfection at an earlier age.

4840. *Though it is extremely desirable to bring the shape of cattle* to as much perfection as possible, yet profit and utility ought not to be sacrificed for mere beauty which may please the eye, but will not fill the pocket; and which, depending much upon caprice, must be often changing. In regard to form, the most experienced breeders seem to concur in the following particulars:—That the form or shape should be compact, so that no part of the animal should be disproportioned to the other parts, and the whole should

be distinguished by a general fulness and rotundity of shape; that the chest should be broad, for no animal whose chest is narrow can easily be made fat; that the carcase should be deep and straight; that the belly should be of a moderate size; for when it is more capacious than common in young animals, it shows a diseased state, and in older ones it is considered a proof that the animal will not return in flesh, in milk, or in labour, the value of the extra quantity of food which it consumes; that the legs should be short, for the long-limbed individuals of the same family or race are found to be the least hardy, and the most difficult to rear or to fatten; and that the head, the bones, and other parts of inferior value, should be as small as is consistent with strength, and with the other properties which the animal ought to possess. In animals bred for the shambles, the form must likewise be such as to contain the greatest possible proportion of the finer, compared with the coarser and less valuable parts of the animal. This, by selection, may be attained, and thus the wishes of the consumer may be gratified. As to the broad loins, and full hips, which are considered as a point of excellence in particular breeds, it is evident that the old narrow and thin make required improvement; but the alteration is now carried to a faulty excess, and often occasions great difficulty and danger in calving.

4841. *The form of animals* has fortunately attracted the attention of an eminent surgeon, Henry Cline, Esq. of London, whose doctrines we have already laid down at length, and the substance of which is:— That the external form is only an indication of the internal structure; that the lungs of an animal form the first object to be attended to, for on their size and soundness the health and strength of an animal principally depend; that the external indications of the size of the lungs are the form and size of the chest, and its breadth in particular; that the head should be small, as by this the birth is facilitated; as it affords other advantages in feeding, &c., and as it generally indicates that the animal is of a good breed; that the length of the neck should be in proportion to the size of the animal, that it may collect its food with ease; and that the muscles and tendons should be large, by which an animal is enabled to travel with greater facility. It was formerly the practice to estimate the value of animals by the size of their bones. A large bone was considered to be a great merit; and a fine-boned animal always implied great size. It is now known that this doctrine was carried too far. The strength of the animal does not depend upon the bones, but on the muscles; and when the bones are disproportionately large, it indicates, in Cline's opinion, an imperfection in the organs of nutrition. Bakewell strongly insisted on the advantage of small bones; and the celebrated John Hunter declared, that small bones were generally attended with corpulence in all the subjects he had an opportunity of examining. A small bone, however, being heavier and more substantial, requires as much nourishment as a hollow one with a larger circumference.

4842. *Among the qualities* for which thorough-bred cattle and sheep are distinguished, that of being good growers, and having a good length of frame, is not the least essential. The meaning of which is, that the animal should not only be of a strong and healthy constitution, but speedily should grow to a proper size. As specimens of rapid growth, a steer of three years old, when well fed, will weigh from 80 to 90 or 100 stone, 14lb. to the stone, and a two-year-old Leicester wether, from 25 to 28lb. per quarter, immediately after his second fleece is taken from him. Animals having the property of growing, are usually straight in their back and belly; their shoulders well thrown back, and their belly rather light than otherwise. At the same time, a gauntness and paucity of intestines should be guarded against, as a most material defect, indicating a very unthriving animal. Being too light of bone, as it is termed, is also a great fault. A good grower, or hardy animal, has always a middling-sized bone. A bull distinguished for getting good growers is inestimable; but one whose progeny takes an unnatural or gigantic size ought to be avoided.

4843. *Arriving soon at perfection*, not only in point of growth or size, but in respect of fitness, is a material object for the farmer, as his profit must in a great measure depend upon it. Where animals, bred for the carcase merely, become fat at an early age, they not only return sooner the price of their food, with profit to the feeder, but in general, also, a greater value for their consumption, than slow-feeding animals. This desirable property greatly depends on a mild and docile disposition; and as this docility of temper is much owing to the manner in which the animal is brought up, attention to inure them early to be familiar cannot be too much recommended. A tamed breed also has other advantages. It is not so apt to injure fences, or to break into adjacent fields; consequently it is less liable to accidents, and can be reared, supported, and fattened at less expense. The property of early maturity, in a populous country, where the consumption of meat is great, is extremely beneficial to the public, as it evidently tends to furnish greater supplies to the market; and this propensity to fatten at an early age is a sure proof that an animal will fatten speedily at a late period of his life.

4844. *The possession of a hardy and healthy constitution*, is, in the wilder and bleaker parts of a country, a most valuable property in stock. Where the surface is barren, and the climate rigorous, it is essential that the stock bred and maintained there should be able to endure the severities and vicissitudes of the weather, as well as scarcity of food, hard work, or any other circumstance in its treatment that might subject a more delicate breed to injury. In this respect, different kinds of stock greatly vary; and it is a matter of much consequence to select, for different situations, cattle with constitutions suitable to the place where they are to be kept. It is a popular belief, that dark colours are indications of hardness. In mountain breeds of cattle, a rough pile is reckoned a desirable property, more especially when they are to be kept out all winter: it enables them to face the storm, instead of shrinking from it. Hardy breeds are exempted from various diseases, such as having yellow fat, and being blackfleshed, defects so injurious to stock.

4845. *The prolific quality of a breed* is a matter deserving attention. The females of some breeds both bear more frequently than usual, and also have frequently more than one at a birth. This property runs more strikingly in sub-varieties, or individual families; and though partly owing to something in the habits of animals, and partly to their previous good or bad treatment, yet in some degree seems to depend upon the seasons, some years being more distinguished for twins than others. In breeding, not only the number, but the sex of the offspring, in some cases, seems to depend upon the female parent. Two cows produced fourteen females each in fifteen years, though the bull was changed every year: it is singular, that when they produced a bull calf, it was in the same year. Under similar circumstances, a great number of males have been produced by the same cow in succession, but not to the same extent.

4846. *By the quality of their flesh*, breeds are likewise distinguished. In some kinds it is coarse, hard, and fibrous; in others of a finer grain or texture. In some breeds, also, the flavour of the meat is superior; the gravy they produce, instead of being white and insipid, is high coloured, well flavoured, and rich; and the fat is intermixed among the fibres of the muscles, giving the meat a streaked, or marbled appearance. Breeds whose flesh have these properties are peculiarly valuable. Hence two animals of nearly the same degree of fatness and weight, and who could be fed at nearly the same expense to the husbandman, will sell at very different prices, merely from the known character of their meat.

4847. *A disposition to fatten* is a great object in animals destined for the shambles. Some animals possess this property during the whole progress of their lives, while in others it only takes place at a more advanced period, when they have attained their full growth, and are furnished at the same time with a suitable supply of food. There are in this respect other distinctions: most sorts of cattle and sheep, which have been bred in hilly countries, will become fat on lowland pastures, on which the more refined breeds would barely live; some animals take on fat very quickly, when the proper food has been supplied, and some individuals have been found, even in the same breed, which have, in a given time, consumed the least proportional weight of the same kind of food, yet have become fat at the quickest rate. Even in the human race, with little food, some will grow immoderately corpulent. It is probably from internal conformation that this property of rapid fattening is derived.

4848. *The advantages and disadvantages of fattening cattle and sheep*, at least to the extent frequently practised at present, are points that have of late attracted much public attention. But any controversy

on that subject can only arise from want of proper discrimination. Fat meat is unquestionably more nourishing than lean, though to digest this oily matter there are required, on account of its difficult solubility, a good bile, much saliva, and a strong stomach; consequently none, except those who are in the most vigorous state of health, or who are employed in hard labour, can properly digest it. Though fat meat, however, is unfit for general consumption, yet experiments in the art of fattening animals are likely to promote useful discoveries; and though, in the course of trying a number of experiments, errors and excesses may be committed, yet on the whole advantage may be derived from the knowledge thus to be obtained. As the bone also gains but little in the fattening animal, and the other offal becomes proportionally less, as the animal becomes more fat, the public has not sustained much loss by over-fatted animals. To kill even hogs till they are thoroughly fat, is exceeding bad economy. An ox or cow, though the little flesh it has may be of good quality, yet presents, when lean, little but skin and bone; and if slaughtered in that state, would neither indemnify the owner for the expense of breeding and maintaining it, nor benefit the public. A coarse and heavy-fleshed ox, which would require a very long time and much good food to fatten, may be slaughtered with most advantage while rather lean. It is not, however, so much the extent of fat, as the want of a sufficient quantity of lean flesh, of which the consumer complains; for it cannot be doubted, that the lean flesh of a fat animal is better in quality, and contains more nourishment, than the flesh of a lean animal.

4849. *Handling well.* The graziers and butchers in various parts of the kingdom have recourse to feeling the skin, or cellular membrane, for ascertaining a disposition to fatten; and since Bakewell directed the public attention so much to breeding, that practice has become more generally known. Handling cannot easily be defined, and can only be learned by experience. The skin and flesh of cattle, when handled, should feel soft to the touch, somewhat resembling that of a mole, but with a little more resistance to the finger. A soft and mellow skin must be more pliable, and more easily stretched out, to receive any extraordinary quantity of fat and muscle, than a thick or tough one. The rigid-skinned animal must, therefore, always be the most difficult to fatten. In a good sheep, the skin is not only soft and mellow, but in some degree elastic. Neither cattle nor sheep can be reckoned good, whatever their shapes may be, unless they are first-rate handlers. The improved short-horned breed, besides their mellowness of skin, are likewise distinguished by softness and silkiness of hair.

4850. *Lightness of offal.* An animal solely bred for the shambles should have as little offal, or parts of inferior value, as possible (consistently with the health of the animal), and consequently a greater proportion of meat, applicable as food for man. This, therefore, the skilful farmer will also keep in view in selecting his species of stock. (*Code, &c.*)

4851. *The Rev. Henry Berry*, who has paid much attention to the subject of breeding and feeding cattle, and written several valuable papers on the subject in the *British Farmer's Magazine*, seems to prefer for general purposes the *improved short-horns*. "These cattle," he says, "at three years old, are equal to Hereford cattle at four years old; and they are bred from cows which prove much more profitable for the dairy than the Herefords." At the same time, he admits that the Hereford cattle are excellent to purchase with a view to fattening, because in a lean state at four years old they will of course not bear an increased price in proportion to the increased time required to render one of them equal to a short-horn of three years. For breeders, therefore, he decidedly recommends the short-horns; and he has given an interesting history of this breed of cattle for the last eighty years, the period which has elapsed since it attracted attention. It was imported from Holland to the banks of the Tees; or, at least, it is the result of a cross between the breed so imported and the native breed of that district. (*Improved Short-Horns, &c.* By the Rev. Henry Berry. 2d edit. 1830.)

SECT. II. Choice of Agricultural Implements, Seeds, and Plants.

4852. *The variety and excellence of agricultural implements* is so great, that the prudent farmer, in regard to these, as well as in every other branch of his art, must study economy. He should not incur an unnecessary expense in buying them, or in purchasing more than are essentially requisite, and can be profitably used. This maxim ought to be more especially attended to by young improvers, who are often tempted, under the specious idea of diminishing labour and saving expense, to buy a superfluous quantity of implements, which they afterwards find are of little use. (*Coventry's Disc.* p. 47.) It is remarked by an intelligent author on matters of husbandry, that a great diversity of implements, as they are more rarely used, prove in general a source of vexation and disappointment, rather than of satisfaction, to the farmer.

4853. *The different implements required by the farmer* are: those of tillage; for drilling or sowing corn; for reaping corn; for harvesting corn; for threshing and cleaning corn; for mowing and harvesting hay; of conveyance; for draining; for harnessing stock; for rolling land; for the dairy; and, for miscellaneous purposes.

4854. *In purchasing implements*, the following rules are to be observed: they should be simple in their construction, both that their uses may be more easily understood, and that any common workman may be able to repair them when they get out of order; the materials should be of a durable nature, that the labour may be less liable to interruption from their accidental failure; their form should be firm and compact, that they may not be injured by jolts and shaking; and that they may be more safely worked by country labourers, who are but little accustomed to the use of delicate tools. In the larger machines, symmetry and lightness of shape ought to be particularly attended to: for a heavy carriage, like a *great horse*, is worn out by its own weight, nearly as much as by what he carries. The wood should be cut up and placed in a position the best calculated to resist pressure; and mortises, so likely to weaken the wood, should, as much as possible, be avoided; at the same time, implements should be made as light as is consistent with the strength that is necessary. Their price should be such, that farmers in moderate circumstances can afford to buy them; yet for the sake of a low price, the judicious farmer will not purchase articles either of a flimsy fabric or a faulty form; and implements ought to be suited to the nature of the country, whether hilly or level, and more especially to the quality of the soil; for those which are calculated for light land will not answer equally well in soils that are heavy and adhesive. (*Code.*)

4855. *In the choice of seed corn*, regard must be had to procure it from a suitable soil and climate, and of a suitable variety. A change from one soil to another of a different

quality, is generally found advantageous; but this is not always the case as to climate. Thus, some of the varieties of oats, as the Angus oat, which answers well in most parts of Scotland, is found not to fill in the ear, but to shrivel up after blossoming, in the south of England. In like manner, the woolly-chaffed white wheats of Essex and Kent rot in the ear when grown in the moist climate of Lancashire. In settling on a farm in a country with which the farmer is little acquainted, he will often find it advisable to select the best seed he can find in the neighbourhood, and probably to resift it and free it from the seeds of weeds and imperfect grains. Particular care is requisite in selecting the seed of the bean and pea, as no crop depends more on the variety being suited to the soil and climate. Thus, on hot gravelly soils in the south, the late grey pea would produce little haulm and no pulse; but the early varieties, or the pearl pea, will produce a fair proportion of both.

4856. *The only small seeds* the farmer has to sow on a large scale, are the clovers, grasses, the different varieties of turnip, and probably the mangold wurzel and carrot. No expense or trouble should be spared to procure the best turnip seed; as if that is either mixed by impregnation with other varieties of the Brassica tribe, or has been raised from a degenerate small-rooted parentage, the progeny will never come to any size. The same may be said of carrot or mangold seed, raised from small misshapen roots. Even rape seed should be raised from the strongest and largest rooted plants, as these always produce a stronger progeny.

4857. *The selection and propagation of improved agricultural seeds* has till lately been very little attended to. But the subject has been taken up by Mr. Sinclair of New Cross, Mr. Shirreff of Mungos Wells, Mr. Gorrie of Raif, and others; and we have little doubt some greatly improved varieties of our more useful field plants will be the result. Mr. Shirreff mentions (*Quar. Jour. Ag.* vol. i. p. 366), that the variety of the Swedish turnip cultivated in East Lothian had, by judicious selection of the roots from which seed was saved, been improved in nutritious value upwards of 300 per cent. "Potatoes and Swedish turnip," Mr. Shirreff says, "appear to be susceptible of farther improvement by judicious selection, as well as the different grains so long cultivated in this country, and which, in almost every instance, have become spurious. But whatever may be the degree of improvement of which the agricultural produce of the country is susceptible, by the propagation of genuine seeds of the best varieties of plants, one remarkable feature of such an improvement is, that it could be carried into effect without any additional investment of capital, or destruction of that already employed. It would require, in the first instance, only a slight degree of observation amongst practical farmers to select the best varieties, and afterwards a small exercise of patience in their propagation. The whole increase of produce obtained by such means would go to support the unagricultural part of the population; it would, in the first instance, be clear gain to the occupiers, and ultimately to the owners of land. The difference of produce, arising from sowing the seed of a good and a bad variety of a plant, is so great, that it does not seem inconsistent with probability to state, that the gross agricultural produce of the country might be augmented, in the course of a few years, through the agency of improved seeds, to the amount of seven per cent.; and as the farmer's home consumption of produce, by such means, would be increased nearly ten per cent., what an enormous fund this forms for maintaining the unagricultural part of the population, and augmenting the income of landholders!"

4858. *The facility of propagating genuine seeds*, will become manifest from a statement of my practice. In the spring of 1823, a vigorous wheat-plant, near the centre of a field, was marked out, which produced 63 ears, that yielded 2473 grains. These were dibbled in the autumn of the same year; the produce of the second and third seasons sown broadcast in the ordinary way; and the fourth harvest put me in possession of nearly forty quarters of sound grain. In the spring of this year, I planted a fine purple-top Swedish turnip, that yielded (exclusively of the seeds picked by birds, and those lost in threshing and cleaning the produce), 100,296 grains, a number capable of furnishing plants for upwards of five imperial acres. One-tenth of an acre was sown with the produce, in the end of July, for a seed crop, part of which it is in contemplation to sow for the same purpose in July 1829. In short, if the produce of the turnip in question had been carefully cultivated to the utmost extent, the third year's produce of seed would have more than supplied the demand of Great Britain for a season.

4859. *Plants and animals are both organic bodies*, from the germs of whose fecundating organs proceed new races, which yield crops; and thus an extensive view of improving agriculture through the agency of genuine seeds embraces the propagation of live stock. Now, however important the propagation of live stock may be, when considered by itself, yet, when viewed in connection with our agricultural system, embracing the cultivation and improvement of the herbage which support animals, as well as those plants, parts of which form the ingredients of human sustenance, it becomes less imposing. The analogy subsisting between animal and vegetable life is known and acknowledged; and it may be stated, that the union of the male and female organs of different varieties of a plant, under favourable circumstances, produces a new race, which partakes of the qualities of both parents, and which is termed a hybrid. Now, hybrid varieties of agricultural plants, when suffered to intermingle with the original kind, disseminate their influence around them like cross-bred animals, unrestrained in their intercourse with the general herd, till the character of the stock becomes changed, and consequently deteriorated or improved. In either case, propagation from the best variety alone would be attended with good effects. The principles of propagating vegetable and animal life are nearly the same; but the propagation of vegetables must exceed that of animals in importance, as much as the vegetable produce of the country surpasses that of animals. Indeed animals may justly be considered mere machines for converting our inferior herbage into nutriment of a different description; grasses and roots are the raw materials, butcher's meat the manufactured commodity."

4860. *The importance of attending to varieties of cultivated plants* has been ably pointed out by Mr. Bishop, an once a scientific botanist, and an experienced practical gardener. "By means of varieties," he says, "the produce of our gardens and fields are not only increased in a tenfold degree, but the quality of the produce is improved in a still greater proportion. In them we perceive the labour and assiduity of man triumphing over the sterility of unassisted nature, and succeeding in giving birth to a race of beings calculated to supply his wants in a manner that original species never could have done. The difference between varieties that have sprung from the same species fits them for different purposes, and for different soils, situations, and climates. Some, by reason of their robust natures, are winter vegetables; and others, by being early, are spring vegetables; while some are in perfection in summer, and others in autumn. The fruit produced by some is fit to eat when pulled off the tree, while the fruit of others is valuable by reason of its keeping till that season, when Nature rests to recruit her strength. Thus, in edible plants and fruits, we are supplied with an agreeable change throughout the year, from a difference in varieties that have sprung from the same species. In the earlier ages of the world, no idea could have been entertained of the

excellence some varieties have attained over their originals. Who, upon viewing the wild cabbage that grows along our sea-coast, would ever imagine that cauliflower or broccoli would have been produced by the same? Or who would expect the well-formed apple of a pound's weight from the verjuice plant in our hedges? Many instances might be noticed of original species that are scarcely fit to be eaten by the beasts of the field, the varieties of which afford a nutritious and wholesome food for man. Upon comparing the original variety of the *Daucus Carota*, the *Pastinaca sativa*, and some others indigenous to our climate, with their varieties produced by culture, we are struck with their great inferiority, and cannot help reflecting on the hapless condition of that hungry savage who first taught us their use; for nothing short of the greatest privation could ever have led to that discovery. Indeed, nothing is more obvious, upon comparing original species with their varieties produced by culture, than that we, by means of the latter, enjoy a vegetable food far preferable to that of our forefathers; a circumstance from which it may be inferred that posterity is destined to enjoy a better than that which we do now. For although it is reasonable to believe that there exists a degree of excellence attainable by varieties over the species whence they have sprung, yet as that degree is unknown, and as it is probably beyond the power of man, of cultivation, or of time, to determine the same, we are justified in regarding it as progressive, and in considering the production of a good variety as the sign or harbinger of a better.

4861. *The power of distinguishing varieties*, and of forming some idea of their worth at sight, is an attainment much to be desired, because valuable varieties may sometimes appear to those who have it not in their power to prove them by trial; and if they have, the probability is, that the means to be employed require more care, time, and attention than they are disposed to bestow on plants the merits of which are doubtful: whereas, were such persons capable of forming an estimate of the worth of varieties from their appearance, then would they use means for their preservation, whenever their appearance was found to indicate superiority. That this is an attainment of considerable importance, will be readily allowed; yet, that it, in some cases, requires the most strict attention, appears from the circumstance of varieties being oftentimes valuable, though not conspicuously so. Let us suppose, for instance, that in a field of wheat there exists a plant, a new variety, having two more fertile joints in its spike, and equal to the surrounding wheat in every other respect: a man accustomed to make the most minute observations, would scarcely observe such a variety, unless otherwise distinguished by some peculiar badge; nor would any but a person versed in plants know that it was of superior value if placed before him. How many varieties answering this description may have existed and escaped observation, which, had they been observed, and carefully treated, would have proved an invaluable acquisition to the community! The number of fertile joints in the spike of the wheat generally cultivated, varies from eighteen to twenty-two; and the inhabitants of Great Britain and Ireland amount to nearly the same number of millions: therefore, as the wheat produced in those islands has been of late years sufficient, or nearly sufficient, to supply the inhabitants thereof with bread, it is evident that a variety with two additional fertile joints, and equal in other respects to the varieties at present in cultivation, would, when it became an object of general culture, afford a supply of bread to at least two millions of souls, without even another acre being brought into cultivation, or one additional drop of sweat from the brow of the husbandman.

4862. *The same varieties are not repeatedly produced by culture*; if they were, there would not exist that necessity for strict observation and skill on the part of observers; because, if a variety were lost or destroyed, we might look forward to its re-appearance: or did we possess the power of producing varieties, and of producing them late or early, tall or dwarf, sweet or sour, or just as we might wish to have them, then might we plead an excuse for inattention. But experience shows, that when a variety is lost, it is for ever lost; and the slightest reflection cannot fail of convincing us, that our power of producing them is most limited. Indeed, our knowledge only enables us to produce those of the intermediate kind; while varieties that confer extension or excellence are as likely to be produced from the seed sown and treated by the humble labourer as from that sown and treated by the ablest horticulturist, the most skilful botanist, or most profound philosopher of the age. From these remarks it is obvious, that the benefits mankind derive from the varieties produced by culture are numerous and important, and that the discovery of those of merit is an object highly deserving of our attention." (*Bishop's Casual Botany*.)

4863. *The varieties of wheat and barley in general cultivation*, Mr. Gorrie observes, are "not numerous; but were a part of that attention paid to the production of new and improved varieties of field-beans, peas, oats, barley, and wheat, which is now almost wasted on live stock, the same success might follow, and varieties of each of these useful species of grain might be found as far surpassing those now in cultivation as the modern breeds of horses and cattle surpass those of former days. To effect this, a simple process only is necessary. When any two varieties are intended to be used in 'crossing,' it is necessary that they should be sown at such periods as may render them likely to flower at the same time; and we would recommend that such plants should be sown or transplanted into flower-pots, particularly the variety to be used as the *female breeder*. The parts of fructification of all the *Cerealia* tribe are composed of a stigma, or fringed substance, which crowns the embryo grain; three anthers or male parts, which have either a purple or yellow colour; and firm, small, round, or rather longish cylindrical knobs, with a hollow line longitudinally along the middle, on the side farthest from the filament which supports these anthers. Allowing that there are six plants, say of wheat, in a pot to be impregnated, let the variety possessing the greatest proportion of desirable qualities be selected for the *male*, from a field or otherwise, and, before the anthers appear outside the glume, let the chaff be opened by a slight touch of the forefinger; cut off the anthers of all the ears growing on the plants in the pot, and then take the male parts of the variety *wished to be improved*, which have been newly out of the chaff, and, before the farina is all dissipated, touch the stigma of all the embryo grains whence the anthers have been previously removed, gently, with newly burst anthers, till the stigma is partially covered with the dust or pollen; keep the plants at a distance from the fields where grain of the *same sort* is coming in the flower, till the *flowering* season is fairly over, then, to prevent sparrows or other birds from picking the impregnated grains, plunge the pots to the brims in a field of the same kind of grain. Save every seed, and sow them carefully next season; if the process has been properly performed, there may be many varieties even from one ear; the best should be marked, and the produce of each stalk worthy of notice kept, and propagated *distinctly by itself*. If all the farmers in a district were to submit five or six plants only to such process, we might soon have hundreds of new varieties, and it is certainly within the limits of probability to expect a few varieties superior to any now in cultivation." (*Perth Miscellany*, vol. I. p. 17.)

4864. *Grain, seeds, and roots intended for reproduction* are not required to have come to the same degree of maturity on the plant, as when intended for meal or other products to be consumed as food. The cause of this has never been satisfactorily explained; all that is alleged being the conjecture, that the cotyledons of the seed are better fitted for entering the vessels of the minute plant, when they are not of such a farinaceous nature, as when these cotyledons are more mature. "That grain not perfectly matured is fully qualified for seed, is evident from places situated near rivers or lakes, where the grain in some seasons is subject to be what the people who cultivate such situations term *blasted* or *mildew'd*. This happens in autumn, before the grain is matured, and is probably caused by fogs or damps which arise from the water. This *blast* discolours the straw, and renders it so friable that it will hardly bind itself; the grain never receives any more nourishment, is shrivell'd and light, and soon assumes a ripe appearance, and so small a quantity of farinaceous matter will be contained in the grains, that a sheaf, after being reaped, will feel as light in the hand as if it had been previously threshed; and yet, for as bad as it appears, it is commonly taken for seed, and never fails to give a luxuriant crop, provided it escape the following autumn." (*Ibid.*)

4865. *Of the plants* which the farmer has to choose for stock, the chief is the potato; and every one knows that no circumstances in the soil, climate, or culture will compensate for planting a bad sort. The potato requires a climate rather humid than otherwise, and rather moderate and equable in temperature than hot: hence the best crops are found in Lancashire, Dumfriesshire, and Ayrshire in Britain, and in Ireland, where the climate is every where moist. Excellently flavoured potatoes are also grown on mossy lands in most parts of the country. The prudent farmer will be particularly careful in choosing this description of plant stock, and also in changing it frequently, so as to ensure prolificacy and flavour. The general result of experience is decidedly in favour of unripe tubers for the purpose of propagation. A number of important papers on this subject will be found in the first and second volumes of the *Gardener's Magazine*, all confirmatory of the advantages of selecting tubers which are immature.

SECT. III. *Choice of Servants.*

4866. *On the moral and professional character of his servants* much of the comfort of the farmer depends; and every one who has farmed near large towns, and at a distance from them, knows how great the difference is in every description of labourers. The servants required in farmeries are, the bailiff or head ploughman, common ploughmen, shepherds, labourers of all-work, herdsmen, and women. Sometimes apprentices and pupils are taken; but their labour is not often to be much depended on.

4867. *A bailiff* is required only in the largest description of farms, occupied by a professional farmer; and is not often required to act as market-man. In general young men are preferred, who look forward to higher situations, as gentlemen's bailiffs or land stewards. Most farmers require only a head ploughman, who works the best pair of horses, and takes the lead of, and sets the example to, the other ploughmen in every description of work.

4868. *Ploughmen* should, if possible, be yearly servants, and reside upon the farm; if married, cottages should be provided for them. Weekly or occasional ploughmen are found comparatively unsteady; they are continually wandering from one master to another, and are very precarious supports of a tillage farm: for they may quit their service at the most inconvenient time, unless bribed by higher wages; and the farmer may thus lose the benefit of the finest part of the season. Where ploughmen and day labourers, however, are married, they are more to be depended upon than unmarried domestic servants, more especially when the labourer has a family, which ties him down to regular industry.

4869. *The mode of hiring servants* at what are called public statutes, so general in many parts of England, is justly reprobated as having a tendency to vitiate their minds, enabling them to get places without reference to character, exposing good servants to be corrupted by the bad, promoting dissipation, and causing a cessation of country business for some days, and an awkwardness in it for some time afterwards. When hiring servants, it would be extremely important, if possible, to get rid of any injurious perquisites, which are often prejudicial to the interests of the master, without being of any advantage to the servant. For instance, in Yorkshire and in other districts it is a custom to give farm servants liquor both morning and evening, whatever is the nature and urgency of the work. Nothing can be more absurd than permitting a ploughman to stop for half an hour in a winter day to drink ale, while his horses are neglected and shivering with cold.

4870. *The following plan of maintaining the hinds or ploughmen in the best cultivated districts in Scotland*, is found by experience to be greatly superior to any other mode hitherto adopted.

4871. *Proper houses* are built for the farm servants contiguous to every farmstead. This gives them an opportunity of settling in life, and greatly tends to promote their future welfare. Thus also the farmer has his people at all times within reach for carrying on his business.

4872. *The farm servants*, when married, receive the greater part of their wages in the produce of the soil, which gives them an interest in the prosperity of the concern in which they are employed, and in a manner obliges them to eat and drink comfortably; while young men often starve themselves in order to save money for drinking or clothes, in either of which cases they are deficient in the requisite animal strength. At least under this mode of payment they are certain of being supplied with the necessaries of life, and a rise of prices does not affect them; whereas, when their wages are paid in money, they are exposed to many temptations of spending it which their circumstances can ill afford, and during a rise of prices they are sometimes reduced to considerable difficulties. From the adoption of an opposite system, habits of sobriety and economy, so conspicuous among the farm servants of Scotland, and the advantages of which cannot be too highly appreciated, have arisen and still prevail in these districts.

4873. A most important branch of this system is, that *almost every married man has a cow* of a moderate size kept for him by the farmer all the year round. This is a boon of great utility to his family. The prospect of enjoying this advantage has an excellent effect upon the morals of young unmarried servants, who in general make it a point to lay up as much of their yearly wages as will enable them to purchase a cow and furniture for a house when they enter into the married state. These savings, under different circumstances, would most probably have been spent in dissipation.

4874. *They have also several other perquisites*, as a piece of ground for potatoes and flax (about one-eighth part of an acre for each); liberty to keep a pig, half a dozen hens, and bees; their fuel is carried home to them; they receive a small allowance in money per journey when sent from home with corn, or for coals or lime; and during the harvest they are maintained by the farmer, that they may be always at hand.

4875. *There are nowhere to be met with more active, respectable, and conscientious servants than those who are kept according to this system.* There is hardly an instance of their soliciting relief from the public. They rear numerous families, who are trained to industry and knowledge in the operations of agriculture, and whose assistance in weeding the crops, &c. is of considerable service to the farmer. They become attached to the farm, take an interest in its prosperity, and seldom think of removing from it. Under this system every great farm is a species of little colony, of which the farmer is the resident governor. Nor, on the whole, can there be a more gratifying spectacle than to see a large estate under the direction of an intelligent landlord, or of an agent competent to the task of managing it to advantage; where the farms are of a proper size; where they are occupied by industrious and skilful tenants, anxious to promote, in consequence of the leases they enjoy, the improvement of the land in their possession; and where the cultivation is carried on by a number of married servants enjoying a fair competence and rearing large families, sufficient not only to replace themselves, but also, from their surplus population, to supply the demand and even the waste of the other industrious classes of the community. Such a system, there is reason to believe, is brought to a higher degree of perfection and carried to a greater extent in the more improved districts of Scotland than perhaps in any other country in Europe. (*Code, &c.*)

4876. *A shepherd is of course only requisite on sheep farms; and no description of farm servant is required to be so steady and attentive.* At the lambing season much of the farmer's property is in his hands, and depends on his unwearied exertions early and late. Such servants should be well paid and comfortably treated.

4877. *The labourers required on a farm are few; in general, one for field operations, as hedge and ditch work, roads, the garden, cleaning out furrows, &c.; and another for attending to the cattle, pigs, and straw-yard, killing sheep and pigs when required, &c. will be sufficient.* Both will assist in harvest, hay-time, threshing, filling dung, &c. These men are much better servants when married and hired by the year, than when accidental day labourers.

4878. *The female servants required in a farmery are casual, as haymakers, turnip hoers, &c.; or yearly, as house, dairy, and poultry maids.* Much depends on the steadiness of the first class; and it is in general better to select them from the families of the married servants, by which means their conduct and conversation is observable by their parents and relations. A skilful dairy-maid is a most valuable servant, and it is well when the cattle-keeper is her husband; both may live in the farmer's house (provided they have no children), and the man may act as groom to the master's horse and chaise, and assist in brewing, butchery, &c. In the cheese districts, men often milk the cows, and manage the whole process of the dairy; but females are surely much better calculated for a business of so domestic a nature, and where so much depends on cleanliness.

4879. *Farmer's apprentices are not common, but parish boys are so disposed of in some parts of the west of England, and might be so generally.* They are said to make the best and steadiest servants; and indeed the remaining in one situation, and under one good master for a fixed period, say not less than three years, must have a great tendency to fix the character and morals of youth in every line or condition of life.

4880. *Apprentices intended for farmers are generally young men who have received a tolerable education beforehand, and have attained to manhood or nearly so.* These pay a premium, and are regularly instructed in the operations of farming. We have already alluded to the example of Walker, who considers such apprentices, notwithstanding the care required to instruct them, rather useful than otherwise. (*Husb. of Scot. vol. ii. p. 106.*)

4881. *To train ploughmen to habits of activity and diligence is of great importance.* In some districts they are proverbial for the slowness of their step, which they teach their horses; whereas these animals, if accustomed to it, would move with as much ease to themselves in a quick as in a slow pace. Hence their ploughs seldom go above two miles in an hour, and sometimes even less; whereas, where the soil is light and sandy, they might go at the rate of three miles and a half. Farmers are greater sufferers than they imagine by this habitual indolence of their workmen, which extends from the plough to all their other employments, for it makes a very important difference in the expense of labour. (*Code.*)

CHAP. IV.

General Management of a Farm.

4882. *The importance of an orderly systematic mode of managing every concern is sufficiently obvious.* The points which chiefly demand a farmer's attention are the accounts of money transactions, the management of servants, and the regulation of labours.

SECT. I. *Keeping Accounts.*

4883. *It is a maxim of the Dutch, that "no one is ever ruined who keeps good accounts," which are said in The Code of Agriculture to be not so common among farmers as they ought to be; persons employed in other professions being generally much more attentive and correct.* Among gentlemen farmers there is often a systematic regularity in all their proceedings, and their pages of debtor and creditor, of expense and profit, are as strictly kept as those of any banking-house in the metropolis. But with the generality of farmers the case is widely different. It rarely happens that books are kept by

4896. *These forms may be useful, by directing the attention of farmers to the particulars of which they should keep an accurate record ; but as to any particular system of accounts applicable to farmers a good deal of delusion seems to prevail, as if the established modes in general use among mercantile men would not answer. In fact, there is no correct mode of keeping accounts but by the principles of double entry.*

4897. *The account books for a common farmer may be, a cash-book for all receipts and payments, specifying each ; a ledger for accounts with dealers and tradesmen ; and a stock book for taking, once a year, an inventory and valuation of stock, crop, manures, tillages, and every thing that a tenant could dispose of or be paid for on quitting his farm. Farming may be carried on with the greatest accuracy and safety, as to money matters, by means of the above books, and a few pocket memorandum books for labourers' time, jobs, &c. With the exception of a time-book, such as we have before described (3383), we should never require more, even from a proprietor's bailiff ; many of whom the nine forms just given (4887) would only puzzle, and some we have known them lead to the greatest errors and confusion. Munro's Guide to Farm Book-keeping (Edin. 12mo. 1821) may be recommended to the practical farmer ; but no form of books, or mode of procedure will enable a farmer to know whether he is losing or gaining but that of taking stock.*

4898. *A form for a cattle stock account has been recommended by Sir Patrick Murray, of which it may be useful to present a specimen. This form, Sir Patrick observes, has been kept at his estate of Ochtertyre, in Perthshire, for twenty-two years, and found perfectly adapted to the purpose in view ; being sufficiently simple in form to be understood by every farm manager, and sufficiently comprehensive in particulars to embrace all the requisite details. They may be either made up quarterly, half-yearly, or yearly. Sir Patrick adopts the half-yearly mode.*

SECT. II. *Management of Servants.*

4900. *In former times, farm servants lived at the same table with their masters, and that is still the practice in those districts where the farms are small. On moderate-sized, and on large farms, they are usually sent to a separate table; but of late a custom has been introduced of putting them on board-wages. This is a most pernicious practice; which often leads them to the ale-house, corrupts their morals, and injures their health. It is a better plan, with a view of lessening trouble, to board them with the bailiff; but it is still more desirable for the farmer to have them under his own eye, that he may attend to their moral conduct. He will find much more useful assistance from the decent and the orderly than from the idle and the profligate.*

4901. *The best mode of managing yearly married servants, whether ploughmen or labourers, we conceive to be that already referred to (4870) as practised in Northumberland, and other northern counties. Marshal (Review of Bailey's Northumberland) calls it a remain of feudal times; but certainly, if it be so, it appears one of those remains which should be carefully preserved. We may challenge the empire to produce servants and farm operations equal to those where this system is adopted. The great excellence of the system consists on its being founded in the comfort of the servant.*

4902. *The permanent labourers on a farm ought to be treated in the same manner as the ploughmen; and indeed it is much to be wished, for the sake both of humanity and morality, that all married labourers, who live in the country, should have gardens attached to their cottages, if not a cow kept, and a pig and fowls, in the manner of the Scottish ploughmen. Some valuable observations on this subject will be found in *The Husbandry of Scotland*.*

4903. *Temporary labourers, or such as are engaged for hay-making, reaping, turnip-hoeing, &c. are for the most part beyond the control of the farmer, as to their living and lodging. It is a good practice, however, where hay-making and reaping are performed by the day, to feed the operators, and to lodge on the premises such of them as have not homes in the neighbourhood; providing them with a dry loft and warm blankets. Piece or job-work, however, is now becoming so very general, in all farm operations performed by occasional labourers, that attention to these particulars becomes unnecessary, and the farmer's chief business is to see that the work be properly done.*

4904. *A day's work of a country labourer, is ten hours during the spring, summer, and autumn quarters. Farmers, however, are not at all uniform in their hours of working during these periods. Some begin at five o'clock, rest three hours at mid-day, during the more violent heat of the sun, and fill up their day's work by beginning again at one o'clock, and ending at six in the evening. Others begin at six, and end at six, allowing half an hour at breakfast, and an hour at dinner. But although these are the ordinary hours, both for servants and labourers, during the more busy seasons of the year, yet neither of them will scruple to work either sooner or later, when occasion requires. In regard to the winter months, the hours of labour are from the dawn of morning, as long as it is light, with the allowance of about half an hour at mid-day for dinner.*

4905. *That the rate of labour must in a great measure depend upon the price of grain, is a general principle. In England, the value of a peck of wheat, and in Scotland, of a peck of oatmeal (being the principal articles of subsistence of the lower orders of the people in the two countries), were long accounted an equivalent to the daily pay of a labourer. In both countries, however, the price of potatoes has, of late years, had a considerable influence on the rate of labour; and in England, the effects of the poor laws have tended to keep down that rate below the increased price of provisions, and thus have deranged the natural progress of things. It has been ascertained, that a man, his wife, and from two to three children, if wheat is their habitual food, will require ten gallons weekly. When they live on bread, hard-working people ought to have the best kind, as that will furnish the most nutrition. How, then, could a labourer and his family exist upon wages of from 6s. to 9s. per week, when wheat is from 8s. to 10s. or 12s. per bushel? The difference is compensated by the poor-rates, a most exceptionable mode of making up the deficiency; for labour would otherwise have found its own level, and the labourer would have obtained the price of a bushel and a half of wheat weekly.*

4906. *In Scotland, the rate of labour has increased beyond the price of provisions. Prior to 1792, the average price of a peck of oatmeal was 1s. 1d., and the average price of a day's labour in summer 1s. 1½d., which nearly corresponded with the principle above stated: but the average price of a peck of oatmeal in 1810 was 1s. 3½d., whilst the average price of a day's labour was 1s. 10½d.; which shows, in a most satisfactory manner, the very great improvement that has taken place in the lot of the labouring classes in that part of the United Kingdom. (Gen. Rep. vol. iii. p. 262.)*

4907. *The practice of giving labourers grain, &c. at a cheap rate was adopted by George III., who carried on farming operations to a considerable extent, allowing his labourers flour at a fixed price, whatever wheat might sell for. This benevolent system has been practised by several gentlemen farmers, some of whom have allowed bread, and others a daily quantity of milk, at moderate prices. The same system is general in several of the western counties, as in Dorset, Devon, and Cornwall, where the labourers have a standing supply of bread-corn; of wheat at 6s. and of barley at 3s. per bushel. In some of the midland*

counties the day-wages are regulated by the price of the best wheaten bread : thus the price of a half-peck loaf forms the day-wages for out-of-door farm servants. Of late years this rule has been departed from in favour of the labourers : thus, when bread is at 1s. 8d. the half-peck, then wages are 1s. 10d. ; and when at 2s., the wages are 2s. 4d.

4908. *Most descriptions of country labour*, performed without the aid of horses, may be let by the job. Farey, in his excellent *Report of Derbyshire*, informs us, that besides all ordinary labour, the late John Billingsley, of Ashwick Grove, in Somersetshire, let his ploughing, harrowing, rolling, sowing, turning of corn when cut, hay-making, &c. by the acre ; from which he found great advantages, even where his own oxen and horses were used by the takers of the work. Whether we regard despatch, economy, perfection of rural works, or the bettering of the condition of the labourers therein, nothing will contribute so much to all these as a general system of letting works at fair and truly apportioned prices, according to the degree of labour and skill required in each kind of work. Few persons have doubted that despatch and economy are attainable by this method ; but those who have indolently or improperly gone about the letting of their labour, have uniformly complained of its being slovenly done, and of the proneness of the men to cheat when so employed. Such frauds are to be expected in all modes of employment, and can only be counteracted, or made to disappear, by competent knowledge and due vigilance in the employer, or his agents and foremen, who ought to study and understand the time and degree of exertion and skill, as well as the best methods, in all their minutiae, of performing the various works they have to let. At first sight these might seem to be very difficult and unattainable qualifications in farmers' bailiffs or foremen, but it is nevertheless certain, that a proper system and perseverance will soon overcome these difficulties. One of the first requisites is, the keeping of accurate and methodical day-accounts of all men employed ; and, on the measuring up and calculating of every job of work, to register how much has been earned per day, and never to attempt abatement of the amount, should this even greatly exceed the ordinary day's pay of the country ; but let this experience gained operate in fixing the price of the next job of the same work, in order to lessen the earnings by degrees, of fully competent and industrious men, to $1\frac{3}{4}$ or $1\frac{1}{2}$ times the ordinary wages when working by the day.

4909. *Form the men into small gangs*, according to their abilities and industry, and always set the best gang about any new kind of work, or one whose prices want regulating : encourage these by liberal prices at first, gradually lowering them ; and by degrees introduce the other gangs to work with or near them at the same kind of work. On the discovery of any material slight of or deceptions in the work, at the time of measuring it, more than their proportionate values should be deducted for them, and a separate job made to one of the best gangs of men, for completing or altering it : by which means shame is made to operate, with loss of earnings, in favour of greater skill, attention, and honesty in future. When the necessity occurs of employing even the best men by the day, let the periods be as short as possible, and the prices considerably below job earnings ; and contrive, by the offer of a desirable job to follow, to make it their interest and wish to despatch the work that is necessary to be done by the day, in order to get again to piece-work. The men being thus induced to study and contrive the readiest and best methods of performing every part of their labour, and of expending their time, the work will unquestionably be better done than by the thoughtless drones who usually work by the day. And that these are the true methods of bettering the condition of the labourers, Malthus has ably shown in theory ; and all those who have adopted and persevered in them have seen the same in practice. (*Farey's Derbyshire*, vol. iii. 192.)

SECT. III. *Arrangement of Farm Labour.*

4910. *The importance of order and system* we have already insisted on (3370), and the subject can hardly be too often repeated. To conduct an extensive farm well is not a matter of trivial moment, or one to the management of which every man is competent. Much may be effected by capital, skill, and industry ; but even these will not always ensure success without judicious arrangement. With it, a farm furnishes an uninterrupted succession of useful labour during all the seasons of the year ; and the most is made that circumstances will admit of, by regularly employing the labouring persons and cattle, at such works as are likely to be the most profitable. Under such a system it is hardly to be credited how little time is lost, either of the men or horses, in the course of a whole year. This is a great object ; for each horse may be estimated at three shillings per day, and each man at two shillings. Every day, therefore, in which a man and horse are unemployed occasions the loss of at least five shillings to the husbandman.

4911. *As the foundation of a proper arrangement*, it is necessary to have a plan of the farm, or at least a list of the fields or parcels of land into which it is divided, describing their productive extent, the quality of the soil, the preceding crops, the cultivation given to each, and the species and quantity of manure they have severally received. The future treatment of each field, for a succession of years, may then be resolved on with more probability of success. With the assistance of such a statement, every autumn an arrangement of crops for the ensuing year ought to be made out ; classing the fields or pieces of land, according to the purposes for which they are respectively intended. The number of acres allotted for arable land, meadow, or pasture, will thus be ascertained. It will not then be difficult to discover what number of horses and labourers will be

required during the season for the fields in culture, nor the live stock that will be necessary for the pasture land. The works of summer and harvest will likewise be foreseen, and proper hands engaged in due time to perform them.

4912. *A farmer should have constantly in view a judicious rotation of crops, according to the nature and quality of his soil, and should arrange the quantity and succession of labour accordingly.* Team labour, when frost and bad weather do not intervene, should be arranged for some months; and hand labour, for some weeks, according to the season of the year. "A general memorandum list of business to be done," may therefore be useful, that nothing may escape the memory, and that the most requisite work may be brought forward first, if suitable to the state of the weather. In this way the labour will go on regularly, and without confusion; while, by a proper attention, either a distribution of labour, or an occasional consolidation of it, may be applied to every part of the farm.

4913. *As general rules, connected with the arrangement, and the successful management of a farm, the following are particularly to be recommended:—*

4914. *The farmer ought to rise early, and see that others do so.* In the winter season breakfast should be taken by candle-light, for by this means an hour is gained which many farmers indolently lose; though six hours in a week are nearly equal to the working part of a winter day. This is a material object, where a number of servants are employed. It is also particularly necessary for farmers to insist on the punctual performance of their orders.

4915. *The whole farm should be regularly inspected, and not only every field examined, but every beast seen, at least once a day, either by the occupier, or by some intelligent servant.*

4916. In a considerable farm, it is of the utmost consequence to have *servants specially appropriated for each of the most important departments of labour; for there is often a great loss of time, where persons are frequently changing their employments.* Besides, where the division of labour is introduced, work is executed not only more expeditiously, but also much better, in consequence of the same hands being constantly employed in one particular department. For that purpose, the ploughmen ought never to be employed in manual labour, but regularly kept at work with their horses, when the weather will admit of it.

4917. *To arrange the operation of ploughing, according to the soils cultivated, is an object of essential importance.* On many farms there are fields which are soon rendered unfit to be ploughed, either by much rain or by severe drought. In such cases, the prudent farmer, before the wet season commences, should plough such land as in the greatest danger of being injured by too much wet; and before the dry period of the year sets in, he should till such land as in the greatest danger of being rendered unfit for ploughing by too much drought. The season between seed-time and winter may be well occupied in working soils intended to be sown with beans, oats, barley, and other spring crops. On farms where these rules are attended to there is always some land in a proper condition to be ploughed, or to be worked by the improved harrows or grubbers; and there is never any necessity either for delaying the work, or performing it improperly.

4918. *Every means should be thought of to diminish labour, or to increase its power.* For instance, by proper arrangement, five horses may do as much labour as six perform, according to the usual mode of employing them. One horse may be employed in carting turnips during winter, or in other necessary farm-work at other seasons, without the necessity of reducing the number of ploughs. When driving dung from the farm-yard, three carts may be used, one always filling in the yard, another going to the field, and a third returning; the leading horse of the empty cart ought then to be unyoked, and put to the full one. In the same manner, while one pair of horses are preparing the land for sowing turnips, the other three horses may be employed in carrying the dung to the land, either with two or three carts, as the situation of the ground may happen to require. By extending the same management to other farm operations, a considerable saving of labour may be effected.

4919. *Previously to engaging in a work, whether of ordinary practice, or of intended improvement, the best consideration of which the farmer is capable ought to be given to it, till he is satisfied that it is advisable for him to attempt it.* When begun, he ought to proceed in it with much attention and perseverance, until he has given it a fair trial. It is a main object, in carrying on improvements, not to attempt too much at once; and never to begin a work without a probability of being able to finish it in due season.

4920. *By the adoption of these rules, every farmer will be master of his time, so that every thing required to be done will be performed at the proper moment, and not delayed till the season and opportunity have been lost.* The impediments arising from bad weather, sick servants, or the occasional and necessary absence of the master, will, in that case, be of little consequence, nor will they embarrass the operations to be carried on; and the occupier will not be prevented from attending to even the smallest concerns connected with his business, on the aggregate of which his prosperity depends.

SECT. IV. Domestic Management and personal Expenses.

4921. *On domestic affairs a hint may suffice.* Young farmers beginning house-keeping, like most others in similar circumstances, are apt to sink too great a proportion of their capital in furniture, and furnishing riding-horses, carriages, &c.; and sometimes to live up to, or even beyond, their income. We do not mean that farmers should not live as well as other men of the same property; but merely that all beginners should live within their income. Even in the marketing expenses care is requisite; and the prudent farmer will do well, every penny or sixpence he lays out, to reckon up in his mind what that sum per day would amount to in a year. The amount will often astonish him, and lead to economy and, where practicable, retrenchment. Saving, as Franklin has inculcated, is the only certain way of accumulating money.

4922. *In regard to housekeeping, it is observed in The Code of Agriculture, that the safest plan is, not to suffer it to exceed a certain sum for bought articles weekly.* An annual sum should be allotted for clothing, and the personal expenses of the farmer, his

wife and children, which ought not to be exceeded. The whole allotted expense should be considerably within the probable receipts; and, if possible, one eighth of the income annually received should be laid up for contingencies, or expended in extra improvements on the farm.

BOOK VI.

CULTURE OF FARM LANDS.

4923. *The business of farming* consists of the culture of vegetables, and the treatment or culture of animals; in practice these are generally carried on together, but may be more conveniently treated of apart. In this Book, therefore, we confine ourselves to the culture of vegetable, and shall consider in succession the general processes of culture; the culture of corn and pulse; of roots and leaves; of herbage plants; of grasses; and of manufactorial plants.

CHAP. I.

General Processes common to Farm Lands.

4924. *Among general processes*, those which merit particular notice in this place are, the rotation of crops, the working of fallows, and the management of manures. The theory of these processes has been already given in treating of soils and manures (PART II. BOOK III.); and it therefore only remains to detail their application to practice under different circumstances.

SECT. I. *Rotation of Crops suitable to different Descriptions of Soils.*

4925. *The proper distribution of crops, and a plan for their succession*, is one of the first subjects to which a farmer newly entered on a farm requires to direct his attention. The kind of crops to be raised are determined in a great measure by the climate, soil, and demand, and the quantity of each by the value, demand, and the adjustment of farm labour.

4926. *In the adjustment of farm labour*, the great art is to divide it as equally as possible throughout the year. Thus it would not answer in any situation to sow exclusively autumn crops, as wheat or rye; nor only spring crops, as oats or barley; for by so doing all the labour of seed-time would come on at once, and the same of harvest work, while the rest of the year there would be little to do on the farm. But by sowing a portion of each of these and other crops, the labour both of seed-time and harvest is divided and rendered easier, and is more likely to be done well and in season. But this point is so obvious as not to require elucidation.

4927. *The succession or rotation of crops* is a point on which the profits of the farmer depend more than on any other. It is remarked by Arthur Young, that agricultural writers, previously to the middle of the eighteenth century, paid little or no attention to it. They recite, he says, courses good, bad, and execrable in the same tone, as matters not open to praise or censure, and unconnected with any principles that could throw light on the arrangement of fields. The first writer who assigned due importance to the subject of rotations seems to have been the Rev. Adam Dickson, in his *Treatise on Agriculture*, published in Edinburgh in 1777; and soon afterwards Lord Kaimes, in his *Gentleman Farmer*, illustrates the importance of the subject: both writers were probably led to it by observing the effects of the Norfolk husbandry, then beginning to be introduced to Berwickshire. But whatever may have been the little attention paid to this subject by former writers, the importance of the subject of rotations, and the rule founded on the principles already laid down, that culmiferous crops ripening their seeds should not be repeated without the intervention of pulse, roots, herbage, or fallow, is now "recognised in the practice and writings of all judicious cultivators, more generally perhaps than any other." (*Edit. of Farmer's Mag.*)

4928. *The system of rotations* is adapted for every soil, though no particular rotation can be given for any one soil which will answer in all cases; as something depends on climate, and something also on the kind of produce for which there is the greatest market demand. But wherever the system of rotations is followed, and the several processes of labour which belong to it properly executed, land will rarely get into a foul and exhausted state, or at least, if foul and exhausted under a judicious rotation, "matters would be much worse were any other system followed."

4929. *The particular crops* which enter into a system of rotation must obviously be such as are suited to the soil and climate, though, as the experienced author so often quoted observes, "they will be somewhat varied by local circumstances, such as the proximity of towns and villages, where there is a greater demand for turnips, potatoes, hay, &c. than in thinly peopled districts. In general, beans and clover, with rye-grass, are interposed between corn crops on clayey soils; and turnips, potatoes, and clover with rye-grass on dry loams and sands, or what are technically known by the name of turnip soils. A variety of

other plants, such as peas, tares, cabbages, and carrots, occupy a part, though commonly but a small part, of that division of a farm which is allotted to green crops. This order of succession is called the system of *alternate husbandry*; and on rich soils, or such as have access to abundance of putrescent manure, it is certainly the most productive of all others, both for food for man and for the inferior animals. One half of a farm is in this course always under some of the different species of cereal grasses, and the other half under pulse, roots, cultivated herbage, or plain fallow.

4930. *But the greater part of the arable land of Britain* cannot be maintained in a fertile state under this management; and sandy soils, even though highly manured, soon become too incohesive under a course of constant tillage. It therefore becomes necessary to leave that division or *break* that carries cultivated herbage to be pastured for two years or more, according to the degree of its consistency and fertility; and all the fields of a farm are treated thus in their turn if they require it. This is called the system of *convertible husbandry*, a regular change being constantly going on from aration to pasturage, and *vice versa*.

4931. *Not to repeat the same kind of crop at too short intervals*, is another rule with regard to the succession of crops. Whatever may be the cause, whether it is to be sought for in the nature of the soil or of the plants themselves, experience clearly proves the advantages of introducing a diversity of species into every course of cropping. When land is pastured several years before it is brought again under the plough, there may be less need for adhering steadily to this rule; but the degeneracy of wheat and other corn crops recurring upon the same land every second year for a long period, has been very generally acknowledged. It is the same with what are called green crops; beans and peas, potatoes, turnips, and in an especial manner red clover, become all of them much less productive, and much more liable to disease, when they come into the course, upon the same land, every second, third, or fourth year. But what the interval ought to be has not yet been ascertained, and, from the great number of years that experiments must be continued to give any certain result, probably cannot be determined until the component parts of soils, and particularly the sort of vegetable nourishment which each species of plant extracts from the soil, have been more fully investigated.

4932. *A change of variety* as well as of the species, and even of the plants of the same variety, is found to be attended with advantage; and in the latter case, or a change of seed, the species and variety being the same, the practice is almost universal. It is well known, that of two parcels of wheat, for instance, as much alike in quality as possible, the one which had grown on a soil differing much from that on which it is to be sown, will yield a better produce than the other that grew in the same or a similar soil and climate. The farmers of Scotland accordingly find that wheat from the south, even though it be not, as it usually is, better than their own, is a very advantageous change; and oats and other grain brought from a clayey to a sandy soil, other things being equal, are more productive than such as have grown on sandy soil. (*Supp. Encyc. Brit. art. Agr. 144.*)

4933. *The following are examples of rotations suited to different soils*, as given in Brown's excellent *Treatise on Rural Affairs*. The basis of every rotation, he says, "we hold to be either a bare summer fallow, or a fallow on which drilled turnips are cultivated, and its conclusion to be with the crops taken in the year preceding a return of fallow or drilled turnips, when of course a new rotation commences.

4934. *Rotation for strong deep lands*. According to this rotation, wheat and drilled beans are the crops to be cultivated, though clover and rye-grass may be taken for one year in place of beans, should such a variety be viewed as more eligible. The rotation begins with summer fallow, because it is only on strong deep lands that it can be profitably practised; and it may go on for any length of time, or so long as the land can be kept clean, though it ought to stop the moment that the land gets into a contrary condition. A considerable quantity of manure is required to go on successfully; perhaps dung should be given to each bean crop; and if this crop is drilled and attentively horse-hoed, the rotation may turn out to be one of the most profitable that can be exercised.

4935. *Rotation for loams and clays*. Where it may not be advisable to carry the first rotation into execution, a different one can be practised, according to which labour will be more divided, and the usual grains more generally cultivated; for instance, the following, which used to be common in East Lothian:—

- | | | |
|-----------------------------------|--------------------------|----------------------------------|
| 1. Fallow, with dung. | 4. Barley. | 7. Beans drilled and horse-hoed. |
| 2. Wheat. | 5. Clover and rye-grass. | 8. Wheat. |
| 3. Beans, drilled and horse-hoed. | 6. Oats or wheat. | |

This rotation is excellently calculated to insure an abundant return through the whole of it, provided dung is bestowed upon the clover stubble. Without this supply the rotation would be crippled, and inferior crops of course produced in the concluding years.

4936. *Rotation for clays and loams of an inferior description*. This rotation is calculated for soils of an inferior description to those already treated of.

- | | | |
|-----------------------|--------------------------|-----------------------------------|
| 1. Fallow, with dung. | 3. Clover and rye-grass. | 5. Beans, drilled and horse-hoed. |
| 2. Wheat. | 4. Oats. | 6. Wheat. |

According to this rotation, also in use in East Lothian, the rules of good husbandry are studiously practised; while the sequence is obviously calculated to keep the land in good order, and in such a condition as to ensure crops of the greatest value. If manure is bestowed either upon the clover-stubble or before the beans are sown, the rotation is one of the best that can be devised for the soils mentioned.

4937. *Rotation for thin clays*. On thin clays gentle husbandry is indispensably necessary, otherwise the soil may be exhausted, and the produce unequal to the expense of cultivation. Soils of this description will not improve much while under grass; but unless an additional stock of manure can be procured, there is a necessity of refreshing them in that way, even though the produce should in the mean time be comparatively of small value. The following rotation is not an improper one:—

- | | | |
|-----------------------|---|-----------|
| 1. Fallow, with dung. | 3. Grass pastured, but not too early eaten. | 5. Grass. |
| 2. Wheat. | 4. Grass. | 6. Oats. |

This rotation may be shortened or lengthened, according to circumstances, but should never extend further in point of ploughing than when dung can be given to the fallow-break. This is the keystone of the whole; and if neglected the rotation is rendered useless.

4938. *Rotation for peat earth soils*. These are not friendly to wheat, unless aided by a quantity of calcareous matter. Taking them in a general point of view, it is not advisable to cultivate wheat, but a crop of oats may almost be depended upon, provided the previous management has been judiciously executed. If the subsoil of peat earth lands is retentive of moisture, the process ought to commence with a bare summer fallow; but if such are incumbent on free and open bottoms, a crop of turnips may be substituted for fallow; according to which method, the surface will get a body which naturally it did not possess. Grass on such soils must always occupy a great space of every rotation, because physical circumstances render regular cropping utterly impracticable.

- | | | |
|----------------------------------|------------------------------------|--|
| 1. Fallow, or turnips with dung. | quantity of perennial rye-grass. | circumstances permit the land to be broken up, when oats are to be repeated. |
| 2. Oats of an early variety. | | |
| 3. Clover, and a considerable | 4. Pasture for several years, till | |

4939. *Rotation for light soils.* These are easily managed, though to procure a full return of the profit which they are capable of yielding, requires generally as much attention as is necessary in the management of those of a stronger description. Upon light soils, a bare summer fallow is seldom called for, as cleanliness may be preserved by growing turnips, and other leguminous articles. Grass also is of eminent advantage upon such soils, often yielding a greater profit than what is afforded by culmiferous crops.

- | | |
|-----------------------------|--------------------------|
| 1. Turnips. | 3. Clover and rye-grass. |
| 2. Spring wheat, or barley. | 4. Oats or wheat. |

This is a fashionable rotation; but it may be doubted whether a continuance of it for any considerable period is advisable, because both turnips and clover are found to fall off when repeated so often as once in four years. Common red clover will not grow every four years, unless gypsum be restored to the land. Perhaps the rotation would be greatly improved were it extended to eight years, whilst the ground, by such an extension, would be kept fresh and constantly in good condition. As, for instance, were seeds for pasture sown in the second year, the ground kept three years under grass, broke up for oats in the sixth year, drilled with beans and peas in the seventh, and sown with wheat in the eighth; the rotation would then be complete, because it included every branch of husbandry, and admitted a variety in management generally agreeable to the soil, and always favourable to the interest of cultivators. The rotation may also consist of six crops, were the land kept only one year in grass, though few situations admit of so much cropping, unless additional manure is within reach.

4940. *Rotation for sandy soils.* These, when properly manured, are well adapted to turnips, though it rarely happens that wheat can be cultivated on them with advantage, unless they are dressed with alluvial compost, marl, clay, or some such substances as will give a body or strength to them, which they do not naturally possess. Barley, oats, and rye, the latter especially, are, however, sure crops on sands, and in favourable seasons will return greater profit than can be obtained from wheat.

- | | |
|---|--------------------------|
| 1. Turnips well manured consumed on the ground. | 3. Clover and rye-grass. |
| 2. Barley sown with clover and rye-grass. | 4. Wheat, rye, or oats. |

By keeping the land three years in grass, the rotation would be extended to six years, a measure highly advisable."

4941. *These examples* are sufficient to illustrate the subject of improved rotations; but as the best general schemes may be sometimes momentarily deviated from with advantage, the same able author adds, that "cross cropping, in some cases, may perhaps be justifiable in practice; as, for instance, we have seen wheat taken after oats with great success, when these oats had followed a clover crop on rich soil; but, after all, as a general measure, that mode of cropping cannot be recommended. We have heard of another rotation, which comes almost under the like predicament; though, as the test of experience has not yet been applied, a decisive opinion cannot be pronounced upon its merits. This rotation begins with a bare fallow, and is carried on with wheat, grass for one year or more, oats, and wheat, where it ends. Its supporters maintain that beans are an uncertain crop, and cultivated at great expense; and that in no other way will corn, in equal quantity and of equal value, be cultivated at so little expense as according to the plan mentioned. That the expense of cultivation is much lessened, we acknowledge, because no more than seven ploughings are given through the whole rotation; but whether the crops will be of equal value, and whether the ground will be preserved in equally good condition, are points which remain to be ascertained by experience." (*Brown on Rural Affairs.*)

4942. *As a general guide to devising rotations on clay soils,* it may be observed, that winter or autumn sown crops are to be preferred to such as are put in in spring. Spring ploughing on such soils is a hazardous business, and not to be practised where it can possibly be avoided. Except in the case of drilled beans, there is not the slightest necessity for ploughing clays in the spring months; but as land intended to carry beans ought to be early ploughed, so that the benefit of frost may be obtained, and as the seed furrow is an ebb one, rarely exceeding four inches in deepness, the hazard of spring ploughing for this article is not of much consequence. Ploughing with a view to clean soils of the description under consideration has little effect, unless given in the summer months. This renders summer fallow indispensably necessary; and without this radical process, none of the heavy and wet soils can be suitably managed, or preserved in a good condition.

4943. *To adopt a judicious rotation of cropping for every soil,* requires a degree of judgment in the farmer, which can only be gathered from observation and experience. The old rotations were calculated to wear out the soil, and to render it unproductive. To take wheat, barley, and oats in succession, a practice very common thirty years ago, was sufficient to impoverish the best of land, while it put little into the pockets of the farmer; but the modern rotations, such as those which we have described, are founded on principles which ensure a full return from the soil, without lessening its value, or impoverishing its condition. Much depends, however, upon the manner in which the different processes are executed; for the best arranged rotation may be of no avail, if the processes belonging to it are imperfectly and unseasonably executed. (See 2221.) The best farmers in the northern counties now avoid over-cropping or treating land in any way so as to exhaust its powers, as the greatest of all evils.

SECT. II. *The working of Fallows.*

4944. *The practice of fallowing,* as we have seen in our historical view of Greek and Roman agriculture, has existed from the earliest ages; and the theory of its beneficial

effects we have endeavoured to explain. (2175.) The Romans with their agriculture introduced fallows in every part of Europe; and two crops, succeeded either by a year's fallow, or by leaving the land to rest for two or more years, became the rotation on all soils and under all circumstances. This mode of cultivating arable land is still the most universal in Europe, and was prevalent in Britain till the middle of the last century; but as a crop was lost every year they occurred, a powerful aversion from naked fallows arose about that time, and called forth numerous attempts to show that they were unnecessary, and consequently an immense public loss. This anti-fallowing mania, as it has been called, was chiefly supported by Arthur Young, Nathaniel Kent, and others, members or correspondents of the Board of Agriculture: it was at its greatest height about the beginning of the present century, but has now spent its force; and after exhausting all the arguments on both sides, as an able author has observed, "the practice does not appear to give way, but rather to extend."

4945. *The expediency or in expediency of pulverising and cleaning the soil by a bare fallow*, is a question that can be determined only by experience, and not by argument. No reasons, however ingenious, for the omission of this practice, can bring conviction to the mind of a farmer, who, in spite of all his exertions, finds, at the end of six or eight years, that his land is full of weeds, sour, and comparatively unproductive. Drilled and horse-hoed green crops, though cultivated with advantage on almost every soil are probably in general unprofitable as a substitute for fallow, and after a time altogether inefficient. It is not because turnips, cabbages, &c. will not grow in such soils, that a fallow is resorted to, but because, taking a course of years, the value of the successive crops is found to be so much greater, even though an unproductive year is interposed, as to induce a preference to fallowing. Horse-hoed crops, of beans in particular, postpone the recurrence of fallow, but in few situations can ever exclude it altogether. On the other hand, the instances that have been adduced, of a profitable succession of crops on soils of this description, without the intervention of a fallow, are so well authenticated, that it would be extremely rash to assert that it can in no case be dispensed with on clay soils. Instances of this kind are to be found in several parts of Young's *Annals of Agriculture*; and a very notable one, on Greg's farm of Coles, in Hertfordshire, is accurately detailed in the sixth volume of *The Communications to the Board of Agriculture*.

4946. *The principal causes of this extraordinary difference among men of great experience*, may probably be found in the quality of the soil, or in the nature of the climate, or in both. Nothing is more vague than the names by which soils are known in different districts. Greg's farm, in particular, though the soil is denominated "heavy arable land," and "very heavy land," is found so suitable to turnips, that a sixth part of it is always under that crop, and these are consumed on the ground by sheep; a system of management which every farmer must know to be altogether impracticable on the wet tenacious clays of other districts. It may indeed be laid down as a criterion for determining the question, that wherever this management can be profitably adopted, fallow, as a regular branch of the course, must be not less absurd than it is injurious, both to the cultivator and to the public. It is probable, therefore, that, in debating this point, the opposite parties are not agreed about the quality of the soil; and, in particular, about its property of absorbing and retaining moisture, so different in soils that in common language have the same denomination.

4947. *Another cause of difference* must be found in the climate. It is well known that a great deal more rain falls on the west than on the east coast of Britain; and that between the northern and southern counties there is at least a month or six weeks' difference in the maturation of the crops. Though the soil, therefore, be as nearly as possible similar in quality and surface, the period in which it is accessible to agricultural operations must vary accordingly. Thus, in the south-eastern counties of the island, where the crops may be all cut down, and almost all carried home by the end of August, much may be done in cleansing and pulverising the soil, during the months of September and October, while the farmers of the north are exclusively employed in harvest work, which is frequently not finished by the beginning of November. In some districts in the south of England, wheat is rarely sown before December; whereas in the north, and still more in Scotland, if it cannot be got completed by the end of October, it must commonly be delayed till spring, or oats or barley be taken in place of wheat. It does not then seem of any utility to enter farther into this controversy, which every skillful cultivator must determine for himself. All the crops, and all the modes of management which have been proposed as substitutes for fallow, are well known to such men, and would unquestionably have been generally adopted long ago, if, upon a careful consideration of the advantages and disadvantages on both sides, a bare fallow was found to be unprofitable in a course of years. The reader who wishes to examine the question fully may consult, among many others, the following:—Young's *Annals of Agriculture*, and his writings generally; Hunter's *Georgical Essays*; Dickson's *Practical Agriculture*; Sir H. Davy's *Agricultural Chemistry*; *The Agricultural Chemistry* of Chaptal; Brown's *Treatise on Rural Affairs*; *The County Reports*; *The General Report of Scotland*, and the *Quarterly Journal of Agriculture*, vol. ii. p. 90.

4948. *The importance of naked fallows* has been ably pointed out by a writer in the work last referred to. "In order," he says, "to show more forcibly the difficulty of cleaning heavy lands for green crops, let us take a review of the time of the year in which these crops should be sown. In clay lands, beans must be sown in March at latest, and before that period of the year no one can pretend to clean land at all. Finding it impossible to use them as a fallow crop, they are sown without dung on that part of the rotation which is penultimate to bare fallow. On light lands, beans will not carry much straw without manure, and their utility as a crop in the rotation is, of course, thereby much decreased on such soils; and if they are to be sown as a fallow crop with dung on the land that is to be appropriated to fallow, they give much less time for the preparatory cleaning of the land than turnips, as they must be sown at latest in April. On all kinds of soil potatoes must be planted by April; and the same observations will, therefore, apply to them as to beans as a cleaner of the land. It is only from their great value as human food, and from their inability to grow without dung, that they are planted as a fallow crop; because it is impracticable to keep land clean, and much more so to make it clean, under a potato fallow. Thus there is difficulty in cleaning land, without summer fallow, with beans and potatoes on every kind of soil in any spring, however favourable; and it is quite impossible to do so in a wet one. There is also difficulty in cleaning strong clay land even by turnip-time in May; and

the greatest facility which a farmer possesses of cleaning his land or keeping it clean, under a green crop, is by a turnip one, on a light soil resting on an open bottom, in a dry season. This last instance amounts, in fact, to all the boasted possibility of keeping land clean by green crops, without the assistance of bare fallow. But even this substitution is only an approximation to cleanliness; for every one knows, who has farmed light soils for a series of rotations, whatever his practice may be, that even the turnip crop cannot be raised on them for an indefinite period without the land getting foul with root-weeds, such as quicks and knot grass; and no better mode of extirpating these formidable robbers of the artificial nourishment of the cultivated crops, than by bare fallowing, has yet been discovered. They are the rooks of the soil. Indeed, the practice of the best farmers of light land, however great their desire to curtail the extent of bare fallow may be, is to have a portion of the land under fallow, though the extent of it may no doubt be limited by the want of manure, from a desire to keep their land clean; and this is accomplished by summer fallowing that portion of it which had carried potatoes in the preceding rotation, and raising the potatoes and turnips on that part which had been previously thoroughly cleaned by summer fallowing. This is a good practice, not only as a means of keeping land clean, but as following out that system of alternate husbandry of white and green crops, which has, by abolishing a succession of white crops with their scouring effects, tended more than any other to render the soil of these islands all alike fertile. But will summer fallow keep land clean? Undoubtedly it will, if properly performed. It gives the opportunity of working land in June and July, when every crop should be in the ground, and when the sun is so powerful, and the atmosphere so warm and dry, as to kill every plant that has not a hold of the ground. The process already described, of ploughing, harrowing, and rolling, according to the state of the ground, is admirably adapted for cutting the matted land in pieces, for shaking the detached lumps of earth asunder, and for bruising to powder every hardened ball of earth into which the fibres or roots of weeds might penetrate; and the hand-picking carries off every bit of weed which might possess any latent vegetative power. Land that cannot be cleaned under such favourable circumstances as to season, must be excessively foul, the season very wet and cold, or the fallowing process conducted with great slovenliness. It must be confessed, that fallowing is too often worked very negligently. It is thought by some, that the land can be cleaned at any time before seed-time in autumn; and other things of less importance too often attract the attention from the more important fallow; that weeds, though they do grow, can be easily ploughed down, and that the ploughing of them down assists to manure the land. Such thoughts too often prevail over better knowledge; and they furnish a strong argument in favour of increasing, rather than of diminishing, the means of cleanliness. But such thoughts display, in their effects, great negligence and ignorance; negligence, in permitting any weeds to cover the land, particularly the root-growing ones, by which the strength of the soil is exhausted, and in losing the most favourable part of the season to accomplish their destruction; and ignorance, in thinking that weeds ploughed down afford nourishment to the soil, when that soil has been exhausting itself in bearing the crop of weeds. These are facts which are known to every practical farmer, and the nature of which presses upon him a conviction of the necessity of summer fallowing more strongly than all the arguments that can be most speciously drawn, by analogy, from the practice of other arts. Reasoning from analogy is feeble when opposed to experience. Gardeners, no doubt, raise crops every year from the same piece of ground; but their practice is not quite analogous to that of the husbandman. They apply a great quantity of manure to the soil, and they permit few or no plants to run to seed, the bringing of which to perfection, in the cereal crops, constitutes the great exhaustion to the soil. Gardeners, however, do something like fallowing their ground at stated periods, as every three or four years they dig the ground a double spit of the spade in depth, and lay it up in winter to the frost; and they reserve alternate pieces of ground for the sowing of late crops; all which practices approach nearly to our ideas of summer fallowing." (*Quar. Jour. Ag. vol. ii. p. 105.*)

4949. *Fallows unnecessary on friable soils.* However necessary the periodical recurrence of fallow may be on retentive clays, its warmest advocates do not recommend it on turnip soils, or on any friable loams incumbent on a porous subsoil; nor is it in any case necessary every third year, according to the practice of some districts. On the best cultivated lands it seldom returns oftener than once in six or eight years; and in favourable situations for obtaining an extra supply of manure, it may be advantageously dispensed with for a still longer period. (*Suppl. to Encyc. Brit. art. Agr.*)

4950. *The operation of fallowing*, as commonly practised in England, is, in usefulness and effect, very different from what it ought to be. In most places the first furrow is not given till the spring, or even till the month of May or June; or, if it is given earlier, the second is not given till after midsummer, and on the third the wheat is sown. Land may rest under this system of management; but to clean it from weeds, to pulverise it, or to give it the benefits of aëration and heat, is impossible. The farmer in some cases purposely delays ploughing his fallows, for the sake of the scanty bite the couch and weeds afford to his sheep; and for the same reason, having ploughed once, he delays the second ploughing. It is not to be wondered at, that under such a system, the theoretical agriculturist should have taken a rooted aversion from what are thus erroneously termed fallows. The practice of the best farmers of the northern counties is very different, and that practice we shall here detail.

4951. *A proper fallow* invariably commences after harvest; the land intended to be fallowed getting one ploughing, which ought to be as deep as the soil will admit, even though a little of the till or subsoil is brought up. This both tends to deepen the cultivated, or manured, soil, as the fresh accession of hitherto uncultivated earth becomes afterwards incorporated with the former manured soil, and greatly facilitates the separation of the roots of weeds during the ensuing fallow process, by detaching them completely from any connection with the fast subsoil. This autumnal ploughing, usually called the winter furrow, promotes the rotting of stubble and weeds; and, if not accomplished towards the end of harvest, must be given in the winter months, or as early in the spring as possible. In giving this first ploughing, the old ridges should be gathered up, if practicable, as in that state they are kept dry during the winter months; but it is not uncommon to split them out or divide them, especially if the land had been previously highly gathered, so that each original ridge of land is divided into two half ridges. Sometimes, when the land is easily laid dry, the furrows of the old ridges are made the crowns of the new ones, or the land is ploughed in the way technically called *crown-and-furrow*. In other instances, two ridges are ploughed together, by what is called *cutting*, which has been already described. After the field is ploughed, all the inter-furrows, and those of the headlands, are carefully opened up by the plough, and are afterwards gone over effectually by a labourer with a spade, to remove all obstructions, and to open up the water furrows into the fence ditches, wherever that seems necessary, that all moisture may have a ready exit. In every place where water is expected to lodge, such as *dishes*, or hollow places in the field, cross or oblique furrows are drawn by the plough, and their intersections carefully opened into each other by the spade. Wherever it appears necessary, cross cuts are also made through the head ridges into the ditches with a spade, and every possible attention is exerted, that no water may stagnate in any part of the field.

4952. *As soon as the spring seed-time is over*, the fallow land is again ploughed end-long. If formerly split, it is now ridged up; if formerly laid up in gathered ridges, it is split or cloven down. It is then

cross-ploughed; and after lying till sufficiently dry to admit the harrows, it is harrowed and rolled repeatedly, and every particle of the vivacious crops of weeds brought up to view, carefully gathered by hand into heaps, and either burnt on the field, or carted off to the compost heap. The fallow is then ridged up, which places it in a safe condition in the event of bad weather, and exposes a new surface to the harrows and roller; after which the weeds are again gathered by hand, but a previous harrowing is necessary. It is afterwards ploughed, harrowed, rolled, and gathered as often as it may be necessary to reduce it into fine tilth, and completely to eradicate all root-weeds. Between these successive operations, repeated crops of seedling weeds are brought into vegetation, and destroyed. The larvæ likewise of various insects, together with an infinite variety of the seeds of weeds, are exposed to be devoured by birds, which are then the farmer's best friends, though often proscribed as his bitterest enemies.

4953. *The use of the harrow and roller in the fallow process*, has been condemned by some writers on husbandry, who allege that frequent ploughing is all that is necessary to destroy root-weeds, by the baking or drying of the cloths in the sun and wind; but experience has ascertained, that frequently turning over the ground, though absolutely necessary while the fallow process is going on, can never eradicate couch-grass or other root-weeds. In all clay soils, the ground turns up in lumps or clods, which the severest drought will not penetrate so sufficiently as to kill the included roots. When the land is again ploughed, these lumps are turned over and no more, and the action of the plough serves in no degree to reduce them, or at least very imperceptibly. It may be added, that these lumps likewise enclose innumerable seeds of weeds, which cannot vegetate unless brought under the influence of the sun and air near the surface. The diligent use, therefore, of the harrow and roller, followed by careful hand-picking, is generally necessary to the perfection of a fallow process. (*General Report of Scotland*, vol. iv. p. 419.)

4954. *The working of fallows by the grubber*, is an important modern improvement. We have already described several of these implements, and shall here introduce one which has been made public since the first five hundred pages of this work were printed.

4955. *Kirkwood's improved grubber* (fig. 721) has this peculiar advantage, that "the whole of the body of the instrument, and of course all the teeth, can be raised out of the ground at pleasure, and even while the machine is in motion; which is extremely convenient, not only in turning at the head ridges,

but whenever an obstruction is met with in the ground, arising from rocky, retentive, or other impenetrable soils. In such of these as would completely interrupt the progress of the ordinary instrument, this proceeds with ease, by merely being lifted more or less over them. The operation is performed by the driver bearing with his weight on the guiding handles of the grubber; and this pressure is made to raise the whole machine by a very skilful application of mechanical power. The pressure on the guiding handles (a), it will be observed, turns the whole handle round the axle of the hind wheels (b b), as round a fulcrum, so that the handle then becomes a lever, on the shorter extremity of which the frame of the teeth rests. It is evident, therefore, that by bearing on the handle which forms the long end of the lever, the shorter end must be raised, and along with it the hinder part of the teeth-frame, and, of course, the teeth also. But there is still another contrivance, by which the force is made to act at the same time on the forepart of the frame, and to raise it likewise. This is done by a long rod (d e), which is attached at the extremity to a fulcrum (d), raised on the handle frame, and at the other to the one end of a bent lever (e f g), which turns on the axle of the fore wheel as a centre, and at an intermediate point carries the fore end of the teeth frame. While the handle, therefore, is depressed, and raises the hinder part of this frame, it at the same time pulls the rod, turns the front lever round the axle of the fore wheel, and by this means elevates the teeth before as well as behind. The whole operation is simple, ingenious, and efficient." (*Highl. Soc. Trans.* vol. viii. p. 132.)

721

4956. *When effectually reduced to fine tilth*, and thoroughly cleaned from roots and weeds, the fallow is ploughed end-long into gathered ridges or lands, usually fifteen or eighteen feet broad. If the seed is to be drilled, the lands or ridges are made of such widths as may suit the construction of the particular drill-machine to be employed. If the seed is to be sown by hand, the lands or ridges are commonly formed into what are called single or double cast ridges; the first of four paces or steps, and the latter of eight steps in width. These widths are found the most convenient for a one-handed sower. An expert sower can, however, measure his handful to almost any width; but the above long experience has made the standard. After the land has been once gathered by a deep furrow, proportioned to the depth of the cultivated soil, the manure is laid on, and evenly spread over the surface, whether muck, lime, marl, or compost. A second gathering is now given by the plough; and this being generally the furrow upon which the seed is sown, great care is used to plough as equally as possible. After the seed is sown and the land thoroughly harrowed, all the inter-furrows, furrows of the headlands, and oblique or *gaw* furrows, are carefully opened up by the plough, and cleared out by the spade, as already mentioned, respecting the first or winter ploughing.

4957. *The expense of fallowing* may appear, from what has been said, to be very considerable, when land has been allowed to become stocked with weeds; but if it be kept under regular management, corn alternating with drilled pulse or green crops, the subsequent returns of fallow will not require near so much labour. In common cases, from four to six ploughings are generally given, with harrowing and rolling between, as may be found necessary; and, as we have already noticed, the *cultivator* may be employed to diminish this heavy expense. But it must be considered, that upon the manner in which the fallow operations are conducted, depend not only the ensuing wheat crop, but in a great measure all the crops of the rotation. (*Supp. to Encyc. Brit. art. Agr.* 128.)

SECT. III. General Management of Manures.

4958. *The manures of animal, vegetable, or mineral origin* have been already described, and their operation explained. (2224.) But a very few of these substances can be obtained by farmers in general; whose standard resources are farm-yard dung and lime, and composts of these with earth. It is on the management of these that we propose to deliver the practice of the best British farmers.

SUBJECT. 1. *Management of Farm-yard Dung.*

4959 *The basis of farm-yard dung* is straw, to which is added, in its progress through the farm-yard, the excrementitious substances of live stock. From every ton of dry straw, about three tons of farm-yard dung may be obtained, if the after-management be properly conducted; and, as the weight of straw per acre runs from one ton to one and a half, about four tons of dung, on an average of the different crops, may be produced from the straw of every acre under corn. (*Husbandry of Scotland*, vol. ii.) Hence (it may be noticed) the great importance of cutting corn as low as possible; a few inches at the root of the stalk weighing more than double the same length at the ear.

4960. *The conversion of straw into farm yard dung* in the farmery, is thus effected:—The straw is served out to cattle and horses in the houses and fold-yards, either as provender or litter, and commonly for both purposes; turnips in winter, and green clover in summer, are given to the stock both in the houses and yards: on this food the animals pass a great deal of urine, and afford the means of converting the straw into a richer manure than if it were eaten alone. All the dung from the houses, as they are cleaned out, is regularly spread over the yards in which young cattle are left loose, where litter is usually allowed in great abundance; or over the dunghill itself, if there is one at hand. This renders the quality of the whole mass more uniform; and the horse-dung, which is of a hot nature, promotes the decomposition of the woody fibres of the straw.

4961. *The preparation of the contents of the farm-yard* for laying on the land, is by turning it over; or, what is preferable, carting it out to a dunghill. The operation of carting out is usually performed during the frosts of winter: it is then taken to the field in which it is to be employed, and neatly built in dunghills of a square form, three or four feet high, and of such a length and breadth as circumstances may require. What is laid up in this manner early in winter, is commonly sufficiently prepared for turnips in June; but if not carried from the straw-yards till spring, it is necessary to turn it once or oftener, for the purpose of accelerating the decomposition of the straw part of the mass. When dung is applied to fallows in July or August, preparatively to autumn-sown wheat, a much less degree of putrefaction will suffice than for turnips: a clay soil, on which alone fallows should ever be resorted to, not requiring dung so much rotted as a finely pulverised turnip soil; and besides, as the wheat does not need all the benefit of the dung for some time, the woody fibre is gradually broken down in the course of the winter, and the nourishment of the plants continued till spring, or later, when its effects are most beneficial.

4962. *Management of stable dung.* There is a most valuable paper on this subject by Lord Meadowbank, in the second volume of the *Com. to the Board of Agr.* "His lordship has ever found, that, instead of dung being the richest manure when completely fermented, it should, if possible, be laid on when very imperfectly fermented, but nevertheless when the process is going on at such a rate as that it must continue after mixture with the soil till it is completed. Every gardener knows, that the dung used in hot-beds has little effect in comparison of fresh dung; and every farmer knows, that a dunghill, which has by any accident been kept for years, is of little more value than so much very rich earth. Every person of attention, too, must have remarked the great effects which ensue from turning over a dunghill recently before using it, and that composts operate most powerfully, if used when sensibly hot, from the activity of the fermentation which the recent mixture of the ingredients has occasioned, and when, consequently, that process is very far from being completed." As farm dunghills are formed by degrees, it is desirable to retard the fermentation of that which is first made, or to retain it in a state of fermentation, "so slow or imperfect, that it may suffer little till after being turned over with the later made dung, it forms one powerfully fermenting mass; and that then it should be put into the soil, when the process is so far advanced that it will be completed, when, at the same time, little loss of substance has yet been suffered, and when what volatile matter is afterwards extricated will diffuse itself through the soil. In these circumstances, every thing is lodged in the soil that the dung can yield, either in point of mass or activity; and at the same time it is in a state when most likely to act as a powerful ferment, for promoting the putrefaction of the decayed vegetables lying inert in the soil. I certainly, therefore, approve of the preservation of dunghills from much sun and much wind, as well as from that redundancy of moisture which is apt to overflow and wash away the manure: but I think the pressure which the feet of animals give them, especially of the lighter sort, does good, and prevents that violent fermentation which wastes the substance, and, in my opinion, exhausts the fertilising powers of dung. This pressure contributes to preserve it fresh till the time of employing it as a manure calls for putting it altogether, and at once, into that highly active state of putrefaction, which, though no doubt checked by its distribution in the soil, is sufficient to ensure a gradual and complete dissolution and diffusion of its substance. Unless, therefore, dung is to be used for composts, it appears to me clearly advantageous to get the dung into the soil as early as possible; it is always wasting somewhat, when kept out of it: but when put into the soil in a proper state, there is the utmost reason to think that what is extricated goes all to fertilise. Give me leave to add, that I do not believe much is lost by dissolution in rain water. I could never discover any thing of the kind in the water of the furrows of a field properly manured and ploughed. The case, every person knows, is quite different in fields recently limed or dressed with ashes; but I am apt to think, that the volatile and soluble parts of common dunghills have some attraction with the substance of soils, that prevents their escape. We know that common loam extracts the noisome smell of the woollen cloths used for intercepting the coarser oils that accompany spirits distilled from the sugar-cane, which scarce any detergent besides can obtain from it; and garden loam, impregnated as it must be with fermented dung, is certainly not easily deprived of its fertility by the washing of rain. I must also observe, that I take one of the great advantages derived from using dung with composts to be, the arresting and preserving the fertilising matter which escapes in the putrefactive fermentation; and another to be, that dung there operates as a ferment, to putrefy substances not sufficiently disposed to putrefy with activity of themselves. You will observe, that this coincides exactly with the effects I have attributed to it upon soil, and affords a very useful corollary with respect to the substances to be used in top-dressings, which are not to be covered with soil; viz. that if fermenting or putrefying substances are used, the process should have been completed, or nearly so, in a combination that has received the full benefit of it: that it is a great waste to spread common dung on grass, without having first mixed it with sand, loam, or other matter in which it has been dissolved and fixed; so that when spread on the ground, the loss, which would otherwise arise from fermentation and evaporation, is avoided; and that, if such a compost is used at the time when the plants are in a growing state, and in a way to cover it soon, it is by far the most advantageous method of laying it on." (*Comm. B. Agr.* vol. ii. p. 387.)

4963. *The husbandman of Brabant* is careful that his manure should never become parched and dried up, by which means all the volatile salts would evaporate. He lays his dung, as often as possible, close to his stables and cow-houses, and sheltered from the sun. If this cannot be avoided, he contrives to lay it under some large tree, to partake of the shade of its boughs. As a receipt for their dung, they generally dig a pit, five or six feet deep, with sufficient dimensions for the necessary deposit, from the month of March till harvest is over. The more opulent farmers are not satisfied with merely digging such a pit: they further pave and line it with bricks, that the earth should not absorb any of its parts; but that the thick matter should remain plunged in a mass of stale, increased further by rain. The stables and cow-houses are paved and sloped in such a manner as to communicate with a drain, which conveys all

the stale of their cattle towards the dung pit, which, by this contrivance, it keeps constantly supplying." (*Comm. B. Agr.* vol. ii.)

4964. *In the application of farm-yard dung to land under tillage*, particular attention is paid to the cleanness of the soil; and to use it at a time when, from the pulverisation of the ground, it may be most intimately mixed with it. The most common time of manuring with farm-yard dung is, therefore, either towards the conclusion of the fallowing operations, or immediately before the sowing of fallow crops. If no dung can be procured but what is made from the produce of the farm, it will seldom be possible to allow more than ten or twelve tons to every acre, when the land is managed under a regular course of white and green crops; and it is thought more advantageous to repeat this dose at short intervals, than to give a larger quantity at once, and at a more distant period in proportion. (*General Report of Scotland*, vol. ii. p. 517.) Farm-yard dung, it is well known, is greatly reduced in value by being exposed to the atmosphere in small heaps, previously to being spread, and still more after being spread. Its rich juices are exhaled by the sun, or washed away by the rains, and the residuum is comparatively worthless. This is in an especial manner the case with long fresh dung, the far greater part of which consists of wet straw in an entire state. All careful farmers, accordingly, spread and cover in their dung with the plough, as soon as possible after it is brought on the land.

4965. *The use of fresh dung* is decidedly opposite to the practice of the best farmers of turnip soils; its inutility, or rather injurious effects, from its opening the soil too much, is a matter of experience with every one who cultivates drilled turnips on a large scale. As the whole farm-yard dung, on such land, is applied to the turnip crop, it must necessarily happen that it should be laid on in different stages of putrefaction; and what is made very late in spring, often after a very slight fermentation, or none at all. The experience of the effect of recent dung is accordingly very general, and the result, in almost every case, is, that the growth of the young plants is slow; that they remain long in a feeble and doubtful state; and that they seldom, in ordinary seasons, become a full crop, even though twice the quantity that is given of short muck has been allowed. On the other hand, when the manure is considerably decomposed, the effects are immediate, the plants rise vigorously, and soon put forth their rough leaf, after which the beetle or fly does not seize on them; and in a few weeks, the leaves become so large, that the plants probably draw the greatest part of their nourishment from the atmosphere. Though it were true, therefore, that more nutritive matter is given out by a certain quantity of dung, applied in a recent state, and allowed to decompose gradually in the soil, than if applied after undergoing fermentation and putrefaction, the objection arising from the slowness of its operation would, in many instances, be an insuperable one with farmers. But there seems reason to doubt if fresh strawy manure would ferment much in the soil, after being spread out in so small a quantity as has been already mentioned; and also if, in the warm dry weather of summer, the shallow covering of earth given by the plough would not permit the gaseous matters to escape to a much greater amount than if fermentation had been completed in a well-built covered dunghill.

4966. *Another great objection to the use of fresh farm-yard dung* is, that the seeds and roots of those plants with which it commonly abounds spring up luxuriantly on the land; and this evil nothing but a considerable degree of fermentation can obviate. The mass of materials consists of the straw of various crops, some of the grains of which, after all the care that can be taken, will adhere to the straw; or the dung of different animals voided, as is often the case with horses fed on oats, with the grain in an entire state; and of the roots, stems, and seeds of the weeds that had grown among the straw, clover, and hay, and such as had been brought to the houses and fold-yards with the turnips and other roots given to live stock.

4967. *The degree of decomposition to which farm-yard dung should arrive*, before it can be deemed a profitable manure, must depend on the texture of the soil, the nature of the plants, and the time of its application. In general, clayey soils, as more tenacious of moisture, and more benefited by being rendered incohesive and porous, may receive manure less decomposed than well pulverised turnip soils require. Some plants, too, seem to thrive better with fresh dung than others, potatoes in particular; but all the small-seeded plants, such as turnips, clover, carrots, &c. which are extremely tender in the early stage of their growth, require to be pushed forward into luxuriant vegetation with the least possible delay, by means of short dung.

4968. *The season when manure is applied*, is also a material circumstance. In spring and summer, whether used for corn or green crops, the object is to produce an immediate effect, and it should therefore be more completely decomposed than may be necessary when laid on in autumn for a crop whose condition will be almost stationary for many months. (*Sup. Ency. Brit.* art. *Agr.*)

4969. *The quantity of putrescent manure requisite for each acre of land during each year* is estimated, by Professor Coventry, at five tons per acre annually. That quantity being supplied, not annually, but in quantities of twenty tons per acre every four years, or twenty-five tons per acre every five years. (*Quar. Jour. Agr.* vol. ii. p. 335.)

SUBJECT. 2. *Lime, and its Management as a Manure.*

4970. *Lime is by far the most important of the fossil manures*; and, indeed, it may be asserted, that no soil will ever be fit for much which does not contain a proportion of this earth, either naturally or by artificial application. Next to farm-yard dung, lime is in most general use as a manure, though it is one of a quite different character; and when judiciously applied, and the land laid to pasture, or cultivated for white and green crops alternately, with an adequate allowance of putrescent manure, its effects are much more lasting, and, in many instances, still more beneficial, than those of farm-yard dung. Fossil manures, Sir H. Davy observes, must produce their effect, either by becoming a constituent part of the plant, or by acting upon its more essential food, so as to render it more fitted for the purposes of vegetable life. It is, perhaps, in the former of these

ways that wheat and some other plants are brought to perfection, after lime has been applied, upon land that would not bring them to maturity by the most liberal use of dung alone. This being an established fact may be considered one of the greatest importance to all cultivators.

4971. *With regard to the quantity of lime that ought to be applied to different soils, it is much to be regretted that Sir Humphry Davy has not thought proper to enter fully into the subject.* Clays, it is well known, require a larger quantity than sands or dry loams. It has been applied accordingly in almost every quantity from 100 to 500 bushels or upwards per acre. About 160 bushels are generally considered a full dressing for lighter soils, and 80 or 100 bushels more for heavy cohesive soils. One of the greatest advantages arising from the use of lime on gravelly or sandy soils, is its power of absorbing moisture from the air, which is in the highest degree useful to the crops in dry summers.

4972. *In the application of lime to arable land, there are some general rules commonly attended to by diligent farmers, which we shall give nearly in the words of a recent publication.*

1. As the effects of lime greatly depend on its intimate admixture with the surface soil, it is essential to have it in a powdery state at the time it is applied.

2. Lime having a tendency to sink in the soil, it should be ploughed in with a shallow furrow.

3. Lime may either be applied to grass land, or to land in preparation for green crops or summer fallow, with almost equal advantage; but, in general, the latter mode of application is to be preferred.

4. Lime ought not to be applied a second time to moory soils, unless mixed up as a compost, after which the land should be immediately laid down to grass.

5. Upon fresh land, the effect of lime is much superior to that of dung. The ground, likewise, more especially where it is of a strong nature, is more easily wrought; in some instances, it is said, the saving of labour would be sufficient to induce a farmer to lime his land, were no greater benefit derived from the application than the opportunity thereby gained of working it in a more perfect manner. (*General Report of Scotland*, vol. ii. p. 536.)

4973. *In liming for improving hilly land, with a view to pasture, a much smaller quantity has been found to produce permanent and highly beneficial effects, when kept as much as possible near the surface, by being merely harrowed in with the seeds, after a fallow or green crop, instead of being buried by the plough.*

4974. *The successful practice of one of the most eminent farmers in Britain cannot be too generally known in a matter of so great importance to farmers of such land, especially when lime must be brought from a great distance, as was the case in the instance to which we are about to allude. "A few years after 1754," says Dawson, "having a considerable extent of outfield land in fallow, which I wished to lime previously to its being laid down to pasture, and finding that I could not obtain a sufficient quantity of lime for the whole in proper time, I was induced, from observing the effects of fine loam upon the surface of similar soil, even when covered with bent, to try a small quantity of lime on the surface of this fallow, instead of a larger quantity ploughed down in the usual manner. Accordingly, in the autumn, about twenty acres of it were well harrowed, and then about fifty-six Winchester bushels only of unslacked lime were, after being slacked, carefully spread upon each English acre, and immediately well harrowed in. As many pieces of the lime, which had not been fully slacked at first, were gradually reduced to powder by the dews and moisture of the earth, to mix these with the soil, the land was again well harrowed in three or four days thereafter. This land was sown in the spring with oats, with white and red clover and ryegrass seeds, and well harrowed, without being ploughed again. The crop of oats was good; the plants of grass sufficiently numerous and healthy; and they formed a very fine pasture, which continued good until ploughed some years after for corn. About twelve years afterwards, I took a lease of the hilly farm of Grubbet; many parts of which, though of an earthy mould tolerably deep, were too steep and elevated to be kept in tillage. As these lands had been much exhausted by cropping, and were full of couch-grass, to destroy that and procure a cover of fine grass, I followed them, and laid on the same quantity of lime per acre, then harrowed, and sowed oats and grass seeds in the spring exactly as in the last-mentioned experiment. The oats were a full crop, and the plants of grass abundant. Several of these fields have been now above thirty years in pasture, and are still producing white clover, and other fine grasses; no bent or fog has yet appeared upon them. It deserves particular notice, that more than treble the quantity of lime was laid upon fields adjoining, of a similar soil, but which being fitter for occasional tillage, upon them the lime was ploughed in. These fields were also sown with oats and grass seeds. The latter thrive well, and gave a fine pasture the first year; but afterwards the bent spread so fast, that, in three years, there was more of it than of the finer grasses."*

4975. *The conclusions which Dawson draws from his extensive practice in the use of lime and dung, deserve the attention of all cultivators of similar land.*

1. That animal dung dropped upon coarse benty pastures, produces little or no improvement upon them; and that, even when sheep or cattle are confined to a small space, as in the case of folding, their dung ceases to produce any beneficial effect, after a few years, whether the land is continued in pasture, or brought under the plough.

2. That even when land of this description is well fallowed and dunged, but not limed, though the dung augments the produce of the subsequent crop of grain, and of grass also for two or three years, that thereafter its effects are no longer discernible either upon the one or the other.

3. That when this land is limed, if the lime is kept upon the surface of the soil, or well mixed with it, and then laid down to pasture, the finer grasses continue in possession of the soil, even in elevated and exposed situations, for a great many years, to the exclusion of bent and moss. In the case of Grubbet hills, it was observed, that more than thirty years have now elapsed. Besides this, the dung of the animals pastured upon such land adds every year to the luxuriance, improves the quality of the pasture, and augments the productive powers of the soil when afterwards ploughed for grain; thus producing, upon a benty outfield soil, effects similar to what are experienced when rich infield lands have been long in pasture, and thereby more and more enriched.

4. That when a large quantity of lime is laid on such land, and ploughed down deep, the same effects will not be produced, whether in respect to the permanent fineness of the pasture, its gradual amelioration by the dung of the animals pastured on it, or its fertility when afterwards in tillage. On the contrary, unless the surface is fully mixed with lime, the coarse grasses will in a few years regain possession of the soil, and the dung thereafter deposited by cattle will not enrich the land for subsequent tillage.

Lastly. It also appears from what has been stated, that the four-shift husbandry is only proper for very rich land, or in situations where there is a full command of dung. That by far the greatest part of the land of this country requires to be continued in grass two, three, four, or more years, according to its

natural poverty; that the objection made to this, viz. that the coarse grasses in a few years usurp possession of the soil, must be owing to the surface soil not being sufficiently mixed with lime, the lime having been covered too deep by the plough. (*Farmer's Magazine*, vol. xiii. p. 69.)

SECT. IV. *Composts and other Manures.*

4976. *Mixing farm-yard dung, in a state of fermentation, with earth*, in which there is much inert vegetable matter, — as the banks of old ditches, or what is collected from the sides of lanes, &c., — will bring this inert, dead matter, consisting of the roots of decayed grasses and other plants, into a state of putridity and solubility, and prepare it for nourishing the crops or plants it may be applied to, in the very manner it acts on peat. Dung, however, mixed with earth, taken from rich arable fields which have been long cultivated and manured, can have no effect as manure to other land that the same earth and dung would not produce applied separately; because there is generally no inert matter in this description of earth to be rendered soluble.

4977. *Mixing dung, earth, and quick-lime together*, can never be advisable; because quick-lime will render some of the most valuable parts of the dung insoluble. (See 2290.) It will depend on the nature of soil or earth, whether even quick-lime only should be mixed with it to form compost. If there be much inert vegetable matter in the earth, the quick-lime will prepare it for becoming food for the plants it may be applied to; but if rich earth be taken from arable fields, the bottoms of dung-pits, or, in fact, if any soil full of soluble matter be used, the quick-lime will decompose parts of this soluble matter, combine with other parts, and render the whole mass less nourishing as manure to plants or crops than before the quick-lime was applied to it. Making composts, then, of rich soil of this description, with dung or lime, mixed or separate, is evidently, to say no more of it, a waste of time and labour. The mixture of earths of this description with dung produces no alteration in the component parts of the earth, where there is no inert vegetable substances to be acted on; and the mixture of earth full of soluble matter with dung and quick-lime, in a mass together, has the worst effects, the quick-lime decomposing and uniting with the soluble matter of the earth, as well as that of the dung; thus rendering both, in every case, less efficient as manures, than if applied separately from the quick-lime, and even the quick-lime itself inferior as manure for certain soils, than if it had never been mixed with the dung and earth at all. (*Farmer's Magazine*, vol. xv. p. 351.)

4978. *Mixing dung in a state of fermentation with peat*, or forming what in Scotland are called Meadowbank middens (2241.), is a successful mode of increasing the quantity of putrescent manure. The peat, being dug and partially dried, may either be carted into the farm-yard and spread over the cattle court, there to remain till the whole is carted out and laid upon a dunghill to ferment; or it may be mixed up with the farm-yard dung as carted out. If care be taken to watch the fermenting process, as the fire of a clay-kiln is watched, a few loads of dung may be made to rot many loads of peat. Adding lime to such composts does not in the least promote fermentation, while it renders the most valuable parts of the mass insoluble. Adding sand, ashes, or earth, will, by tending to consolidate the mass, considerably impede the progress of fermentation.

4979. *Bone manure*. Crushed bones were first introduced to Lincolnshire and Yorkshire, about 1800, by a bone merchant at Hull; and the effect has been, according to a writer in the *British Farmer's Magazine*, vol. iii. p. 207., to raise wild unenclosed sheep-walks from 2s. 6d. or 5s. to 10s. 6d. or 20s. an acre. The quantity at present laid on is 12 bushels per acre drilled in, in the form of dust, with turnip seed. The turnips are fed off with sheep, and succeeded by a corn crop, and by two crops of grass. It seems to be generally admitted, that bone dust is not beneficial on wet retentive soils, as continued moisture prevents decomposition; but in all descriptions of dry soils it never fails of success. On the poor soil, or chalk or lime-stone of the woods of Lincolnshire and Yorkshire, the turnip crops are said to equal those of any part of England; and the barley, though coarse, to produce a greater quantity of saccharine matter than even the brightest Norfolk samples. (*Brit. Farm. Mag.* vol. iii. p. 208.)

4980. *The Doncaster Agricultural Association* appointed a committee, in 1828, to make enquiries, and report the result of them, on the use and advantages of bones as a manure. The report is full of interest, and highly satisfactory as to the great value of this species. The following is a summary of deductions from the details collected:—

1. That on dry sands, lime-stone, chalk, light loams, and peat, bones form a very highly valuable manure; they may be laid on grass with great good effect; and, on arable lands, they may be laid on fallow for turnips, or used for any of the subsequent crops.
2. That the best method of using them, when broad-cast, is previously to mix them up with earth, dung, or other manures, and let them lie to ferment.
3. That if used alone, they may either be drilled with the seed or sown broad-cast.
4. That bones which have undergone the process of fermentation are decidedly superior to those which have not done so.
5. That the quantity should be about 25 bushels of dust, or 40 bushels of large, increasing the quantity if the land be impoverished.
6. That upon clays and heavy loams, it does not yet appear that bones will answer.

4981. *Salt, nitre, and other manures* have been already treated of in Part II. at sufficient length. It is clear that both salt and nitre may be advantageously used in many cases. Nitre continues to be a good deal used in Hertfordshire, on which it is sown at the rate of $1\frac{1}{2}$ cwt. per acre. It has been tried at this rate in Scotland to wheat and to grass, and the effect is said to have been wonderful. Salt has been extensively used with almost every crop at different rates, from 20 to 40 bushels per acre; and it appears in many, if not in most, cases to have proved useful. (*Quar. Jour. Agr.* vol. i. p. 208., and *Higl. Soc. Trans.* vol. i. p. 147.)

CHAP. II.

Culture of the Cereal Grasses.

4982. *The corn crops* cultivated in Britain are, wheat, rye, barley, and oats. Other culmiferous plants, as the maize, millet, and rice, have been tried with partial success in warm districts, but they have no chance of ever becoming general in our climate. The best description of the different species and varieties of *Ceræalia* cultivated in Europe will be found in Metzger's *Europäische Cerealien in Botanischer und Landwirthschaftlicher Hinsicht*, &c. Heidelberg, 1824. Folio, 20 plates. The plates are exceedingly well executed; and there are popular as well as scientific descriptions, with synonyms in all the European languages.

4983. *On the culture of culmiferous plants*, a few general remarks may be of use to the young farmer. Culmiferous plants, particularly wheat and rye, like most others, have two sets of roots. The first originate with the germination of the grain, are always under the soil, and are called the seminal roots; the second spring from the first joint which is formed near the surface of the soil, and from that joint strike down into the soil; these are called the coronal roots. The coronal roots appear chiefly intended for drawing nourishment from the soil; and, as Professor Martyn has observed, are judiciously placed for this purpose, the richest part of all soils being on or near the surface. These fibres are of larger diameter, more succulent, and never so long as the seminal. From these facts, as to the roots of culmiferous plants, some important hints may be derived regarding their culture. The use of stirring the surface in spring to facilitate the extension of the coronal roots, is obvious; the immediate effect of a top-dressing is also apparent, and also that manures may be ploughed in too deep to give the full amount of their beneficial effects to corn crops or grasses. Sageret, a scientific French agriculturist, proved experimentally, that where any of the grains or grasses are etiolated immediately after germination, by growing too rapidly, or by being sown too thick or in too warm a season, the first joint from which the coronal or nourishing roots spring is raised above the ground, and in consequence either throws out no roots at all, or so few as to nourish it imperfectly; in which case it either dies before it comes into flower, or before the seed is matured. (*Mem. de la Soc. Ag. de Seine*, tom. ii.)

4984. *Whether corn ought to be sown broadcast or in drills*, is a question which has given rise to considerable discussion. The cultivation in rows of such plants as admit of intertillage during the summer months, is known to supersede the use of a summer fallow on lighter soils. "In truth, the row culture of certain green crops is one of the greatest improvements of modern agriculture, and should be extended by every effort of instruction and example. By no other means yet known to us can so large a produce be raised from land under constant tillage, so beneficial a rotation of crops be adopted, or so great an economy be practised in the application of manures. But, while the advantages are thus apparent with regard to the application of this species of culture to our preparatory green crops, it does in no degree follow that advantages equally great will result from its application to our crops of white corn. The analogy, as it regards the nature of the plants which form the subject of cultivation, does not hold. The cereal grains send forth numerous shoots or suckers, and the goodness of the crop mainly depends on the vigour and number of the shoots which they send forth. The other kind of crops do not, generally speaking, tiller like wheat, barley, or oats, but rise from one stem. Reasoning from these principles, we should infer that the former class of plants should be cultivated in that manner in which they are best suited to summer tillage; that is, in rows: the latter in that manner in which the seed is most equally deposited in the upper stratum of the soil, which is in broadcast. The opinions, however, of intelligent agriculturists are not agreed as to the superiority in practice of the broadcast over the row system, even as it relates to the cereal grains. The farmer of Norfolk, or of the light soils of Sussex, will contend as strenuously for the superiority of the row system as the farmer of East Lothian for the broadcast system; and each may be right as it regards the application of the principle to the circumstances of his own situation. The question which is to be settled, however, is, — Which of the two systems

is to be regarded as the rule in husbandry, and which the exception? Now, — Independently of the circumstances just adverted to, and judging only from the greater extent to which the broad-cast system is carried on in the country; from the fact of the row system having declined in favour in districts where it had once been most extensively practised; and from its having recently ceased to make progress in general practice, — we should be inclined to hold that, with respect to the cereal grains, the rule of agriculture is the broad-cast system, and the exception the row system. The cases falling under the exception may be, and doubtless are, very numerous and important. There are many light soils in which the seeds require to be deposited at a considerable and equal depth, and this the drill-machine effects better than sowing on the surface; and there are many thin cold clays which tend to throw out the plants, the best remedy for which is thought to be deep sowing.”

4985. *The sowing of corn from the hand*, “ however, is known to be attended with some uncertainty; being dependent for the accuracy of the execution upon the skill and attention of the sowers. The regularity of the work is also affected by winds; and, unfortunately, the means rarely exist of detecting the degree of inaccuracy in the work until too late to correct it.” As a remedy for these inconveniences, we have already described a broad-cast hand drill (2576.), and shall here introduce a horse machine for the same purpose (fig. 722 a. b.), that has been for some years employed in “ the agriculture of Northumberland, North Durham, and some of the southern counties of Scotland, for sowing broad-cast. As it regards economy alone, little perhaps is effected by the employment of this machine: its recommendations are the regularity and certainty with which it performs the work, and the rendering of the execution independent of unskilfulness or want of care in the operator.” (*Quar. Jour. Agr.* vol. ii. p. 250.)

“ A man and a horse with this machine will sow between 25 and 30 acres in a day. The regular manner in which the seed is disseminated renders less seed necessary than in the common method of sowing by the hand. Besides the advantages arising from a saving of seed, the greater regularity, as it regards their distance from each other, with which the plants spring up, generally renders the crop superior to that sown in the other way. The machine has been described as adapted to the sowing of the common sorts of grain, but it is equally well calculated for sowing the cultivated grasses.” (*Quar. Jour. Agr.* vol. ii. p. 254.)

4986. *The preservation of corn* after it is threshed and cleaned is generally effected in granaries, where the grain is kept well ventilated by passing it frequently from one floor to another, or through winnowing machines.

4987. *It has been proposed and attempted in France* to preserve it in pits or dry cells at an equal temperature, and included from the atmosphere; but the experiments now going on for this purpose, more

especially by M. Ternaux at St. Ouen, near Paris, are not yet sufficiently matured to enable us to lay any useful result before the public. That corn has been so preserved in former ages, and that to a considerable extent, is beyond a doubt; and it is equally certain that in the interior of Africa, among the Caffres and other nations, as well as in the south of Russia, in Turkey, and in Egypt, the practice is still employed on a small scale. It may be doubted, we think, whether, with the present population of Europe, it could ever be generally adopted.

4988. *Preservation of corn in siloes.* Some account of the opening of a siloe was lately read to the Agricultural Society of Paris. "The place consisted of an icthouse, and the grain when put in was of the finest appearance, perfectly dried, and in excellent condition. The door had been hermetically sealed; and yet, when opened, a considerable thickness of the mass of corn was found destroyed by weevils, the latter being in such quantity as to occasion an elevated temperature. As part of the same corn had been perfectly well preserved in other siloes, the cause of this deterioration was sought for, and a hole was found in the lower part which had been made by mice, and which, by admitting air in sufficient quantity, had allowed the weevils originally in the corn to live, and increase their numbers to the degree mentioned. After some observations upon experiments which showed that insects could live for a very long time in vitiated air, a committee was named to ascertain the requisite state of the air, and the circumstances connected in the enquiry with the preservation of grain in these repositories. At another meeting of the society, M. Hachette described the method proposed by M. Clement to prevent the destruction of corn by weevils. It is founded upon a fact observed by him, that these insects cannot live in an atmosphere which contains less than a certain proportion of moisture. He therefore proposes that the corn should be subject to a continued ventilation of air dried by passing over quick-lime or chloride of calcium. All the weevils originally in the corn would thus be quickly destroyed." (*Recueil Industriel*, vol. xii. p. 208.)

4989. *The preservation of corn in the north of Russia* may deserve notice more as matter of curiosity, and for supplying ideas on the subject, than for imitation. The corn is dried in small ovens or chambers, which communicate with a larger chamber or oven by small tubes that enter the smaller chambers at the top. The oven is then filled with straw closely pressed, which is lighted and left to consume during the night. Next morning the corn is taken from the smaller chambers, the smoke from the ovens having passed into them and perfectly dried it. This practice has several advantages: the corn is lighter to move, and is kept much easier, without requiring to be constantly turned, being preserved from vermin by the smoky taste communicated to it by the straw, which does not quit it until it has passed through the mill. The corn intended to be kept for any length of time is put into pits, in shape like a bottle, sufficiently high for a man to stand erect in, which are dug in elevated places with a clayey soil. When they are dug a fire is lighted for four and twenty hours, which forms a hard crust round the pit. The interior is lined with the bark of the birch tree, fastened with wooden nails. Some straw is then put at the bottom, upon which the corn is placed, and more straw at the top, the mouth of the pit being then closed with a wisp of straw in the form of a cone. Each pit contains from twenty-five to one hundred bushels, and the grain in them will keep for twenty years without being injured. (*Biblioth. Univer. de Genève*.)

4990. *The uses to which the straw of corn may be applied* are various. Besides food for cattle, litter for animals, thatch, &c., it is bleached and plaited into ribands for forming hats, and bleached, dyed of different colours, split, and glued to flat surfaces, so as to form various works useful and ornamental. Paper is also made from straw; and the same pulp which forms the paper may be moulded into all the forms given to papier maché, medallion portraits, embossed works, &c. Whoever wishes to enter into the details of the great variety of articles that may be manufactured from straw, should consult the *Dictionnaire Technologique*, art. *Paille*; or an abridged translation of a part of the article in Gill's *Technological Repository*, vol. vi. new series, p. 228.

4291. *The diseases peculiar to the cereal grasses* have been included in the diseases common to vegetables in general. (1671.) They are chiefly the smut, the rust, the mildew, and the ergot; and we shall notice them more at length under the different species of corn which are most subject to suffer from them.

4992. *The practice of reaping corn before it is perfectly ripe* originated in France, and has lately been recommended by M. Cadet de Vaux.

4993. *Corn reaped eight days before the usual time*, this author says, has the grain fuller, larger, finer, and better calculated to resist the attacks of the weevil. An equal quantity of the corn thus reaped, with corn reaped at the period of maturity, gave more bread, and of a better quality. The proper time for reaping is that when the grain, on being pressed between the fingers, has a doughy appearance like the crumb of bread just hot from the oven, when pressed in the same manner. This does not seem to agree altogether with the experience of some agriculturists in the Carse of Gowrie, Perthshire, where oats intended to be made into meal are always found to yield most when allowed to stand as long as possible. Corn for seed, however, it is acknowledged by the same agriculturists, will answer the purpose perfectly though cut before fully matured. (*Perth Miscellany*, vol. i. p. 41.) If the doctrine of Cadet de Vaux be confined to wheat, it may be perhaps considered as confirmed by the following passage from Waistell:—"It is well known," he observes, "that wheat produces the most flour and the sweetest bread when threshed out before it has been stacked; and as all corn is more or less injured in both these respects, accordingly as it is more or less heated in the rick, it would be highly desirable totally to prevent its heating or becoming musty, in the ricks. In wet harvests it is sometimes impossible to get corn sufficiently dried; and we see that even in hot and dry harvests, such as that of 1819, a great deal of corn is sometimes spoiled in the ricks: we should, therefore, be extremely cautious to have corn well dried in the field, the ricks made of a moderate size, and raised off the ground, to admit the air to circulate under them, with chimneys to allow a current of air to pass upwards through them, to carry off the hot and musty air from the centre of the rick, which, without such a chimney, has its tendency to heat four-fold greater than one with a chimney. Chimneys being easily made, and so beneficial, it were to be wished that they were in general use." (*Waistell's Designs for Agr. Buildings*, p. 101.)

4994. *For seed corn*, it not only appears that unripe grain is preferable, but even that mildewed wheat and oats answer perfectly. Mr. S. Taylor, the editor of the *Country Times*, and formerly an extensive farmer, has been in the practice of sowing from 100 to 130 acres of wheat annually for 20 years and upwards. "The seed was invariably chosen, not from the best and plumpest, but the thinnest and most mildewed seed." He has seen the most beautiful samples of wheat produced from seed of the most ordinary description. (*Country Times*, March 22. 1830.) In Perthshire, the same is stated with respect to oats. (*Perth Miscellany*, vol. i. p. 41.)

4995. *The methods of reaping corn* are various. The most general mode is by the sickle, already described (2482. and 2483.); the scythe is also used, more especially for barley and oats; and a reaping machine (2737.) is beginning to be used in some parts of Scotland; in which country an effectual bean-reaping machine (2740.) was

in use many years ago. A method of mowing corn much practised in the county of Durham, and possibly Yorkshire, has lately been introduced into Northumberland, but does not appear to make much progress, the low priced Irish reapers doing the work so much more neatly and with less waste, though it costs more money to the owner. The scythe has a cradle similar to that described (405.); it is handled and used differently from the bow and grass scythes, and has only one short handle or "nib" on the "sneel," or long handle, for the right hand; the left grasps the "sneel" with the palm upwards: this enables the mower, who generally mows "from the corn," to bring the back of the scythe and cradle to the ground, and leave the cut corn in a beautiful state for being put into sheaves. A good workman can do two, and some three acres a day: they charge about 5s. per acre for mowing, binding, and stooking (shocking): this practice may be advantageously followed wherever the crop is not stricken down by rains, particularly barley crops. (*C. near Abwick, in Gard. Mag. vol. vi.*)

4996. *Frosted corn*, like frosted seeds of any sort, may be detected by dissection and comparison with unfrosted corn. By frosted corn is to be understood corn that has been frozen on the plant before it was perfectly ripe, in consequence of which the germ of the future plant or vital part of the seed is deprived of its vitality by the expansion produced by the freezing of its watery parts.

4997. *Frosted oats*. The oat being one of the latest corns, and a corn of cold rather than of warm countries, is more liable to be frozen than any other; but fortunately, also, frozen oats are more easily detected than either frozen wheat or barley. The Rev. James Farquharson, who has paid much attention to this subject, and written an elaborate article on it in the *Farmer's Magazine* (vol. xix.), observes, that every kernel, when stripped of the husk, will be found to exhibit the appearance of a groove on one side. If the bottom of the groove has a smooth clear translucent appearance from end to end; if it is not much shrunk into the substance of the kernel; and if the kernel splits with difficulty in its direction, then we may pronounce the vital part of the seed to be free from injury by frost. If, on the contrary, there is a black speck seen in the groove at the root end of the kernel; if the groove cuts deep into the kernel, so that it may be split in that direction; and if, when the kernel is so split, the blackness, accompanied with a rotten scaly appearance, is seen extending from end to end at the bottom of the groove, then the vital part or future plant may be pronounced entirely unfit for being used as seed.

4998. *Frosted barley*. The nature of the injury that ripening barley suffers from frost is similar to that suffered by oats. The husk of barley, like that of oats, consists of two unequal parts; the small part covering the groove of the kernel. In sound grain, when dry, the hull is firmly attached to the kernel; but in frosted grain the small part of the hull becomes loose, and feels soft on being pressed; and if, in such grain, this part of the hull is stripped away, a blackness and rottenness, resembling that in frosted oats, will be seen in the bottom of the groove. In frosted barley the husk becomes loose all round the root end; but, as this is a circumstance that is occasionally observed likewise in barley that was never exposed to frost, it certainly sometimes arises from other causes, — perhaps from wet; and this, unless the grain has germinated, does not render it unfit for seed or malting. The only sure mark of damage from frost is the blackness and rottenness in the bottom of the groove.

4999. *Frosted wheat*. Upon an attentive inspection of wheat that has been exposed to the frost, it will be observed that in a large proportion of grains there is a rotten scaly appearance where the embryo of the plant is attached to the cotyledon or mealy part of the grain; that the groove is much deeper than in wheat that was sowed before the frost; and that the grains are easily split in its direction. From this it is inferred that wheat, in its ripening stage, suffers from frost an injury of the same nature with that sustained by oats and barley. (*Farm. Mag. vol. xix.*)

5000. *The nutritive products* of the plants to be treated of in this section, are thus given by Sir H. Davy.

Systematic Names.	English Names. The quantity analysed, of each sort 1000 parts.	Whole quantity of soluble or nutritive matter.	Mucilage or starch.	Saccharine matter or sugar.	Gluten or albumen.	Extract, or matter rendered insoluble during the operation.
<i>Triticum hybernum æstivum</i>	Middlesex wheat, average crop	955	765	—	190	
	Spring wheat	940	700	—	240	
	Mildewed wheat of 1806	210	178	—	32	
	Blighted wheat of 1804	650	520	—	130	
	Thick-skinned Sicilian wheat of 1810	955	725	—	230	
	Thin-skinned Sicilian wheat of 1810	961	722	—	239	
	Wheat from Poland	950	750	—	200	
<i>Hordeum vulgare</i>	North American wheat	955	730	—	225	
	Norfolk barley	920	790	70	60	
	Oats from Scotland	743	641	15	87	
<i>Secale cereale</i>	Rye from Yorkshire	792	645	38	109	

SECT. I. *Wheat*. — *Triticum* L.; *Triandria Digynia* L., and *Gramineæ* J. *Froment*, Fr.; *Weizen*, Ger.; *Grano*, Ital.; and *Trigo*, Span.

5001. *Wheat is by far the most important of the cereal grasses*, the flour made from its grains or seeds, from the quantity of gluten they contain, making the best bread in the world. A greater proportion of mankind are nourished by rice than by wheat, but there is no grain which comes near wheat in its qualities for bread-making. Rice and maize are comparatively unfit for it, and oats, barley, and rye but imperfectly adapted. Rye, however, comes nearer to wheat in its bread-making qualities than any other grain.

5002. *Of what country wheat is a native*, is totally unknown; it has been supposed indigenous to Asia and Africa, and unquestionably it is more likely to belong to these

parts of the world than any other; but all that can be advanced on this subject is conjecture. Wheat, with the exception it is said of some parts of the southern coast of Africa, is cultivated in every part of the temperate and torrid zones, and in some places as high as 2000 feet above the level of the sea. It has been grown from time immemorial in Britain, but in few places at a greater elevation than 600 feet. Of course the elevation to which any plant can be cultivated always depends on the latitude of the situation.

5003. *Species and varieties.* (fig. 723.) Botanists reckon seven species of *Triticum*, which are or may be cultivated for their grains, besides many varieties and subvarieties of those in common culture. The species or subspecies are,

- | | |
|---|--|
| 1. <i>Triticum aestivum</i> , Summer wheat or spring wheat (a). | 5. <i>Triticum polonicum</i> , Polish wheat (e). |
| 2. <i>hybernum</i> , Lammas wheat (b). | 6. <i>Spelta</i> , Spelt wheat (f). |
| 3. <i>compósitum</i> , Egyptian wheat (c). | 7. <i>monocóccum</i> , One-grained wheat (g). |
| 4. <i>turgidum</i> , Turgid wheat (d). | |

The first, second, fourth, and fifth sorts are by many botanists considered as only varieties, and it is doubtful whether the third and sixth may not be the same; the seventh has all the marks of a distinct species, but it is very questionable whether, if much cultivated, it would always continue to produce one row of grains.

5004. *The spring or summer wheat (a), Blé de Mars, Fr.*, is distinguished from that generally sown, by its narrower ears, longer beards, smaller grains, and shorter and more slender straw, and also by its inability to endure our winters. It is commonly sown in April, or even so late as May. It was known to Parkinson in 1666, but has never been much cultivated, except in Lincolnshire. It was tried and given up in Northumberland and Mid Lothian, and also in some counties near London. Many varieties of summer wheat were transmitted a few years ago to the president of the Board of Agriculture from the Agricultural Society of Paris, for the purpose of experiment, and were divided among several distinguished agriculturists, (*Comm. to the Board of Agr.*, vol. vii. p. 11.); but there has not yet been time for establishing their comparative merits, or their adaptation to the climate of Britain. Summer, or, as it is often called, spring, wheat has however been long and extensively cultivated in some parts of England, particularly in Lincolnshire; and it is probable may be found a valuable crop in the southern counties; but the trials that have been made in the north, do not seem to entitle it to a preference over winter wheat sown in spring, or even oats or barley, in that climate.

5005. *Of the winter or common wheat (b), Froment blanc, Fr.*, there are a great number of varieties. Professor Martyn, in Miller's *Dictionary*, has described forty-nine sorts, and Professor Thier speaks of a hundred, but affirms that those who describe them know nothing about them, and in all probability include one sort under different names. All the varieties may be reduced to two, the white, and the brown or red grained. As subvarieties, there are the bearded and beardless, the woolly-chaffed, and thin or hairy chaffed, both of the reds and whites. To these some add another variety, which is the spring-sowing common wheat. It is stated by those who maintain that this variety exists, that through long sowing the progeny, after a number of generations, acquires a habit of coming earlier into blossom than seed from winter-sown grain. This we think very likely, but are not aware that the variety is distinctly known by any recognisable marks in the plants. The red or brown wheats are universally considered more hardy than the white, but as yielding an inferior flour: the woolly-white is supposed to yield the best flour; but woolly-chaffed wheats are considered more liable to the mildew than any other.

5006. *The Egyptian, or many-spiked wheat (c), Blé de miracle ou de Smyrne, Fr.*, the turgid grey pollard or duck-bill wheat (d), and the Polish wheat (e), may, for all agricultural purposes, be considered only varieties of the common winter wheat. They are cultivated in a few places in England, and seeds of them may be procured from the public botanic gardens; but they are in little estimation.

5007. *Spelt wheat (f), the Epautre of the French*, is known by its stout straw, which is almost solid, and by its strong pikes, with chaff partially awned, the awns long and stiff. The chaff adheres so closely to the grain as not to be separated without great difficulty. This grain, as we have seen, is a good deal sown in the south of Europe. In France it is sown in spring, on land too coarse for common wheat, and it ripens in July and August. It is the principal wheat sown in Suabia and the north of Switzerland; and is a good deal sown in Spain. The grain is light, and yields but little flour; but it is said to contain a larger portion of gluten than common wheat, and for that reason is recommended as superior to any other in pastry and confectionary. It is not cultivated in Britain.

5008. *The one-grained wheat (g), Petit épautre, Fr.*, is known by its small thin spike, and single row of grains; the leaves and straw are remarkably small, but very hard; and the plants tiller very much. It is chiefly cultivated in the mountainous parts of Switzerland, where its straw, like that of the former species, is much used for thatching. The grain makes a brown light bread; but its great excellence, according to Villars, is for gruel.

5009. *To procure new varieties of wheats*, the ordinary mode is to select from a field a spike or spikes from the same stalk, which has the qualities sought for; such as larger grains, thinner chaff, stiffer straw, a tendency to earliness or lateness, &c.; and picking out the best grains from this ear or ears, to sow them in suitable soil in an open airy part of a garden. When the produce is ripe, select the best ears, and from these the best grains, and sow these, and so on till a bushel or more is obtained, which may then be sown in a field apart from any other wheat. In this way, many of the varieties of our common winter wheat have been obtained; as the hedge-wheat which was reared from the produce of a stalk found growing in a hedge in Sussex, by one Wood, about 1790. Other varieties have assumed their distinctive marks from having been long cultivated on the same soil and climate, and take local names, as the Hertfordshire red, Essex white, &c.

5010. *Marshall*, (Yorkshire) mentions a case in which a man of accurate observation, having in a piece of wheat perceived a plant of uncommon strength and luxuriance, diffusing its branches on every side, and setting its closely-surrounding neighbours at defiance, marked it; and at harvest removed it separately. The produce was 15 ears, yielding 604 grains of a strong-bodied liver-coloured wheat, differing, in general appearance, from every other variety he had seen. The chaff was smooth, without awns, and of the colour of the grain; the straws stout and reedy. These 604 grains were planted singly, nine inches asunder, filling about 40 square yards of ground, on a clover stubble, the remainder of the ground being sown with wheat in the ordinary way; by which means extraordinary trouble and destruction by birds were avoided. The produce was two gallons and a half, weighing 204lbs. of prime grain for seed, besides some pounds for seconds. One grain produced 35 ears, yielding 1235 grains; so that the second year's produce was sufficient to plant an acre of ground. What deters farmers from improvements of this nature is probably the mischievousness of birds; from which at harvest it is scarcely possible to preserve a small patch of corn, especially in a garden or other ground situated near a habitation; but by carrying on the improvement in a field of corn of the same nature, that inconvenience is got rid of. In this situation, however, the botanist will be apprehensive of danger from the floral farina of the surrounding crop. But from what observations Marshall has made he is of opinion his fears will be groundless. No evil of this kind occurred, though the cultivation of the above variety was carried on among white wheat.

5011. *But the most systematic mode of procuring new varieties*, is by crossing two sorts, as in breeding; that is, by impregnating the female organs of the blossoms of one ear with the fecundating matter or pollen of the male organs of the blossom of another variety of a different quality. Thus, supposing a farmer was in the habit of cultivating a very good variety, which he wished to render somewhat earlier, let him procure in the blossoming season, from a very early soil, some spikes of an early sort just coming into blossom; and let him put the ends of these in water, and set them in the shade so as to retard their fully blossoming till the plants he has destined to become the females come into flower. Then let him cut out all the male organs of the latter, before they have advanced so far as to impregnate the stigma; and, having done this, let him dust the stigma with the blossoming ears of the early or male parent. The impregnated stalks must then be kept apart from other wheats that the progeny may be true. When the grains ripen, let him sow the best; and from the produce, when ripe, select the earliest and finest spikes for seed. Let him sow these, and repeat the choice till he procures a bushel or two of seed. This operation has been successfully performed by T. A. Knight (1633); and though it may be reckoned too delicate for farmers in general, it will be looked on by the philosophical agriculturist as not improbably leading to results as important as those which have attended the practice in the case of garden fruits and flowers. The scientific farmer may consult on this subject *Bishop's Causal Botany* already referred to; the *Gardener's Magazine*, and *Saggio Botanico Georgico intorno l'ibridismo delle Piante*, by Billardi. Pavia, 1809.

5012. *The propagation of wheat by transplanting* may be employed to expedite the progress of cultivating a new variety of ascertained excellence. To show what may be gained in time by this mode, we shall quote from *The Philosophical Transactions* an account of an experiment made by C. Miller, son of the celebrated gardener of that name, in 1766. On the 2d of June, Miller sowed some grains of the common red wheat; and on the 8th of August, a single plant was taken up and separated into 18 parts, and each part planted separately. These plants having pushed out several side shoots, by about the middle of September, some of them were then taken up and divided, and the rest of them between that time and the middle of October. This second division produced 67 plants. The 6 plants remained through the winter, and another division of them, made about the middle of March and the 15th of April, produced 500 plants. They were then divided no further, but permitted to remain. The plants were, in general, stronger than any of the wheat in the fields. Some of them produced upwards of 100 ears from a single root. Many of the ears measured seven inches in length, and contained between 60 and 70 grains. The whole number of ears which, by the process above mentioned, were produced from one grain of wheat, was 21,109, which yielded three pecks and three quarters of clean corn, the weight of which was 47lbs. 7 ounces; and, from a calculation made by counting the number of grains in an ounce, the whole number of grains was about 386,840. By this account we find, that there was only one general division of the plants made in the spring. Had a second been made, Miller thinks the number of plants would have amounted to 2000 instead of 500, and the produce thereby much enlarged.

5013. *In making a choice from all the species and varieties* which we have named, the thin-skinned white wheats are preferred by all the best British farmers whose soil and climate are suitable for this grain, and for sowing in autumn. In late situations, and less favourable soils and climates, the red varieties are generally made choice of; and these are also generally preferred for sowing in spring. Red wheats, however, are considered as at least fifteen per cent. less valuable than the white varieties. No subvariety ever continues very long in vogue; nor is it fitting that it should, as degeneracy soon takes place, and another and better is sought for as a successor. Hence the only recommendation we can give, as to the choice of subvarieties, is, to select the best from among those in use by the best farmers in the given situation, or nearest well-cultivated district.

5014. *The soils best adapted for the culture of wheat*, are rich clays and heavy loams; but these are not by any means the only description of soils on which it is cultivated. Before the introduction of turnips and clover, all soils but little cohesive were thought unfit for wheat; but, even on sandy soils, it is now grown extensively, and with much advantage, after either of these crops. The greater part of the wheat crop throughout

Britain, however, is probably still sown upon fallowed land. When it succeeds turnips consumed on the ground, or clover cut for hay or soiling, it is commonly sown after one ploughing. In Scotland, when wheat is to be sown after clover upon heavier soils, or after grass of two or more years, the land is ploughed twice or thrice, or receives what is called a rag fallow. In Norfolk and Suffolk, wheat is seldom sown after fallow or turnips; but the farmer there thinks himself almost sure of a good wheat crop after a good clover crop. One ploughing only is required, and the seed is dibbled in the flag, as they call it; that is, on the turned-over surface or furrow slice.

5015. *On rich clays*, wheat may be cultivated almost every second year, provided due care is taken to keep the land clean, and in good condition. A summer fallow once in four, six, or eight years, according to seasons and circumstances, is, however, necessary; and manure should either be applied on that fallow for the first crop of wheat, or, what some people think preferable, should be laid on the wheat-stubble for a crop of drilled beans, which ensures the succeeding crop of wheat. If the first crop of beans has been completely cleaned, there is no difficulty in repeating, and even in extending the course; and the crops will be little inferior to those gained at the beginning of the rotation, provided manure has been bestowed to each crop of beans. In this way, when the ground is fallowed every fourth year, two crops of wheat and one of beans are gained from manuring once; when fallowed every sixth year, three crops of wheat and two of beans are gained from manuring twice; and, when fallowed every eighth year, four crops of wheat and three of beans from manuring thrice. In the first-mentioned shift, less manure is bestowed than in either of the others; and, if the soil is of good quality, it will support itself: whereas, in the shifts of six and eight, unless foreign manure be procured, it rarely happens that they can go successfully for any length of time, without abstracting dung from other parts of the farm on which they are practised. (*Brown's Tr. on Rural Affairs.*)

5016. *In cultivating wheat on thin clays*, the rotations just mentioned are inapplicable. A six-course shift of a different kind has, however, been successfully followed by many people; but it requires every branch of the work to be well executed. 1st, a summer fallow, dunged at the rate of twelve or fourteen double loads per acre; 2d, wheat; 3d, grass; 4th, oats; 5th, peas and beans drilled; 6th, wheat. If manure can be given in the middle of the shift, every one of the crops may be expected good; but if that is withheld, there will necessarily be a proportionable falling off in the two last crops. Husbandmen must, however, regulate their practice according to their means, though it deserves to be remarked, that, if greater attention were paid to the collecting of materials which ultimately are converted into manure, many deficiencies in the article would be fully supplied. (*Brown.*)

5017. *Excellent wheat may be grown on light soils*, with the exception of soft sands. Such soils, however, are not constitutionally disposed to the growth of that grain; nor will they, under any management, bear such a frequent repetition of it as those already mentioned. Summer fallow on them may safely be dispensed with; because a crop of turnips, which admits every branch of the cleaning process to be more perfectly executed than even a naked or bare fallow does, may be profitably substituted. Wheat here comes in with propriety after turnips, though, in general cases, it must be sown in the spring months, unless the turnips are stored; in which case it may be sown in November, or it may be sown after clover, for the fourth crop of the rotation; or in the sixth year, as a way-going crop, after drilled peas and beans, if the rotation is extended to that length. But, take it any way, it is scarcely possible to raise wheat as extensively upon light soils, even where they are of the richest quality, as is practicable upon clays; nor will a crop of equal bulk upon the one, return so much produce in grain as may be got from the other. To enlarge upon this point would only serve to prove what few husbandmen will dispute, though it may be added, that, on thin sands, wheat ought not to be ventured, unless they are either completely clayed or marled; as it is only with the help of these auxiliaries that such a soil can gain stamina capable of producing wheat with any degree of success. (*Brown.*)

5018. *The culture of the soil intended for wheat varies according to its nature, and the preceding and following crops.*

5019. *On soils really calculated for wheat*, though in different degrees, summer fallow is the first and leading step to gain a good crop or crops of that grain. The first furrow should be given before winter, or so early as other operations upon the farm will admit; and every attention should be used to go in as deep as possible; for it rarely happens that any of the succeeding furrows exceed the first one in that respect. The number of after-ploughings must be regulated by the condition of the ground and the state of the weather; but, in general, it may be observed, that ploughing in length and across, alternately, is the way by which the ground will be most completely cut, and the intention of fallowing accomplished. It has been argued, that harrowing clay soils, when summer-fallowed, is prejudicial to the wheat crop; but without discussing this point (such a discussion being unnecessary), it may merely be stated, that, in a dry season, it is almost impracticable to reduce real clays, or to work them too small; and that, even in a wet one, supposing they are made surface-smooth, they will, when ploughed up again, consolidate into clods or big lumps after forty-eight hours' drought, and become nearly as obdurate as ever. It is only on thin soils, which have a mixture of peat earth, and are incumbent on a bottom impervious to water, that damage is at any time sustained by over-harrowing. Such are generally of a weak texture, and may be broken down with facility by the roller and harrow. If caught by much rain before the pores are in some measure closed, the moisture is greedily absorbed; and being prevented from going downwards by the hardness of the subsoil, the whole surface becomes a kind of mortar or paste, unless previously well ridged up; which, to a certain extent, prevents the consequences from being dangerous. These evils, however, must be submitted to by the possessors of such soils, if they want to have them sufficiently fallowed and prepared in a proper manner; for, without reducing them, couch-grass, and especially moss, with which they are commonly stored, cannot be eradicated. If they are reduced in the early part of the season, the danger is small; but to break them down in the latter part ought always to be avoided, unless called for by imperious necessity.

5020. *When wheat is sown after beans* it rarely happens, in this northern climate, that more than one ploughing can be successfully bestowed. Before this is given, it is advantageous to cross-harrow the land, which levels the drills, and permits the ploughing process to be executed with precision. Almost in every case the ridges should be gathered up, so that the furrows may be well cleared out, and the plants preserved from injury during the inclement winter season. Clover land should be neatly ploughed, and well laid over, so that the roots of the grasses may be buried and destroyed; for it frequently happens that crops of wheat, after clover and rye-grass, are greatly injured by inattention to the ploughing process. In short, sowing wheat after clover on clayey soils in Scotland may be considered as the most hazardous way in which that grain can be cultivated. (*Brown's Tr. on Rural Affairs.*)

5021. *The manures best calculated for wheat*, are allowed by all agricultural chemists to be animal matters and lime. The former has a direct influence in supplying that essential constituent to wheaten flour, gluten; and the latter azote and lime, both actually found in the straw of wheat. At all events, it is certain that wheat will not

thrive on any soil which does not contain lime. In this Sir H. Davy, Chaptal, Professor Thaer, and Grisenthwaite fully agree.

5022. *A more abundant supply of manure* is generally required for wheat than for any other grain. Professor Thaer says it absorbs more nourishment from the soil than any of the corn tribe; and he calculates (hypothetically, as he allows,) that for every 100 parts of nutriment in a soil sown with this grain, 40 will be carried off by the crop. (*Principes Raisonnés*, tom. iv. art. *Froment*.) At the same time, too large a dose of manure on land in good tilth is very apt to cause the crop to lodge; and hence some people think it improper to dung rich clays or loams when fallowed, and choose rather to reserve that restorative till the succeeding season, when they are prepared for a crop of drilled beans. Delaying the manuring process for a year is attended with many advantages; because good land, fully wrought, contains such a principle of action within itself, as often causes the first wheat crop to be lodged before it is filled; under which circumstance, the produce is diminished both in quantity and quality. The delay in manuring is, however, attended with disadvantages; because, when dung is kept back till the end of autumn or beginning of winter, to be laid on the stubbles, the weather is often so wet that it cannot be carted on without subjecting the land to injury from poaching, whilst the labour in laying it on is also increased. On thin clays, or even upon soils of the other description not in high condition, there can be no doubt but that the end of summer, and upon summer fallow, is the most proper time for manuring, though it will be found, that an improvident expenditure of dung on such occasions ought always to be steadily avoided. (*Brown*.)

5023. *Where manure is abundant*, it is stated by some that wheat alternating with a green crop, or indeed any corn crop and a green crop, may be grown alternately for an indefinite time. (*Farm. Mag.* vol. xxiii. p. 298.) It is alleged by others, that this doctrine is not supported by experience. Constant tillage, they say, wears out the best soils, and the grain degenerates in quality, if not in quantity too. Instances, however, are given in *The Communications to the Board of Agriculture* of potatoes and wheat having been grown alternately on the same soil for a number of years, and very good crops produced. It may be useful to know that the thing is not impossible.

5024. *The climate* required to bring wheat to perfection must be such as affords a dry and warm season for the blossoming of the ear, and the ripening of the grain. Wheat will endure a great deal of cold during winter, if sown in a dry or well drained soil; and if it be covered with snow. Hence it is that wheat is sown as far north as Petersburg and in Sweden. Moderately moist weather before the flowering season, and after the grain is set or formed, is favourable to wheat; but continued heavy rains after the flowering season produce the smut. The dry frosty winds of February and March, and even of April in some districts, are more injurious to the wheats of Britain than any other description of weather. Hoar frosts, when the plant is in the ear, produce blights; and mildews often result from or follow sultry winds and fogs. Cold, in the blossoming and ripening season in July, even unaccompanied by wind or rain, produces an inferior grain, greatly deficient in gluten; and heat the contrary. The most valuable wheat of Europe, in this respect, is that of Sicily; which Sir H. Davy found to contain much more gluten than the best wheat of Britain.

5025. *The season for sowing* wheat on clays is generally the latter end of autumn; on early turnip soils it is sown after clover or turnips, at almost every period from the beginning of September till the middle of March; but the far greater part is sown in September and October. For summer wheat, in the southern districts, May is sufficiently early, but in the north, the last fortnight of April is thought a more eligible seed-time. In the cultivation of spring-sown winter wheat, it is of importance to use the produce of spring-sown grain as seed, as the crop of such grain ripens about a fortnight earlier than when the produce of the same wheat winter-sown is employed as spring seed. (*Encyc. Brit.* art. *Agr.*)

5026. *Seed wheat is prepared for sowing by the process called pickling*. According to Brown (*Treatise on Rural Affairs*, art. *Wheat*), this process is indispensably necessary on every soil; or otherwise smut, to a greater or less extent, will, in nine cases out of ten, assuredly follow.

5027. *Though almost all practical farmers are agreed as to the necessity of pickling*, yet they are not so unanimous as to the *modus operandi* of the process, and the article which is best calculated to answer the intended purpose. Stale urine may be considered the safest and surest pickle; and where it can be obtained in a sufficient quantity, it is commonly resorted to. The mode of using it does not, however, seem to be agreed upon; for, while one party contends that the grain ought to be steeped in the urine, another party considers it sufficient to sprinkle the urine upon it. Some, again, are advocates for thoroughly steeping the grain in a pickle made of salt and water, sufficiently strong to buoy up a fresh egg. But whatever difference of opinion there may be as to the kind of pickle that ought to be used, and the mode of using it, all admit the utility of mixing the wetted seed with hot lime, fresh slaked; and this, in one point of view, is absolutely necessary, so that the seed may be equally distributed. It may be remarked, that experience justifies the utility of all these modes, provided they are attentively carried into execution. There is some danger from the first; for if the seed steeped in urine is not immediately sown, it will infallibly lose its vegetative power. The second, viz. sprinkling the urine on the seed, seems to be the safest, if performed by an attentive hand; whilst the last may do equally well, if such a quantity of salt be incorporated with the water as to render it of sufficient strength. It may also be remarked, that this last mode is oftener accompanied with smut, owing no doubt to a deficiency of strength in the pickle; whereas a single head with smut is rarely discovered when urine has been used.

5028. *An improved mode of preparing wheat for sowing* has recently been adopted in the south of Scotland, and followed with great success. It is thus described:—“Take four vessels, two of them smaller than the other two, the former with wire bottoms, and of a size to contain about a bushel of wheat, the latter large enough to hold the smaller within them. Fill one of the large tubs with water, and putting the wheat in the small one, immerse it in the water, and stir and skim off the grains that float above, and renew the water as often as is necessary, till it comes off almost quite clean. Then raise the small vessel in which the wheat is contained, and repeat the process with it in the other large tub, which is to be filled with stale urine; and in the mean time wash more wheat in the water tub. When abundance of water is at hand, this operation is by no means tedious; and the wheat is much more effectually cleansed from all impurities, and freed more completely from weak and unhealthy grains and seeds of weeds, than can be

done by the winnowing machine. When thoroughly washed and skimmed, let it drain a little, then empty it on a clean floor or in the cart that is to take it to the field, and sift quick-lime upon it, turning it over and mixing it with a shovel till it be sufficiently dry for sowing." (*Supp. E. Brit. art. Agr.*)

5029. *The quantity of seed* necessarily depends both on the time of sowing and the state of the land; land sown early requiring less than the same land when sown in winter or spring; and poor land being at all times allowed more seed than rich. The quantity accordingly varies from two bushels, or less, to three, and sometimes even to four, bushels per English statute acre. Winter wheat, when sown in spring, ought always to have a liberal allowance, as the plants have not time to tiller much without unduly retarding their maturation. (*Supp. &c.*) Upon well prepared lands, if the seed is distributed equally, it can scarcely be sown too thin; perhaps two bushels per acre are sufficient; for the heaviest crops at autumn are rarely those which show the most vigorous appearance through the winter months. Bean stubbles require more seed than summer fallows; because the roughness of their surface prevents such an equal distribution; and clover layers ought to be still thicker sown than bean stubbles. Thin sowing in spring ought not to be practised, otherwise the crop will be late, and imperfectly ripened. (*Brown.*)

5030. *The modes of sowing wheat* are either broad-cast, drilling, ribbing, or dibbling. The first mode is by far the most general, more especially in the north of England and Scotland, and the seed is for the most part covered by the harrows. No more harrowing, *Brown* observes, should be given to fields that have been fallowed than what is necessary to cover the seed, and level the surface sufficiently. Ground which is to lie in a broken-down state through the winter, suffers severely when an excessive harrowing is given, especially if it is incumbent on a close bottom; though as to the quantity necessary none can give an opinion except those who are present.

5031. *Ploughing in.* Many farmers allege that wheat which is harrowed in is apt to be thrown out in spring; or if not thrown out at that season, that it does not tiller well, and that the stalks are apt to dwindle away and fall down in the flowering season. It is certain that this is the case in many parts of England; and the cause assigned by the northern farmers is the defective manner in which the land is ploughed, by which there is not sufficient covering for the seed. To guard against these evils it is a very general practice in most of the southern counties, when wheat is sown broad-cast, to plough it in with a shallow furrow. This is done even after beans and on clover leys, and is a favourite practice on very opposite soils, as in Norfolk and Middlesex.

5032. *Drilling*, however, is extensively practised in some districts, and is becoming more general on lands infested with the seeds of annual weeds, especially when sown in spring. A machine which sows at three different intervals, according to the judgment of the farmer, of twelve, ten and a half, or nine inches, is much approved of in the northern districts. It deposits six, seven, or eight rows at once, according to its adjustment to one or other of these intervals, and the work is done with ease and accuracy when the ridges are previously laid out of such a breadth (twelve feet and a half) as to be sown by one bout; the machine going along one side of such a ridge, and returning on the other, and its direction being guided by one of its wheels, which thus always runs in the open furrow between the ridges. If the ten and a half inch interval be adopted, and it is the most common one in that country, the machine sows seven rows at once, or fourteen rows on a ridge of twelve feet and a half. But the space between the rows varies in some parts still more than this machine admits of; it ought not, however, to be so narrow as to prevent hand-hoeing, even after the crop has made considerable progress in growth; and it cannot advantageously be so wide as to admit the use of any effective horse-hoe.

5033. *Ribbing is a mode of sowing common in some places*, by which a drill machine is dispensed with, though the same purpose is nearly answered. This we have already adverted to in the section on tillage. The seed is scattered with the hand in the usual broad-cast manner, but as it necessarily falls for the most part in the furrows between the ribs, the crop rises in straight parallel rows, as if it had been sown by a drill machine; after sowing, the ribs are levelled by harrowing across them. This plan has nearly all the advantages of drilling in, as far as it regards exposure to the rays of the sun, and the circulation of air among the plants; but as some plants must always rise between the rows, it is not quite so proper when hoeing is required. (*Sup. E. Brit.*)

5034. *The dibbling of wheat* is practised in some parts of Norfolk. The furrow is laid over flat, and a row of holes is made along the middle of each by a man who uses a dibber in each hand. A middling workman will make four holes in a second. One dibber is sufficient for three droppers; whence one man and three children are called a *set*. The dibbler carries on three flags or turned furrows; going on some yards upon one of the outside furrows, and returning upon the other, after which he takes the middle one; and thus keeps his three droppers constantly employed; and at the same time is in no danger of filling up the holes with his feet. The droppers put two or three grains of wheat into each hole; but much time and patience is necessary to teach them to perform the business properly and quickly. An expert dibbler will hole half an acre in a day; though one third of an acre is usually reckoned a good day's work. The seed is covered by means of a bush harrow; and from one bushel to six pecks is the usual quantity for an acre. Notwithstanding the advantages of saving seed, as well as some others which are generally reckoned undeniable, it is asserted by some very judicious farmers, that dibbling of wheat on the whole is not really a profitable practice. It is particularly said to be productive of weeds, unless dibbled very thick: which, indeed, may probably be the case, as the weeds are thus allowed a greater space to vegetate in. *Marshall* is of opinion, that the dibbling of wheat appears to be peculiarly adapted to deep rich soils, on which three or four pecks dibbled early may spread sufficiently for a full crop; whereas light, weak, shallow soils, which have lain two or three years, and have become grassy, require an additional quantity of seed, and consequently an addition of labour, otherwise the plants are not able to reach each other, and the grasses of course find their way up between them, by which means the crop is injured, and the soil rendered foul. It is alleged, that if a single grain of good size and sound could be dropped in each hole and no more, there might be an advantage in dibbling, where it could be accomplished at a moderate rate; but where two or three grains are put in each hole, and often six or eight, the source of profit is diminished or destroyed by twofold means; first, by using too much seed; and secondly, because three or four grains springing out of one hole will not make such a strong plant or stool as one sound grain. In answer to these remarks, we are informed, that an inquisitive farmer himself dibbled a great many holes, and dropped carefully one, two, three, &c. to ten grains of wheat in each hole. He carefully gathered the wheat, and put the produce of all the one grain holes, and of the two grain holes, and of the three, and so on to the ten, apart: on cleaning the ten portions, those holes which had three, four, and five grains were decidedly the heaviest produce; and he reasonably concluded that three, four, and five grains were the properest number to drop into each hole. To attempt dibbling either wheat or beans by hand on a large scale, we

consider quite unsuitable to the present improved state of agriculture; but it may sometimes happen, that on rich loamy land, especially in a showery season, there may be no other way of getting in the seed.

5035. *The after-culture of wheat, or culture of the growing crop, depends on the manner in which it has been sown.*

5036. *When wheat is sown broad-cast, the subsequent culture must generally be confined to harrowing, rolling, hand-weeding, or hand-hoeing with a pronged hoe. As grass seeds are frequently sown in spring on winter-sown wheat, the harrows and roller are employed to loosen the soil, and cover the seeds. But these operations, to a certain extent, and at the proper season, are found beneficial to the wheat crop itself, and are sometimes performed even when grass seeds are not to be sown. One or two courses of harrowing penetrate the crust which is formed on tenacious soils, and operate like hand-hoeing in raising a fresh mould to the stems of the young plants. Rolling in spring ought never to be omitted on dry porous soils, which are frequently left in so loose a state by the winter frosts, that the roots quit the soil and perish; and, if the land is rough and cloddy, the roller has a still more beneficial effect than the harrows in pulverising the inert masses, and extending the pasture of the plants. Hand-weeding, so far as to cut down thistles and other long weeds, is never neglected by careful farmers; but the previous culture ought to leave as little as possible of this work to be done when the crop is growing. (Supp.)*

5037. *When wheat has been drilled, ribbed, or dibbled, the intervals may be hoed or stirred either by hand-hoes, common or pronged, or by horse-hoes or drill barrows. In general, the drill used at sowing will, by the changes it admits of in its double character of drill and horse-hoe, be the best to use for hoeing or stirring; or if a single drill should have been used, the expanding horse-hoe, or Wilkie's brake harrow, may be successfully adopted. The operation of hoeing or stirring should generally be performed in March, and need not be repeated. When grass-seeds are to be sown among the wheat, the hoeing is an excellent mode of covering them. Weeding the rows should not be neglected, nor delayed later than the beginning of June.*

5038. *Where wheats rise too thin in some places, and too thick in others, whether in rows or broad-cast, the practice of transplanting from the latter to the former has been recommended. This is said to be practised occasionally in Essex and Norfolk, and the time is the end of March. To be attended with success the soil must be in a good state, and the blanks to which the plants are to be transplanted must be stirred up with a trowel or small two-pronged fork. Under such circumstances we have no doubt of the plan being attended with success; but we are certain that without stirring the soil, the operation will not pay for the expense. Blanks are sometimes filled up by sowing summer wheat, dibbling beans, &c. but these are obviously bad modes; a better is either to stir the soil well, by the hand pronghoe, and encourage the tilering of the plants, or to stir the soil and then transplant.*

5039. *Top-dressing wheat crops has been recommended in cases where the land is not in a sufficient state of fertility or preparation to bring the crops to perfection. Substances of both the solid and fluid kinds have been made use of for this purpose; the first consist chiefly of the dung of different sorts of birds, after being brought into a powdery state, bone-dust, soot, peat ashes, and various saline matters. The latter are principally the drainings of dunghills and similar liquid materials. The former should be thinly sown over the crop with as much evenness as possible, as early in the spring as horses can be admitted upon the land without injury; and if it can be done when the weather is inclined to be moist, it is the better, a roller may then be passed over the crop with advantage. Where the latter substances are made use of, care should always be taken that the plants be not injured by having too large a quantity applied to them. In this practice the expense should be a primary consideration, and small trials first made where dungs have not been used. The proper season for performing the business is the beginning of February.*

5040. *When wheat appears too forward and luxuriant, it is sometimes eat down in April with sheep or even with horses, but this requires great judgment to be effected without injuring the crop.*

5041. *In harvesting wheat, the best farmers both of Britain and the continent agree, that it ought to be cut before it becomes dead ripe. When this is the case, the loss is considerable, both in the field and stack-yard; and the grain, according to Professor Thaer, produces a less white flour.*

5042. *In ascertaining the proper state, Brown observes, it is necessary to discriminate betwixt the ripeness of the straw, and the ripeness of the grain; for, in some seasons, the straw dries upwards; under which circumstance, a field, to the eye, may appear to be completely fit for the sickle, when, in reality, the grain is imperfectly consolidated, and perhaps not much removed from a milky state. Though it is obvious that, under such circumstances, no further benefit can be conveyed from the root, and that nourishment is withheld the moment that the roots die; yet it does not follow, that grain so circumstanced should be immediately cut; because, after that operation is performed, it is in a great measure necessarily deprived of every benefit from the sun and air, both of which have greater influence in bringing it to maturity, so long as it remains on foot, than when cut down, whether laid on the ground or bound up in sheaves. The state of the weather at the time also deserves notice; for, in moist, or even variable weather, every kind of grain, when cut prematurely, is more exposed to damage than when completely ripened. All these things will be studied by the skilful husbandman, who will also take into consideration the dangers which may follow, were he to permit his wheat crop to remain uncut till completely ripened. The danger from wind will not be lost sight of, especially if the season of the equinox approaches; even the quantity dropped in the field, and in the stack-yard, when wheat is over-ripe, is an object of consideration. Taking all these things into view, it seems prudent to have wheat cut before it is fully ripe, as less damage will be sustained from acting in this way than by adopting a contrary practice.*

5043. *The mode of reaping wheat is almost universally by the sickle. When cut, it is usually tied up in sheaves, which it is better to make so small as to be done by bands the length of the straw, than so thick as to require two lengths to be joined for bands. The sheaves are set up in shocks or stooks, each containing in all twelve, or, if the straw be long, fourteen sheaves. In the latter case, two rows of six sheaves are made to stand in such a manner as to be in contact at the top, though in order to admit the circulation of air they are placed at some distance below: along this line, two sheaves more are placed as a covering, the corn end of both being towards the extremities of the line. In a few days of good weather the crop is ready for the barn or stack-yard. In the stack-yard it is built either in oblong or circular stacks, sometimes on frames supported with pillars to prevent the access of vermin, and to secure the bottom from dampness; and as soon afterwards as possible the stacks are neatly thatched. When the harvest weather is so wet as to render it difficult to prevent the stacks from heating, it has been the practice to make funnels through them, a large one in a central and perpendicular direction,*

and small lateral ones to communicate with it. In the best cultivated counties the use of large barns for holding the crop is disapproved of, not only on account of the expense, but because corn keeps better, or is less exposed to damage of any kind, in a well-built stack.

5044. *The threshing of wheat*, before machines for that purpose were introduced, was an arduous and difficult task. The expense was very considerable; whilst the severity of the labour almost exceeded the power of the strongest man, especially in unfavourable seasons, when the grain adhered pertinaciously to the ear, and could not, without difficulty, be completely loosened and removed. In such seasons, expense was the smallest consideration which influenced the husbandman; it was the quantity of grain unavoidably lost which occupied his attention; and, as it appeared difficult to find out a remedy, most people considered it as an evil which could scarcely be avoided. In short, the loss was great in almost every case, but greater with wheat than any other grain. Every thing of this nature, however, may be prevented, now that threshing machines are introduced, provided the feeder is careful, and proportions the quantity on the board to the strength of the impelling power. Wheat, in fact, is now the cleanest threshed grain; because the length of the straw allows it to be properly beat out before it passes the machine, which sometimes is not the case with short oats and barley. If horses are used as the impelling power, thin feeding is necessary, otherwise the animals may be injured; but where wind or water is employed, the business of threshing is executed speedily, completely, and economically. (*Brown.*)

5045. *In performing the operation*, one man feeds the grain in the straw into the machine, and is assisted by two half-grown lads, or young women, one of whom pitches or carries the sheaves from the bay close to the threshing-stage, while the other opens the bands of every sheaf, and lays the sheaves successively on a small table close by the feeder, who spreads them evenly on the feeding stage, that they may be drawn in successively by the fluted rollers, to undergo the operation of threshing. In the opposite end of the barn or straw-house, into which the rakes or shakers deliver the clean-threshed straw, one man forks up the straw from the floor to the *straw-mow*, and two lads, or young women, build it and tread it down. In a threshing-machine, worked by water or wind, this is the whole expense of hand labour in the threshing part of the operation, and, as a powerful machine can easily thresh from two to three hundred bushels of grain in a working day of nine hours, the expense is exceedingly small indeed. Assuming two hundred and fifty bushels as an average of the work of these people for one day, and their wages to be nine shillings, the expense does not amount to one halfpenny for each bushel of grain. Even reducing the quantity of grain threshed to one hundred and fifty bushels, the easy work of a good machine of inferior size and power, the expense does not exceed three farthings the bushel. But the whole of this must not be charged against the threshing only, the grain being half-dressed at the same time, by passing through one winnowing-machine, which is always attached to a complete threshing-mill; and where a second can be conveniently connected with it, as is commonly the case if the mill is of considerable power, the corn comes down nearly ready for market: so that the threshing, dressing, and building of the straw, with the use of a powerful water-mill, will scarcely cost more than dressing alone when the flail is employed; after every reasonable allowance for the interest of money, and the tear and wear of the machine.

5046. *When grain is threshed with a machine worked by horses*, the expense is necessarily and considerably enhanced. One capable of effecting the larger quantity of work, already calculated on, will require eight good horses, and a man to drive them, who may perhaps require the aid of a boy. The value of the work of eight horses for a day cannot be less than forty shillings, and the wages of the driver may be called two shillings and sixpence. Hence the total expense of threshing two hundred and fifty bushels will amount to 2*l.* 2*s.* 6*d.*; or about two-pence per bushel, when the wages of the attendants are added; still leaving a considerable difference in favour of threshing by the machine, in preference to the flail. Were it even ascertained that the expense of threshing by horses and by the flail is nearly the same, horse-mills are to be recommended on other accounts; such as better threshing, expedition, little risk of pilfering, &c.

5047. *The produce of wheat* must of course vary, according to the soil, climate, culture, and kind grown. Professor Thaer says, that in general it gives double the weight of straw that it does of grain; on elevated grounds something less; and on low grounds something more. The yield of grain in some seasons has been under twenty, while in others it is upwards of thirty bushels the acre, the soil and culture being in every respect the same. The average produce of Britain has been estimated at three, three and a half, and four quarters; and one of the largest crops ever heard of, at ten quarters, and the least at one quarter and a half. The proportion which the corn bears to the straw, in Middlesex, is eleven and a half bushels to a load of thirty-six trusses of thirty-six pounds each, or eleven and a half cwt.; no great deviation from Professor Thaer's general estimate, a bushel of wheat weighing about 60 or 61 pounds.

5048. *To judge of a sample of wheat*, examine by the eye if the grain is perfectly fed or full, plump and bright, and if there is any adulteration proceeding from sprouted grains, smut, or the seeds of weeds; and by the smell, if there is any improper impregnation, and if it has been too much heated in the mow or upon the kiln; and finally, by the feel, to decide if the grain is sufficiently dry, as when much loaded with moisture it is improper for the uses of the miller and baker. In cases where a sample handles coarse, rough, and does not slip readily in the hand, it may be concluded not to be in a condition either for grinding or laying up for keeping. When melilot and wild chamomile abound among the wheat crop, are reaped with it, and undergo fermentation in the rick, the grain will have the flavour of these strong smelling plants. To detect this in the sample, hold the grain close in the hand, moisten it with the breath, and then smell or taste it. This is the practice at Ampthill and other markets in Bedfordshire.

5049. *The yield of wheat in flour* is, on an average, thirteen pounds of flour to fourteen pounds of grain. In the chemical analysis of wheat, Sir Humphrey Davy found that one hundred parts of good full-grained wheat, sown in autumn, yield of starch seventy-seven, and of gluten nineteen; one hundred parts of wheat, sown in spring, seventy of starch, and twenty-four of gluten. American wheats he found to contain more gluten than the British; and, in general, the wheat of warm climates to abound more in gluten and in insoluble parts, and to be of greater specific gravity, harder, and more difficult to grind.

5050. *The uses of wheat* in the baking, culinary, and confectionary arts are well known. It is also used for making starch, by steeping the grain and then beating it in hempen bags. The mucilage is thus mixed with the water, produces the acetous fermentation, and the weak acid thus formed renders the mucilage white. After settling, the precipitate is repeatedly washed, and then moulded into square cakes and kiln-dried. In drying, the cakes separate into flakes, as in the starch of the shops. Starch is soluble in hot water, but not in cold; and hence, when ground down, it makes an excellent hair powder. Its constituents are: carbon, 43.55; oxygen, 49.68; and hydrogen, 6.77 = 100.

5051. *The uses of wheat straw* are various and well known. As fodder it is, according to Professor Thaer, the most nourishing of any; and it makes the best thatch: it is generally preferred for litter, though rye and barley straw are softer: it is used for making bee-hives, horse collars, mattresses, huts, boxes, baskets, and all kinds of what is called Dunstable work; for the cider press; and, among other things, for burning, to procure potash from the ashes. The straw of wheat from dry chalky lands is manufactured into hats for both men and women. For this purpose, the middle part of the tube, above the last joint, is taken; and, being cut into a length of eight or ten inches, is split in two. These splits are then plaited, by females and children, into various kinds of plait or ribands, from half an inch to an inch broad: these, when sewed together according to fancy or fashion, form different descriptions of ladies' bonnets, and the commoner plait and coarser straw of men's hats. The hats are whitened by being placed in the vapour of sulphur. Leghorn hats are made from the straw of a bearded variety of wheat, which some have confounded with rye. It is cultivated on the poorest sandy soils in the neighbourhood of the Arno, between Leghorn and Florence, expressly for this manufacture. It is of humble growth, and not above eighteen inches high; is pulled up when green, and bleached white by spreading and watering on the gravelly banks of the Arno. The straws are not split; but in other respects the manufacture into ribands is the same as at Dunstable in England and in the Orkney Islands.

5052. *The Leghorn manufacture of wheat straw* into the well-known hats has lately been enquired into, and detailed in several publications. The variety of wheat cultivated in Tuscany for this purpose is known as the *grano marzuolo*, or *marzolano*, a variety of summer wheat with long bearded ears. It is cultivated on the sandy hills on both sides of the valley of the Arno. The seed is sown in March, very thick, and pulled when the ear is fully shot, but before the grain is formed. It is then 18 inches high, if the crop is good; it is bleached as we do flax, and afterwards tied up in bundles in the same manner, and carried home, to have the part between the ear and the first fruit in the stalk selected, that being the only part used. (*Gard. Mag.* vol. v. p. 70.)

5053. *To obtain the whiteness so much prized*, the straw is smoked with sulphur previously to being worked; the plait is also smoked; and, lastly, the hat. About Sienna the process is simply a little sulphur set on fire in the bottom of a large chest, bunches of the straw being placed on long hazel rods across, and the lid shut down. Elsewhere the articles are described as being placed in a small close room, in which a chafing dish of sulphur is placed, and set fire to. Sometimes the operation requires to be done twice before it succeeds.

5054. *The straw for use is classed or stapled like our wool*. Children or inferior hands work the coarse thick straw, while good hands work the fine only. Whether fine or coarse, it is only the part on which the spike grows that is made use of; and it is always the same plait, consisting of thirteen straws, which is worked. In the fine plait there is a very great waste of straw, as they reject all that is in the least too thick, and they cut off a considerable part of the straw when it comes near the flower-spike. Fine plait is not accounted good unless very much drawn together; for which end it is worked very wet. The bunches of straw are always put into a small jar, filled with cold water, which stands beside the worker. After being smoked and pressed, the plait is made up into hats by women, who do nothing else; it is not put together by edges, nor overlapped. On the operation of pressing, a great deal depends: there are only two good machines for that purpose in the country. Such is the practice for procuring the hat straw: what they sow for seed is in other ground: not one fourth of the seed is used, and the grain is allowed to come to maturity in the usual way. It is said to be a capital wheat for vermicelli, macaroni, &c. and also for making into bread. (*Gard. Mag.* vol. v. p. 71.)

5055. *The introduction of the grano marzuolo into Britain* has been tried, but not attended with success. Messrs. J. and A. Muir, after various trials, found the straw of rye preferable.

5056. *The mode of plaiting is as follows*: — The straws being picked, and put into separate bundles, according to their quality, let thirteen of them be taken and tied firmly together by the seed ends; attach them to any thing, such as the back of a chair, to keep them steady; then take hold of the loose end of the bundle, putting six straws into the one hand, and seven into the other. Take the outermost, and with it cross over two; then carry it behind the next two; and lastly, before the remaining two; after which lay the straw into the other parcel of six. The first parcel of six being now made seven, take the outermost straw of it, and carry it across the bundle, by two, as in the former case, laying at last this seventh straw into the outer parcel as before. It will be understood by this, that the outermost straw of each parcel is always made the acting straw, and that, in the progress of the operation, each of the straws of both parcels is thus employed in its turn.

5057. *As the work goes on*, it will be necessary now and then to join in new straws. Seeing any one needing to be renewed, watch until it becomes the acting straw; and, when it is to be laid into the other parcel, after performing its round, lay it up over the piece of plait, instead of putting it into the

parcel as formerly, and in place of it lay in a new straw, which is then to be used exactly as if it were the old one.

5058. *If by chance, in working, any of the straws should break, a thing which can scarcely happen with wine-straws to any but the outermost straw, and to it only through want of attention, it may be remedied without any more trouble than putting in a new one in its place; and though the outside of the plait with the old and new straw should exhibit the appearance of a broken loop, yet, in the knitting up of the work, it can easily be so managed that the defect shall be entirely concealed.*

5059. *The knitting need not be begun till as much of the plait is made as may be supposed sufficient to form a hat, as an entire hat of any desired shape may be made up of a single piece of plait. About 70 or 80 yards will be sufficient to make a lady's hat.*

5060. *Outside and inside of the hat.* In joining in new straws during the plaiting, the ends of the new and old having been kept on the upper side of the plait, this will therefore be made the inside of the hat. After twisting and turning the plait a little, to make it form the round piece for the top, the plait will be found to lie with the one side to the other, like the teeth of two saws turned to each other; and then so to unite these two opposite sides that they may present the appearance of one piece, begin to sew by putting the needle in through the sort of stitch or loop on the outside of the plait, inserting the needle from below. Take the stitch of the opposite piece in exactly the same way, and, after four or five stitches of each side are taken on the thread, draw it up tightly, so that the stitches of both may be brought firmly the one beside the other. In this manner, in the course of the operation, it will soon be seen that the place where the seam is can scarcely be discovered from the rest of the plait.

5061. *To sew the crown of the hat so that it may be quite plain, every stitch of the one side must not be taken with every one of the other, but every second or third only of one of the sides, till the work get on a little.*

5062. *The blocking of a hat may be done with any round piece of smooth stick that will fill it. After the hat is well steeped, and put on the block, it may be made quite smooth by beating it gently with a hammer. (Quar. Jour. Ag. vol. i. p. 294.)*

5063. *The diseases of wheat are the rust, smut, or black mildew, the latter including what is vulgarly called blight. These have been already treated of in our view of the vegetable economy, and we shall merely offer a few practical observations on the smut and mildew.*

5064. *The proximate cause of smut, in whatever manner the smut may be transmitted from the seed pickle in the ground to the ear, it seems certain, is in general the infection of the seed by the dust of the smut-ball, which B. de Jussieu first conjectured to be Lycoperdon globosum, and which M. Prevost ascertained to be a microscopic vegetable of some sort; and that though the most careful washing, even with the application of caustics, may not in every case insure against smut, yet if the seed be prepared in the way already mentioned, the disease will never prevail to such a degree as to affect materially the value of the crop. This is all that cultivators need to know, and all, perhaps, in the present state of science, that can be known, of the cause and prevention of smut. See an article at length on this subject in the British Farmer's Magazine, vol. iii. p. 176.*

5065. *Mildew is a much more destructive distemper than smut; and, as it is probably occasioned by a peculiar state of the atmosphere during the periods of flowering and ripening, it is likely to baffle all attempts at prevention. The prevalence of heavy fogs or mist, drizzling rains, and sudden changes in the temperature, have been assigned as the causes of mildew; and as it has been found that open airy exposures are much less affected than low sheltered lands, in years when mildew prevails most generally, the disorder may perhaps be somewhat diminished by drilling, which admits a freer circulation of air. Spring or summer wheat is less liable to mildew than the winter species, though it does not always escape. Minute parasitical Fungi, Puccinia Graminis (Enc. of Plants), are commonly detected on the straw of mildewed wheat; and there cannot be the least doubt that the barberry bush, and probably several other shrubs on which these Fungi abound, have a powerful influence in communicating the disease to a certain distance. (Sir Joseph Banks on Mildew, and Com. to the B. of Agr. vol. vii.)*

5066. *The wheat fly has, of late years, been one of the greatest enemies to the wheat crop in Scotland. In North America this insect, or one of the same family, has been known for many years, more especially in New England; and its alarming ravages are depicted from time to time in the newspapers, under the name of the Hessian fly. In the modern nomenclature, the Rev. W. Kirby informs us that the wheat fly, formerly the Tipula tritici Lin., is now the Cecidomyia tritici (fig. 724 a), and the Hessian fly the*

*C. destructor (b). The wheat fly generally makes its appearance about the end of June; and, according to the observations of Mr. Shirreff, they exist throughout a period of thirty-nine days. The hue of the fly is orange, the wings transparent, and changing colour according to the light in which they are viewed. It lays its eggs within the glumes of the florets, in clusters varying in number from two to ten, or even fifteen; and the larvæ feed upon the grain. "They are produced from the eggs in the course of eight or ten days: they are at first perfectly transparent, and assume a yellow colour in a few days afterwards. They travel not from one floret to another, and forty-seven have been numbered in one. Occasionally there are found in the same floret larvæ and a grain, which is generally shrivelled, as if deprived of nourishment; and although the pollen may furnish the larvæ with food in the first instance, they soon crowd around the lower part of the germen, and there, in all probability, subsist on the matter destined to form the grain." (Mag. Nat. Hist. vol. ii. p. 450.) The larvæ are preyed on by the Cérâphron destructor, an ichneumon fly, which deposits its eggs in the body of the larvæ of the wheat fly; and this is the only check hitherto discovered for preventing the total destruction of the wheat crops attacked by the Cecidomyia. Mr. Shirreff, speaking of this ichneumon, says, "I could not determine if it actually deposits its eggs in the maggot's body; but there can be no doubt, however, of the ichneumon piercing the maggots with a sting; and, from stinging the same maggot repeatedly, it is probable the fly delights to destroy the maggots, as well as to deposit eggs in their bodies. The earwig, also, devours the maggots as food. (Brit. Farm. Mag. vol. iii. p. 453.) Mr. Gorrie estimates the loss sustained by the farming interest in the Carse of Gowrie district alone by the wheat fly, at 20,000*l.* in 1827, at 30,000*l.* in 1828, and at 35,000*l.* in 1829. (Perth Miscellany, vol. i. p. 42.) The same writer, in May 1830, thus depicts the prospect of the wheat crop in the Carse of Cowrie:—"The Cecidomyia are still alive in formidable legions. That the flies will this season be in as great plenty as ever, is now quite certain; that they will lay their eggs on no other plant than those of the wheat genus, is also true; the only chance of escape is in the time the pupæ appear the fly state. Should this sunny weather bring them forward within a fortnight or three weeks from this date, the greater part will have perished before the wheat is*

in the ear; or should the earing take place before the flies appear, then only the late or spring-sown wheats will suffer: but these appear slender chances. We know the history and habits of the insect too well to believe that either mist, or rain, or dew, or drought, will either forward or retard their operations, if the main body appear about the time the wheat comes in the ear. In addition to that vile gnat, our neighbours in the Lothians are threatened with a no less formidable invader in the *Asciis pumiliarius*, which, as we are informed on respectable authority, have already commenced their depredations, and are thinning the wheat plants rather liberally in that quarter. It, like the Hessian fly in America, attacks the under joints, which become habitations for the young larvæ. As far as our observation extends, this pest has not yet reached us in noticeable numbers." (*Country Times*, May 17. 1830.)

5067. *The culture of summer wheat* differs from that of winter or spring-sown winter wheat, in its requiring a more minutely pulverised and rather richer soil. It need not be sown sooner than April, and it advances so rapidly to maturity that it hardly affords time for hoeing (if sown in rows), or harrowing and rolling. When grass or clover seeds are sown on the same ground, they are sown immediately after the wheat, and harrowed in with a light harrow or rolled in. In this respect, and indeed in all others, the preparation of the soil and sowing of this grain are the same as for barley.

5068. *The produce of summer wheat*, both in grain and straw, is considerably less than that of winter wheat: the straw is only fit for litter or inferior fodder; the flour produced by the grain is rather coarser and darker than that of common wheat. Of course this sort of wheat cannot, as already observed, be recommended for general culture.

SECT. II. *Rye*. — *Secale cereale* L.; *Triándria Digýnia* L., and *Gramíneæ* J. *Seigle*, Fr.; *Rogon*, Ger.; *Segale*, Ital.; and *Centeno*, Span. (fig. 725.)

5069. *Rye*, according to some, is a native of Crete; but it is very doubtful whether any country can be now ascertained to be its native soil. It has been cultivated from time immemorial, and is considered as coming nearer in its properties to wheat than any other grain. — It is more common than wheat on most parts of the continent, being a more certain crop, and one which requires less culture and manure. It is the bread corn of Germany and Russia. In Britain it is now very little grown, being no longer a bread corn, and therefore of less value to the farmer than barley, oats, or peas. Many consider it the most impoverishing of all corn crops.

5070. *The varieties of rye* are not above two, known as winter and spring rye: but there is so little difference between them that spring rye sown along with winter rye can hardly be distinguished from it.

5071. *The soil for rye* may be inferior to that chosen for wheat: it will grow in dry sandy soils, and produce a tolerable crop; and, on the whole, it may be considered as preferring sands to clays. The preparation of the soil should be the same as for wheat. According to Professor Thær, rye abstracts 30 parts in 100 of the nutriment contained in the soil on which it is grown.

5072. *The climate for rye* may be colder than for wheat; but it is rather more injured by rains during winter, and equally injured by moist weather during the flowering season.

5073. *Rye is sown* either in autumn or spring, and either broad-cast or in drills: two bushels and a half is the usual allowance when it is sown broad-cast. As it vegetates more slowly than wheat, it should be sown when the soil is dry; a wet soil being apt to rot the grain before it has completely germinated. No pickling or other preparation is given.

5074. *The after culture, harvesting, and threshing* are the same as for wheat; and the produce in grain is, under similar circumstances, equal in bulk; but in straw it is greater in rye than in any other grain. Sir H. Davy found, in 1000 parts of rye, 61 parts of starch and five parts of gluten. Professor Thær says rye is the most nourishing grain next to wheat. It contains an aromatic substance, which appears to adhere more particularly to the husk, since the agreeable taste and smell peculiar to rye bread are not found in that which is made from rye flour that has passed through a very fine bolting-cloth; while the fragrance may be restored by a decoction of rye bran in the warm water used to make the dough. This substance, Thær says, seems to facilitate digestion, and has an action particularly refreshing and fortifying on the animal frame.

5075. *The use of rye* is chiefly for bread, especially for gingerbread. It is also used in the distilleries; and the straw is used for the same purposes as that of wheat, except that it is useless as fodder. Some prefer it for thatching and litter, and also for collar-making; it is also employed in Dunstable work. Tanners are said to use it in some districts.

5076. *Rye is sometimes sown as a green crop*, with a view of affording some keep for sheep early in the spring, and also for being ploughed in as manure; but that husbandry

must be bad or unfortunate which requires recourse to either mode. In some districts it is customary to sow the head lands of wheat fields with rye, which is said to keep poultry from penetrating to the wheat.

5077. *The manufacture of rye straw into plait for hats* is a new application, for which the public are indebted to Messrs. J. and A. Muir of Greenock, manufacturers of straw hats in imitation of those of Leghorn. Messrs. Muir had previously tried rye grass, crested dog's-tail grass, sweet-scented vernal grass, and the straw of wheat, raised both from British and foreign seed, without success. At last the idea of employing rye straw was suggested to them; and they now send annually to their establishment in the Orkney Islands (founded by an English gentleman about 1820) "from 40 to 45 bolls, which are sown on about twelve English acres of sandy soil, manured with sea-weed. Several acres of heath for bleaching the straw, and water for steeping it, are required in the neighbourhood of the rye fields. The rye is cut when the seed is beginning to form; and it is necessary to attend to the precise time, for ten days too early or too late produce a considerable difference in the look of the straw. When the rye is cut, women are employed to tie it at the lower extremity in handfuls; it is then put into boxes, and covered with boiling water, in which it remains for half an hour. After this it is spread out upon the heath in a fan form, and turned twice daily, until the bleaching, which takes about ten days, is completed. If exposed to much rain while bleaching, the straw is injured in colour, and rendered very liable to take mildew. It is of great importance to have the crop well housed."—"The seed of the rye is sown in April, in mossy ground, recently rendered arable; and if the season is at all favourable, it comes into flower in July, when it is cut down. The whole stem is then immersed in boiling water, in a trough made for the purpose, and remains in this state for two hours. When taken out, it is spread upon a grass field, and exposed to the sun, till it is properly bleached, which requires from two to four days, according to the weather. When bleached, the stalk is divided into separate parts at each joint, and put up into bundles by the lengths. In this manner, the bundles lie in a proper place till wanted by the plaiters. This last process is done chiefly by old people, who are unable for the finer work, or by those pupils who have only lately joined the manufactory. (*Trans. Highl. Soc.* vol. vii. pp. 286. and 280.) The mode of plaiting has been already described. (§ 5056.)

5078. *Rye is less subject to disease than most other grain*, and is even sown among wheat and round wheat fields from an idea that it will keep off blight and mildew as well as poultry.

5079. *The spur or ergot of rye* is by some considered as a fungus, a species of *Sclerotium*, somewhat analogous to that which produces the smut. It is not peculiar to rye, but it is very seldom found on any other gramineous plant. "It is a production of the seeds; is long, horny, and cartilaginous; and is sometimes straight, at others curved; sometimes it is found more than two inches in length. The resemblance of this substance to cocks' spurs has given it the name by which it is distinguished. On breaking a spurred seed, you find within it a substance of a dull white colour adhering to the violet skin that surrounds it. Rye thus attacked cannot germinate. M. Tessier remarked that the most rainy years were the most productive of this disease; that the soils on which most spurred rye grew were most moist; that high grounds were nearly free from them, unless when the furrows prevented the water from running freely off, while the lower parts of the same field produced more than the upper parts." (*Brit. Farm. Mag.* vol. iii. p. 302.) In France a disease, called the chronic or dry gangrene, has been produced by eating ergot. This disease is also known in Switzerland, where it was observed that most animals refused to eat diseased rye, or rye affected with the cocks spur, as it is called. The Royal Society of Medicine at Paris employed M. Tessier, a distinguished agricultural writer and man of science, to go into the countries where the dry gangrene prevailed, and collect a sufficient quantity of the ergot or cocks spur rye for experiments. The result confirmed the opinion of those who attributed the disease to the cause assigned. "France afforded, also, a simple explanation of the fact that persons might live for a considerable time upon rye affected with the cocks spur, without suffering any sensible injury from its use; since, in all the animals upon which it was tried experimentally, a given quantity was required to produce the specific effect; and they suggested the only measure, that of separating the diseased from the sound rye, which could prevent so great a national calamity as that which has been so often produced by its use." The spurred rye occasionally occurs in this country, but there are no instances recorded of its producing any such effects as it is said to do in France; but in the *Philosophical Transactions* Dr. Wollaston has narrated several cases in which dry gangrene was produced in one family by partaking of damaged wheat; and nearly the same effects were produced in a family in Wiltshire by the *Lilium temulentum* entering largely into the composition of bread. (*Stephenson and Churchill's Med. Bot. art. Scetele.*) M. Lagasca states that the ergot is covered with a thin pellicle and filled with a grey powder. It is collected in Spain by women and children, who wade in the fields of standing rye for the purpose, and with their utmost vigilance can obtain it but in very small quantities, in consequence of which it sells high as an article of the materia medica. (*Brit. Farm. Mag.* vol. iii. p. 158.) Medicinally it is used in uterine diseases.

SECT. III. *Barley*. — *Hórdeum* L.; *Triándria Digýnia* L., and *Gramíneæ* J. *L'Orge*, Fr.; *Gerste*, Ger.; *Orzo*, Ital.; *Byg*, Dan. and Swed.; and *Cebada*, Span.

5080. *Barley*, though less calculated for a bread corn than rye, may be considered as next in value to wheat in Britain. Of what country it is a native is unknown. Some assign it to Tartary, others to Siberia, and even Scotland has been mentioned. It has been cultivated from the earliest antiquity, and was much in use among the Romans, both as food for soldiers and horses. In Sweden and Lapland it is more cultivated than any other grain, on account of its requiring to be so short a period in the soil; sometimes not longer than six weeks, and seldom more than seven or seven and a half. In Spain and Sicily they have two crops a year on the same soil: one is sown in autumn and ripens in May, and the other is sown in May and reaped in autumn. In Britain barley is a tender grain, and easily hurt in any of the stages of its growth, particularly at seed time: a heavy shower of rain will then almost ruin a crop on the best prepared land; and in all the after processes greater pains and attention are required to insure success than in the case of other grains. The harvest process is difficult, and often attended with danger; even the threshing of it is not easily executed with machines, because the corn generally adheres to the grain, and renders separation from the straw a troublesome task.

5081. *Species and varieties.* (fig. 726.) There are six species and subspecies of this grain in cultivation besides varieties. These are,—

- | | |
|--|---|
| <p>1. <i>Hordeum vulgare</i>, Spring barley (a).
 2. <i>céleste</i>, Siberian barley.
 3. <i>hexastichon</i>, Winter barley (b).</p> | <p>4. <i>Hordeum distichon</i>, Common or long-eared barley (c).
 5. <i>distichon nudum</i>, Naked barley.
 6. <i>Zoecriton</i>, Sprat or battledore (d).</p> |
|--|---|

The second and fifth sorts are allowed to be subspecies or varieties of the first and fourth, and indeed there can be little doubt that the whole do not constitute more than one species.

5082. *The spring barley or early barley (a), Orge carrée, Sucrion de printemps, Fr.*, is distinguished by its double row of beards or awns standing erect, and its thin husk, which renders it favourable for malting. This is the sort principally cultivated in the southern and eastern districts of both England and Scotland, and of which the farmers make two sorts, viz. the common, and the rath-ripe barley: but these two sorts are in reality the same; for the rath-ripe is only an alteration of the common barley, occasioned by being long cultivated upon warm gravelly soils. The seed of this, when sown on cold or strong land, will, the first year, ripen near a fortnight earlier than the seed taken from strong land, and therefore the farmers in the vales generally purchase their seed-barley from the warm or gravelly lands; for, when preserved in the vales two or three years, it becomes full as late, in ripening as the common barley of their own product: on the other hand, the farmers on warm lands are also obliged to procure their seed-barley from the strong lands, otherwise their grain would degenerate in bulk or fulness, which by this change is prevented.

5083. *The Siberian barley, Orge céleste, Fr., and Himmel gerste, Ger.*, is a variety of early barley with broader leaves, and reckoned more productive than the other. It is much grown in the north of Europe, and was introduced to this country in 1763, but is believed to be now lost or merged in the parent species.

5084. *Winter barley, late barley, or square barley (b), Orge carrée d'hiver, Escourgeon, Fr.*, has the grains disposed in four or in six rows, large and thick skinned. It is chiefly cultivated in the north of England and in Scotland, on account of its hardness; but from the thickness of its rind it is ill adapted for malting, and is going out of use.

5085. *Bigg, byg, or barley big*, is a variety of winter barley known by always having six rows of grains, by the grains being smaller and the rind thicker, and by its being earlier than the parent variety. Professor Martyn says, he has frequently counted forty-two grains on one ear of bigg, when common or long-eared barley had only twenty-two.

5086. *Common or long-eared barley (c)*, is known by its very long spike or ear, flattened transversely, greater in breadth than thickness, with chaff ending in an awn sixteen times the length of the grain. This sort is cultivated in many parts of England and Scotland; though some object to it because the ears being long and heavy they think it apt to lodge.

5087. *Naked barley, or wheat barley, Orge nue à deux rangs, Fr.*, is known by the grain separating easily from the chaff, and is by some considered as nothing else than spelt wheat, which it greatly resembles. It does not appear to be cultivated at present in any part of Britain.

5088. *Sprat, or battledore barley (d), Orge éventail, Orge-riz, Fr.*, is known by its low stature, coarse straw, short broad ears, and long awns. The long awns and closeness of the ears protect it better from birds than most other sorts, but as the straw is scanty and of little use it is not much cultivated.

5089. Besides these sorts there are some *local varieties*, as Thanet barley, Putney barley, &c. which are merely names given to the varieties common in those places. The Thanet is the winter, and the Putney the sprat barley.

5090. *New varieties* may be procured by selection or crossing, as in the case of wheat. (5009.)

5091. *In choosing a sort of barley for cultivation*, regard must be had to the soil and climate. The hardest may be considered the winter barley, and the earliest, and perhaps the best, is the spring barley. The long-eared is also a much esteemed variety.

5092. *In choosing from any particular variety, the best grain for sowing* is that which is free from blackness at the tail, and is of a pale lively yellow colour, intermixed with a bright whitish cast; and if the rind be a little shrivelled, it is so much the better, as it shows that it has sweated in the mow, and is a sure indication that its coat is thin. The husk of thick-rinded barley being too stiff to shrink, will lie smooth and hollow, even when the flour has shrunk from it within. The necessity of a change of seed from time to time, by sowing that of the growth of a different soil, as it has been observed, is in no instance more evident than in the culture of this grain, which otherwise becomes coarser and coarser every year. But in this, as well in all other grain, the utmost care should be taken that the seed is full bodied.

5093. *The best soil for barley* is a light rich loam, finely pulverised. It will neither grow well on a sandy or soft soil, nor on strong clays, such as are suitable for wheat.

5094. *The preparation of the soil* is sometimes by a naked fallow, but generally by a turnip fallow; sometimes it is taken after peas and beans, but rarely by good farmers either after wheat or oats, unless under special circumstances.

5095. *When sown after turnips* it is generally taken with one furrow, which is given as fast as the turnips are consumed, the ground thus receiving much benefit from spring frosts. But often two or more furrows are necessary for the fields last consumed; because, when a spring drought sets in, the surface, from being poached by the removal or consumption of the crop, gets so hardened as to render a greater quantity of ploughing, harrowing, and rolling necessary than would otherwise be called for. When sown after beans and peas, one winter and one spring ploughing are usually bestowed; but, when after wheat or oats, three ploughings are necessary, so that the ground may be put in proper condition. These operations are very ticklish in a wet and backward season, and rarely in that case is the grower paid for the expense of his labour. Where land is in such a situation as to require three ploughings before it can be sowed with barley, it is better to summer fallow it at once, than to run the risks which seldom fail to accompany a quantity of spring labour. If the weather be dry, moisture is lost during the different processes, and an imperfect germination necessarily follows: if it be wet, the benefit of ploughing is lost, and all the evils of a wet seed-time are sustained by the future crop. (*Brown.*)

5096. *To whatever crop barley succeeds,* the harrow and roller, when the plough alone is insufficient, should be employed in reducing the soil to a considerable degree of fineness. In most cases more than one earth is given; though, after a winter furrow, the grubber may be used in spring instead of the plough. After turnips, eaten on the ground by sheep, the land, being consolidated by their treading, sometimes receives two ploughings; but, if only one, it should be well harrowed and rolled; and it is often finished by harrowing after the roller, especially if grass-seeds be sown, which are covered by this last harrowing. Barley is sometimes sown on the first ploughing, and covered by a second shallow ploughing. As it is found of great importance, with a view to speedy and equal vegetation, that the ground should be fresh and moist, barley is generally sown upon what is termed *hot-fur*, that is, as soon as possible after it is turned up by the plough.

5097. *Manure* can seldom be given with advantage to a crop that occupies the soil so short a period as barley, and therefore it generally is sown on land which has been enriched for a preceding crop.

5098. *The climate* in which barley delights is warm and dry. There are instances of a crop being sown and ripened without having enjoyed a single shower of rain; but gentle showers from the time it is sown till it begins to shoot into the ear, are favourable; while heavy rains at any period, and especially immediately after sowing, or during the blossoming, ripening, and reaping seasons, are highly injurious.

5099. *The best season for sowing* barley is considered to be from the beginning of April to the middle of May; but bigg may be sown either in autumn to stand the winter, or as late as the first week of June. In England, the winter or four-rowed barley is frequently sown in autumn, and stands the most severe winters. With respect to the lateness at which bigg and summer barley may be sown, much depends on the sort of weather which occurs during the first three weeks after sowing.

5100. *When barley is sown late* it is sometimes steeped in common water to promote its germination; but it is seldom pickled or otherwise prepared. The advantages of steeping are, procuring an equal germination, and consequently ripening, and getting the start of weeds. The following directions are given for performing the operation:—First, take out about one-third of the contents of the sacks of seed barley or bear to allow for the swelling of the grain; lay the sacks with the grain to steep in clean water; let it be covered with it for at least twenty-four hours; when the ground is very dry, and no likelihood of rain for two or three days, it is better to lie thirty-six hours. Sow the grain wet from steeping without any addition. The seed will scatter well as clean water has no tenacity; only the sower must put in a fourth or a third more seed in bulk than is usual of dry grain, as the grain is swelled in that proportion. Harrow it in as quickly as possible after it is sown; and, though not necessary, give it the benefit of a fresh furrow if convenient. You may expect it up in a fortnight at farthest. (*Brown.*)

5101. *The quantity of seed* is different in different cases, according to the quality of the soil and other circumstances. Upon very rich lands, eight pecks per acre are sometimes sown; twelve is very common; and upon poor land, more is sometimes given.

5102. *Whether the practice of giving so small a quantity of seed to the best lands is advantageous* or the reverse, seems a disputed point among the best farmers. That there is a saving of grain there can be no doubt; and that the bulk may be as great as if more seed had been sown, there can be as little question. Little argument, however, is necessary to prove that thin sowing of barley must be attended with considerable disadvantage; for if the early part of the season be dry, the plants will not only be stunted in their growth, but will not send out offsets; and if rain afterwards fall, an occurrence that must take place some time during the summer, often at a later period of it, the plants begin to stool, and send out a number of young shoots. These young shoots, unless under very favourable circumstances, cannot be expected to arrive at maturity; or if their ripening be waited for, there will be a great risk of losing the early part of the crop, a circumstance that frequently happens. In almost every instance an unequal sample is produced, and the grain is for the most part of an inferior quality. By good judges, it is thought preferable to sow a quantity of seed sufficient to ensure a full crop, without depending on its sending out offsets; indeed, where that is done, few offsets are produced, the crop grows and ripens equally, and the grain is uniformly good. (*Brown on Rural Affairs.*)

5103. *The modes of sowing* barley are either broad-cast, or in rows by the drill or ribbing. The broad-cast mode is almost universally adopted; unless in lands much infested with annual weeds, where drilling and hand-hoeing, and in particular cases horse-hoeing, may be employed with advantage.

5104. *The only culture* which barley requires while in a growing state, is hoeing and weeding if in rows, and weeding alone if broad-cast. Sometimes barley is rolled to compress a soft soil and exclude the drought, and when very thick it may be first harrowed and then rolled. Grass seeds and clover are sown with the grain before the last harrowing, when the broad-cast mode is adopted; and immediately before hoeing, when the barley is in rows. The former is much the best mode for insuring a strong plant of clover.

5105. *Eating down barley*, which from winter or very early sowing is over-luxuriant, is practised in some districts, but it is alleged that mowing is much better than feeding it; because the scythe takes off only the rank tops, but the sheep feed upon all indifferently; nor should they even, in any case, be left

upon it too long, because, being particularly fond of the sweet end of the stalk next the root, they bite so close as to injure the future growth of the plant.

5106. *Barley is ripe* when the red roan, as the farmers term it, meaning a reddish colour on the ear, is gone off; or when the ears droop, and fall, as it were, double against the straw, and the stalks have lost their verdure; but in the latter case it is too ripe.

5107. *In the harvesting of barley* more care is requisite than in taking any of the other white crops, even in the best of seasons; and in bad years it is often found very difficult to save it. Owing to the brittleness of the straw, after it has reached a certain period it must be cut down; as, when it is suffered to stand longer, much loss is sustained by the breaking of the heads. On that account it is cut at a time when the grain is soft, and the straw retains a great proportion of its natural juices, consequently requires a long time in the field before either the grain is hardened or the straw sufficiently dry. When put into the stack sooner it is apt to heat, and much loss is frequently sustained.

5108. *Barley is generally cut down* in England with the cradle scythe, and either tied up or carted home loose after lying in the swath some days to dry. It is not apt to shed; but in wet weather it will be likely to spout or grow musty; and therefore every fair day after rain it should be shaken up and turned: and when it is tolerably dry, let it be made up into shocks; but be careful never to house it till thoroughly dry, lest it mow-burn, which will make it malt worse than if it had spired in the field. It is remarked by Lisle, that poor thin barley should be cut a little sooner than if the same plants were strong and vigorous; as the straw, when the plants are full ripe, in such cases will not stand against the scythe. In this situation, barley in particular should lie in swath till it is thoroughly dry. Some of his barley, which lay out in swath five or six days in very fine weather, though both blighted and edge-grown, grew plump, and acquired very near as good a colour as the best. He reckons short scythes the best for mowing lodged or crumpled corn, because they miss the fewest plants; and observes, that a bow upon the scythe, which carries away the swath before it, is preferable to a cradle, the fingers of which would be pulled to pieces by the entangled corn, in drawing back the scythe. In Scotland and Ireland it is generally reaped with the sickle, bound in sheaves, and set up in shocks.

5109. *In stacking barley* many farmers make an opening in the stack from top to bottom. This opening is generally made by placing a large bundle of straw in the centre of the stack, when the building commences, and in proportion as it rises the straw is drawn upwards, leaving a hollow behind; which, if one or two openings are left in the side of the stack near the bottom, insures so complete a circulation of air, as not only to prevent heating, but to preserve the grain from becoming musty.

5110. *The threshing and dressing of barley* require more labour than those of any other grain, on account of the difficulty of separating the awns from the ears. For this purpose some threshing machines are furnished with what is called a hummelling machine, already described (2799): and where this is wanting, it is customary to put the grain, accompanied with a portion of threshed straw, a second time through the machine. Where barley has been mown, the whole of the straw requires to be twice threshed, independently of the necessity of getting rid of the awns.

5111. *The produce of barley*, taking the average of England and the south of Scotland, Donaldson considers, might be rated at thirty-two bushels; but when Wales and the north of Scotland are included, where, owing to the imperfect modes of culture still practised, the crops are very indifferent, the general average over the whole will not probably exceed twenty-eight bushels the acre. Middleton states it as varying in England from fifteen to seventy-five bushels per acre. The average produce of the county of Middlesex, he says, is about four quarters of corn and two loads of straw per acre.

5112. *The uses of barley* are various. In Wales, Westmorland, Cumberland, and in the north, as well as in several parts of the west of Scotland, the bread used by the great body of the inhabitants is made chiefly from barley. Large quantities of the barley cultivated in England are converted into beer, ale, porter, and what is called British spirits, as English gin, English brandy, &c. The remainder, beyond what is necessary for seed, is made into meal, and partly consumed in bread by the inhabitants of the above-mentioned districts, and partly employed for the purpose of fattening black cattle, hogs, and poultry. There is a much greater share of the Scotch barley consumed in distillation, in proportion to the quantity cultivated, than of the English. Exclusive of what is used for seed, the Scotch barley is either converted into beer or ale; or made into pot-barley, or into meal, for the use of the inhabitants in the more remote and less cultivated parts of the kingdom; or, lastly, into whisky. In *The Report of Middlesex* it is stated, that much of the most ordinary barley is given to poultry: the rest is sold to the maltsters, except so much as is reserved for seed.

5113. *But malt is the great purpose to which barley is applied* in Britain. To understand the process of malting, it may be necessary to observe that the cotyledons of a seed, before a young plant is produced, are changed by the heat and moisture of the earth into sugar and mucilage. Malting grain is only an artificial mode of effecting this by steeping the grain in water and fermenting it in heaps, and the arresting of its progress towards forming a plant by kiln drying, in order to take advantage of the sugar in distillation for spirit or fermentation for beer. The grain of barley contains starch and sugar; and the chemical constituents of both these ingredients are very nearly alike. In the process of malting, a portion of the starch is converted into sugar, so that the total quantity of sugar, and consequently the source of spirit, is increased by the transformation.

5114. *To choose a proper sample of barley for malting*, observe the directions given for choosing secd barley. (5091.)

5115. *Of pot-barley* there are two sorts, pearl and Scotch; both are produced by grinding off the husk, and the pearl barley is produced by carrying the operation so far as to produce roundness in the kernel. It is used in soups, gruels, and medicinal drinks.

5116. *Barley meal* is ground like oatmeal or flour; the coarser sort, with the bran, is used for fattening live stock, especially pigs and poultry; but fine bolted barley flour, made into a thin pottage or pudding, and spread out in thick cakes, and toasted on a hot plate of metal, forms a light breakfast bread, much esteemed in some parts of Scotland. It is served in a recent state, hot, and spread with butter and honey, and eaten in several folds. Two parts of barley flour, one of wheat flour, and one of rye, are said to make a light and very agreeable loaf of bread.

5117. *The produce of barley in flour* is 12lbs. to 14lbs. of grain. Sir H. Davy found 1000 parts of barley meal to afford 920 parts of soluble or nutritious matter; viz. 790 of mucilage or starch, 70 of sugar, and 60 of gluten.

5118. *Barley straw* is chiefly used for litter and packing; it is unfit for thatch or rope-making, and of little value as fodder.

5119. *The diseases of barley* are few, and chiefly smut, but of quite a different species from that which affects the wheat, and one which it is found cannot be prevented by pickling and liming.

SECT. IV. *The Oat.*—*Avèna sativa* L.; *Triándria Digýnia* L., and *Gramíneæ* J. L'Avoine, Fr.; Haber, Ger.; Vena, Ital.; and Avena, Span.

5120. *The oat* is a very useful grain, and more peculiarly adapted for northern climates than either wheat, rye, or barley. Its native country is unknown, unless the wild oat be considered as the parent species, which is highly probable. The culture of the oat in France is chiefly confined to latitudes north of Paris. It is scarcely known in the south of France, Spain, or Italy; and in tropical countries its culture is not attended to. In Britain it has long been very generally cultivated, formerly as a bread corn, but now chiefly as horse-food. Of all the grain this is the easiest of culture, growing in any soil that admits of ploughing and harrowing.

5121. *The varieties of oats* are more numerous than those of the other grains, and some of them are very distinctly marked. The principal are as follows:—

5122. *The white oat or common oat* (fig. 727. a), *Avoine blanche*, Fr., in most general cultivation both in England and Scotland, and known by its white husk and kernel.

727

5123. *The black oat*, *Avoine à grappe noir*, Fr., in the north by its black husk; cultivated on poor soils, in the kingdom of England and Scotland.

5124. *The red oat*, known by its brownish red husk, thinner and more flexible stem, and firmly attached grains. It is early, suffers little from winds, meals well, and suits windy situations and late climates. It is understood to have originated in Peebleshire, on the estate of Magbie-hill, by which name it is sometimes known.

5125. *The Poland oat*, known by its thick white husk, awnless chaff, solitary grains, short white kernel, and short stiff straw. It requires a dry warm soil, but is very prolific. The black Poland oat is one of the best varieties; it sometimes weighs 50lbs. per bushel. It is, however, very liable to be shed by the wind after it begins to ripen; it requires a fine dry tilth.

5126. *The Friesland or Dutch oat*, has plump, thin-skinned, white grains, mostly double, and the large one sometimes awned. It has longer straw than the Poland, but in other respects resembles it.

5127. *The potato oat* has large, plump, rather thick-skinned, white grains, double and treble, with longer straw than either of the last two sorts. It is almost the only oat now raised on land in a good state of cultivation in the north of England and south of Scotland, and usually brings

a higher price in the London market than any other variety. It was discovered growing in a field of potatoes in Cumberland, in 1788; and from the produce of the single stalk which there sprung up by accident, probably from the manure, has been produced the stock now in general cultivation.

5128. *The Georgian oat*, is a large, grained, remarkably prolific variety introduced from Georgia, by R. Barclay, Esq. of Bury Hill, to Britain and the north of Europe. On rich soil in good tilth, Mr. Barclay finds it yield more grain per acre than the potato oat or any variety whatever.

5129. *The Siberian or Tatarian oat* (b), is considered by some as a distinct species. The grains are black or brown, thin and small, and turned mostly to one side of the panicle; and the straw is coarse and reedy. It is little cultivated in England, but found very suitable for the poor soils and exposed situations on the sides of the Dublin and Wicklow hills.

5130. *A variety called the winter oat*, *Avoine d'hiver*, Fr., has lately come into notice in some parts of England, but we have not been able to ascertain its origin. Mr. Bennett of Chaxhill, near Gloucester, sows two bushels per acre in October; finds the plants very luxuriant at Christmas, tillering like wheat: he depastures them with ewes and lambs all the spring, and then shuts them up, and reaps an ample crop early in August. The grain is rather longer than that of the white oat, and the colour rather lighter than that of the black oat; Mr. Bennett received the seed from a friend in Monmouthshire, who he conjectures received it from Bristol, so that it is probably a recent importation. (*Country Times*, Feb. 8th, and Cor. with Mr. Bennett.)

5131. *There are other varieties*, as Church's oat, the Angus oat, the dun oat, &c., but they are either too local or obsolete to require particular notice. In the oat, as in other plants extensively cultivated, new varieties will always be taking the place of old ones.

5132. *To procure new varieties* adopt the mode by selection, by which, as it appears above, the potato and red oat were brought forward; or proceed systematically by cross impregnation, as directed for raising new varieties of wheat. Degeneracy, Brown

observes, has taken place to a certain extent in the potato oat; but it is presumed that the consequences might be removed with ease, were first principles returned to. To make a selection of the strongest ears, which carried the purest grain, is not a difficult business; and were this selection attended to by half a dozen farmers in a district, it is obvious, that the breed, or variety, might be preserved pure and uncontaminated. If slovenly farmers were not provided with good seed, it would be their own fault; since, if they would not take the trouble to select and breed for their own use, they might always be provided by those who were either better qualified for making the selection, or were more attentive to the interests of agriculture. (*Brown.*) Some of the Northumbland farmers have been at the pains to select the grains, instead of the ears, after being threshed. The best seeds are picked out by hand by women.

5133. *In choosing a sort* from among the varieties described, the potato and Poland are the best for lowlands, and the red oat for uplands and late climates in a state of good cultivation. For inferior soils the white or common oat, and for the poorest of all the black oat, may be adopted.

5134. *The soil* for oats may be any kind whatever, from the stiffest clays to moss or bog, provided it be laid sufficiently dry. The most tenacious clays, and meagre gravels and sands, where scarcely any useful seed-bearing plant, except buck-wheat, could be grown, will produce a crop of oats if ploughed at a proper season, and the seed judiciously sown and covered.

5135. *The preparation of the soil* for oats is less than for any other grain. It is almost always the first crop on newly broke-up lands; and as it prospers best on a soil not too finely pulverised, it is commonly sown on one earth. In regular rotations, oats are chiefly sown after grass; sometimes upon land not rich enough for wheat, that had been previously summer-fallowed, or had carried turnips; after barley, and rarely after wheat, unless cross-cropping, from particular circumstances, becomes a necessary evil. One ploughing is generally given to the grass-lands, usually in the month of January, so that the benefit of frost may be gained, and the land sufficiently mellowed for receiving the harrow. In some cases a spring furrow is given when oats succeed wheat or barley, especially when grass-seeds are to accompany the crop. The best oats, both in quantity and quality, are always those which succeed grass; indeed, no kind of grain seems better qualified by nature for foraging upon grass-land than oats; as a full crop is usually obtained in the first instance, and the land left in good order for succeeding ones. (*Tr. on Rural Affairs.*)

5136. *The climate* for oats should be cool and moist; when dry and warm, the panicles are so dried and contracted that they cease to convey sufficient nourishment to the ears, which thus never become plump, but thick husked, long awned, and unproductive in meal. This is very often the case with the oats in Scotland in a very dry year, and very common in the south of England in most years.

5137. *The season of sowing oats* is from the last week in February to the end of April. About the middle of March is preferred by the best farmers. No preparation is ever given to the seed; but it should be plump, fresh, and free from the seeds of weeds. Common oats sown in autumn are generally killed during winter, the plant being in this respect more tender than wheat, rye, or barley bigg. In some parts of Ireland, and especially in the county of Dublin, the Friesland oat is sown in autumn; and the advantage is they ripen nearly a month sooner than those sown in spring, an important object in a moist climate.

5138. *The quantity of seed*, where oats are sown broad-cast, is usually from four to six bushels to the acre. Land sown with potato oats requires less seed, in point of measure, than when any of the other sorts is used: first, because this variety tillers better than any other; and next, because having no awn, a greater number of grains are contained in a bushel.

5139. *The mode of sowing oats* is almost universally broad-cast; but where they are sown after turnips, or on other well pulverised soils, some adopt the row culture.

5140. *The after-culture* depends on the mode of sowing, but seldom consists of more than weeding before the flower-stalks begin to shoot up.

5141. *In harvesting oats* in England, they are generally cut down with the scythe, and carried loose to the barn or stack; but in the northern districts, and where threshing machines are used, whether mown, or, what is most usual, reaped with the sickle, they are tied in sheaves to facilitate the process of threshing. Oats are ready for the scythe or sickle when the grain becomes hard, and the straw yellowish. They should generally be cut before they are dead ripe, to prevent the shedding of the grain, and to increase the value of the straw as fodder. They rarely get much damage when under the harvest process, except from high winds, or from shedding, when opened out after being thoroughly wetted. The early varieties are much more liable to these losses than the late ones; because the grain parts more easily from the straw,—an evil to which the best of grain is at all times subject. Early oats, however, may be cut a little before

dead ripe, which, to a certain extent, lessens the danger to which they are exposed from high winds; and if the sheaves are made small, the danger from shedding after rains is considerably lessened, because they are thus sooner ready for the stack. Under every management, however, a greater quantity of early oats will be lost during the harvest process than of the late ones; because the latter adhere firmly to the straw, and consequently do not drop so easily as the former. (*Brown.*) In harvesting oats in wet seasons, the practice of gaiting the sheaves (3176.) is generally adopted. In Sweden, in most seasons, the oat crop is dried on frames or poles (704.); and in Russia, not only oats, but barley and rye, are kiln-dried in the straw.

5142. *Kiln-drying oats and other corns in the straw* has been found necessary, and is very generally practised through the north of Russia, Livonia, Courland, and Lithuania, being the last operation of harvest for preserving all kinds of corns, peas, beans, and buck-wheat. They are dried in the fields as much as can be; but, when brought home, they are kiln-dried, and are then ready to be either threshed out immediately, or put up in barns, without any danger of either corn or straw becoming musty or rotting. The common practice of the boors is, during winter, to thresh out by degrees, as in this country, their oats and barley, in order to have straw fresh for their cattle, such straw being their only provender. The process of kiln-drying by no means prevents the germination of the grain when used for seed, while it not only preserves the grain and straw but improves their taste and salubrity. It enables Russia to export large quantities of rye and wheat, with less risk of damage to the grain than is incurred by other nations of the north of Europe.

5143. *The kiln* (fig. 728.) in general and established use throughout Russia, for the purpose of drying corn in the straw, is heated commonly by fires of wood. It is a simple and cheaply erected structure, the walls eight feet high, and fifteen feet square within. At this height there are two strong cross-beams (*a*), to support the small timbers, laid over them as ribs. The corn stands in sheaves above these ribs (*b*), closely set up, the band ends of the sheaves down,

and the corn or grain ends up: the walls then rise above the ribs about five or six feet more, the kiln being closed by a simple ceiling of cross joists at this height, covered with thin turf. Any cheap and ordinary roof answers to cover the whole. The fire-place is constructed so as to throw back the ascending spark; a small porch (*c*), directly opposite to the fire-place, prevents violent blasts of wind, and covers from rain the fuel and the attendant. About 300 sheaves (twenty-five stooks) of corn are dried at one time. It is put on in the evening, and left on the kiln through the night, after the wood has been burned into charcoal, and the door above the fire-place closed. At one end of the kiln there is frequently an open shed or barn (*d*), for convenience in bringing corn to, or taking it from, the kiln.

5144. *The produce of oats* is generally considered greater and of better quality in the northern than in the southern counties; and the reasons are obviously that, in the former, more attention is paid to their culture, and the climate is more favourable for the maturation of the grain. Ten quarters an acre is reckoned a good crop in the north, but the produce is often twelve and thirteen quarters, and the straw from two to three and a half loads per acre.

5145. *The produce of oats in meal amounts to 8lbs. for 14lbs. of corn.* Sir H. Davy found 100 parts of oats afford 59 parts of starch, six of gluten, and two of saccharine matter.

5146. *The use of oats* in the north, in Ireland, and in some parts of Yorkshire and Derbyshire, is partly for meal and partly for horse-food. In the south it is almost entirely for horse-food, poultry, and groats for gruel. It is occasionally malted and used in distillation. The fine powder which is produced by husking the corn, or making grist, forms the sowens of the Scotch (the flummery of the Irish), an agreeable light and wholesome supper dish.

5147. *The diseases of the oat* are few. Sometimes it is found attacked by the smut; but the more common injury sustained by oats is from wire-worms, or larvæ of insects which generally abound in lands newly broken-up from turf. One of the most certain modes of avoiding these is, by not ploughing the ground, especially if old turf, till immediately before sowing. By this means the insect is turned down, and before it can work its way to the surface (if ever it does) the corn is beyond its reach. In this way gardeners destroy and retard the progress of the gooseberry caterpillar by digging under the bushes; for it is found that the eggs and larvæ of insects, like seeds and bulbs, when buried too deep in the ground, have their progress retarded, or their vital principle destroyed. In late harvests, more especially in the northern parts of the island, the oat is liable to be frosted and rendered unfit for seed before being harvested. There is no remedy for such an accident; but we have shown (4997.) how it may be detected, so as not to disappoint the sower of such grain. (*Encyc. of Gard. 4663.*)

SECT. V. Cereal Grasses cultivated in Europe, some of which might be tried in Britain.

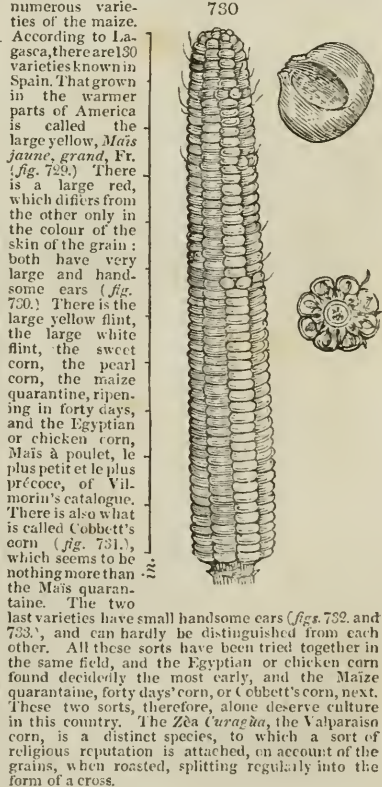

5148. *The cereal grasses which the climate of Britain does not readily admit of cultivating,* are the maize, Canary corn, millet, and rice.

SUBJECT. 1. *Maize, or Indian Corn.* — *Zèa Mays L.*; *Monœcia Triándria L.*, and *Gramineæ J.* *Le Mais, or Blé de Turquie, Fr.*; *der Mays, Germ.*; *Gran turco, Ital.*; and *Maiz, Spän.*

5149. *The maize* is the noblest looking of the cereal grasses. It is considered to be a native of South America, to have been cultivated in Mexico and Peru from time immemorial, to have been introduced to Europe about the beginning of the 16th century, and to England in 1562. It is at present cultivated in almost every part of the universe where the summer temperature equals or exceeds that common to latitude 45°, and even to 48°. In France, in Arthur Young's time (1787), the principal country of the maize was to the south of a line drawn from Bordeaux to Strasbourg, in lat. 48° 35'; but it is at present cultivated as far north as Nancy, which is in latitude 49°, — a fact which shows that this grain is taking a wider range of temperature. "It flourishes on the western continent from about the 40th degree of southern to higher than the 45th degree of northern latitude. It is extensively produced in Africa and in Asia; on all the shores of the Mediterranean, in Spain, Italy, part of France, and the countries of the Levant, it is the food in most common use. Of the cultivated Cerealia, indeed, it is that which, next to the rice, supplies food to the greatest number of the human race; and it may be held to be the most valuable gift of the new world to the old." (*Quar. Jour. Ag.* i. 485.) In England it has been cultivated for upwards of a century, in nursery gardens in the neighbourhood of the metropolis, for the curious purpose of supplying seedsmen in all parts of the island with ears of the corn to ornament their shop windows: it has also been grown in the kitchen gardens of some individuals who have lived in America, for the purpose of using the ears in a green state: it has been tried also in the fields, and more especially in 1828 and 1829, in consequence of the public attention being called to the subject by Mr. Cobbett.

5150. *As a bread corn* it cannot be greatly commended; the ear is highly productive of flour, but that flour is deficient in gluten, and cannot be made into bread without a large admixture of the flour of wheat. For fattening cattle and poultry of every description it is found excellent, and its culture in Europe can only be recommended with a view to this object.

5151. *Varieties.* Like other plants which have been long in cultivation in various countries, there are

numerous varieties of the maize. According to La-gasca, there are 130 varieties known in Spain. That grown in the warmer parts of America is called the large yellow, *Mais jaune, grand, Fr.* (fig. 729.) There is a large red, which differs from the other only in the colour of the skin of the grain: both have very large and handsome ears (fig. 730.) There is the large yellow flint, the sweet corn, the pearl corn, the maize quarantine, ripening in forty days, and the Egyptian or chicken corn, *Mais à poulet, le plus petit et le plus précoce*, of Vil-morin's catalogue. There is also what is called Cobbett's corn (fig. 731.), which seems to be nothing more than the *Mais quarantine*. The two last varieties have small handsome ears (figs. 732. and 733.), and can hardly be distinguished from each other. All these sorts have been tried together in the same field, and the Egyptian or chicken corn found decidedly the most early, and the *Maize quarantine*, forty days' corn, or Cobbett's corn, next. These two sorts, therefore, alone deserve culture in this country. The *Zèa Curagùà*, the Valparaiso corn, is a distinct species, to which a sort of religious reputation is attached, on account of the grains, when roasted, splitting regularly into the form of a cross.

5152. *Soil ana cimate.* A rich loamy soil, which will grow good wheat, tobacco, or potatoes, will

grow the strongest plants; but the corn on such plants will be much less likely to ripen than that produced on a dry, warm, sandy, or calcareous soil. It must be obvious, from what has been before advanced, that there are few, if any, parts of Britain north of York where the climate will be at all suitable to this grain.

5153. *Culture.* This grain is almost every where sown or planted in rows, placed at such a width as to admit of horse-hoeing the intervals. When this is practised, as the grain contains very little gluten, the crop may be considered as a good preparation for wheat in very rich soils; it accordingly precedes that grain in the best cultivated parts of North America; but we question if it would be advisable to follow this practice in old cultivated countries, notwithstanding that maize and wheat differ so much in regard to gluten.

5154. *The preparation of the soil* may be the same as for a crop of barley, according to Cobbett; but we should say, the same as for a crop of turnips on the raised ridglet or Northumberland system.

5155. *Sowing.* The quantity of seed required is from one bushel to three bushels per acre. In Long Island, near New York, the time of sowing is from the 10th to the 20th of May; in France, from the 15th of April to the 15th of May; in England, from the 15th of April to the 20th of the same month, according to Cobbett; but we have no doubt that, in situations where the earliest varieties will succeed at all, they will succeed if sown a week or ten days later. The grain will retain its vegetative powers for at least six years. (*Gard. Mag.* vol. vi. p. 444.)

5156. *The mode of planting the corn* in America is by drawing shallow drills, commonly three or four feet distant from each other, and dropping the seeds by hand, at eight inches apart, in the row. This distance is evidently too great for the early dwarf varieties; and we think three furrows, or twenty-seven inches, the ordinary width between rows of potatoes and turnips, much more suitable. We should decidedly prefer dibbling, either by hand or by a machine, to opening a drill and depositing the seeds. In several places in France the seeds are sown broad-cast and harrowed in, and the after-culture consists in hand-hoeing between them. By sowing on raised drills the horse-hoeing system may be applied as effectually as in the culture of turnips or beans. Cobbett recommends intervals between the rows of five feet, and the plants at six inches' distance in the row, with a view to admit a superior degree of tillage between, with a view to the wheat crop. He also describes the mode of planting in hills. The situations of these hills having been marked out by a light plough, or even by trailing a log of wood, first in lines five feet apart in one direction, and next in lines in the opposite direction at right angles to the former, so as to leave the surface in squares, the planter takes a hoe, and at every intersection of the lines makes a little hole about an inch and a half deep, and about six inches in diameter, and in this hole five or six seeds are regularly distributed, and covered over with fine earth to the depth of an inch and a half. It is evident that by this mode of planting the ground may be very thoroughly worked during the growth of the crop; but it is evident also that it could only be adopted in this country on dry soils, that would admit of being kept during spring and autumn without water furrows.

5157. *Transplanting maize* may be adopted on a small scale, the advantages of which are that the ground may be better prepared before planting, and that the crop may be made to come in in succession with one which has stood in the ground during winter. The plants may be raised in a hotbed, and protected by mats; or they may be raised in a warm border of dry rich soil, covered with straw or straw mats during nights till the common ash, the mulberry, or the walnut are in leaf; they may then be carefully raised and transferred to the field, with a small portion of earth attached to each, planted with a spade or trowel, and watered unless it should happen to rain.

5158. *The after culture,* according to Cobbett, commences with scaring away birds and destroying slugs, and afterwards in removing weeds and stirring the soil. The plants will be one foot and a half high in July; and no one at that season, Cobbett says, need be afraid of tearing about the roots with the plough as much as he will. One thing is certain, he says, that if the ground between the rows be not ploughed at all, there will be no crop at all. The last process with the plough is earthing up, which is said to be useful for two purposes: first, to keep the plants steady, in case of very rough winds; and, second, to give it a fresh stock of roots. "Leave a corn-plant with nothing but flat hoeing, and without earthing up, and you will see all around its roots coming out just above the ground, and going immediately down into the ground."

5159. *Topping the plants.* The male and female blossoms being on different parts of the plant, have given rise to this operation. The male flowers are always situated on the top or summit of the stem, and the female flowers below, near the bottom. "The flowers at the top having performed their function, and deposited the pollen on the stigma beneath, become no longer necessary to the plant; and they, accordingly, with all the elevated part of the stem which supports them, may be wholly removed. This process is termed topping by the Americans, and is delayed until the blades or leaves may be also stripped off

without injury. The period for performing this is denoted by the state of forwardness of the vegetation. The time for topping is, when you, upon stripping the husks, open a little at the tops of the ears, find the grains of the corn to be hard, — not hard enough to grind, nor dry, — but hard enough to resist the strong pressure of the thumb nail. A second criterion is, all the farina having completely quitted the *tassel*, and the tassel being completely dead and dry. A third is, the perfect deadness of the ends of the silk; where, instead of the bright green that appeared before, hanging gracefully down, like the beard of an extraordinarily cunning and blaspheming Jew, you will perceive it to be a little contemptible bunch of withered-up and brown-looking stuff. When all these signs appear, the *top* and the *blades* have performed their office, and the sooner they are taken away the better; because, after this, they do no good, and only serve to retard the ripening of the ears by the exclusion which they cause to the sun and the wind.* The tops and leaves being removed, they are laid in bunches in the intervals, suffered to dry, and then carried away and stacked. This part of the produce, we are told, is now a precious deposit for the winter: "it is liable to no inconvenience to which hay is not liable; and weight for weight, and weather for weather, an acre of corn tops and blades will give more nutriment to cattle." They are reserved by the American farmers as food for their horses and oxen in spring; they are given to race horses and other delicate and highly prized animals. They are cut into chaff, and then mixed with barley and rye. Mr. Cobbett has stated this part of the produce to be more valuable than a crop of hay; but he has not given us data, either as regards the weight of the crop, or the quantity of the animals it will feed, to enable us in judgment of the correctness of his opinion. In France and southern Europe, these parts of the plant are, in like manner, used for fodder; but we are not aware that they are held in any thing like such high estimation as a crop of hay is with us." (*Treatise on Cobbett's Corn*, and *Quar. Journ. Agr. vol. i. p. 502.*)

5160. *Harvesting.* The season of harvesting is generally October and November. In America, the ears are slipped or broken from the stem by the hand, and are carried directly to the barn-floor to undergo the process of husking. The huskers, who are generally women and children, are seated around or alongside of a large heap of ears; they have baskets placed before them; they strip off the husks, fling them behind them, and throw the ears into a basket. These baskets as filled, are carried to the granary, or corn-crib, as it is called in America. It may be two feet wide at the bottom, five feet high up the sides to the eaves, and five feet across at the top. It is open or grated at the bottom, with spars at the sides, has a weather-tight roof, and is raised from the ground by posts surrounded with tin as a protection against rats and mice. The husks form an excellent material for stuffing mattresses, and are used for this purpose in America and on the continent of Europe. The now almost leafless stalks which remain in the fields in America are frequently burnt, but on the continent are used as litter for cattle running loose in the farmyard. The ears remain in the granary till they are wanted for shelling, or separating the grains from the receptacle. On the continent the ears are cut or broken from the stems as in America, and on a large scale are preserved in small open granaries, such as have been described; but more frequently they are hung up unhusked under the projecting eaves of all manner of buildings, and remain there till wanted for husking and shelling.

5161. *Shelling or threshing.* This, Cobbett tells us, is done in America by scraping or rasping the ears

734

upon a piece of iron, fixed across a tub, into which the grains fall. The iron is commonly a bayonet. In this country there are machines of different kinds (*fig. 734. and 2550.*), which perform the operation of shelling with great rapidity; but whoever has a threshing machine might, by setting the rollers and drum somewhat wider than usual, dispense with manual labour, both in the operations of husking and shelling; and indeed we see no reason why the crop should not be harvested like a crop of drilled beans, with Gladstone's bean reaper (2740.), and sheaved, shocked, stacked, and threshed, like any other grain.

5162. *Produce.* In America and Australia, the produce in corn is from fifty to seventy bushels to the acre; on the continent it is generally between fifty and sixty; and the produce in this country, as it appears by some experiments recorded in the *Gard. Mag.* vol. vi. p. 60 to 67., would probably be similar, notwithstanding the circumstance of Mr. Cobbett, Mr. Moore of Sandy, in Bedfordshire, and some others, having raised on small spots at the rate of 100 bushels per acre and upwards. The produce in straw in America and warm countries, where the tallest sorts can be grown, is considerable; but in this country, where only the dwarfest sorts could be cultivated with success, it would not equal that of a crop of oats or barley.

5163. *The application of this crop, according to Cobbett, is various and important: "pig-feeding, sheep-feeding, oxen and cow-feeding, poultry-feeding, horse-feeding, and man-feeding;" to which we may add fish, carp being fed with maize in France. For "man-feeding" it is only made use of in America till the farmer can afford to grow wheat; and on the continent it is only used as a bread corn by the poorest of the people. The wretched inhabitants of the southern part of the Neapolitan territory live chiefly on maize; as those of some mountainous districts in the north of Italy live on bread made from chestnuts, or buck-wheat. The most important purpose to which the corn uncrushed can be applied in Europe, appears to us to be the feeding of poultry. All the fat geese noted for their large livers in the north-west of France and south-east of Germany are fed with maize, the grains unbroken; and the smaller poultry in these countries are also chiefly fed with this corn, broken or ground into meal.*

5164 *Turkey feeding,* according to Cobbett, is one of the many purposes to which the corn may be applied in this country: "We killed, last spring, one single pullet, not of a large breed, out of which we took loose fat weighing three quarters of a pound. We fattened most perfectly and finely ten turkeys in the same manner; and as to geese and ducks, which fat still easier than either of the former, they will get fat in this manner in a short space of time. If you wish to have fresh eggs in winter, you need resort to no steeping of barley in beer or in wine, or to giving the hens hempsed, or the seed of nettles, as the French do; nor to make such a fuss about keeping the hens warm: give them plenty of corn, *whole*, and you will have fresh eggs all the winter long. To the very little chickens, or very young turkeys, you must give some in a *cracked* state; but they very soon take it down whole; and large as it is, the sparrows will eat it as fast as the fowls; and, if you be much infested with them, and do not wish to have a numerous and early breed of them next spring, you must feed the poultry close to the door, or stand by them during the meal, which, however, is conveniently short; for the grain is so large that their craws are filled in a minute. It is very well known that,

in order to have a *fat turkey*, or even a really fat fowl, we are compelled to resort to cramming. If the farmer's wife have a dozen of these, there she sits (for she can trust nobody else to do it), with a leathern apron before her, or rather upon her, with balls of barley-meal rolled into an oblong form, and with a bowl of warm milk, or with some greasy water, taking one turkey out of the coop at a time upon her lap, forcing its mouth open with her left hand, putting in the balls with her right, and stroking with her fingers the outside of the neck to make them descend into the craw, every now and then pouring down a spoonful of the warm liquid, upon the principle that good victuals deserve good drink. There she sits, if she has two dozen of these animals to cram, two good hours at least. Sometimes they reject the food, and flutter about, and splash the woman with the contents of the bowl. It is always a disagreeable, troublesome, and nasty job; it takes up a great deal of time; and yet these things cannot be made sufficiently fat without this operation, in which, I dare say, 20,000 women are at this very moment (eight o'clock in the morning) engaged, in the counties of Norfolk and Suffolk. If all these women could be brought together, and were to hear me say

and prove, that I could save them all this trouble, they would say, 'God bless you, Sir; you are the best friend (the inventor of tea and sugar excepted) that ever administered to the comfort of womankind.' Well, then, this I do for them now; let their husbands raise some Calbeck's corn, the leathern aprons may be converted into spatterdashs for them, the warm milk or greasy water may be given to young pigs, the bowl may be

converted into a porringer for a boy to eat porridge out of, the coops, well broken up by the pole of the axe, may go to light the fire, and the four hours saved morning and evening may be employed in spinning and preparing the stuff to make shirts and shifts, and sheets, or, which makes less noise, in knitting stockings for the whole family." (*Quar. Jour. Agr.* vol. i. p. 507.)

5165. *In common with other grain, maize may be fermented, so as to produce beer; or distilled from, so as to produce spirits; the straw containing a good deal of saccharine matter that also might be extracted.*

5166. *The green ears of maize are applied to various purposes. In the neighbourhood of Paris, before the male blossom has expanded, the female is gathered and pickled, in the manner of cucumbers; and this is practised to some extent by the French and Germans. When the grain has arrived at its milky state, the ears are then gathered for the purpose of boiling or roasting. In America they are roasted on or before good hot embers, and eaten with salt and butter. Boiled, they are not quite so delicate; but are still very good, especially if boiled with fat pork. The ears are generally fit for these purposes during the month of September, and a large field may afford soft ears for six weeks.*

5167. *The meal of maize, besides being given to the smaller poultry, is also used for fattening swine, old sheep which have lost part of their teeth, and for feeding old horses which cannot grind the ears whole. Of a finer quality it is given to negroes, and eaten by various persons in America, in the form of porridge, puddings, and cakes. In this country, the Rev. Henry Berry of Pesham House, Worcestershire, has found maize meal, purchased from Liverpool, superior to oatmeal in maintaining the condition of his hounds. (*Country Times*, March 2d, 1830.) The meal of maize, made into paste, and fried with fat bacon, is the ordinary food of the peasants of great part of the Brabant. It serves them likewise for fattening their fowl, of which they feed great quantities for the markets of the rest of Brabant and of Holland. (*Comm. Board of Agr.*)*

5168. *Diseases and enemies. The Phalæna forficella Lin. is said to deposit its eggs in the stems of the plant, and the larvæ which these produce eat out its interior, so as to weaken the strength of the spikes. There are also three species of smut, *Uredo Pers.*, which are parasitic on the maize, and destroy the grain by reducing it to a black powder. One species is peculiar to the flower, attacks it before it arrives at maturity, and finishes by leaving it in a state of black powder. The French writers recommend washing and pickling in the same manner as for wheat. The stalks and leaves, being very sweet, are greedily sought for by field rats, mice, and other enemies. In the granary, the maize, like other grains, is attacked by different species of weevil, this insect produces serious injury in America, but is not very likely to be troublesome in this country.*

SUBJECT. 2. *Canary Corn.* — *Phálaris canariensis L.*; *Triándria Digýnia L.*, and *Gramínea J. Alpiste de Canaire, Fr.*; *Kanariengras, Ger.*; *Falari, Ital.*; and *Alpiste, Span.* (*fig.* 735.)

5169. *The Canary grass is an annual, with a culm from a foot to eighteen inches in height, and lively green leaves almost half an inch in width. The seeds are thickly set in a subovate panicle or spike. It is a native of the Canary Islands; but now naturalised in several parts of England, and on the Continent. It flowers from June to August, and ripens its seeds from September to October. It has long been cultivated in the Isle of Thanet, and a few other places in Kent and Essex: it is there considered an uncertain crop, both on account of the seasons, it being the latest of all the grasses in ripening its seeds, and of the fluctuation of prices.*

5170. *The culture of the Canary grass consists in pulverising a loamy soil in good heart, or manuring it if worn out; though every judicious farmer tries to avoid giving manure to a corn crop unless after a naked fallow. The seeds are sown in rows at about a foot apart, generally by the ribbing process: the season the month of February, and the quantity of seed four or five gallons per acre. The after-culture consists in repeated hoeings and weedings.*

5171. *The reaping process seldom commences before the end of September. The culm being leafy, and the seed difficult to separate from the chaff, it requires to lie in handfuls for a week or more, and to remain more than that time in the field after being tied up in sheaves. In the Isle of Thanet it is cut with a hook, provincially called a *twibil* and a *hink*; by which it is laid in lumps, or wads, of about a sheaf each. The seed clings remarkably to the husk; and, in order to detach it, the crop is left a long time on the ground, to receive moisture sufficient to loosen the enveloping chaff, otherwise it would be hardly possible to thresh out the seed. The wads are turned from time to time, to have the full benefit of the rains and sun.*

5172. *The common produce of Canary grass is from thirty to thirty-four bushels per acre; but under the best management in the Isle of Thanet it is often fifty bushels per acre.*

5173. *The use of the seed is chiefly as food for Canary and other cage and aviary birds. The chaff is superior to that of every other culmiferous plant for horse-food, and the straw, though short, is also very nutritive.*

SUBJECT. 3. *The Millets.* — *Panicum* and *Sorghum L.*; *Triándria Digýnia* and *Polygýmia Monácia L.* and *Gramínea J. Panis and Sorgho, Fr.*; *Panick and Hirse, Ger.*; *Panico and Sageno or Sorgo, Ital.*; and *Alcandia, Span.*

5174. *Of the millet there are three distinct genera: the Polish millet (*Digitaria*), cultivated in Poland; the common millet (*Panicum*), or panic grass, cultivated in Germany,*

and sometimes in this country; and the great or Indian millet (*Hóleus*), cultivated in India, Italy, and America.

5175. Of the common millet there are three species: *Setària germànica* (fig. 736. *a*), a native of the south of Europe; the *P. miliàccum* (*b*), a native of the East Indies; and the *Setària itàlica* (*c*), also of Indian origin.

5176. The German millet (*Moha de Hongrie*, Fr.; *S. germànica*, *a*) rises with a jointed reed-like stalk, about three feet high, and about the size of the common reed, with a leaf at each joint a foot and a half long, and about an inch broad at the base where broadest, ending in an acute point, rough to the touch, embracing the stalk at the base, and turning downwards about half the length. The stalks are terminated by compact spikes, about the thickness of a man's finger at bottom, growing taper towards the top, eight or nine inches long, and closely set with small roundish grain. It is annual, and perishes soon after the seeds are ripe. There are three varieties of it, the yellow, white, and purple grained. It was formerly cultivated for bread in some of the northern countries.

5177. The common or cultivated millet (*Millet commun*, Fr.; *Panicum miliàccum*, *b*) rises with a reed-like channelled stalk, from three to four feet high; at every joint there is one reed-like leaf, joined on the top of the sheath, which embraces and covers that joint of the stalk below the leaf, and is clothed with soft hairs; the leaf has none, but has several small longitudinal furrows running parallel to the midrib. The stalk is terminated by a large loose panicle hanging on one side. Of this species there are two varieties, the brown and the yellow; the latter of which was formerly in cultivation, and is now sometimes sown for feeding poultry, and as a substitute for rice.

5178. The Italian millet (*Panis d'Italie*; *Millet à grappe*, Fr.; *Setària itàlica*, *c*) rises with a reed-like stalk, nearly four feet high, and much thicker than that of the preceding; the leaves are also broader. The spikes are a foot long, and twice the thickness of those of the common millet, but not so compact, being composed of several roundish clustered spikes; the grain is also larger. There are two or three varieties of this, differing only in the colour of the grain. It is frequently cultivated in Italy (whence its trivial name), and other warm countries. It is a native of both Indies, and of Cochin China.

5179. The Polish millet, or manna grass of the Germans (*Digitaria sanguinalis*, formerly *Panicum sanguinalis*, fig. 737.), is a low decumbent, annual plant, seldom rising above nine inches or a foot high, with hairy leaves and slender panicles. It tillers much, and forms a close tuft, spreading and rooting at the joints. It is a native of England but not common. It grows in abundance in Poland, and is sometimes cultivated, the seeds being used like those of the other millets as a substitute for rice or sago.

5180. The great or Indian millet (*Hóleus Sórghum L.*, *Sórghum vulgàre*, *W. en.* fig. 738. *Sorgho*, *gros millet d'Italie*, Fr.; *Sorgsamcn*, Ger.; *Sagina*, Ital.; and *Melao*, Span.) has a stem which rises five or six feet high, is strong, reedy, and like those of the maize, but smaller. The leaves are long and broad, having a deep furrow through the centre, where the midrib is depressed in the upper surface, and is very prominent below. The leaves are two feet and a half long, and two inches broad in the middle, embracing the stalks with their base. The flowers come out in large panicles at the top of the stalks, resembling, at first appearance, the male spikes of the Turkey wheat; these are succeeded by large roundish seeds, which are wrapped round with the chaff. This grain is a native of India, where it is much used to feed poultry, and is frequently sent to Europe for the same purpose. It is much cultivated in Arabia, and most parts of Asia Minor; and has been introduced into Italy, Spain, Switzerland, and some parts of Germany, also into China, Cochin China, and the West Indies, where it grows commonly five or six feet high, or more, and being esteemed a hearty food for labourers, is called negro Guinea corn. Its long awns or bristles defend it from the birds. In England, the autumn is seldom dry and warm enough to ripen the seed well in the field. In Arabia it is called *dora* or *durra*; the flour is very white, and they make good bread of it, or rather cakes, about two inches in thickness. The bread which they make of it in some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons; sometimes for swine, kine, and horses. Cæsalpinus says, that cattle fed on the green herb are apt to swell and die, but thrive on it when dried. They make brushes and brooms of its stalks in Italy, which Ray observed in the shops at Venice, and which are sent to this country. Of this species there are two distinct varieties; one distinguished by black, and the other by red, husked seeds, besides subvarieties.

5181. The only sorts of millet which can be cultivated with success in this country are the German, cultivated, and the Polish sorts. According to Professor Thær, the cultivated is to be preferred, as having the largest grain.

5182. The soil for the millet should be warm, sandy, rich, and well pulverised to a good depth. The seed is sown in May, very thin, and not deeply covered. In the course of its growth no plant, Professor Thær observes, is more improved by stirring the soil, after which it grows astonishingly fast, and smothered all weeds.

5185. In harvesting the millet, great care is requisite not to shed the seed; and as it ripens rather unequally, it would be an advantage to cut off the spikes as they ripen, as

in reaping maize. No grain is easier to thresh, or to free from its husk by the mill. It is used instead of rice, and in Germany bears about the same price. It produces a great bulk of straw, which is much esteemed as fodder.

5184. *The great Indian millet* will grow in this country to the height of five or six feet; but will not ripen its seeds, or even flower, if the season is not dry and warm. If its culture is attempted, it should be raised in a hotbed and transplanted.

SUBJECT. 4. *Rice, and some other Cereal Gràmina.*

5185. *The rice* (*Oryza sativa*, fig. 739.) has been tried in this country, and, if sown very early, would probably ripen its seeds. The hill variety, which does not require watering, would probably succeed best. But there is no inducement to cultivate this and other grains or seeds when they can be imported at so low a rate. We merely introduce them to record the resources of British agriculture in case of necessity.

5186. *The Zizània aquática* (fig. 740.) might be cultivated on the margin of ponds for its seeds, which much resemble those of Polish millet. It is exceedingly prolific, grows in great luxuriance, and produces abundance of bland farinaceous seeds, in all the shallow streams of the dreary wilderness in north-west America, between the Canadian lakes and the hilly range which divides Canada from the country on the Northern Pacific Ocean. Its seeds contribute essentially to the support of the wandering tribes of Indians, and feed immense flocks of wild swans, geese, and other water fowl, which resort there for the purpose of breeding. Productive as is this excellent plant, and habituated to an ungenial climate, and to situations which refuse all culture, it is

surprising, says Pinkerton (*Geog.* vol. iii. p. 330.), that the European settlers in the more northern parts of America have as yet taken no pains to cultivate and improve a vegetable production which seems intended by nature to become, at some future period, the bread corn of the north.

5187. *The Glycèria fluitans* resembles the *Zizània*, and the seeds are used in Germany like those of Polish millet. Various species of *Panicum*, *Hordeum*, and *Bromus* afford tolerable supplies of edible seeds.

5188. *The buck-wheat* (*Polýgonum Fagopyrum*; *Riz*, Fr.; *Reiss*, Ger.; *Riso*, Ital.; *Arroz*, Span.) is vulgarly considered as a grain; but not being a bread-corn grass, we have classed it among manufactorial plants. (Chap. VIII. Sect. IV.)

CHAP. III.

Culture of Leguminous Field-Plants, the Seeds of which are used as Food for Man or Cattle.

5189. *The seeds of the cultivated legumes* are considered to be the most nutritive of vegetable substances grown in temperate climates. They contain a large proportion of matter analogous to animal substances, having when dry the appearance of glue, and being as nourishing as gluten. To the healthy workman this substance supplies the place of animal food; and Von Thaeer states, that in Germany neither sailors nor land labourers are content unless they receive a meal of legumes at least twice a week. The straw or haulm, he says, cut before it is dead ripe, is more nourishing than that of any of the cereal grasses. But leguminous plants are not only more than all others nourishing to man and animals, but even to vegetables they may be said to supply food; since they are not only known to be less exhausting to the soil than most other plants, but some of them, and more especially the lupine, have been ploughed in green as manure from the earliest times. Many scientific agriculturists consider a luxuriant crop of peas or tares as nourishing the soil by stagnating carbonic acid gas on its surface; which corresponds with the universal opinion of their being equal to a fallow, and with the value set on them in rotation, as already explained. (4939.) Two reasons may be given for the circumstance of peas and tares not exhausting the land so much as other crops: first, because they form a complete shade for the ground; and next, because they drop so many of the

leaves upon the surface. The legumes cultivated in British farming are, the pea, bean, tare, and vetch, to which might be added the lentil, kidneybean, and chick pea.

5190. *The nutritive products of these plants are thus given by Sir H. Davy, Einhoff, and Thaer:—*

Systematic Name.	English Name.	In 100 Parts.				
		Whole quantity of soluble or nutritive matter.	Mucilage or starch.	Saccharine matter, or sugar.	Gluten or albumen.	Extract, or matter rendered insoluble during evaporation.
<i>Pisum sativum</i> -	Dry peas -	574	501	22	35	16
<i>Vicia Faba</i> -	Common bean -	570	426	—	103	41
<i>sativa</i> -	Tares -	65	36	—	29	—
<i>Ervum Lens</i> -	Lentils -	71	39	—	32	—
<i>Phaseolus vulgaris</i> -	Kidneybean -	89	67	—	22	—

SECT. I. *The Pea.* — *Pisum sativum* L.; *Diadelphia Decandria* L., and *Leguminosæ* J. *Les Pois*, Fr.; *Erbse*, Ger.; *Piscello*, Ital.; and *Pesoles*, Span. (fig. 741.)

741

5191. *The pea is the most esteemed legume in field cultivation, both for its seed and haulm.* It is supposed to be a native of the south of Europe, and was cultivated by the Greeks and Romans. In this country it has been grown from time immemorial: but its culture appears to have diminished since the more general introduction of herbage, plants, and roots; and the pea, except near large towns for gathering green, and in a few places for boiling, has given way to the bean, or to a mixture of peas and beans. There are various inducements, however, to the cultivation of peas in dry warm soils near large towns. When the crop is good and gathered green, few pay better: the payment is always in cash, and comes into the pocket of the farmer in time to meet the exigencies of the hay, and sometimes even of the corn, harvest. The ground, after the peas have been removed, is readily prepared for turnips, which also pay well as a retail crop near towns; and the haulm is good fodder.

5192. *The varieties of the pea are numerous; but they may be divided into two classes: those grown for the ripened seed, and those grown for gathering in a green state.* The culture of the latter is chiefly near large towns, and may be considered as in part belonging to gardening rather than agriculture. There has lately a new sort of pea been brought into notice about Banbury in Oxfordshire. It is called the “nimble hog pea.” It appears to be a grey variety of the early frame, as it has single flowers, and is fit to cut about the end of June, notwithstanding it must not be sown earlier than the middle of April. On the excellent land about Banbury the produce is four quarters to the acre, and turnips sowed on the stubble are up and sometimes hoed out before the regular turnip crop!

5193. *The grey varieties (Pois gris, Pois-agneau, Bisaille, Fr.) are, the early grey, the late grey, and the purple grey; to which some add the Marlborough grey, and horn grey.*

5194. *The white varieties (Pois blanc, Fr.) grown in fields are the pearl, early Charlton, golden hotspur, the common white or Suffolk, and other Suffolk varieties.*

5195. *New varieties of the pea are readily procured by selection or impregnation, of which a striking example given by Knight has been already referred to. (1632.)*

5196. *In the choice of sorts, where it is desired to grow grey peas for the sake of the seeds or corn, the early variety is to be preferred in late situations, and the late variety in early ones; but when it is intended to grow them chiefly for covering the ground and for the haulm, then the late varieties claim the preference, and especially the purple grey. Of white peas, to be grown for gathering green, the Charlton is the earliest, and the pearl or common Suffolk the most prolific. When white peas are grown for boilers, that is for splitting, the pearl and Suffolk are also the best sorts.*

5197. *To have recourse to early sorts is supposed by some to be of considerable importance in the economy of a farm, when the nature of the soil is suitable, as by such means the crops may in many cases be cut and secured while there is leisure, before the commencement of the wheat harvest; and that where the nature of the soil is dry and warm, and the pea crop of a sufficiently forward kind, it may be easy to obtain a crop of turnips from the same land in the same year, as has been suggested above. But in this view it is the best practice to put in the crops in the row method, and keep them perfectly clean by means of attentive hand and horse hoeing; as in that way the land will be in such a state of preparation for the turnips, as only to require a slight ploughing, which may be done as fast as the pea crop is removed, and the turnip seed may be drilled in as quickly as possible upon the newly turned up earth. In some particular districts a third crop is even put into the same land, the turnips being sold off in the autumn, and coleworts substituted for the purpose of greens in the following spring. This, according to Middleton, is the practice in*

some places in Middlesex. But it is obviously a method of cultivation that can only be attempted on the warm and fertile kinds of turnip soil, and where the pea crops are early; on the cold heavy and wet descriptions of land it is obviously impracticable, and wholly improper.

5198. *The soil best suited for peas is a dry calcareous sand; it should be in good till, not too rich nor dunged along with the crop. In Norfolk and Suffolk peas are often sown on clover leys after one furrow, or after corn crops on two furrows, one given in autumn, and the other early in spring.*

5199. *The climate required by the pea is dry and not over warm, for which reason, as the seasons in this country are very often moist and sometimes exceedingly dry and hot in June and July, the pea is one of the most uncertain of field crops.*

5200. *The season of sowing must differ considerably according to the intentions of the cultivator.*

5201. *For podding early to be sold green, they should be sown at different times, from January to the end of March, beginning with the driest and most reduced sorts of land; and with this intention in some southern counties they are sown in the autumn. For the general crops from February to April, as soon as the lands can be brought into proper order, is the proper season; the grey sorts being employed in the early sowings, and the white sorts in the later. Young says, that where these crops cannot be sown in February, they should always be completed in the following month. It is observed by the same writer, that, in sowing after a single furrow, the white boiling pea, of many sorts and under various names, is more tender than the greys and various kinds of hog peas; but he has many times put them into the ground in February, and, though very smart frosts followed, they received no injury. He has uniformly found, that the earlier they were sown the better. There is also a particular motive for being as early as possible; that is, to get them off in time for turnips. This is most profitable husbandry, and should never be neglected in dry and warm soils and situations. If they are sown in this month, and a right sort chosen, they will be off the land in June, so that turnips may follow at the common time of sowing that crop.*

5202. *Steeping the seed in water is sometimes practised in late sowings.*

5203. *The quantity of seed must be different in different cases and circumstances, and according to the time and manner in which the crop is put into the ground; but, in general, it may be from two and a half to three bushels, the early sowings having the largest proportion of seed. In planting every furrow slice, Young says, two bushels and a half constitute the usual proportion; but, when drilled at greater distances, six or seven pecks will answer.*

5204. *The most common mode of sowing peas is broad-cast; but the advantages of the row culture in the case of a crop so early committed to the soil must be obvious.*

5205. *The best farmers always sow peas in drills either after the plough, the seed being deposited commonly in every second or third furrow; or, if the land is in a pulverised state, by drawing drills with a machine or by ribbing. In Norfolk and Suffolk peas are generally dibbled on the back of the furrow, sometimes one and sometimes two rows on each; but dibbling in no manner appears to us so well suited for a farmer's purpose as the drill. In Kent, where immense quantities of peas are grown, both for gathering green and for selling ripe to the seedsmen, they are generally sown in rows from eighteen inches to three feet asunder, according to the kind, and well cultivated between. Peas laid a foot below the surface will vegetate; but the most approved depth is six inches in light soil, and four inches in clay soil, for which reason they ought to be sown under furrow when the ploughing is delayed till spring. Of all grain, beans excepted, they are the least in danger of being buried.*

5206. *The after culture given to peas is that of hoeing, either by hand or horse. Where the method of hand-culture prevails, it is the general custom to have recourse to two hoeings; the first when the plants are about two or three inches in height, and again just before the period in which they come into blossom. In this way the vigorous vegetation of the young crop is secured, and a fresh supply of nourishment afforded for the setting of the pods and the filling of the peas. At the latter of these operations the rows should be laid down, and the earth well placed up to them, the weeds being previously extirpated by hand labour. It has been stated, that in some parts of Kent, where this sort of crop is much grown, it is the practice, when the distance of the rows will permit, to prevent the vegetation of weeds, and forward the growth of pea crops, by occasionally horse-hoeing, and the use of the brake-harrow, the mould being laid up to the roots of the plants at the last operation by fixing a piece of wood to the harrow. This should, however, only be laid up on one side, the peas being always placed up to that which is the most fully exposed to the effects of the sun.*

5207. *In harvesting the ripened pea considerable care is requisite, both on account of the seed and haulm.*

5208. *When pea crops become ripe they wither and turn brown in the haulm or straw, and the pods begin to open. In this state they should be cut immediately, in order that the loss sustained by their shedding may be as little as possible. It is observed that in the late or general crops, after they are reaped or rather cut up by means of a hook, it is the usual practice to put them up into small heaps, termed wads, which are formed by setting small parcels against each other, in order that they may be more perfectly dried both in the seed and stem, and be kept from being injured by the moisture of the ground. But, in the early crops, the haulm is hooked up into loose open heaps, which, as soon as they are perfectly dry, are removed from the ground and put into stacks for the feeding of animals, which are said to thrive nearly as well on it as on hay. When intended for horses, the best method would seem to be that of having them cut into chaff and mixed with their other food. Young says, that forward white peas will be fit to cut early in July; if the crop is very great they must be hooked; but if small, or only middling, mowing will be sufficient. The stalks and leaves of peas being very succulent, they should be taken good care of in wet weather: the tufts, called wads or heaps, should be turned, or they will receive damage. White peas should always be perfectly dry before they are housed, or they will sell but indifferently; as the brightness and plumpness of the grain are considered more in them than in hog peas at market. The straw also, if well harvested, is very good fodder for all sorts of cattle and for sheep; but if it receives much wet, or if the heaps are not turned, it can be used only to litter the farmyard with. It is the practice in some districts to remove the haulm, as soon as it has been cut up by hooks constructed*

with sharp edges for the purpose, to every fifth ridge, or even into an adjoining grass field, in order that it may be the better cured for use as cattle-food, and at the same time allow of the land being immediately prepared for the succeeding crop. When wet weather happens whilst the peas lie in wads, it occasions a considerable loss, many of them being shed in the field, and of those that remain a great part will be so considerably injured as to render the sample of little value. This inability in peas to resist a wet harvest, together with the great uncertainty throughout their growth, and the frequently inadequate return in proportion to the length of haulm, has discouraged many farmers from sowing so large a portion of this pulse as of other grain; though on light lands which are in tolerable heart, the profit, in a good year, is far from inconsiderable.

5209. *In gathering green peas for the market, it is frequently a practice with the large cultivators of early green-pea crops in the neighbourhood of London to dispose of them, by the acre, to inferior persons, who procure the podders; but the smaller farmers, for the most part, provide this description of people themselves, who generally apply at the proper season.*

5210. *The business of picking or podding the peas is usually performed by the labourers at a fixed price for the sack of four heaped bushels. The number of these labourers is generally in the proportion of about four to the acre, the labour proceeding on the Sundays as well as other days. It is sometimes the custom to pick the crops over twice, after which the rest are suffered to stand till they become ripe, for the purpose of seed. This, however, mostly arises from the want of pickers, as it is considered a loss, from the peas being less profitable in their ripe state than when green. Besides, they are often improper for the purpose of seed, as being the worst part of the crop. It is therefore better to have them clear picked when hands can be procured. After this they are loaded into carts, and sent off at suitable times, according to the distance of the situation, so as to be delivered to the salesmen in the different markets from about three to five o'clock in the morning. In many cases in other parts, the early gatherings are, however, sent to the markets in half-bushel sieves, and are frequently disposed of at the high price of five shillings the sieve; but at the after periods they are usually conveyed in sacks of a narrow form, made for the purpose, which contain about three bushels each, which, in the more early parts of the season, often fetch twelve or fourteen shillings the sack, but afterwards mostly decline considerably; in some seasons so much as scarcely to repay the expenses. This sort of crop affords the most profit in such pea seasons as are inclined to be cool, as under such circumstances the peas are most retarded in their maturation or ripening, and of course the markets kept from being overabundantly supplied.*

5211. *The threshing of peas requires less labour than that of any other crop. Where the haulm is to be preserved entire it is best done by hand; as the threshing-machine is apt to reduce it to chaff. But where the fodder of peas is to be given immediately to horses on the spot, the breaking of it is no disadvantage.*

5212. *The produce of the pea in ripened seeds is supposed by some to be from three and a half to four quarters the acre; others, however, as Donaldson, imagine the average of any two crops together not more than about twelve bushels; and that on the whole, if the value of the produce be merely attended to, it may be considered as a less profitable crop than most others. But as a means of ameliorating and improving the soil at the same time, it is esteemed of great value.*

5213. *With respect to the produce in green peas in the husk, the average of the early crops in Middlesex is supposed to be from about twenty-five to thirty sacks the acre, which, selling at from eight to eighteen shillings the sack, afford about eighteen pounds the acre. The author of *The Synopsis of Husbandry*, however, states the produce about Dartford, in the county of Kent, at about forty sacks the acre, though, he says, fifty have sometimes been gathered from that space of land.*

5214. *The produce of peas in straw is very uncertain, depending so much on the sort and the season; in general it is much more bulky than that of the cereal grasses; but may be compressed into very little room.*

5215. *The produce of peas in flour is as 3 to 2 of the bulk in grain, and husked and split for soups as 4 to 2. A thousand parts of pea flour afforded Sir H. Davy 574 parts of nutritive or soluble matter; viz. 501 of mucilage or vegetable animal matter, 22 of sugar, 35 of gluten, and 16 of extract or matter rendered insoluble during the operation.*

5216. *The use of peas for soups, puddings, and other culinary purposes, is well known.*

5217. *In some places porridge, brose, and bread are made of pea-flour, and reckoned very wholesome and substantial. In Stirlingshire it is customary to give pea or bean biscuits to horses, as a refreshment, while in the yoke. The portion of peas not consumed as human food is mostly appropriated to the fattening of hogs and other domestic animals; and, in particular instances, supplies the place of beans, as the provender of labouring horses; but care should be taken, when used in this way, that they are sufficiently dry, as, when given in the green state, they are said to produce the gripes, and other bowel complaints, in those animals. Bannister, after observing that the haulm is a very wholesome food for cattle of every kind, says, there is generally a considerable demand for peas of every denomination in the market, the uses to which they may be applied being so many and so various. The boilers, or yellow peas, always go off briskly; and the hog-peas usually sell for 6d. or 1s. per quarter more than beans. For feeding swine the pea is much better adapted than the bean, it having been demonstrated by experience, that hogs fat more kindly when fed with this grain than with beans; and, what is not easy to be accounted for, the flesh of swine which have been fed on peas, it is said, will swell in boiling, and be well tasted; whilst the flesh of the bean-fed hog will shrink in the pot, the fat will boil out, and the meat be less delicate in flavour. It has, therefore, now become a practice with those farmers who are curious in their pork, to feed their hogs on peas and barley-meal; and if they have no peas of their own growth, they rather choose to be at the expense of buying them, than suffer their hogs to eat beans. Nay, so far, says he, do some of them carry their prejudice in this particular, as to reject the grey peas for this use, as bearing too near an affinity to the bean, and therefore reserve their growths of white peas solely for hog-fattening.*

5218. *In boiling split peas, some samples, without reference to variety, fall or moulder down freely into pulp, while others continue to maintain their form. The former are called boilers. This property of boiling depends on the soil; stiff land, or sandy land, that has been limed or marled, or to which gypsum has been applied, produces peas that will not melt in boiling, no matter what the variety may be. The same effect is produced on beans, on kidneybeans in the pod, and indeed on the seeds and pods of all leguminous plants; this family having a great tendency to absorb gypsum from the soil. To counteract this fault in the boiling, it is only necessary to throw into the water a small quantity of subcarbonate of soda. (*Bull. de Sci. Agr. Feb. 1828.*)*

5219. *Pea straw cut green and dried is reckoned as nourishing as hay, and is considered excellent for sheep.*

5220. *In the saving of any particular sorts of peas for seed, they should be carefully looked over while in flower, in order to draw out all such plants as are not of the right kind; as there will always be, in every sort, some roguish plants, which, if left to mix, will cause degeneration. As many rows as may be thought sufficient to furnish the desired quantity of seed should then be marked out, and left till their pods turn brown, and begin to split, when they should immediately be gathered up, with the haulm; and if the farmer has not room to stack them till winter, they may be threshed out as soon as they are dry, and put up in sacks for use: but particular care should be taken not to let them remain too long abroad after they are ripe; as wet would rot them; and heat, after a shower of rain, makes their pods burst in such a manner that the greater part of their seeds would be lost.*

5221. *The diseases of peas are few, and chiefly the worm in the pod and the fly on the leaves and flower. They are also liable to be mildewed or blighted. None of these evils, however, are very common; and there is no known way of preventing them but by judicious culture. Late sown peas are particularly liable to be injured by the mildew and Aphis; and should either of these attack the plant before the pods are filled, they invariably fail. In 1826 almost all the crops of peas were destroyed by the Aphides, so that they were mown for the haulm only.*

SECT. II. *The Bean.*—*Vicia Faba L.; Diadelphía Decándria L., and Leguminosæ J. Féverole, Fr.; Bohn, Ger.; Fava, Ital; and Alverjanas, Span.*

5222. *The bean is a valuable field plant, as affording food for live stock, and in part for man. It is said to be a native of Egypt; but, like other long domesticated plants, its origin is very uncertain. It has been cultivated in Europe and Asia time out of mind. Beans have been long known in Britain; but it is only of late years that they were extensively cultivated upon general soils, being formerly considered as adapted only to rich and moist clays. At that time they were all sown according to the broad-cast system; in which way, instead of benefiting the ground, they were of incalculable detriment. Weeds got away at the outset, and in dry seasons often ruined the crop; whilst in every season the grass or perennial weeds which happened to be in the ground increased in strength and in quantity, the openness of the bean crop at bottom allowing them to thrive without interruption.*

5223. *The drilling of beans with a small mixture of peas is now become a general practice in every well cultivated district of the north, more particularly in those where soil and climate permit the practice to be successfully executed. In this way not only heavy crops are raised, but, what is of great importance, the ground is kept constantly in good order, provided suitable attention is bestowed upon the cleaning process. This is generally carried on by horse-hoeing the crop at different times, so long as the hoe can be used without doing damage; and in this way an able auxiliary is brought forward to the assistance of summer fallow, whereby less stress need be laid upon that radical process than otherwise would be indispensably necessary. (Brown.)*

5224. *The varieties of the bean may be included under two general heads,—the white or garden beans, and the grey or field beans.*

5225. *Of the white or garden beans (Fève de marais, Fr.) sown in the fields, the mazagan and long-pod are almost the only sorts. Of the grey beans, that known as the horse bean, the small or ticks, and the prolific or Heligoland, are the chief sorts. New varieties are procured in the same manner as in other plants. A variety is in use in some parts of Lincolnshire, called the winter bean (Féverole d'hiver, Fr.). It is planted in October in the usual manner, and is ready to harvest in the last week in July or the first week in August. They are said to have been introduced from the Continent in 1825. We have lately seen a field of this bean at the Oaks Farm, near Woking, in Surrey, which was planted in October 1829, and in full bloom May 12th following. This circumstance, after so severe a winter, is a proof to us that this is a most valuable variety. (Gard. Mag. vol. vi.)*

5226. *In the choice of sorts, tick beans are supposed by some farmers to be more productive than horse-beans; but the latter grow higher in the stem, and produce a more stagnated state of the air, or smother the land more, consequently are the most suitable for the stronger sorts of soil; and Young remarks, that “the common little horse-bean has the advantage of all others in being more generally marketable; for in certain situations it is not always easy to dispose of ticks, Windsors, long-pods, and various other large sorts. They also grow higher, shade the ground in summer more from the sun, and yield a larger quantity of straw, which makes excellent manure. But some of the other sorts are generally supposed to yield larger products. In purchasing beans for seed, care should be taken to choose such as are hard and bright, without being shrivelled in their appearance.”*

5227. *The best soils for beans are clays and strong loams. On such soils they generally succeed wheat or oats, but sometimes also clover leys. Turnip soils or sands are by no means proper for them.*

5228. *In the preparation of the soil much depends on the nature of the land and the state of the weather; for as beans must be sown early in the spring, it is sometimes impossible to give it all the labour which a careful farmer would wish to bestow. It must also be regulated in some measure by the manner of*

sowing. In all cases it ought to be ploughed with a deep furrow after harvest or early in winter; and as two ploughings in spring are highly advantageous, the winter furrow may be given in the direction of the former ridges, in which way the land is sooner dry in spring than if it had been ploughed across. The second ploughing is to be given across the ridges, as early in spring as the ground is sufficiently dry; and the third furrow either forms the drills or receives the seed. (*Supp. E. Brit. art. Agr.*)

5229. *Brown*, one of the best bean-growers in Britain, gives the following directions:—The furrow ought to be given early in winter, and as deep as possible, that the earth may be sufficiently loosened and room afforded for the roots of the plant to search for the requisite nourishment. This first furrow is usually given across the field, which is the best method when only one spring furrow is intended; but as it is now ascertained that two spring furrows are highly advantageous, perhaps the one in winter ought to be given in length, which lays the ground in a better situation for resisting the rains, and renders it sooner dry in spring, than can be the case when ploughed across. On the supposition that three furrows are to be given, one in winter and two in spring, the following is the most eligible preparation:—The land being ploughed in length as early in winter as is practicable, and the cross gutter and headland furrows sufficiently dug out, take the second furrow across the first as soon as the ground is dry enough in spring to undergo the operation; water-furrow it immediately, and dig again the cross gutter and headland furrows, otherwise the benefit of the second furrow may be lost. This being done, leave the field for some days till it is sufficiently dry, when a cast of the harrows becomes necessary, so that the surface may be levelled; then enter with the ploughs and form the drills. (*Treatise on Rural Affairs.*)

5230. *Manure is frequently applied to the bean crop*, especially if it succeeds wheat. By some, dung is spread on the stubble previously to the winter ploughing; but this cannot always be done in a satisfactory manner, at least in the northern parts of the island, unless during frost, when it may lie long exposed to the weather before it can be turned down by the plough. The most desirable mode, therefore, is to lay the manure into drills immediately before the beans are sown. (*Supp. &c.*)

5231. *The best way*, according to *Brown*, is to apply the dung on the stubble before the winter furrow is given, which greatly facilitates the after process. Used in this way, a fore stock must be in hand; but where the farmer is not so well provided, spring dunging becomes necessary, though evidently of less advantage. At that season it may either be put into the drills before the seed is sown, or spread upon the surface and ploughed down, according to the nature of the drilling process which is meant to be adopted. Land dunged to beans, if duly hoed, is always in high order for carrying a crop of wheat in succession. Perhaps better wheat, both in respect of quantity and quality, may be cultivated in this way than in any other mode of sowing.

5232. *The climate most favourable to the bean is one neither very dry nor very moist; the first brings on the fly, and the last prevents the setting of the blossoms.* In general, however, a dry summer is most favourable to the production of seed, and moist weather to the growth of the haulm.

5233. *The time of sowing beans is as early as possible after the severity of winter is over; in the south, sometimes in January, but never later than the end of March, as the ripening of the crop and its safe harvesting would otherwise be very precarious in this climate.* *Bannister* thinks that the proper time for planting beans in Kent is towards the latter end of January or early in the following month; though this business may be continued with advantage till the middle or latter end of March, if the weather should prevent their being got in at an earlier season: but in general it is best to embrace the first opportunity of sowing them after Candlemas, as they often miscarry when the season is protracted beyond that time, especially if a dry summer should succeed.

5234. *The mode of sowing is almost always in rows.* Though still sown broad-cast in several places, and sometimes dibbled, they are for the most part drilled by judicious cultivators, or deposited after the plough in every furrow, or only in every second or third furrow. In the latter method the crop rises in rows, at regular intervals of nine, eighteen, or twenty-seven inches, and the hand-hoe ought invariably to be employed; but it is only where the widest interval is adopted that the horse-hoe can be used with much effect in their subsequent culture.

5235. *There are two modes of drilling beans.* In one of these the lands or ridges are divided by the plough into ridgelets or one bout stitches, at intervals of about twenty-seven inches. If dung is to be applied, the seed ought to be first deposited, as it is found inconvenient to run the drill-machine afterwards. The dung may then be drawn out from the carts in small heaps, one row of heaps serving for three or five ridgelets, and it is evenly spread and equally divided among them in a way that will be more minutely described when treating of the culture of turnips. The ridgelets are next split out or reversed, either by means of the common plough or one with two mould-boards, by which means both the seed and the manure are perfectly covered. When beans are sown by the other method, in the bottom of a common furrow, the dung must be previously spread over the surface of the winter or spring ploughing. Three ploughs then start in succession, one immediately behind another; and a drill harrow either follows the third plough or is attached to it, by which the beans are sown in every third furrow, or at from twenty-four to twenty-seven inches asunder, according to the breadth of the furrow-slice.

5236. *Another approved way of sowing beans*, when dung is applied at seed-time, is to spread the dung and to follow it down with a strong furrow; after this shallow furrows are drawn, into which the seed is deposited by the drill-machine. Whichever of these modes of sowing is followed, the whole field must be carefully laid dry, by means of channels formed by the plough, and when necessary by the shovel; for neither then nor at any former period should water be allowed to stagnate on the land.

5237. *The dibbling of beans is considered by Arthur Young as an excellent method when well performed; but the grand objection to it is the difficulty of getting it well done.*

5238. *When dibbling becomes the common husbandry of a district*, the workmen find that great earnings are to be made by it, and this is much too apt to make them careless and eager to earn still more; and if a very minute attention is not paid to them by the constant attendance of the farmer, they strike the holes so shallow that the first peck of a rook's bill takes the seed, and acres may be destroyed if the breed of those birds be encouraged. Boys are employed for weeks together to keep the fields, but all works that depend on boys are horribly neglected, and thus the farmer suffers materially; however, if the seed is deposited two and a half or (better) three inches deep, it is not so easily eradicated. In some districts, as Middlesex, Surrey, &c., the method is to plant this pulse in rows struck out by a line, by which a great saving is made in the article of seed, a circumstance which is thought to compensate for the extraordinary charge of this mode of husbandry; and thus far it may be fairly acknowledged that the method of planting beans by the dibber is greatly to be preferred to that of sowing in seed at random. The economy of this agricultural process is thus explained:—The rows are marked out one foot asunder,

and the seed planted in holes made two inches apart : the lines are stretched across the lands, which are formed about six feet over ; so that when one row is planted, the sticks to which the line is fastened are moved by a regular measurement to the distance required, and the same method pursued till the field is completed. The usual price for this work is ninepence per peck, and the allowance two bushels per acre. Great confidence must necessarily be reposed in the people who transact the business of planting beans by the dibber ; for, if inclined to fraud, they have it in their power to deceive their employer, by throwing a great part of the seed into the hedge ; by which means their daily profits are considerably enhanced, their own labour spared, and every discovery effectually precluded till the appearance of the crop. Then, indeed, the frequent chasms in the rows will give sufficient indications of the fraud ; but by this time perhaps the villainous authors of the mischief may have escaped all possibility of detection, by having conveyed themselves from the scene of their iniquity.

5239. *The quantity of seed* allowed is very different in the southern and northern parts of Britain : in the former, even when the rows are narrow, only two bushels or two bushels and a half ; but in Scotland, seldom less than four bushels to the English statute acre, even when sown in ridgelets twenty-seven inches distant, and a bushel more when sown *broad-cast*. When beans are sown or planted thick, the top pods only fill to the number of three, and four, and half a dozen ; when thin, the plants will pod and fill to the bottom. Both in the broad-cast and drill husbandry, it is common to mix a small quantity of peas along with beans. This mixture improves both the quantity and quality of the straw for fodder, and the pea straw is useful for binding up the sheaves in harvest.

5240. *The after culture* of the bean crop commences with harrowing just before the young plants reach the surface. When sown in rows, in either of the modes already mentioned, the harrows are employed about ten or twelve days after ; and, being driven across the ridgelets, the land is laid completely level for the subsequent operations, and the annual weeds destroyed.

5241. *After the beans have made some growth*, sooner or later, according to the state of the soil with regard to weeds, the horse-hoe is employed in the intervals between the rows ; and followed by the hand-hoe for the purpose of cutting down such weeds as the horse-hoe cannot reach ; all the weeds, that grow among the beans beyond the reach of either hoe, should be pulled up with the hand. The same operations are repeated as often as the condition of the land, in regard to cleanness, may require.

5242. *Before the introduction of the horse-hoe*, which merely stirs the soil, and cuts up the weeds, a common small plough, drawn by one horse, was used in working between the rows, and is still necessary where root-weeds abound. This plough goes one bout, or up and down in each interval, turning the earth from the beans, and forming a ridgelet in the middle ; then hand-hoes are immediately employed ; and, after some time, a second hand-hoeing succeeds, to destroy any fresh growth of weeds. The same plough, with an additional mould-board, finally splits open the intermediate ridgelet, and lays up the earth to the roots of the beans on each side. The benefit of laying up the earth in this manner, however, is alleged to be counterbalanced by the trouble which it occasions in harvest, when it is difficult to get the reapers to cut low enough ; and it may be properly dispensed with, unless the soil is very wet and level.

5243. *In moist warm seasons*, this grain hardly ever ripens effectually ; and it is exceedingly difficult to get the straw into a proper condition for the stack. In such cases, it has been found of advantage to switch off the succulent tops with an old scythe blade set in a wooden handle, with which one man can easily top dress two acres a day. This operation, it is said, will occasion the crop to be ready for reaping a fortnight earlier, and also, perhaps, a week sooner ready for the stack-yard after being reaped.

5244. *Before reaping beans* the grain ought to be tolerably well ripened, otherwise the quality is impaired, whilst a long time is required to put the straw in such a condition as to be preserved in the stack. In an early harvest, or where the crop is not weighty, it is an easy matter to get beans sufficiently ripened ; but, in a late harvest, and in every one where the crop takes on a second growth, it is scarcely practicable to get them thoroughly ripened for the sickle. Under these circumstances, it is unnecessary to let beans stand uncut after the end of September, or the first of October ; because any benefit that can be gained afterwards, is not to be compared with the disadvantages that accompany a late wheat seed-time.

5245. *Beans are usually cut with the sickle*, and tied in sheaves, either with straw ropes, or with ropes made from peas sown along with them. It is proper to let the sheaves lie untied several days, so that the winning process may be hastened, and, when tied, to set them up on end, in order that full benefit from the air may be obtained, and the grain kept off the ground. (*Brown.*)

5246. *Beans are sometimes mown*, and, in a few instances, even pulled up by the roots. They should in every case be cut as near the ground as possible, for the sake of the straw, which is of considerable value as fodder, and because the best pods are often placed on the stems near the roots. They are then left for a few days to wither, and afterwards bound and set up in shocks to dry, but without any head sheaves. (*Supp. &c.*)

5247. *Beans are stacked* either in the round or oblong manner ; and it is always proper, in the northern counties at least, if the stack is large, to construct one funnel or more to allow a free circulation of air.

5248. *The threshing of beans* is nearly as easy as that of peas. Threshing them by a machine may be considered advantageous as breaking the coarser ends of the straw, and separating the earth from their root-ends, or roots, if they have been reaped by pulling.

5249. *The produce of beans*, when proper management is exercised, and where diseases have not occurred, is generally from twenty-five to thirty-five bushels per acre. Donaldson says, that a crop of beans, taking the island at large, may be supposed to vary from sixteen to forty bushels, but that a good average crop cannot be reckoned to exceed twenty. In Middlesex, Middleton tells us, that bean-crops vary from ten to eighty bushels per acre. They are rendered a very precarious crop by the ravages of myriads of small black insects of the *Aphis* kind. The lady-birds (*Coccinella*) are supposed to feed on them, as they are observed to be much among them. Foot says, the average produce is from

three and a half to four quarters per acre. In Kent, A. Young thinks, they probably exceed four quarters; but in Suffolk, he should not estimate them at more than three; yet five or six are not uncommon.

5250. *The produce in haulm*, in moist seasons, is very bulky.

5251. *In the application of beans*, the grain in Scotland is sometimes made into meal, the finer for bread, and the coarser for swine; but beans are for the most part applied to the purpose of feeding horses, hogs, and other domestic animals. In the county of Middlesex, all are given to horses, except what are preserved for seed, and such as are podded while green, and sent to the London markets. When pigs are fed with beans, it is observed that the meat becomes so hard as to make very ordinary pork, but good bacon. It is also supposed that the mealmen grind many horse-beans among wheat to be manufactured into bread.

5252. *The flour of beans is more nutritive than that of oats*, as it appears in the fattening of hogs; whence, according to the respective prices of these two articles, Dr. Darwin suspects that peas and beans generally supply a cheaper provender for horses than oats, as well as for other domestic animals. But as the flour of peas and beans is more oily, he believes, than that of oats, it may in general be somewhat more difficult of digestion; hence, when a horse has taken a stomachful of peas and beans alone, he may be less active for an hour or two, as his strength will be more employed in the digestion of them than when he has taken a stomachful of oats. A German physician gave to two dogs, which had been kept a day fasting, a large quantity of flesh food; and then taking one of them into the fields, hunted him with great activity for three or four hours, and left the other by the fire. An emetic was then given to each of them; and the food of the sleeping dog was found perfectly digested, whilst that of the hunted one had undergone but little alteration. Hence it may, he says, be found advisable to mix bran of wheat with the peas and beans, a food of less nutriment, but of easier digestion; or to let the horses eat before or after them the coarse tussocks of sour grass, which remain in moist pastures in the winter; or, lastly, to mix finely cut straw with them. It is observed in the fifth volume of *The Bath Papers*, that it has been found by repeated experience, that beans are a much more hearty and profitable food for horses than oats. Being out of old oats the two last springs, the writer substituted horse-beans in their stead. In the room of a sack of oats with chaff, he ordered them a bushel of beans with chaff, to serve the same time. It very soon appeared the beans were superior to the oats, from the life, spirit, and sleekness of the horses.

5253. *Bean straw*, when mixed with peas, Brown considers as affording almost as much nourishment when properly harvested as is gained from hay of ordinary quality; when it is well got the horses are fonder of it than of pea straw. It should either be given when newly threshed, or else stacked up and compressed by treading or coverings, as the air is found materially to affect both its flavour and nutritive quality.

5254. *The produce of beans in meal* is, like that of peas, more in proportion to the grain than in any of the cereal grasses. A bushel of beans is supposed to yield fourteen pounds more of flour than a bushel of oats, and a bushel of peas eighteen pounds more, or, according to some, twenty pounds. A thousand parts of bean flour were found, by Sir H. Davy, to yield 570 parts of nutritive matter, of which 426 were mucilage or starch, 103 gluten, and 41 extract, or matter rendered insoluble during the process.

5255. *The diseases of beans* are, the rust, mildew, black fly or A'phides, and in consequence the honey dews.

5256. *A'phides, when they live on beans*, are of a dirty bluish-black colour, similar to those on the elder and cherry. The larvæ of the *Coccinella septempunctata*, as well as the perfect insects, devour the A'phis. Several of the small summer birds, viz. largest willow-wren, middle, and smallest wren, white-throat, lesser white-throat, black-cap, and Dartford warbler, also live on them. The A'phides of beans are brought on by very dry weather: they are most prevalent on the summits of the plants; and some have attempted to mitigate the evil by cutting off the tops. In general, however, the disease is without remedy, either preventive or positive. In extreme cases they destroy the leaves, stalks, and fruit; and when this is foreseen, the best thing the farmer can do is to mow the crop or plough it down, and prepare the land for wheat or otherwise, according to the rotation.

SECT. III. *The Tare.* — *Vicia sativa* L.; *Diadélphia Decandria* L., and *Leguminosæ* J. *Vesce commun de printemps et d'hiver*, Fr.; *Wicke*, Ger.; *Loglio*, Ital.; and *Arveja*, Sp.

5257. *The tare, vetch, or fitch* (*Vicia sativa*, fig. 742.), has been cultivated for its stem and leaves from time immemorial. It is considered as a native plant, and is found wild also in China and Japan. Ray, in 1686, informs us, that the common tare or vetch was then sown almost all over Europe; that it was chiefly used in England, mixed with peas and oats, to feed horses: but that it was sometimes sown separately for soiling cattle, and was reputed to cause milch cows to yield much milk. The tare, Brown observes, is of hardy growth, and, when sown upon rich land, will return a large supply of green fodder for the consumption of horses, or for fattening cattle.

5258. *The varieties of tares* are chiefly two, the winter and spring tare; both have local names, as gore vetch, rath ripe vetch, &c. Some consider them as distinct species, but this is doubtful.

5259. *As the result of an experiment* tried for two years at Bury, in Suffolk, Professor Martyn observes, that there appears a material difference in the constitution, if we may so call it, of the two tares in question. Not to say any thing of a trifling difference in the colour and size of their seeds, the only visible mark of distinction seems to be a disparity in the first leaves of the upright stalks, which in the spring

tare are elliptic, and rounded or notched at the end, but in the winter tare linear and drawn to a point. The leaves on the branches which afterwards issue below, and in time form the bulk of the plants, are the same in both vetches. But, whatever the difference may be, it is evident that the seeds of the two sorts ought to be kept separate; since each sown out of its proper season is found not to prosper.

5260. *New varieties of tare* may be obtained by the usual means; and it is thought that some of the numerous species of this plant, which are natives of Europe, might be cultivated with advantage. The French cultivate a variety which they call *Vesce blanche*, or *Lentille du Canada*, *Vicia sativa* álba. They include also among their forage vetches *Vicia angustifolia*, *Cracca*, *Pseudo-Cracca*, *Vicia sépium*, and *lútea*. The *Vicia narbonensis* and *serratifolia* are cultivated in Germany. Dr. Anderson has recommended the *V. sépium*; and a writer in *The Bath Agricultural Transactions*, the *V. Cracca*. Some species of *Láthyrys*, *O robus*, and *Ervum* might probably also be tried with success.

5261. *In choosing between the spring and winter tare*, every thing must depend on the intention of the crop. If the object is to have early feed, the winter variety is undoubtedly to be preferred; but where the land is foul and requires to be two or three times ploughed in spring, or where a late crop is desired, or a crop for seed, then the spring variety will generally deserve the preference.

5262. *The soil preferred by the tare* is a clay, but they will grow in any rich soil not over dry. In a moist climate, the haulm grows so luxuriant as to rot at bottom; and in one over dry it is deficient in length. A dry season, however, is on the whole more favourable than a moist one, as this crop soon covers the surface.

5263. *The preparation of the soil* seldom consists of more than one ploughing, if for autumn sowing; and of a winter and spring ploughing, when to be sown in spring. If in the latter case the land is very foul, several ploughings are given, or one ploughing and several stirrings with the cultivator. In general, tares succeed some of the corn crops. In England manure is sometimes given either with a view to eating them off early, and following with a crop of turnips, or to enriching the soil for a crop of wheat.

5264. *The time of sowing* depends on the kind of tare, and the purpose in view.

5265. *The winter variety* is sown in September and October; and the first sowing in spring ought to be as early as the season will permit. If they are to be cut green for soiling throughout the summer and autumn, which is the most advantageous method of consuming them, successive sowings should follow till the end of May. Summer tares, when meant for seed, Brown observes, ought to be sown early, "otherwise the return will be imperfect; but when for green food, any time betwixt the first of April and the latter end of May will answer well, provided crops in succession, from the first to the last-mentioned period, be regularly cultivated. Instances are not wanting of a full crop being obtained even when the seed was sown so late as the middle of June, though sowing so late is a practice not to be recommended. In Middlesex, the winter sowings are commenced about the beginning of August: in the northern counties no winter sowings are made, as the tare there will not endure the severity of that season.

5266. *The mode of sowing tares* is mostly broad-cast, which should be performed as evenly as possible over the surface of well-prepared land; the seeds being afterwards covered in by proper harrowing, in order to prevent their being picked up by birds, and ensure their perfect vegetation and growth. It has been suggested, however, that, in rich clean soil, it is probable the row-method would succeed well with this sort of crop, which, as Marshal states, is the practice in some of the southern districts of the island. After the seed is sown, and the land carefully harrowed, a light roller ought to be drawn across, so that the surface may be smoothed, and the scythe permitted to work without interruption. It is proper also to guard the field for several days against the depredations of pigeons, who are remarkably fond of tares, and will pick up a great part of the seed, unless constantly watched.

5267. *The quantity of seed* to an acre is from two and a half to three and a half bushels, according to the time of sowing, and to whether they are to be consumed green or left to stand for a crop.

5268. *When tares are intended for seed*, less seed is required than when they are grown for soiling or for drying the haulm. A writer in *The Farmer's Magazine* (vol. i.) has suggested, that the most productive method of sowing this crop, when intended for seed, is to mix them amongst beans when drilled, at the rate of one firlo of tares to one boll of beans. From trials made it is ascertained, it is said, that the quality of the tares is vastly improved by being blended with beans, as, by clinging to the latter, they are kept from the ground, and enjoy the full benefit of the sun for ripening them in a perfect manner; and they are in this way much easier harvested than when sown by themselves. They answer, at the same time, for bands to tie the principal crop; and the produce may, on an average of seasons, be considered as at least double. A little rye sown with winter tares, and a few oats with the spring sort, not only serve to support the weak creeping stems of the tares, but add to the bulk of the crop by growing up through the interstices.

5269. *In the choice of the seed* it is hardly possible to distinguish the grain of the winter from that of the spring variety: the former is alleged to be rather smaller and lighter coloured; but the only reliance must be on the honesty of the vendor. Plump seed, and a sample free from the seeds of weeds, will of course be selected, whatever be the variety.

5270. *The after culture* given to tares consists merely in pulling out the larger weeds, unless they are in rows, in which case the horse or hand hoe is applied; or intended for seed, in which case weeding must be more particularly executed.

5271. *In reaping tares for soiling* they ought always to be cut with the scythe, as the sickle, by breaking asunder the stalks, and tearing up a number by the roots, renders the second crop of little value. When mown early, they will in a moist season produce three mowings, but generally two. In reaping tares for seed, they may be either mown or taken with the sickle, and treated like peas in drying, stacking, and threshing.

5272. *Tares are eaten off the ground* in some places by different kinds of live stock, particularly by sheep; and as the winter-sown variety comes early in spring, the value of this rich food is then very considerable. The waste, however, in this way, even

though the sheep are confined in hurdles, must be great; and still greater when consumed by horses or cattle.

5273. *Tare crops are sometimes made into hay*, in which case more attention is found necessary than in those of most of the artificial grasses, as wet is more injurious to them, and they require more sun and air; but in other respects they demand the same cautious management, in order to preserve the foliage from being lost. The time for cutting for this purpose is, according to the author of *The Synopsis of Husbandry*, when the blossoms have declined and they begin to fall and lie flat. When well made, the hay is of the best and most nutritious quality.

5274. *The produce of tares cut green* is, according to Middleton, ten or twelve tons per acre, which is a large crop; and when made into hay about three tons per acre, which shows the disadvantage of making these crops into hay. It is found that the spring tares are lighter, and most liable to be injured by a dry season.

5275. *The produce in seed* is likewise found to be considerable, being by some stated at from three to six sacks; but in other instances forty bushels, or more, have been obtained from the acre.

5276. *In the application of tares* they are found to be a hearty and most nourishing food for all sorts of cattle.

5277. *Cows give more butter* when fed with this plant than with any other food whatsoever. Horses thrive better upon tares than they do upon clover and rye-grass; and the same remark is applicable to the fattening of cattle, which feed faster upon this article of green fodder than upon any kind of grass or esculent with which we are acquainted. Danger often arises from their eating too much, especially when podded; as colics, and other stomach disorders, are apt to be produced by the excessive loads which they devour. Perhaps a great quantity of fixed air is contained in this vegetable; and as heavy crops are rarely dry at the root when cut, it is not to be wondered that accidents often happen, when the animal is indulged with the unrestrained consumption of them. Were oat straw mixed with the tares in the racks or stalls in which they are deposited, it is probable that fewer accidents would follow, though this assistant is only required when the tares are wet, foul, or over succulent. If the plants are cut green, and given to live stock, either on the field or in the fold-yards, there is, perhaps, no green crop of greater value, nor a better calculated to give a succession of herbage from May to November. The winter-sown tare, in a favourable climate, is ready for cutting before clover. The first spring-crop comes in after the clover must be all consumed or made into hay; and the successive spring sowings give a produce more nourishing for the larger animals than the aftermath of clover, and may afford green food at least a month longer. In the county of Sussex, Young observes, "tare crops are of such use and importance that not one tenth of the stock could be maintained without them; horses, cows, sheep, hogs, all feed upon them; hogs are soiled upon them without any other food. This plant maintains more stock than any other plant whatsoever. Upon one acre Davis maintained four horses in much better condition than upon five acres of grass. Upon eight acres he has kept twelve horses and five cows for three months without any other food; no artificial food whatever is equal to this excellent plant." This statement must be coupled with the usual produce of turnips in Sussex, 10 or 15 tons per acre: hence the supposed superiority of tares to every other green crop. Tares cut green, Professor Thar observes, draw no nourishment from the soil whatever; while made into hay, they afford a fodder preferred by cattle to pea straw, and more nutritive than hay or any other herbage.

5278. *The use of the grain of tares* is generally for reproduction; but they are also given to pigeons, by which they are highly relished, and it is thought they would form a very good food for poultry. In Germany they are given to horses, cows, sheep, and swine.

5279. *The diseases of tares* are so few as to be of no consequence. A crop is sometimes, but rarely, lost by mildew.

SECT. IV. Various Legumes which might be cultivated in British Farming.

5280. *The lentil, kidneybean, and chick pea* are grown both in France and Germany, as field plants, for their seeds, which are used as food. They are by no means likely to become articles of general culture in Britain; but it is worth while to know that they may be cultivated here instead of being imported, and also that they form very excellent articles of human subsistence.

5281. *The lentil* is the *Ervum Léns L.*; *Lentillon*, Fr.; *Lentzen*, Ger.; and *Lenticcia*, Ital. (fig. 743.)

It is a legume of the greatest antiquity, being in esteem in Esau's time, and much prized in Eastern countries ever since. In Egypt and Syria, they are parched in a frying-pan and sold in the shops, and considered by the natives as the best food for those who undertake long journeys. The lentil is considered a native of France, but has been known in England from the earliest agricultural records. In Gerarde's time they were sown like tares, their haulm given to cattle, and the seed to pigeons, and used in meagre soups.

5282. *There are three varieties of lentils* cultivated in France and Germany: the small brown, which is the lightest-flavoured, and the best for haricots and soups; the yellowish, which is a little larger, and the next best; and the lentil of Provence, which is almost as large as a pea, with luxuriant straw, and more fit to be cultivated as a tare than as food for man. The French have also a winter lentil, *Lentillon d'hiver*; and they cultivate the *Ervum Ervilia*, *Lentille Erse* ou *Ervillier*, and the *E. monanthos*, *Len à une fleur*, *Jarosse d'Auvergne*. The Spanish lentil, — *Gesse cultivée*, *Lentille d'Espagne*, Fr., *Lenteja*, Span., — is the *Láthyrus sativus*. (fig. 744.) It is sometimes grown in gardens in this country, and occasionally in the fields in France. The lentil of Canada, *Lentille du Canada*, Fr., is the

Vicia pisiformis Lin. (fig. 745.) *Vicia Ervilia* Willd., *Ervum tetraspermum* Lin., and *E. hirsutum* Lin., are also cultivated in some places as lentils; and indeed the seeds of all the tribe *Viciæ* (*Encyclopædia of Plants*, p. 1066.) may be eaten by man.

5283. *A dry, warm, sandy soil* is requisite for the lentil; it is sown rather later than the pea, at the rate of a bushel or a bushel and a half to the acre; in other respects its culture and harvesting are the same,

and it ripens sooner. The lentil, Young observes, is a crop not uncommon about Chesterford in Essex, where they sow a bushel an acre on one ploughing in the beginning or middle of March. It is there the custom to make hay of them, or seed them for cutting into chaff for trough-meat for sheep and horses, and they sow them on both heavy and dry soils. It is, however, added, that the whole country is of a calcareous nature. It is likewise stated, that attention should be paid not to water horses soon after eating this sort of food, as they are apt to hove them. They are asserted to be cultivated for the same purpose in Oxfordshire, and probably in other districts.

5284. *The produce of the lentil* in grain is about a fourth less than that of the tare; and in straw it is not a third as much, the plants seldom growing above one foot and a half high. The straw is, however, very delicate and nourishing, and preferred for lambs and calves; and the grain on the Continent sells at nearly

double the price of peas. Einhoff obtained from 3840 parts of lentils, 1260 parts of starch, and 1433 of a matter analogous to animal matter.

5285. *The use of the lentil* on the Continent is very general, both in soups and dressed with a butter sauce as haricot. They are imported from Hamburg, and sold in London for the same purpose.

5286. *The chick pea (Pisicicche Gaucance, Fr.; Cicer arietinum, fig. 52.)*, grows naturally in the south of Europe, and is cultivated there for the same purposes as the lentil, but it is too delicate for field culture in this country.

5287. *The kidneybean (Phaseolus vulgaris L.; Haricot, Fr.; Schminkbohne, Ger.; and Fagiuolo, Ital.)* is a native of India, but ripens readily in dry summers in most parts of Britain. Its culture has been hitherto confined to gardens; but it might be grown equally well in dry, warm, rich, and sheltered soils, being grown in the fields of Germany, Switzerland, and in similar climates. The sort generally used for

this purpose is the small dwarf white; the ground is prepared by several stirrings, and the seed is dibbled in rows eighteen inches or two feet asunder in the beginning of May. The ground is hoed and weeded during the summer, and the crop is ripe in August. It is usually harvested by pulling up the plants, which, being dried, are stacked or threshed. The haulm is of little bulk or use, but the seed is used in making the esteemed French dish called haricot, which it is desirable the cottagers of this country should be made acquainted with. There is, perhaps, no other vegetable dish so cheap and easily cooked, and at the same time so agreeable and nourishing. The beans are boiled and then mixed with a little salt butter or other fat, and a little milk or water and flour. From 3840 parts of kidneybean, Einhoff obtained 1805 parts of matter analogous to starch, 851 of vegetable-animal matter, and 799 parts of mucilage. Haricots and lentils are much used in all Catholic countries during Lent and *maigre* days, as they, from their peculiar constituents, form so excellent a substitute for animal food. During the prevalence of the Roman religion in this country, they were probably much more generally used than at present; as reformations are often carried farther than is necessary, possibly lentils may have been left off by Protestants, lest the use of them should be considered a symptom of popery.

5288. *The white lupine (Lupin blanc, Fr.; Lupinus albus L., fig. 746.)* was cultivated by the Romans as a legume, and is still occasionally grown in Italy and France. The seeds were formerly, and are sometimes now, used as food; but more generally the whole plant is mown and given as herbage to cattle, and sometimes the crop is ploughed down as manure.

CHAP. IV.

Plants cultivated for their Roots or Leaves in a recent State as Food for Man or Cattle.

5289. *Plants cultivated for their roots or leaves* are various, and most of them are adapted both for human food and that of domestic animals; but some are chiefly or entirely grown for the nurture of live stock. The plants which we include under this head, are the potato, turnip, carrot, parsnep, beet, cabbage tribe, lettuce, and chicory. The culture of roots may be considered a branch of farming almost entirely of modern origin, and more peculiarly British than any other department. Turnips were cultivated by the Romans, and in modern times brought into notice as objects of field culture in the last century; but they were most imperfectly managed, and of very little utility in agriculture till their culture was undertaken by the British farmer. The potato, carrot, and parsnep were also first cultivated in the fields of this country. Friable or light soil, superior pulverisation and manuring, the row-method, and careful after-culture, are essential to the maturation of the plants to be treated of in this Chapter; and hence the importance of such crops as preparations for those of the bread cereals.

5290. *The nutritive products of these plants are thus given by Sir H. Davy: —*

Systematic Name.	English Name.	In 1000 Parts.				
		Whole quantity of soluble or nutritive matter.	Mucilage or starch.	Saccharine matter or sugar.	Gluten or albumen.	Extract, or matter rendered insoluble during evaporation.
<i>Solanum tuberosum</i> -	Potato - - -	From 260 to 200.	From 500 to 155.	From 20 to 15.	From 40 to 30.	
<i>Beta vulgaris</i> -	Red beet - - -	148	14	121	13	
<i>Helicta</i> -	Mangold wurtzel - -	136	13	119	4	
<i>Brassica Rapa</i> -	Common turnip - -	42	7	84	1	
var. <i>rutabaga</i>	Swedish turnip - -	64	9	51	2	2
<i>Daucus Carota</i> -	Carrot - - -	98	3	95		
<i>Pastinaca sativa</i> -	Parsnep - - -	59	9	40		
<i>Brassica oleracea</i> -	Cabbage - - -	73	41	24	8	

SECT. I. *The Potato.* — *Solanum tuberosum* L.; *Pentándria Monogýnia* L., and *Solanee* J. *Pomme de Terre*, Fr.; *Cartoffel*, Ger.; *Tartufflo* or *Pomo di Terra*, Ital.; and *Betata*, Span.

5291. *The potato is ascertained to be a native of South America*, having been found wild both in Buenos Ayres and in Chili; though Humboldt was very doubtful if that could be proved: he admits, however, that it is naturalised there in some situations. Sir J. Banks (*Hort. Trans.* vol. i. p. 8.) considers that the potato was first brought into Europe from the mountainous parts of South America, in the neighbourhood of Quito, where they were called *papas*, to Spain, in the early part of the sixteenth century. From Spain, where they were called *battatas*, they appear to have found their way first to Italy, where they received the same name with the truffie, *taratouffi*. The potato was received by Clusius, at Vienna, in 1588, from the governor of Mons, in Hainault, who had procured it the year before from one of the attendants of the Pope's legate, under the name of *taratouffo*, and learned from him that it was then in use in Italy. In Germany it received the name of *cartoffel*, and spread rapidly even in Clusius's time.

5292. *To England the potato was brought from Virginia* by the colonists sent out by Sir Walter Raleigh in 1584, who returned in July 1586, and "probably," according to Sir Joseph Banks, "brought with them the potato." Thomas Herriot, in a report on the country, published in De Bry's *Collection of Voyages*, (vol. i. p. 17.), describes a plant called *openank* (not *openawk*, as in the *Hort. Trans.*), with "roots as large as a walnut, and others much larger; they grow in damp soil, many hanging together, as if fixed on ropes; they are good food, either boiled or roasted." Gerarde, in his *Herbal*, published in 1597, gives a figure of the potato, under the name of the *potato of Virginia*, whence, he says, he received the roots; and this appellation it appears to have retained, in order to distinguish it from the *battatas*, or sweet potato (*Convólulus Batatas*), till the year 1640, if not longer. "The sweet potato," Sir Joseph Banks observes, "was used in England as a delicacy long before the introduction of our potatoes: it was imported in considerable quantities from Spain and the Canaries, and was supposed to possess the power of restoring decayed vigour. The kissing comfits of Falstaff, and other confections of similar imaginary qualities, with which our ancestors were duped, were principally made of these and of eringo roots."

5293. *The potato was first planted by Sir Walter Raleigh*, on his estate of Youghall, near Cork, and, Gough says, was "cherished and cultivated for food" in that country before its value was known in England; for, though they were soon carried over from Ireland into Lancashire, Gerarde, who had this plant in his garden in 1597, under the name of *Bathia virginiana*, recommends the roots to be eaten as a delicate dish, not as common food. Parkinson mentions, that the tubers were sometimes roasted, and steeped in sack and sugar, or baked with marrow and spices, and even preserved and candied by the comfit-makers. There is a tradition among the peasantry in the county of Galway, that the potato was introduced there previous to its being known in any other part of Ireland, owing to a vessel with some of the roots on board having been wrecked on their coast, and a few of the roots having been roasted by children who found them, they were so much approved of, as to induce the planting of the remainder.

5294. *For encouraging the cultivation of potatoes*, with the view of preventing famine, the Royal Society took some measures in 1633. Still, however, although their utility as an article of food was better known, no high character was bestowed on them. In books of gardening, published towards the end of the seventeenth century, a hundred years after their introduction, they are spoken of rather slightly. "They are much used in Ireland and America as bread," says one author, "and may be propagated with advantage to poor people." — "I do not hear that it hath been essayed," are the words of another, "whether they may not be propagated in great quantities, for food for swine or other cattle." Even the enlightened Evelyn seems to have entertained a prejudice against them: "Plant potatoes," he says, writing in 1699, "in your worst ground. Take them up in November for winter spending; there will enough remain for a stock, though ever so exactly gathered." But the use of potatoes gradually spread, as their excellent qualities became better understood. It was near the middle of the eighteenth century, however, before they were generally known over the country: since that time they have been most extensively cultivated. In 1796, it was found that, in the county of Essex alone, about 1700 acres were planted with potatoes for the supply of the London market. This must form, no doubt, the principal supply; but many fields of potatoes are to be seen in the other counties bordering on the capital, and many ship-loads are annually imported from a distance. In every county in England, it is now more or less an object of field culture.

5295. *Potatoes, as an article of human food*, are, next to wheat, of the greatest importance in the eye of the political economist.

5296. *From no other crop* that can be cultivated will the public derive so much food as from this valuable esculent; and it admits of demonstration, that an acre of potatoes will feed double the number of people that can be fed from an acre of wheat. Potatoes are also a nourishing and healthy food, relished by almost every palate; and it is believed there is hardly a dinner served up for six months in the year without them, in any part of the kingdom. Notwithstanding all these things, and they are of great importance in one point of view, we are doubtful whether potatoes can be placed so high in the scale as

They require a great deal of manure, while, generally speaking, little is returned by them; they are a bulky unhandy article, troublesome in the lifting and carrying processes, and interfering with the seed season of wheat, the most important one to him; and, from particular circumstances, they cannot be vended unless when raised in the vicinity of large towns: hence they are in most respects an unprofitable article. To the farmer, the real criterion is the profit which potatoes will return in feeding beasts; and here, we apprehend, the result will altogether be in favour of turnips, and rutabága, as the most profitable articles for that purpose.

5297. *What is called the yam, or Surinam potato*, was formerly considered of importance to the farmer, as an assistant to his turnip crop, or rather a succedaneum, which is of material benefit when turnips are consumed; but as this variety cannot be used as human food, the extension of its culture cannot be recommended. By cultivating any of the good eating sorts for the use of cattle, a succedaneum may be had for the human species in years of scarcity.

5298. *The value of potatoes as a fallow crop*, and as an article of food for cattle compared with turnips and cabbages for the same purposes, Marshal observes, may be considered thus: —

5299. *Potatoes are more nutritious*; and, in the opinion of those who have used them, fatten cattle much quicker than either turnips or cabbages. Potatoes, too, being secured from the severities of winter, are a more certain article of fattening than turnips or cabbages; both of which are liable to perish under an alternation of frost and thaw; and the turnip, more particularly, is locked up, or rendered more difficult to be come at, during a continuance of snow or frost. Turnips and cabbages, if they out-weather the severities of winter, occupy the soil in the spring when it should be prepared for the succeeding crop; while potatoes, if properly laid up, are a food which may be continued without inconvenience until the cattle be finished, or the grass has acquired the requisite bite for finishing them in the field. On the other hand, potatoes are a disagreeable crop to cultivate: the planting is a tedious dirty business; and taking them up may be called the filthiest work of husbandry, especially in a wet autumn. A powerful argument for the extensive culture of potatoes as food for live stock is, that in seasons of scarcity they can be adopted as human food. Here, as in many other points, the opinion of Marshal and other English agriculturists is rather at variance with that of the Northumberland and Berwickshire cultivators. In Berwickshire and Roxburghshire, a crop of potatoes is often taken before turnips, by means of which the land is restored to a fertile state.

5300. *The varieties of the potato* are innumerable: they differ in their leaves and bulk of haulm; in the colour of the skin of the tubers; in the colour of the interior compared with that of the skin; in the time of ripening; in being farinaceous, glutinous, or watery; in tasting agreeably or disagreeably; in cooking readily or tediously; in the length of the subterraneous stolones to which the tubers are attached; in blossoming or not blossoming; and, finally, in the soil which they prefer.

5301. *The earliest varieties of the potato* are chiefly cultivated in gardens, and therefore we shall only notice such early sorts as are grown in the fields. These are —

The early kidney, The nonsuch, The early shaw, and The early champion.

The last is the most generally cultivated round London; it is very prolific, hardy, and mealy. Early varieties, with local names, are cultivated near most large towns, especially Manchester, Liverpool, Glasgow, Edinburgh, and the metropolis.

5302. *The late field varieties* in most repute are —

The red-nosed kidney.

Large kidney.

Bread fruit, raised in 1810, from seed, and esteemed one of the best field potatoes, being white, mealy, well tasted, and prolific.

Lancashire pink eye, good.

Black skin, white interior, and good.

Purple, very mealy, productive, and keeps well.

Red apple, mealy; keeps the longest of any.

Tartan, or purple and white skinned, an esteemed Scotch potato, prolific, mealy, exceedingly well tasted, and keeps well.

5303. *The varieties grown exclusively as food for live stock* are —

The yam or Surinam potato; large, red and white skinned, and the interior veined with red; flavour disagreeable, and not such as to admit of its being used as human food. It succeeds best on heavy lands.

The ox noble; large, yellow without and within, very prolific, not fit to eat.

The late champion; large and prolific, white skinned, and may be used as human food.

5304. *New varieties of potatoes* are procured with the greatest ease. The following directions are given in a useful work on this plant: — Pluck off the apples when the stalk has ceased to vegetate and is drying up. The seed being then fully ripe, break the apple in a hair sieve, wash the pulp clean from the seeds, and dry them in the sun; then sow the seed in beds in March, and take the potatoes up in October. They will attain the size of nutmegs, or at most be no larger than walnuts. Select the fairest and best, and keep them secure from frost by thorough drying, and intermixing, and covering them with sifted wood or coal-ashes. Plant them in April following, at the distance of fifteen inches asunder; and when the plant is two inches high, hill them with fresh earth. This may be done several times, constantly taking care to keep them clear from weeds. Observe when the stalks decay: some will be found decaying much sooner than others; these are the early kinds, but those that decay last are the sorts which come late. Take them up in rotation as they ripen, and let the produce of each potato be kept separate till the next year. Such as come early may be tried as soon as they are taken up, by dressing one or two: should they be approved, the remainder may be preserved; but those which are late should not be tried before January or February, for it will be found that the late kind of potatoes, newly raised, are very soft, and cut like soap, until they have been hoarded a certain time, when they become mealy. Under each stalk you may expect to find a gallon of potatoes; those planted the third year may, perhaps, produce two sacks; and their increase afterwards will be very considerably greater. Thus it takes its full three years to form an adequate judgment of potatoes raised from seed; and, after all, if one in ten succeed so as to be worth preserving, it is as much as can be reasonably expected. In general, the produce of the seed will resemble the parent stock; but red varieties will give both white and red offspring, and among the offspring of kidneys will be found round-shaped tubers. One great advantage of raising varieties from seed is alleged to be the invigoration of the vegetative principle.

5305. *Some of the earlier sorts of potatoes do not blossom*, and consequently do not, under ordinary management, produce seeds. To procure blossoms and seeds from these, it is necessary, from time to time, during the early part of the summer, to remove the earth from the roots of the plants, and pick off the tubers or potatoes as they begin to form. By thus preventing the strength of the plant from being employed in forming tubers at the root, it will flow into the leaves and herbage, and produce blossoms and apples. Knight, the president of the Horticultural Society, by adopting this practice, succeeded in procuring seeds from some sorts of potatoes which had never before produced blossoms; and from these seeds he raised excellent varieties, some hardy and less early, others small and very early. He farther impregnated the blossoms produced by these early potatoes with other sorts, some early and some late (in the way in which graziers cross the breeds of cattle to improve the offspring), and he succeeded in producing varieties, more early than late sorts, and more hardy and prolific than any early potatoes he had seen.

These he cultivated in his fields, deeming them preferable to all other sorts as admitting of later planting and earlier removal; and this practice he justly considered as highly favourable to the succeeding crop of wheat.

5306. *In choosing a sort* or sorts of potatoes from the numerous varieties which are to be found every where, perhaps the best way is, for the selector to procure samples and taste them, and to fix on what best pleases his palate. The shaw is one of the best early potatoes for general field culture; and the kidney and bread-fruit are good sorts to come in in succession. The Lancashire pink is also an excellent potato; and we have never in any part of the British Isles tasted a potato equal in meanness and flavour to this variety, as cultivated round Prescot, near Liverpool. The red apple and tartan are of undoubted preference as late or long keeping potatoes. The yam is decidedly the best potato for stock, and will produce from twelve to fifteen tons per acre.

5307. *The soil* in which the potato thrives best is a light loam, neither too dry nor too moist, but if rich, it is so much the better. They may, however, be grown well on many other sorts of lands, especially those of the mossy, moory, and similar kinds, where they are free from stagnant moisture, and have had their parts well broken down by culture, and a reasonable portion of manure added. The best-flavoured table potatoes are almost always produced from a newly broken up pasture ground not manured; or from any new soil, as the site of a grubbed up copse or hedge, or the site of old buildings or roads. Repeated on the same soil they very generally lose their flavour. The yam produces the largest crops on a loamy and rather strong soil, though it will grow well on any that is deeply ploughed and well manured.

5308. *In preparing the soil for potatoes*, it is of much importance to free it as completely as possible from root weeds, which cannot be so well extirpated afterwards, as in the culture of turnips, and some other drilled crops, both because the horse-hoe must be excluded altogether at a time when vegetation is still vigorous, and because at no period of their growth is it safe to work so near the plants, especially after they have made some progress in growth. It is the earlier time of planting, and of finishing the after-culture, that renders potatoes a very indifferent substitute for fallow, and in this respect in no degree comparable to turnips. For this reason, as well as on account of the great quantity of manure required, their small value at a distance from large towns, and the great expense of transporting so bulky a commodity, the culture of potatoes is by no means extensive in the best managed districts. Unless in the immediate vicinity of such towns, or in very populous manufacturing counties, potatoes do not constitute a regular rotation crop, though they are raised almost every where to the extent required for the consumption of the farmer and his servants, and, in some cases, for occasionally feeding horses and cattle, particularly late in spring. The first ploughing is given soon after harvest, and a second, and commonly a third, early in spring; the land is then laid up into ridgelets, from twenty-seven to thirty inches broad, as for turnips, and manured in the same manner.

5309. *The best manure for the potato* appears to be littery farmyard dung; and the best mode of applying it, immediately under the potato sets. Any manure, however, may be applied, and no plant will bear a larger dose of it, or thrive in coarser or less prepared manure: even dry straw, rushes, or spray of trees, may be made use of with success. It is alleged, however, that recent horse manure, salt, and soapers' ashes, have a tendency to give potatoes a rank taste, and to render them scabby.

5310. *The best climate* for the potato is one rather moist than dry, and temperate or cool, rather than hot. Hence the excellence of the Irish potatoes, which grow in a dry, loamy, calcareous soil, and moist and temperate climate: and hence, also, the inferiority of the potatoes of France, Spain, and Italy, and even Germany. In short, the potato is grown nowhere in the world to the same degree of perfection as in Ireland and Lancashire, and not even in the south of England so well as in Scotland, and the north and western counties: all which is, in our opinion, clearly attributable to the climate.

5311. *The season for planting* potatoes in the fields, depends much on the soil and climate. Where these are very dry, as they always ought to be for an early crop, the sets are usually put in the ground in March or earlier; but for a full crop of potatoes, April is the best time for planting. Potatoes, indeed, are often planted in the end of May, and sometimes even in June; but the crops, although often as abundant, are neither so mellow nor mature as when the sets are planted in April, or in the first eight or ten days of May. For seed, however, they are preferable.

5312. *In preparing the sets of potatoes*, some cultivators recommend large sets, others small potatoes entire, and some large potatoes entire. Others, on the ground of experience, are equally strenuous in support of small cuttings, sprouts, shoots, or even only the eyes or buds. With all these different sorts of sets, good crops are stated to have been raised, though tolerable-sized cuttings of pretty large potatoes, with two or three good eyes or buds in each, are probably to be preferred.

5313. *Independently of the increased expense of the seed*, it is never a good practice to make use of whole potatoes as sets. The best cultivators in Ireland and Scotland invariably cut the largest and best potatoes into sets, rejecting, in the case of kidney potatoes, the root or mealy end as having no bud, and the top or watery end as having too many. No objection is made to two or even three buds on each set, though one is considered sufficient. A very slight exercise of common sense might have saved the advocates for shoots, scooped out eyes, &c., their experiments and arguments; it being evident, as Brown has observed, to every one with any practical knowledge of the nature of vegetables, that the strength of the stem at the outset depends in direct proportion upon the vigour and power of the set. The set, therefore, ought to be large, rarely smaller than the fourth part of the potato; and if the potato is of small size, one half of it may be profitably used: at all events, rather err in giving over-large sets, than in making them too small; because by the first error no great loss can be sustained; whereas, by the other, a feeble and late crop may be the consequence. It is ascertained beyond doubt in Lancashire, Cheshire, and other counties in the north and west of England, that sets taken from the top or watery end of the potato, planted at the same time with sets taken at the root or mealy end, will ripen their tubers a fortnight sooner. It is ascertained also, and accounted for on the same general principle, that the plants raised from unripe tubers are both vigorous and more early than such as are raised from tubers perfectly ripe. (See *Gard. Mag.* vol. ii.)

5314. *Sets should always be cut some days before planting*, that the wounds may dry up; but no harm will result from performing this operation several weeks or months beforehand, provided the sets are not exposed too much to the drought so as to deprive them of their natural moisture.

5315. *The quantity of sets depends on the size of the potatoes; in general, where the sets are sufficiently large, from eight to ten cwt. will be required for an acre: more than ten for yams, and fewer than eight cwt. for the early nonsuch and ash-leaved.*

5316. *The modes of planting the potato are various.*

5317. *Where spade culture is employed, they are very frequently planted on beds (provincially lazy-beds), of four or six feet wide, with a trench or gutter of a foot or eighteen inches in width between, which supplies soil for earthing up the potatoes. This is the rudest mode of planting and cultivating potatoes, and unworthy of being imitated either on a farm or in a garden. The next mode is planting on a plain surface, either with or without manure, according to the state of the soil. Here the sets are placed in rows, with a distance of from eighteen inches to two feet and a half between the rows according to the kind of potato, and from four to nine inches in the row. In planting, a hole for each set is made by a man with a spade, while a woman or boy drops the set, and the earth is replaced; or the potato dibber is used, and the ground afterwards slightly harrowed. Another mode of planting on a plain surface, when the soil is inclined to be dry, is in some cases practised, which is, after the land has been brought into a proper condition by ploughing over twice or oftener and well harrowed, to spread the manure regularly over the whole surface, the sets being planted in every third furrow, and the dung with the fine earth turned upon them by the next furrow of the plough. In this way the manure is however placed upon the sets, which has on experiment been fully shown to be injurious to the produce. Besides, from the whole of the surface of the ground being covered with dung, a considerably larger proportion must be requisite than when deposited only in the drills, and of course the crop cannot be cultivated to advantage in that respect.*

5318. *In planting the potato on sward land, after it has been prepared by the use of a plough that just pares off the surface and deposits it in the furrow, it is advised by Somerville to place the sets upon the inverted sod, and cover them with the loose mould from below by means of a common plough; or the trench plough may be used with perhaps more advantage; but a better method is that of paring and burning. In some cases the practice is, however, to turn down the turf with or without manure, and then to put in the sets by a dibble; though the former is probably the better practice, as the turfy material on which the sets are put soon begins to decay, and the purpose of a manure is in some measure answered by it. It is a plan that may be adopted with advantage where manure is scarce, as in bringing waste and other coarse grass lands into the state of preparation for grain crops.*

5319. *A mode of planting potatoes and at the same time trenching the land, is practised in Lancashire, and in some districts in the north-east of Scotland. The farmer having carried the dung, and laid it on the field in heaps, at proper distances, the operation is performed by the manufacturers and people who rent the field, and in the following manner:—Across the end of the ridge a trench is formed, about three feet wide, and from ten to fourteen inches deep, according to the depth and quality of the subsoil. That being done, a second trench of the same breadth is marked off, and the surface-soil, to the depth of six or eight inches, is thrown into the bottom of the former trench, over which a sufficient quantity of dung being laid, the potatoes are planted at the distance of eight or ten inches from each other, and then as much earth is taken from the bottom of the second trench as is necessary for covering the potato sets, and making up the first trench to its former level. Thus the field being completely trenched, well manured, and kept thoroughly clean by repeated hand-hoeings, must not only produce an abundant crop of potatoes, but must also be in high condition for receiving whatever kind of seed may be afterwards sown.*

5320. *The mode of planting potatoes practised by the best farmers of the northern districts, is in drills formed by the plough in the same manner as in preparing the land for turnips. The soil is laid up into ridglets from twenty-seven to thirty inches broad, the manure is distributed between them, and on this manure the sets are placed from four to eight inches asunder: they are then covered by reversing the ridglets.*

5321. *The planting of early potatoes is carried to a very high degree of perfection in Lancashire. It is stated in The Lancashire Agricultural Report, in respect to the raising of seed potatoes, that upon the same ground from which a crop has already been taken, the early seed-potatoes are in some places afterwards planted; which, after being got up about November, are immediately cut up into sets, and preserved in oat husks or saw-dust, where they remain till March, when they are planted, after having had one sprout taken off, which is also planted. The sprouts are of a length sufficient to appear above ground in the space of a week. But the most approved method is, to cut the sets, and put them on a room-floor, where a strong current of air can be introduced at pleasure, the sets laid thinner, as about two layers in depth, and covered with the like materials (chaff or saw-dust) about two inches thick; this screens them from the winter frosts, and keeps them moderately warm, causing them to vegetate; but at the same time admits air to strengthen them, and harden their shoots, which the cultivators improve by opening the doors and windows on every opportunity afforded by mild soft weather. They frequently examine them; and when the shoots are sprung an inch and a half, or two inches, they carefully remove one half of their covering, with a wooden rake, or with the hands, taking care not to disturb or break the shoots. Light is requisite, as well as air, to strengthen and establish the shoots; on which account a green-house has the advantage of a room, but a room answers very well with a good window or two in it, and if to the sun still better. In this manner they suffer them to remain till the planting season, giving them all the air possible by the doors and windows, when it can be done with safety from frost; by this method the shoots at the top become green, leaves are sprung, and are moderately hardy. They then plant them in rows, in the usual method, with a setting-stick; and carefully fill up the cavities made by the setting-stick; by this method they are enabled to bear a little frost without injury. The earliest potato is the superb white kidney; from this sort, upon the same ground, have been raised four crops, having sets from the repository ready to put in as soon as the others were taken up; and a fifth crop is sometimes raised from the same lands, the same year, of transplanted winter lettuce. The first crop had the advantage of a covering in frosty nights. It is remarked that this useful information was communicated by J. Blundell, Ormskirk, and has hitherto been known only among a very few farmers.*

5322. *In the western parts of Lancashire the early potato is cultivated in the fields in warm situations, and brought to market in the end of May and during June. The chief sorts there grown for this purpose are, the lady's finger, or early Rufford kidney, and the early round potato. The cultivators, aware that the buds from the root and top end of the tuber germinate at different periods, assort their sets in the following manner:—The sets near the top end (fig. 747, a) are found to come to maturity a fortnight earlier than those at the root end (b); and these, therefore, form two classes of sets for an earlier and a later crop. The sets from the middle (b, c) are put together for an intermediate crop. The sets are planted in the month of March or beginning of April, in drills of twenty-four drills in twenty yards, in the following manner:—*

After the drills are formed (fig. 748, a), loose earth is brushed with a spade or harrowed down to the depth of six inches, in the interval between them (b); dung is then placed over this loose earth, to the depth of four or five inches (c); the potato sets of the earliest degree (fig. 747, a) are then laid on the manure, at four or five inches apart, for the early crop; and sets of the second degree (fig. 747, b), at from six to eight inches apart, for later crops; and so on. The sets for the early crop are then covered with a spade, to the depth of two inches, and subsequently covered, at two or three different times, to the depth of about five inches. The second and third crops are usually covered with the plough.

Some lay the potatoes intended for plants early in the year, before they are wanted to be cut, loose and separate in straw, or on warm boarded floors; and others put them on flakes or frames, in warm situations near the fire, for the same purpose, in order that they may sprout; and when so sprouted to the length of half an inch or an inch, they are then carefully cut as described, assorted, and planted. (*Gard. Mag.* vol. i. p. 407.)

748

5324. In *Denbighshire* the early potatoes cultivated are the Foxley, the Nelson, and the Rufford kidney. Potatoes intended for sets the following year are taken up before they are ripe, just when the outer skin peels off, and before the stalk or stem begins to wither; they are then laid upon a gravel walk, or any dry surface fully exposed to the sun: they remain in that situation for a month or six weeks, when they become quite green and soft, as if roasted, and often much shrivelled; they are then put away in a cellar or pit, where they will remain dry, and neither invaded by frost nor much heat. In February they are examined, and every eye being then generally found full of long sprouts, they are fit to be planted. The tubers are therefore cut, seldom into more than two sets, viz. the eye or top part, which is planted by itself, and found to come a fortnight earlier; and the root or bottom part, which succeed them. (*Gard. Mag.* vol. ii. p. 172.)

5325. In gardens in the south of England potatoes are planted in a warm border from the first week of October, till the latter end of November. They are placed nine or ten inches under the surface, and well covered with dung. About the latter end of March they begin to appear above the surface, when the ground is deeply hacked with a mattock, and made very loose about the plants; then in a fortnight or three weeks move the surface again, but the plants need not be earthed up unless they are very much exposed to the wind, when a little may be drawn about them to keep them steady. By this method fine ash-leaved kidney potatoes may be gathered by the 12th or 15th of May, even in situations not very favourable for early crops, and nearly three weeks earlier than they can be gathered from sets planted in the same situation in the latter end of February; and if ordinary care is taken in planting, no danger need be apprehended from the frost. (*Gard. Mag.* vol. vi. p. 59.) Every farmer knows that, among the corn raised after a crop of potatoes, potato plants will be found which can only have sprung from tubers preserved there all the winter, in consequence of having been buried by the plough deeper than the frost could reach. It is evident, therefore, that this garden mode of raising a crop of early potatoes might be adopted in the field, more especially where the soil was dry; but the success would depend entirely on the deep pronging or grubbing of the soil between the rows early in spring. This might be done to the same degree of perfection as in the garden by the excellent implements of Wilkie or Kirkwood. (2656. and 4955.)

5326. In *Cornwall* early potatoes are planted in October, spring up a few weeks afterwards, are ready before the autumnal frost stops their growth, and the soil being covered with litter to exclude the frost, they are begun to be used about the end of December, and continue in use till May, when they are succeeded by the spring planted crops. Of late years Covent Garden market has received supplies of early potatoes from Cornwall, treated in the above manner. (*Gard. Mag.* vol. ii. v. vi.) Early potatoes, when they first come through the ground, are liable to be injured by spring frosts; but there is an easy and effectual remedy to every cultivator who will take the trouble — and that is to water them, so as to thaw off the frost before sunrise. In Ayrshire, where even late potatoes are liable to this injury, acres are sometimes so watered on a single farm; all the hands being called to business by the break of day, and the water being sprinkled on the young sprouts, from vessels of any sort, by means of a handful of straw. A garden-pot and rose would of course answer better.

5327. The after culture of potatoes consists in harrowing, hoeing, weeding, and earthing up.

5328. All potatoes require to be earthed up, that is, to have at least one inch in depth of earth heaped on their roots, and extending six or eight inches round their stem. The reason of this is, that the tubers do not, properly speaking, grow under the soil, but rather on, or just partially bedded in, its surface. A coating of earth, therefore, is found, by preserving a congenial moisture, greatly to promote their growth and magnitude, as well as to improve their quality, by preventing the potatoes from becoming green on the side next the light. The earth may be thrown up from the trenches between the beds by the spade; or, where the potatoes are planted in rows, the operation may be performed with a small plough, drawn by one horse, or by the hoe. In Scotland, where the potato is extensively cultivated by the farmer, as food for cattle as well as man, the plough is universally used. In Ireland, where the bed, or lazy-bed, manner is adopted, the earth is thrown up from the intervening trenches. The hoe is generally used by market-gardeners.

5329. The after-culture, where potatoes are planted in ridgelets, as above described (5319.), commences when the plants begin to rise above the surface. They are then harrowed across, and afterwards the horse-hoe, or small hoeing plough, and the hand-hoe are repeatedly employed in the intervals, and between the plants, as long as the progress of the crop will permit, or the state of the soil may require. The earth is then gathered once, or oftener, from the middle of the intervals towards the roots of the plants, after which any weeds that may be left must be drawn out by hand; for when the radicles have extended far in search of food, and the young roots begin to form, neither the horse nor hand-hoe can be admitted without injury.

5330. The after-culture adopted in some parts of Devonshire is somewhat singular, and deserves to be noticed. The sets are there generally cut with three eyes, and deposited at the depth of three inches with the spade or dibber: when the first shoot is three inches high, prepare a harrow with thorns interwoven between the tines, and harrow the ground over till all the weeds are destroyed, and not a shoot of the potatoes left. It may seem strange that such an apparent destruction of a crop should cause an increase; but it may be affirmed as an incontestable fact, that by this means the produce becomes more abundant. The reason appears to be this: although three eyes are left to a piece of potato, one always vegetates before the others, and the first shoot is always single; that being broken off, there is for the present a cessation of vegetation. The other eyes then begin to vegetate, and there appear fresh shoots from the broken eye; so that the vegetation is trebled, the earth made loose, and the lateral shoots more freely expanded. If these hints are observed, the produce of potatoes, it is said, will exceed a fifth of the crop obtained by the usual mode of cultivation.

5331. *The culture of potatoes in the district of Kintyre is thus given by an intelligent writer in the Transactions of the Highland Society.*

5332. *The land is generally ploughed as early in spring as possible, and that at least twice. In cases where the two ploughings do not sufficiently pulverise the ground, it receives a third, and after every ploughing is well harrowed. The greatest attention ought always to be given to these preparatory operations.*

5333. *The ground being now prepared, and the season for planting arrived, drills are made for receiving the seed with the common plough; these are drawn about two feet asunder, and three inches in depth. The first seven of them are all drawn from one end of the field, the plough returning out of work from the other end, in order to afford time and room for the operation of putting in the seed, and also the dung, where this last operation is rendered necessary. By the time the ploughman has drawn three of these shallow drills or furrows, the persons in charge of the seed begin to plant the first of them, laying each plant at a distance of from nine to ten inches; these are followed by others who put the dung on the top of it, in the case already mentioned, where the manure is to be put into the drill. The ploughman, having completed seven of these drills, may now proceed to return, by ploughing to the depth of seven inches between the first and second drills, so as to cover the seed in the first. He then opens another of the shallow drills of three inches, at the distance of two feet, as before mentioned, from the last which he had made, being the seventh; and returning back, he makes another of the seven inch deep furrows between the second and third rows of seed, which covers the second; returning, he opens another seed-drill; and so on back again a deep one, between the drilling and planting will proceed, without any interruption or interference the one with the other, the plough having at first attained a sufficient distance from the planters to have always a drill open before they can overtake it. The great advantage of placing the seed so much nearer the surface than the deeper furrow alongside of it, is that it is more effectually preserved from the bad effects of wet or damp, consequently less liable to be injured by frost, and it springs sooner.*

5334. *In this state the field is allowed to remain from a fortnight to three weeks, when it is cross harrowed to a perfect level. Afterwards, as soon as the drills can be distinguished by the potatoes shooting above the ground, the plough is again applied, and the drills are formed as before; but in doing so, the plough is taken as close as possible to the plant upon both sides; on one side the plough is lightly put in, but on the other it is inserted as deep as possible, throwing the soil over on its neighbouring row of seed, filling up other it is inserted as deep as possible, throwing the soil over on its neighbouring row of seed, filling up the vacuum which the plough had previously left at it, and forming at the same time a ridge, as it was originally, on the top of the plant. What is thus ploughed in the forenoon is cross harrowed completely level during the same afternoon. The great advantage which I apprehend to be derived from this process is the loosening of the soil, destroying the weeds, and the saving of hand-hoeing. I am satisfied, from my own particular experience and observation, that this mode of treating the young growth of the potato is far preferable to any other I have seen practised, either here or elsewhere, however forbidding the rough usage thus given to the young plant may appear to one inexperienced in this particular mode of cultivating it.*

5335. *As soon as the weeds begin to appear, the plough is again introduced, which, in the idiom of this country, is called "taking from the potatoes," which is done by running pretty close to the plant on both sides, so that a slight ridge is thrown up between the line of plants; and in this situation they remain for eight days, when the plant is "put to" by again applying the plough between the rows, and separating the earth composing the middle ridge above mentioned, towards the plant on each side, but without covering it. After this, the process of "putting to" of earth is continued as the plant grows, and takes place at least twice, until the stems are so high that a single horse going among them may seriously injure them. The "putting to" will now be understood as a deeper insertion of the plough in the middle of the drill. The whole of the labour of ploughing, drilling, "taking from," and "putting to" the potatoes, as above described, is performed with the common plough." (*High. Soc. Trans. vol. viii. p. 68.*)*

5336. *The field culture of the potato in Argyleshire is thus given by an experienced cultivator, in the Gardener's Magazine. The manure is sometimes applied to the field during winter and ploughed in, it is by the better economists reserved till the field is drilled for planting. When the first plan is adopted, another ploughing is given across the field, which is then planted, the plough going one bout along the furrow of which the set is placed, and then covered by the return of the plough. The best way is to prepare the field in the same way as for turnips, and place*

5337. *Pinching off the whole of the potato blossoms is a part of after-culture not unworthy the attention of the farmer. This may at first sight appear too minute a matter to enter into the economy of farm management. But when it is considered that the seed is the essential part of every plant, and that to which the ultimate efforts of nature are always directed, it will be allowed that an important part of the management of every vegetable must be devoted to this purpose. In the case of the potato, every person who knows that the weight of the potato-apples, grown by a single plant, is very considerable. Now we have ascertained (5304.) that apples may be produced instead of tubers in early potatoes; whence it may justly be inferred, that more tubers may be produced in late ones by preventing the growth of the apples. Such was the reasoning of Knight; and, by repeatedly making the experiment, he came to this conclusion, that in ordinary cases of field culture, by pinching off the blossoms of late crops of potatoes, more than one ton*

forming others (b): a fortnight or so afterwards, the whole field is harrowed across (c). As soon as the plants have so far sprouted as that the drill can safely be traced from end to end (d), then the whole field is drilled again, as at first, with a very strong furrow (e), and then the harrows are set immediately to work after the plough has finished drilling, and the field is levelled again (f). Any one that is unacquainted with the system would suppose the crop ruined, but it is far otherwise. The after-culture is no way different from the common practice of paring away the earth, drill harrowing, and earthing up, as in other countries. It is advisable only to pare or earth, as the case may be, one side of the drill at each turn; as, by this means, the operations are sooner performed at the time, the earth can be more frequently stirred, and at the same expense. The charm of this system consists in this additional drilling up and harrowing down; by this harrowing, all the larger clods are thrown by the drill harrow and after culture, and all the weeds are so effectually drawn from between the plants that there is no use of hand-hoeing. The expense may be calculated at less than a third of hand-hoeing, from the effect and expedition; of course, dry weather is the time for the second drilling and cross harrowing to be performed. (*Gard. Mag. vol. ii. p. 316.*)

per acre of additional tubers will be produced. The experiments are related in the second volume of *The Horticultural Transactions*, and the practice is similar to one common among the growers of bulbous roots in Holland, as alluded to by Dr. Darwin, who also recommends its application to the potato. A woman or boy will crop the blossoms from an acre of potatoes in a day, or even in less time, when the crop is not excessively luxuriant.

5338. *The taking of the crop of potatoes on a small scale is generally performed with the spade or three-pronged fork; but under judicious farm management, and the row culture, by the common plough.*

5339. *The coultter is removed and the plough goes first along one side of all the ridglets of a ridge, or any convenient breadth, and then, when the potatoes so brought to view are gathered by women placed at proper distances, it returns and goes along the other side. When the land is somewhat moist, or of a tenacious quality, the furrow-slice does not give out the roots freely, and a harrow which follows the plough is commonly employed to break it and separate them from the mould. Various contrivances have been resorted to for this purpose. A circular harrow or break, of very recent invention, to be attached to the plough, has been found to answer the purpose well, and to effect a considerable saving of labour. A machine for taking up and collecting potatoes is said to have been invented by Mr. Michael Barry of Swords near Dublin; but though we have written to that gentleman, we have been unable to procure a description or drawing of his invention.*

5340. *A mode of taking part of a crop suited to cottagers and others, especially in years of scarcity, deserves to be mentioned. Having ascertained that some of the tubers have attained an eatable size, go along the rows and loosen the earth about each plant with a blunt stick, taking two or three of the largest tubers from each and returning the earth carefully. By keeping the edge of the blunt spatula or spade perpendicular to the main stem of the plant, the flat side will be parallel to the radiating roots, by which means they will be comparatively little injured. By this means both an early supply, and the advantage of two crops, may be obtained; for the tubers which remain will increase in size, having now the nourishment destined to complete the growth of those removed.*

5341. *Potatoes intended for seed should be taken up a fortnight or three weeks before being fully ripe, for reasons that have been given in treating of early potatoes, and will be recurred to in treating of the diseases of this plant. The ill shaped, small, bruised, or diseased tubers should be laid aside, and the fairest and best dried in the sun, spread on a cellar or loft floor, and covered with ashes, or chaff of sufficient thickness to keep out the frost. In this state they may remain till wanted for cutting. Some persons in Ireland plant potatoes from which they intend to procure sets extremely late, namely, the first week in July. The produce consequently never attains the same degree of size or ripeness as that of an earlier planted crop.*

5342. *Potatoes are stored and preserved in houses, cellars, pits, pies, and camps. Whatever mode is adopted, it is essential that the tubers be perfectly dry, otherwise they are certain of rotting, and a few rotten potatoes will contaminate a whole mass.*

5343. *The most effectual mode, and that which is generally adopted, consists in putting them into close houses, and covering them well up with dry straw. In some parts of Scotland it is a common practice to dig pits in the potato-field, when the soil is dry and light, and, putting in potatoes to the depth of three or four feet, to lay a little dry straw over them, and then cover them up with earth, so deep that no frosts can affect them. Another method, which is practised in England as well as Scotland, is to put them together in heaps, and cover them up with straw, in the manner of preserving turnips, with this addition, that the heaps are afterwards well covered with earth, and so closely packed together as to exclude frost. The farmers in Lancashire in the course of taking them up sort and separate their potatoes according to their sizes, and are particularly careful to throw aside all those that are spoiled before raising, or that are cut in the taking up. This is a very necessary and proper precaution (although by no means generally attended to), as the crop must have a much better chance for keeping, than when diseased or cut potatoes are stored up with it. It is also of great advantage to have the work performed in a dry season, as the potatoes seldom keep well when taken up wet, or when placed in any sort of repository for keeping while in that state.*

5344. *Potato pies, as they are called, are recommended by Young as the best mode in which potatoes can be stored. A trench, one foot deep and six wide, is dug, and the earth cleanly shovelled out, and laid on one side, and on the bottom of the trench is laid over them a bedding of straw. One horse carts shoot down the potatoes into the trench; and women pile them up about three feet high, in the shape of a house roof. Straw is then carefully laid over them six or eight inches thick, and covered with earth a foot thick, neatly smoothed by flat strokes of the spade. In this method he never lost any by the severest frosts; but in cases of its freezing with uncommon severity, another coat of straw over all gives absolute security. These pies when opened should each be quite cleared, or they are liable to depreciation. To receive one at a time, besides also being at first filled for immediate use, he has a house that holds about 700 bushels, formed of posts from pit plantations with wattled sides, against which is laid a layer of straw, and against the sides exteriorly earth six feet thick at the bottom and eighteen inches at top; the roof flat, with a stack of beans upon it. This he has found frost-tight. The beans keep out the weather, he says, and yet admit any steam which rises from the roots, which, if it did not escape, would rot them.*

5345. *Several other modes of preserving potatoes are in use in different places. In Rutlandshire, Marshal says, the method of laying up potatoes is universally that of shallow pits, filled and ridged up as similar to the above, but which requires to be described. Camps are called the pit. This is a happy mean, he thinks, between burying them in deep pits and laying them upon the surface. Camps are of various sizes; being too frequently made in a long square form like a corn-criek, and of a size proportioned to the quantity to be laid up. It has, however, been found by experience, that when the quantity is large, they are liable to heat and spoil; much damage having sometimes been sustained by this imprudence. Experienced campers hold that a camp should not be more than three feet wide; four feet are perhaps as wide as it can be made with propriety, proportioning the length to the quantity; or, if this is very large, forming a range of short ones by the side of each other. The usual depth is a foot. The bottom of the trench being bedded with dry straw, the potatoes are deposited, ridging them up as in measuring them with a bushel. On each side of the roof long wheat straw is laid, neatly and evenly, as thatch; and over this the mould raised out of the trench is evenly spread; making the surface firm and smooth with the back of the spade. A coat of coal ashes is sometimes spread over the mould, and as still better guard against frost. It is needless to observe that a camp should have a dry situation; and that the roots ought to be deposited in as dry a state as possible. These camps are tapped at the end, some havins, or a quantity of loose straw, being thrust close in the open end, as a bung or safeguard. As it is a matter of the highest importance to preserve this root without spoiling during the whole year, it has been suggested, that the best method yet discovered for keeping potatoes sound for the longest period, is to spread them on a dry floor early in the spring, and to rub off the eyes occasionally, as they appear to have a tendency to push out; by using these precautions, Donaldson has frequently seen potatoes kept in good condition till the month of June.*

5346. *In Canada and Russia the potato is preserved in boxes in houses or cellars, heated when necessary to a temperature one or two degrees above the freezing point by stoves. (Farm. Mag. vol. xx. p. 149)*

5347. To keep potatoes any length of time, the most effectual way is to place them in thin layers on a platform suspended in an ice cellar. There the temperature being always below that of active vegetation, they will not sprout; while not being above one or two degrees below the freezing point, the tubers will not be frost bitten. Another mode is to scoop out the eyes with a very small scoop, and keep the roots buried in earth. A third mode is to destroy the vital principle by kiln-drying, steaming, or scalding. A fourth mode is to bury them so deep in dry soil that no change of temperature will reach them, and consequently, being without air, they will remain upwards of a year without vegetating.

5348. The produce of the potato varies from five to eight, and sometimes ten or twelve tons per acre; the greatest produce is from the yam, which has been known to produce twelve tons or 480 bushels per acre. The haulm is of no use but as manure, and is sometimes burned for that purpose, being slow of rotting.

5349. The most important application of the potato crop is as human food; on this it is unnecessary to enlarge.

5350. Einhoff found mealy potatoes to contain twenty-four per cent. of their weight of nutritive matter, and rye seventy parts; consequently, sixty-four and a half measures of potatoes afford the same nourishment as twenty-four measures of rye. A thousand parts of potato yielded to Sir H. Davy from 200 to 260 parts of nutritive matter, of which from 155 to 200 were mucilage or starch, fifteen to twenty sugar, and thirty to forty gluten. Now, supposing an acre of potatoes to weigh nine tons, and one of wheat one ton, which is about the usual proportion; then as 1000 parts of wheat afford 950 nutritive parts, and 1000 of potato say 230, the quantity of nutritive matter afforded by an acre of wheat and potatoes will be nearly as nine to four; so that an acre of potatoes will supply more than double the quantity of human food afforded by an acre of wheat. The potato is perhaps the only root grown in Britain which may be eaten every day in the year without satiating the palate, and the same thing can only be said of the West India yam and bread fruit. They are, therefore, the only substitute that can be used for bread with any degree of success; and indeed they often enter largely into the composition of the best loaf bread without at all injuring either its nutritive qualities or flavour. (*Edin. Encyc. art. Baking.*) In the answer by Dr. Tissot to M. Liqueur, the former objects to the constant use of potatoes as food, not because they are pernicious to the body, but because they hurt the faculties of the mind. He owns that those who eat maize, potatoes, or even millet, may grow tall and acquire a large size; but doubts if any such ever produced a literary work of merit. It does not, however, by any means appear that the very general use of potatoes in our own country has at all impaired either the health of body or vigour of mind of its inhabitants.

5351. The manufacture of potato flour is carried on to a considerable extent in the neighbourhood of Paris, and the flour is sold at a price considerably higher than that of wheat, for the use of confectioners and for bakers who prepare the finer sorts of bread. The potatoes are washed and grated, and the starch separated from the pulp so obtained by filtration; it is dried on shelves in a room heated by a flue, and afterwards broken on a floor by passing a cast iron roller over it. It is then passed through a bolting machine and put up in sacks for sale. The most complete manufactory in the neighbourhood of Paris in 1829 was that of M. Delisle at Bondy. (*Gard. Mag. vol. vi.*) Most of the operations there are performed by a steam engine attended by children. It is reported by the Count de Chabrol, in his *Statistical Account of Paris*, that 40,000 tons of potatoes are annually manufactured into flour within a circle of eight leagues around that city.

5352. The quantity of farina which potatoes produce varies not only according to the species, but according to the period when the extraction takes place. The variations produced by this last cause are nearly as follows:—Two hundred and forty pounds of potatoes produce of farina, or potato flour, in

August, from 23 to 25 pounds.	March from 45 to 38 pounds.
Sept..... 32 .. 38	April..... 38 .. 28
Oct..... 32 .. 40	May..... 28 .. 20
Nov..... 38 .. 45	

The extraction of the farina should be discontinued at the period when the potatoes begin to grow, the farina being destroyed by germination. Red potatoes produce a smaller quantity of farina. Those which are blue on the outside give little, but it is of good quality; the white, which is often tinged with red in the interior, is the least proper for this extraction. The best of all is that which has a yellow tint, as its farina is of very good quality, and abundant. (*Hygie de Bruxelles.*)

5353. Potato flour is made into bread in a very simple manner. Its adhesive tendency does not admit of baking or kneading mixed with meal or wheaten flour; but it may be made into cakes in the following manner:—A small wooden frame nearly square is laid on a flat pan like a frying-pan; this frame is grooved, and so constructed, that, by means of a presser or lid introduced into the groove, the cake is at once fashioned according to the dimensions of the mould. The frame containing the farina may be almost immediately withdrawn after the mould is formed upon the pan; because, from the consistency imparted to the incipient cake by the heat, it will speedily admit of being safely handled. It must not, however, be fired too hastily, otherwise it is apt to become unpleasantly hard and unfit for mastication. This precautionary measure being observed, it will be found, that, where thoroughly ready, the bread of potato flour, even unaided by any foreign ingredient, will eat very palatably. It might thus, from time to time, be soaked for puddings, like the tapioca; or it might be used like the cassada-cake, which in appearance and quality it so much resembles; that is, when well buttered and toasted, it will make an excellent breakfast appendage. (*Quar. Journ. Agr. vol. ii. p. 69.*)

5354. The meal of potatoes may be preserved for years closely packed in barrels, or unground in the form of slices; these slices having been previously cooked or dried by steam, as originally suggested by Forsyth, of Edinburgh. (*Encyc. Brit.*) Some German philosophers have also proposed to freeze the potato, by which the feculent matter is separated from the starch, and the latter being then dried and compressed, may be preserved for any length of time, or exported with ease to any distance. (*Annalen des Ackerbauwes.* vol. iii. s. 389.)

5355. The manufacture of tapioca from potatoes is thus given in the *Quarterly Journal of Agriculture*. The potatoes selected are thoroughly washed, after which they are grated in a machine constructed for the purpose. The parts thus reduced or grated fall into a vessel placed underneath. From this vessel they are removed, and strained into a tub. On the juice being well expressed for the first time, the fibrous matter is set apart, and cold clean water is thrown over them. These fibres are again put through the same strainer, till the whole of the substance is collected, when they are finally cast aside. On this being done, the contents of the tub, now in a state of mucilage or starch, are allowed to settle. A reasonable interval being suffered to elapse, the old water is poured gently off, and fresh water supplied. After this process of fining and washing, the blanched matter is passed through a smaller strainer.

5356. The offals are separated. The starch becomes now much whiter; still fresh water is abundantly dashed over it. When by frequent ablution the surface of this vegetable mass is rendered quite smooth and clean, it is filtrated a third and last time.

5357. The strainer now used is of very fine texture, so that no improper or accidental admixture may interfere. As soon as the starch, thus purified, has firmly subsided, it is spread on a board, and exposed to the open air. The damp speedily evaporates, on which it is, as a security for cleanliness, put through a sieve.

5358. A large circular pan is now procured, and set upon the fire. The farina is gradually put into the pan, till what is conceived to be sufficient for one cooking be supplied. As the natural tendency of the farina, in a warm state, is to adhere to the pan, great care is requisite in constantly turning and stirring it. This is effectually done with a broad flat piece of wood, having a long handle to prevent inconvenience from the heat. A temperature of 150° Fahrenheit suits best for perfecting the tapioca. When the farina becomes quite hard, dry, and gritty, it is then ready, and may be taken off the fire. (*Quar. Journ. Agr.* vol. ii. p. 68.)

5359. The ordinary economical applications of the potato, next to those of the culinary and baking arts, are in starch-making and the distillery. Starch is readily made from the scraped and washed tubers cut into small pieces and steeped in water; and a spirit is distilled from mashed potatoes, fermented so as to change a portion of the starch into sugar. In general it is found that three and a half bushels of potatoes afford the same quantity of spirit as one of malt.

5360. Potash may be extracted from potato leaves and stalks by the following process:—Cut off the stalks when the flowers begin to fall, as that is the period of their greatest vigour; leave them on the ground eight or ten days to dry, cart them to a hole dug in the earth about five feet square and two feet deep, and then burn them, keeping the ashes red-hot as long as possible. Afterwards take out the ashes, pour boiling water on them, and then evaporate the water. "There remains after the evaporation a dry saline reddish substance, known in commerce under the name of *salin*; the more the ashes are boiled, the greyer, and the more valuable the *salin* becomes. The *salin* must be calcined in a very hot oven, until the whole mass presents a uniform reddish brown. In cooling it remains dry, and in fragments bluish within, and white on the surface; in which state it takes the name of potash." (*Smith's Mechanic*, vol. ii. p. 381.)

5361. Among extraordinary applications of the potato, may be mentioned cleaning woollens, and making wine and ardent spirit.

5362. *Cleaning woollens.* The refuse of potatoes used in making starch when taken from the sieve, possesses the property of cleansing woollen cloths, without hurting their colour; and the water decanted from the starch powder is excellent for cleansing silks, without the smallest injury to the colour.

5363. *Wine*, of a good quality, may be made from frosted potatoes, if not so much frosted as to have become soft and watery. The potatoes must be crushed or bruised with a mallet, or put into a cider press. A bushel must have ten gallons of water, prepared by boiling it, mixed with half a pound of hops, and half a pound of common white ginger. This water, after having boiled for about half an hour, must be poured upon the bruised potatoes, into a tub or vessel suited to the quantity to be made. After standing in this mixed state for three days, yeast must be added to ferment the liquor. When the fermentation has subsided, the liquor must be drawn off, as fine as possible, into a cask, adding half a pound of raw sugar for every gallon. After it has remained in the cask for three months, it will be ready for use.

5364. *Ardent spirit.* Potatoes that have been injured by the frost produce a much greater quantity of spirit, and of a much finer quality, than those that are fresh; they require a proportion of malt-wash to promote the fermentation. About one fourth part of malt-worts, or wash, ought to be fermented at least six hours before the potato-wash is joined to it; otherwise the potato-wash, having an aptitude to ferment, will be ripe for the still before the malt-wash is ready; hence the effect will be, to generate an acid which renders the spirit coarse, and, when diluted with water, of a milky or bluish colour. When the spirit is strong, the acid is held in solution; but appears as above, when diluted with water. (*Farmer's Mag.* vol. xvii. p. 325.)

5365. In the application of potatoes as food for live stock, they are often joined with hay, straw, chaff, and other similar matters, and have been found useful in many cases, especially in the later winter months, as food for horses, cows, and other sorts of live stock. With these substances, and in combination with others, as bean or barley-meal and pollard, they are used in the fattening of neat cattle, sheep, and hogs.

5366. *Potatoes are much more nutritive when boiled*; they were formerly cooked in this way, but are now very generally steamed, especially in the north. The practice has been carried to the greatest extent by Curwen in feeding horses. He gives to each horse, daily, a stone and a half of potatoes mixed with a tenth of cut straw. One hundred and twenty stones of potatoes require two and a quarter bushels of coals to steam them. An acre of potatoes, he considers, goes as far in this way as four of hay. Von Thaez found them, when given to live stock, produce more manure than any other food: 100 lbs. of potatoes producing 66 lbs. of manure of the very best description. The baking of potatoes in an oven has also been tried with success. (*Comm. Board of Agriculture*, vol. iv.); but the process seems too expensive. Potatoes should not be given raw to animals of any description, except, perhaps, when hogs are let in to root and pick up what may have escaped notice in the field. Washing was formerly a disagreeable and tedious business, but is now rendered an easy matter, whether on a large or small scale, by the use of the washing machine.

5367. *Machines for washing potatoes* are numerous, and in addition to that already described, we shall here notice two other forms. One of the simplest is a trough (fig. 750, *a, b*) containing a hollow cylinder (c) with a handle (d), which is made fast to the axis which passes through the cylinder.

"A number of the spars (which run longitudinally) are so constructed as to form a kind of door, which is made fast by two lynch-pins at each end of the cylinder. The vessel being charged with potatoes, and the trough filled with water, all that is necessary for the purpose of cleaning is only to turn the handle of the machine." A machine for washing potatoes by Mr. John Lawson, of Elgin, consists of a wooden or iron trough, with a movable bottom above the fixed one, composed of spars three quarters of an inch apart. The potatoes are laid over the movable ribbed bottom, and water being admitted at one end by a cock, they are moved backwards and forwards by a wooden hoe, till they are clean, when the dirty water which has collected between the two bottoms is let

off by another cock at the opposite end. (*Brit. Farm. Mag.* vol. ii.)

5368. *The boiling of potatoes*, though a simple operation, is in many districts not performed in the best manner. The following is the Lancashire method:—Set them on the fire in cold water; when boiled, pour off the water completely, add a little salt, and dry them well on the fire. Another method:—Choose your potatoes of equal size, and put them into a saucepan, or pot without a lid, with no more water than is sufficient to cover them; more would only spoil them, as the potatoes themselves, on being boiled, yield a considerable portion of water. By being boiled in a vessel without a lid, they do not crack, and all waste

is prevented. After the water is come nearly to boil, pour it off, and replace the hot by cold water, into which throw a good portion of salt. The cold water sends the heat from the surface to the heart of the potato, and makes it mealy. Like all other vegetables, they are improved by being boiled with salt, which ought not, therefore, to be spared. (*Mech. Mag.* i. 13.)

5369. *Frosted potatoes* may be applied to various useful purposes, for food by thawing in cold water, or being pared, then thawed, and boiled with a little salt. Salt, or saltpetre, chaff, or bruised oats, boiled with them, will render them fit food for cattle, swine, poultry, &c. Starch, and paste for weavers, bookbinders, and shoemakers, may be made from them when too sweet to be rendered palatable, and also an ardent spirit, from hydrometer proof to 10 per cent over proof.

5370. *The diseases of the potato* are chiefly the scab, the worm, and curl.

5371. *The scab, or ulcerated surface of the tubers*, has never been satisfactorily accounted for; some attributing it to the ammonia of horse-dung, others to alkali, and some to the use of coal ashes. Change of seed, and of ground, are the only resources known at present for this malady. The worm and grub both attack the tuber, and the same preventive is recommended. The only serious disease of the potato is the curl, and this is now ascertained to be produced by the too great concentration of the sap in the tuber; and this concentration, or thickening, is prevented by early taking up. This discovery was first made by the farmers near Edinburgh, who observed that seed potatoes procured from the moors, or elevated cold ground, in the internal parts of the country, never suffered from the curl, and it consequently became a practice, every three or four years, to procure a change of seed from these districts. On enquiry, it was found, that the potatoes in these upland grounds continued in a growing state till the haulm was blackened by the first frosts of October. They were then taken up, when, of course, they could not be ripe. Subsequent experiments, which will be found detailed in *The Farmer's Magazine*, and *Caledonian and London Horticultural Transactions*, have firmly established the fact, that the curl is prevented by using unripe seed; therefore the farmer ought to select his seed stock a fortnight or three weeks before he takes up the general crop, as already recommended. It is also a safe practice frequently to change the seed, and also to change the variety.

5372. *Shirreff*, an ingenious speculator and practical agriculturist, is of opinion that there are only two causes for the curled disorder in potatoes. The first is excessive seed-bearing, that is, carrying great quantities of plums or apples; from the effects of which, if the plant be not too far advanced in life, it may recover for a time, by removing it to a shady or upland situation. The second cause is time or old age, which never fails ultimately to bring the curled or shrivelled disorder, followed by death, on the whole animal and vegetable kingdoms. An old decaying oak is an instance of the curled or shrivelled state of trees from age, as is "the lean and slipped pantaloons" of the curled disorder from old age in the human species. An apple tree, again, that has carried extraordinary crops of fruit within a few years, is often in the state of a potato curled from excessive apple-bearing; so is a hart, or a buck, immediately after the rutting season. Both the tree and animals will recover their health and vigour for a time, unless they are too old, or have gone to the very greatest and last extremity in seed-bearing and ventry, in which cases the effects will be the same as those of time, viz. death. It is not then to over-ripening the tubers that the curled disorder in potatoes is to be attributed, but to time and seed-bearing; that is, carrying great quantities of plums or apples.

SECT. II. *The Turnip.* — *Brássica Râpa* L.; *Tetradymia Siliquosa* L., and *Crucifera* J. *Rave*, Fr.; *Rübe*, Ger.; *Rapa*, Ital.; and *Nabo*, Span.

5373. *The turnip* is a native of Britain, but in its wild state it is not to be recognised by ordinary observers from wild mustard. It was cultivated as food for cattle by the Romans; and has been sown for the same purpose in the fields of Germany and the Low Countries from time immemorial.

5374. *When they were introduced in this country, as a field plant*, is unknown: but it is probable turnips would be found in some gardens of convents from the time of the Romans; and it is certain that they were in field culture before the middle of the seventeenth century, though then, and for a long time afterwards, in a very inferior and ineffectual manner. It has been stated that turnips were introduced from Hanover in George I.'s time; but so far from this having been the case, George II. caused an abstract of the Norfolk system of turnip husbandry to be drawn up for the use of his subjects in Hanover. (*Campbell's Polit. Survey*, &c. vol. iii. p. 80.) The introduction of improved turnip culture into the husbandry of Britain, Brown observes, "occasioned one of those revolutions in rural art which are constantly occurring among husbandmen; and, though the revolution came on with slow and gradual steps, yet it may now be viewed as completely and thoroughly established. Before the introduction of this root, it was impossible to cultivate light soils successfully; or to devise suitable rotations for cropping them with advantage. It was likewise a difficult task to support live-stock through the winter and spring months; and as for feeding and preparing cattle and sheep for market during these inclement seasons, the practice was hardly thought of, and still more rarely attempted, unless where a full stock of hay was provided, which only happened in very few instances. The benefits derived from turnip husbandry are, therefore, of great magnitude. Light soils are now cultivated with profit and facility; abundance of food is provided for man and beast; the earth is turned to the uses for which it is physically calculated; and, by being suitably cleaned with this preparatory crop, a bed is provided for grass seeds, wherein they flourish and prosper with greater vigour than after any other preparation." (*Treatise on Rural Affairs.*)

5375. *Turnips and clover*, it is elsewhere observed, "are the two main pillars of the best courses of British husbandry; they have contributed more to preserve and augment the fertility of the soil for producing grain, to enlarge and improve our breeds of cattle and sheep, and to afford a regular supply of butcher's meat all the year, than any other crops; and they will probably be long found vastly superior, for extensive cultivation, to any of the rivals which have often been opposed to them in particular situations. Though turnips were long cultivated in Norfolk before they were known in the northern counties, yet it is an undoubted fact that their culture was first brought to perfection in Roxburghshire, Berwickshire, and Northumberland, and chiefly through the exertions of Dawson, of Frogden, in the first named county, and of Culley, in the latter.

5376. *Drilling turnips*, as well as other crops, evidently originated with Tull, whose first work, *Specimen of a Work on Horse-drawing Husbandry*, appeared in 1731. It appears that Craig, of Arbigland, in Dumfriesshire, began to drill turnips about 1745; and next we find Philip Howard, of Corby, drilling in 1755; and Pringle, drilling "from hints taken from Tull's book," in 1756 or 1757. William Dawson, who was well acquainted with the turnip culture in England, having been purposely sent to reside in those districts

for six or seven years, where the best cultivation was pursued, with an intention not only of seeing, but of making himself master of, the manual operations, and of the minutæ in the practice, was convinced of the superiority of Pringle's mode over every other he had seen, either in Norfolk or elsewhere; and in 1762, when he entered on Frogmore Farm, near Kelso, in Roxburghshire, he immediately adopted the practice upon a large scale, to the amount of 100 acres yearly. Though none of Pringle's neighbours followed the example, yet no sooner did Dawson, an actual or rent-paying farmer, adopt the same system, than it was immediately followed, not only by several farmers in his vicinity, but by those very farmers adjoining Pringle, whose crops they had seen, for ten or twelve years, so much superior to their own: the practice in a few years became general. Drilling turnips was first introduced to the county of Northumberland, about the year 1780.

5577. *The varieties of turnip grown by farmers may be arranged as whites and yellows.*

5578. *Of white turnips*, by far the best and most generally cultivated is the globe; but there are also the green-topped, having the bulb tinged greenish; and purple-topped, with the bulb reddish: which, though they do not produce so large a crop as the globe or oval, stand the winter better, and the red-topped, it is said, will keep till February. The pudding, or tankard turnip, has a white bulb which rises from eight to twelve inches high, standing almost wholly above ground. It is less prolific than any of the others, and more liable to be attacked by frost.

5579. *Of yellow turnips*, there are the field or Aberdeen yellow, which is more hardy than the globe, and answers well for succeeding that variety in spring; and the rutabåga, or Swedish turnip, which may be preserved for consumption till June. The Siberian turnip has a bulb and a branchy top, but both of inferior quality. It is a hybrid between a white rutabåga and field cabbage, or between rape and cabbage.

5580. *New varieties* are obtained by selection and by counter impregnation; but in either case the greatest care is requisite to keep the plants at least a furlong from any others of the brassica tribe likely to flower at the same time, otherwise the progeny will certainly be hybridised.

5581. *The choice of sorts* may be considered as limited to the white, globe, yellow, and Swedish, according as early, middling, or late supplies are wanted. No other varieties are grown by the best farmers.

5582. *In the choice of seed* the farmer must rely on the integrity of the seed-dealer, as it is impossible to discover from the grains whether they will turn out true to their kinds.

5583. *Turnip-seed requires to be frequently changed*; and the best is generally procured from Norfolk and Northumberland. The Norfolk seed, Forsyth observes, is sent to most parts of the kingdom, and even to Ireland: but after two years it degenerates; so that those who wish to have turnips in perfection should procure it fresh every year from Norwich, and they will find their account in so doing: for, from its known reputation, many of the London seedsmen sell, under that character, seed raised in the vicinity of the metropolis, which is much inferior in quality.

5584. *Turnip-seed of any age will grow*, if it has been carefully preserved; that which is new, comes up first, and therefore it is not a bad plan to mix new and old together, as a means of securing a braird against drought or the fly. Whether plants from new or old seed are most secure from the deprecations of the fly, is perhaps a question which cannot be easily determined, even by experiments; for concomitant circumstances are frequently so much more operative and powerful as to render the difference between them, if there be any, imperceptible. It is, however, known to every practical man, that new seed vegetates several days before the old, and more vigorously; and it is equally well known that the healthy and vigorous plants escape the fly, when the stunted and sickly seldom or never escape it. Hence it would seem, that new seed, *cæteris paribus*, is more secure from the fly than old.

5585. *The soil* for turnips should always be of a light description. In favourable seasons very good crops may be raised on any soil; but from the difficulty of removing them, and the injury which the soil must sustain either in that operation, or in eating them on the spot with sheep, they never on such soils can be considered as beneficial to the farmer. Turnips cannot be advantageously cultivated on wet tenacious soils, but are grown on all comparatively dry soils under all the variations of our climate. On dry loams, and all soils of a looser texture, managed according to the best courses of cropping, they enter into the rotation to the extent of a fourth, a sixth, or an eighth part of the land in tillage; and even on clayey soils they are frequently cultivated, though on a smaller scale, to be eaten by cattle, for the purpose of augmenting and enriching the manure, into which the straw of corn is converted.

5586. *The climate* most desirable for the turnip is cool and temperate. This was long ago noticed by Pliny, and it is so obvious on the Continent that it admits of no dispute. Von Thæer observes that the turnips grown on the fields of Germany seldom exceed half a pound in weight, and that all his care could not raise one beyond fourteen pounds. In France and Italy they are still less. A rapid climate is equally disadvantageous to the turnip; and they are accordingly found of no size in Russia, Sweden, and many parts of North America. Even turnips grown in the southern counties of England, in the same excellent manner as in Northumberland, never equal the size of those grown in the latter county, or further north, or in Ireland.

5587. *The field culture of turnips* is effected either by sowing the seed of the plant from the hand on a flat surface, or by depositing it on the tops of little ridges. In the best cultivated districts, the latter method is universally practised and approved of, chiefly for these reasons:—1. By this method the land may be more easily and perfectly cleaned during the growth of the plants; the width of the rows affording the means of better tilling the intervals. 2. The plants can be more cheaply and quickly hand-hoed, the process being so simple as to be taught to young persons in a few hours; whereas when the plants are not regularly disposed in rows, a considerable degree of experience and time are requisite. 3. The manure may be more perfectly covered, and by being applied in a more effectual manner to the roots of the plants, a smaller quantity will suffice. And lastly, the turnips may be kept drier, and crops of them in conse-

quence raised on land so wet as otherwise to be incapable of yielding a return of any value. We shall give their culture from an excellent paper in the *Quarterly Journal of Agriculture*, vol. i., from which also this paragraph is quoted.

5388. *Preparation of the land.* The land intended for the turnip crop is ploughed in autumn, after the preceding crop of grain has been reaped. If the soil be not of a very dry nature, the land is formed into ridges of fifteen feet or more, and care is taken that no water shall stagnate on the ground. In this condition the land remains during the winter; and it is ploughed again in spring as soon as the ground is sufficiently dry for that purpose, and as soon as the other labour of the farm will allow: this second ploughing is generally made in a direction to cross the previous one. The land is then repeatedly grubbed and harrowed in various directions, for the purpose of pulverising it, and of dragging to the surface, and disengaging all weeds and roots; to assist in which process the aid of the roller is frequently requisite; the roots and weeds disengaged are then gathered with care, and either burnt in little heaps on the ground, or removed away to a larger heap, to be mixed with quick-lime and other substances, to form a compost for the succeeding year; at the same time such stones as impede the tillage may be removed: after this the land is again ploughed, and generally, as before, in a direction crossing the last furrows; and the same process of harrowing, rolling, and collecting the disengaged weeds, is repeated. The earth is once more ploughed, and again the same operations are resorted to; after which the land is usually in a fit state to be formed into ridges or drills. Should this not be so, the operations of ploughing, harrowing, and gathering of weeds must be repeated, and that until the land is cleared of all injurious roots, and reduced to a loose or friable state. The perfect preparation of the ground in this stage of its culture, is of very great importance to the future crop.

5389. *Forming the ridges.* After the preparation described, the land is formed into little ridges or ridgelets, either by the common plough, or by a plough with two mould-boards, formed for that purpose. The first of these is to be preferred when the method of performing the work is once pointed out in the fields. The ridges are formed with a sharp top, as a transverse section (*fig. 751*) will show. The distance

751

of these ridgelets may be from twenty-seven to thirty inches, measuring from top to top. This interval is necessary to allow of the horse-hoe tilling the intervals, in the manner to be afterwards described, and to admit a sufficient circulation of air between the rows of the plants.

5390. *Manner of applying the manure.* The chief manure applied to this crop is farmyard dung, or that which is produced by the consumption of the straw and other produce of the farm. This manure ought to be well rotted, and to that end either turned over in the court-yard some weeks previously to its being used, or carried out in winter to the fields intended for the turnips, and there laid in one or more large heaps. If the carts are not suffered to go upon these heaps, the putrefactive process will proceed with greater quickness. When the ridgelets are formed in the manner described, the dung is filled into carts drawn by one horse, and transported quickly to the land. The manner of applying it is this:—The horse with the loaded cart walks in the interval of the ridges, so that a wheel of the cart shall go in each of the hollows of the two ridges adjoining. The person who directs the horse follows the cart, which is open behind, and with a crooked two-pronged fork or dung-hack, (*fig. 752*) drags out the dung, as the horse moves along, into little heaps in the hollow of every third ridge, at the distance from each other of from eight to ten feet. Be-

752

hind follow three young persons, with each a two-

753

new ridge for the reception of the seed is at once

formed, so that a wheel of the cart shall go in each of the hollows of the two ridges adjoining. The person who directs the horse follows the cart, which is open behind, and with a crooked two-pronged fork or dung-hack, (*fig. 752*) drags out the dung, as the horse moves along, into little heaps in the hollow of every third ridge, at the distance from each other of from eight to ten feet. Be-

hind follow three young persons, with each a two-pronged or three-pronged fork (*fig. 753*), each walking in the interval of a ridge, and spreading out the dung in as regular a manner as possible; as a cross section of the ridgelets with the dung deposited in the intervals would show (*fig. 754*).

754

operation at once, the common plough by going and returning up the middle of each ridge.

755

5392. *Broad-cast dunging.* Instead of depositing the manure in the manner described, it is sometimes laid upon the stubble after harvest, and then ploughed in. This is only practicable where there is a supply of manure remaining from the preceding year, or where it can be elsewhere procured; and is only advisable when the land is so clean as to require little preparation in the succeeding spring. As liberal an expenditure as can be afforded of manure is always expedient in the case of this crop, the goodness of which will much depend upon the fertility we are able to communicate to the soil. Ten or twelve tons per acre may be considered the regular manuring on a turnip-farm, where a proper rotation of crops is followed.

5393. *Lime, sea-weed, ashes.* Sometimes lime is applied to the turnip crop, together with dung. This may be done by laying the lime upon the stubble after harvest, or better still, by spreading it upon the ground, and harrowing it well immediately, before the forming of the ridgelets for the reception of the dung. Putrescent manures, however, are considered superior to the calcareous for the production of this plant; and all of the former kind may be used with effect. Street dung is an exceedingly good manure; sea-weed will also be useful: this last, however, is not applied in the manner of the farmyard dung, but is carried off as it is cast on shore, laid on the surface, and suffered to remain so till the land is

ploughed. Ashes generally produce a good effect in causing the seeds to vegetate quickly, but the fertilising powers of some of these do not appear to be of a permanent nature. Bruised bones and various other substances have been used with much benefit; but it is to be observed, that putrescent manures form the main support of the turnip cultivator, and that the others are only to be regarded as subsidiary.

5394. *Sowing the turnips.* The land being formed into ridgelets in the manner described, is ready for the reception of the seed. This is sown on the tops of the ridgelets by machines of various forms.

5395. *The most simple of these* consists of a hollow cylinder of tin, fixed upon an axle, and moving round with two light wheels, distant from each other twenty-seven or thirty inches, which are made to run in the hollows of the ridges. (2688.) The seed is put into the cylinder through an aperture which opens and shuts for that purpose: this cylinder turning round with the axle, the seed drops, through small equidistant holes made in it, into a tin tube, by which it is conveyed to the ground. Immediately before this tube is a hollow couler of iron, sharp before, which incloses the forepart of the tin tube, and makes a track in the ground from one to two inches deep, into which the seed drops. This simple apparatus is mounted upon a light wooden frame-work, having two shafts behind, by which the workman holds and keeps it steady in its course. It is then attached by a rope to a light wooden roller, in the shafts of which the animal of draught is yoked. More perfect machines, however, may be employed where turnips are cultivated upon a large scale, and we may refer to that of French (2688.) as one of the best.

5396. *The preparation of turnip-seed for sowing*, by steeping in the drainings of dung-hills and other similar matters, has been recommended as a likely mode to prevent the fly; but it is not found to have this effect, and is never followed.

5397. *The following mode of preparation is sometimes adopted*:—Half new and half old seed are mixed together; then half is taken and steeped in water for three or four hours; afterwards both steeped and unsteeped seed are mixed and immediately sown. The object of this preparation is to obtain four different braids or risings of the seed, which are supposed to give four chances of escaping the fly that attacks the infant plants, instead of one. Another mode is to join radish-seed to the above, new and old, steeped in the foregoing manner, it being found that the fly prefers the radish to the turnip. Some recommend the mixing of an equal quantity of rape-seed with the turnip-seed, alleging, that if a fly cuts off the turnips, the rape may be left for a crop; and that if the turnips escape, the rape may be treated as weeds. The most common precaution, however, as to the fly, is to sow thick, or to mix the seed with soot, lime, or ashes.

5398. *The quantity of seed used* may be from two pounds to two and a half pounds avoirdupoise per acre. It is necessary to give a sufficient quantity of seed, to provide against the loss of plants from the ravages of insects, and other contingencies. But the quantity should not be excessive; because the plants, when too thick, get interwoven together, and thence become difficult to be thinned in a proper manner.

5399. *The sowing process being completed*, the ridgelets remain flattened and compressed. (fig. 756.)

756

5400. *The several operations of forming the ridgelets*, spreading the dung, covering it by the plough, and sowing the seed, ought to be carried on in close succession. The dung must be immediately covered, that none of its powers may be lost by evaporation; and the seed, to ensure its early vegetation, ought to be sown as soon as possible upon the moist earth turned up. The various works of the turnip culture, thus carried on at the same time, furnish the best specimen which the culture of the fields affords of the beneficial effects of a proper division of labour. The process has all the appearance and effects of garden culture, with the difference of its being conducted with incomparably greater economy and despatch.

5401. *The period of sowing in the north of England and Scotland* is from the 1st to the end of June, though it is often continued to the middle of July. The turnips, however, sown after the latter of these periods seldom attain to a proper size; and, when sown earlier than the 1st of June, they are apt to shoot forth the seed-stem before winter, by which not only the soil is deteriorated, but the nutritive juices of the root exhausted. In the south of England they may be sown somewhat later than in the north.

5402. *The time of sowing in other countries* must be varied by the nature of the climate and soil. It is to be inferred, that in warmer countries, where vegetation is more rapid, the sowing should be deferred till a later period. At Benville, in the north of France, M. de Dombasle sometimes sows in August, and yet obtains a medium crop.

5403. *Hoeing.* When the plants are an inch or more in height, or when weeds appear amongst them, the process of hoeing commences. This is done either by a small plough drawn by one horse, going and returning along the hollow of each ridgelet, and cutting of a slice of earth from the sides, as near to the turnips as possible (fig. 757.)

757

or by the horse-hoe, of which there are various kinds. The most simple of these consists of a flat triangular share (fig. 758. a), with two lateral arms (b, b), formed to set wider or narrower, and fixed to a beam and handles by three upright coulters of iron; or, which is better, the lateral arms are omitted, the triangular share fixed to the beam, and two moveable upright coulters attached by a cross bar.

5404. One of the best turnip horse-hoes is formed from the skeleton of a common plough (fig. 759), by

two coulters of iron curved inwards (a, b), and fixed to wooden bars (c, f, and c, d), which last again are hooked to the beam of the implement, and made, by means of a cross iron bar (g, h), to be set at a greater or smaller distance from each other as it may be required. A broad iron share (i) moves in the middle of the hollow of the ridges, while the two coulters on each side go as near to the rows of turnips as can be done with safety; and in this manner the intervals of the ridges are tilled, and the weeds within them, and as near to the plants as the coulters can go, cut up and destroyed. By removing the wooden bar and coulters of this machine, and hooking to it, on each side, a small cast-iron mould-board, it is converted to the double mould-board plough also, as we have seen.

5405. The brakes or horse-hoes of Wilkie (2666.), Finlayson (2667.), or of Kirkwood (4955.), may easily be set and arranged for this or any other description of culture; so that it requires no new implements.

5406. The hand-hoes go to work, each having a little iron hoe, fixed upon a wooden handle about three feet in length (fig. 760). The breadth of the blade (a) of this hoe is eight inches; and the workers, standing in the hollow with their faces to the ridges, hoe the turnip plants, leaving them standing singly, at the distance from each other of from ten to twelve inches. By this operation the rows of the turnips are cleaned of all weeds; the superfluous plants cut up and pushed into the intervals, where they die; and the plants to be preserved left standing singly at the distance required. A transverse section of the ridges will then appear thus (fig. 761.), and

a longitudinal section thus: (fig. 762.) The plants should not be nearer to each other than ten inches, that they may increase to a proper size.

5407. Second horse-hoeing. Soon after the operation in question, weeds will again sprout up in the intervals of the ridges and amongst the plants. In the course, therefore, of twelve days or more the horse-hoe again passes through the intervals of the ridges, cutting up all the weeds that may have sprung up; and soon after the hand-hoes again go to work with the same instrument as before, cutting up all weeds which may have grown amongst the turnips, and carefully singling any plants that may by chance have been omitted in the first hoeing. After this process, a section of the ridges will appear thus: (fig. 763.)

5408. Third horse-hoeing. Sometimes the horse-hoe passes once more down the intervals after a short period; but more generally the previous hand-hoeing concludes the process upon all the drier lands, the weeds being now kept down by the rapid growth of the plant, and the overshadowing of the intervals by its leaves. Very commonly, however, at an interval of eight or ten days after the last hand or horse-hoeing, the earth which had been taken from the roots of the plants by these several hoeings is again laid back, either by the little one-horse plough already mentioned, or by the double mould-board plough, passing down the intervals of the rows and ridging up the earth thus: (fig. 764.) The design in this operation is, that any weeds remaining in the intervals after the former hoeings may be destroyed, and that the land and turnips may be kept more dry during wet weather and the months of winter. This concludes the culture of the turnip, which now grows rapidly without further care; and by the beginning of September the leaves of a good crop will have covered the entire surface, making a transverse section of the ridges appear thus: (fig. 765.)

ration is, that any weeds remaining in the intervals after the former hoeings may be destroyed, and that the land and turnips may be kept more dry during wet weather and the months of winter. This concludes the culture of the turnip, which now grows rapidly without further care; and by the beginning of September the leaves of a good crop will have covered the entire surface, making a transverse section of the ridges appear thus: (fig. 765.)

5409. The Swedish turnip is cultivated, used, and stored precisely in the same manner as the common turnip; but it is generally sown several weeks earlier. It does not attain to the same weight by the acre; and, as it is more difficult to raise, it ought to receive a greater quantity of manure, and to be always upon good land. The Swedish has a property which the common turnip has not, that of bearing to be transplanted

when young; so that, where blanks appear in a field, the spaces may be filled up by transplanting. Analogous to the Swedish turnip, in hardness and nutritive qualities, is the large yellow or Aberdeen turnip. This root is perhaps superior to the Swedish turnip, in so far as it may be raised with less difficulty. It serves the same purpose of a succedaneum to the common turnip in spring.

5410. *Consumption of the turnips.* By the end of October or beginning of November, when the pastures have decayed, the turnips begin to be used for food.

5411. *When sheep are to be fed,* the turnips are either pulled up by the hand, and carried away, as wanted, into the fields, in which the sheep are kept, and there spread regularly upon the ground; or more frequently and economically the sheep are at once driven into the fields of turnips, and suffered to consume the roots as they stand. In this case the animals are not suffered to range over the whole field at first, but are confined to a space of an acre or more, by means of nets, or a series of moveable rails or hurdles. When the sheep have eaten the roots very nearly, the remnant in the ground may be picked up by a little hoe (*fig. 766.*) or by the turnip chopper already described (2372); and when the whole are consumed, the nets or rails, or hurdles, are moved to another division, and so on throughout the field, leaving the spaces before cleared open to the sheep to move upon. This manner of consuming the turnips affords an admirable manure to the land, and prepares it well for the subsequent crops of grain and herbage. In feeding in this manner, it is frequent to place in the field a little rack with a cover, containing a small quantity of hay, which seems

766

to be relished by the animals amid their moister food.

5412. *In the feeding of oxen,* the turnips may be laid down on a dry field, as in the case first mentioned; but the proper and regular manner of feeding these animals is to supply them with the turnip in the house or open yard, littering them at the same time plentifully and regularly with straw, and giving them what they choose to consume of it as provender, with their turnip-food. Cattle are fed either by being tied to upright posts in the house, or they are suffered to go at large in the straw-yard. This last is greatly the better mode of feeding, the turnips being supplied from troughs or otherwise, and a shed for shelter being always at hand and open to the cattle to repose in. It is well, however, that too many animals, of different strength and size, be not put together, lest they disturb each other in feeding. Sometimes courts are made and divided into separate compartments, holding only two cattle in each, and this is found to be an exceedingly good practice. When cattle are of value, and put up for quick fattening, it is common to cut off the leaves and tails of the turnip, giving the leaves to the younger and less valuable stock, and the bulb only to that which is to be fed.

5413. *Young cattle,* not intended to be immediately fattened, receive only a limited portion of turnips, their principal provender being straw. By receiving a portion of turnips with their drier provender, these animals are kept in a much more healthy condition than if confined to the latter food, and continue to grow throughout the whole season, instead of pining away at the time when green herbage can no longer be found for them. With the design, too, of keeping them in a good condition, turnips are supplied in a limited quantity to milch cows, and in particular at the time of calving. The turnip, however, though it adds to the quantity of milk, gives it a strong and disagreeable flavour.

5414. *When both sheep and cattle are fed* upon a farm, it is usual to pull up every alternate four or five rows of turnips for the cattle, leaving the remainder on the ground for the sheep, so that the land on which the turnips had grown may receive its proportion of the manure produced. (*Quar. Jour. Ag. vol. i. p. 286.*)

5415. *The advantages of eating turnips on the place of their growth by sheep,* both in manuring and consolidating the ground, are sufficiently well known to every farmer. One great defect of the inferior sort of turnip soil is the want of tenacity; and it is found that valuable crops of wheat may be obtained upon very light porous soils, after turnips so consumed. It is not uncommon to let turnips at an agreed price, for each sheep or beast, weekly. This varies according to age and size, and the state of the demand, from four-pence or less, to eight-pence or more, for each sheep weekly, and from two shillings to five for each beast. An acre of good turnips, say thirty tons, with straw, will fatten an ox of sixty stone, or ten Leicester sheep. Supposing the turnips worth six guineas, this may bring the weekly keep of the ox to six shillings and three-pence halfpenny, and of the sheep to about seven-pence halfpenny a week. In this way of letting, however, disputes may arise, as the taker may not be careful to have them eaten up clean. The person who lets the turnips has to maintain a herd for the taker; and when let for cattle, and consequently to be carried off, the taker finds a man and horse, and the letter maintains both. The taker has to provide hurdles or nets for fencing the allotments to sheep; but the letter must fence his own hedges if necessary. The period at which the taker is to consume the whole is usually fixed in the agreement, that the seller may be enabled to plough and sow his land in proper season. (*Suppl. to Encyc. Brit.*) The rule for selling turnips in Norfolk is calculated from the fact, that *one acre of good turnips is sufficient for 100 sheep for one week.* Then, whether turnips be dear or cheap, the price per week may be easily found — at 5*l.* per acre, 1*s.* per week per head, and so of all other prices. This is under the supposition that the crop is to be eaten off on the ground.

5416. *The Swedish and yellow turnips* are eaten greedily by horses; and afford a very nutritive and salutary food along with hay or straw for working stock. The best mode is to steam them after previously passing them through the slicing machine, as no root requires so much cooking as the Swedish turnip. Horses will also eat the white turnip, but not freely, unless they have been early accustomed to them, as in some parts of Norfolk.

5417. *Cattle fatten much faster with clean turnips* than with such as are dirty, and therefore Waistell recommends that they should never be given without being previously washed. "The earth upon unwashed turnips," he says, "scours the cattle, and keeps their bodies too loose and open; their dung being thin and almost liquid, carries off with it a white mucous matter from the bowels, which is frequently seen among the dung, the loss of which must necessarily retard the fattening of the cattle; and with washed turnips their dung is wax-like, and figured similarly to the dung of cattle fed on rich meadow hay. Cisterns are also found very useful in frosty weather; for when frozen turnips are thrown into spring water, it speedily draws out of them all the icy particles, which, when retained, must undoubtedly render them much less nourishing and improving to the cattle that eat them." (*Waistell's Designs, &c. p. 40.*)

5418. *Near large towns* the most profitable mode of disposing of turnips is to the cow-keepers and green-grocers.

5419. *The application of turnips in domestic economy* is well known. They may also be used in the distillery; and a wine is said to be made from them by the London manufacturers of imitations of foreign wine.

5420. *The storing of turnips* is attended with too much labour and risk to be of much advantage in the greater part of the kingdom. Common turnips are never stored in any great quantity, though sometimes a portion is drawn and formed into heaps, like

potato camps, and lightly covered with straw, or preserved for some time under a shed. On these occasions, before storing up, the shaws or leaves and the tap-roots must be cut off and removed, to prevent heating and rotting. The heaps must not be covered with earth-like potatoes, for in this case their complete destruction is inevitable. This root contains too much water to be preserved for any length of time in a fresh and palatable state, after being removed from the ground; and though the loss in seasons unusually severe, particularly in the *white globe* variety, is commonly very great, it is probable that a regular system of storing the whole, or the greater part, of the crop every season would, upon an average of years, be attended with still greater loss; besides the labour and expense, where turnips are cultivated extensively, would be intolerable. (*Supp. &c.*)

5421. *Taking up and replacing* is a mode by which turnips have been preserved, by Blaikie of Holkham, and some others. The mode is to cart the turnips from the field where they grow, to a piece of ground near the farm-offices, before the winter rains set in, when, the tap-root being cut off, the plants are set on the surface of the ground, in an upright position, as close to each other as they can stand, where they keep much better than in a store during the whole season. The advantages of having them quite close to the homestead, in place of bringing them most probably from a distant part of the farm in wet or stormy weather, are so obvious, as fully to justify a recommendation of the practice.

5422. *Replacing and earthing* have also been tried with success, especially with the Swedish turnip. Being pulled and freed from their roots and leaves, they are carted to a piece of well worked dry soil near the farmery, and there deposited in rows, so close as nearly to touch each other in the bottom of shallow furrows, the plough covering one row as another furrow is opened. In this way many tons are quickly earthed in, and on a very small space, and they can be turned out when wanted with equal facility. (*Farmer's Magazine*, vol. xxiii. p. 282.)

5423. *The produce of turnips* cultivated in the broad-east manner in England varies from five to fifteen tons per acre: the latter is reckoned a very heavy crop. In Northumberland and Berwickshire, a good crop of white globe turnips drilled usually weighs from twenty-five to thirty tons per acre, the yellow and Swedish commonly a few tons less. Of late there have been instances of much heavier crops, and in Ayrshire it would appear that above sixty tons have been raised on an English acre, the leaves not included. (*Farmer's Magazine*, vols. xv. and xvi.) But such an extraordinary produce must have been obtained by the application of more manure than can be provided, without injustice to other crops, from the home resources of a farm; and where turnips form a regular crop in the rotation, no such produce is to be expected under any mode of culture.

5424. *The produce of the turnip in nutritive matter*, as proved by Sir H. Davy, was forty-two parts in a thousand; of which seven were mucilage, thirty-four sugar, and one gluten. Swedish turnips afforded sixty-four parts in a thousand of nutritive matter, of which nine were starch, fifty-one sugar, two gluten, and two extract. According to Von Thaer, 100 lbs. of turnips are equal to twenty-two of hay; and an ox to get fat on turnips ought to have one third of its weight daily.

5425. *To raise turnip seed*, the usual mode is to select the most approved specimens of the variety to be raised at the season when they are full grown; and either to remove all others from the field and leave them to shoot into flower stems next year, or to transplant them to a place by themselves, where they will be secure from the farina of other plants of their genus. In either case they must be protected by earthing up from the winter's frost and rains, and in the ripening season from the birds.

5426. *The true sort of Swedish turnip* can very easily be kept by only attending to the plants when in flower. All the degenerated ones bear bright yellow flowers, which should be pulled out before the seed ripens. The true sort have a *brownish* yellow flower. This saves the expense of transplanting if a corner or one ridge of a field can be found convenient for sowing.

5427. *The Norfolk seed-growers* have a sort of theory on the subject of transplanting turnips for seed which it may be worth while to attend to. According to that theory, where turnip seed is collected from such turnips as have been sown three or four years in succession, the roots are liable to be numerous and long, and the necks or parts between the bulbs and leaves coarse and thick; and when taken from such as have been transplanted every year, these parts are liable to become too fine, and the tap-roots to be diminished in too great a proportion. Of course the most certain plan is to procure seed from turnips that are transplanted one year and sown the next; or, if they be transplanted once in three years, it is supposed, that the stock may be preserved in a proper state of perfection. It is stated, that the method of performing this business in the best way, is to select such turnips as are of the best kinds and of the most perfect forms from the field crops, and after cutting their tops off, to transplant them, about the month of November, or following month, into a piece of ground that has been put into a fine state of tillage by repeated ploughing or digging over, and which should be situated as near the house as it can be, in order that the birds may be better kept from it. The seed will mostly be ready for gathering in the end of July, or in the following month.

5428. *Others cultivators*, however, advise that the seed collected from a few turnips thus transplanted should be preserved and sown in drills, in order to raise plants for seed for the general crop, drawing out all such as are weak and improper, leaving only those that are strong and which take the lead; and that when these have formed bulbs, such as do not appear good and perfect should be taken out, as by this means turnip seed may be procured, not only of a more vigorous nature, but capable of vegetating with less moisture, and of producing stronger and more hardy plants. The practice of transplanting the whole of the turnips for seed for the main crops, they contend, is not only highly expensive, but injurious, by diminishing the strength of the plants from the destruction of their tap-roots. Very good seed may, however, be raised in either of the methods that have been here described.

5429. *The best Norfolk turnip-seed growers* are of opinion that unless the seed be *always* saved from transplanted roots, the stock will infallibly degenerate in the manner here described. The statement that transplanting once in three years is sufficient, was a mere pretence with some of the growers to enable them to save two thirds of the heavy expense which attends transplanting turnips, and to get the same price for their seed as if it had been properly saved. The only exception to this is in what the Norfolk farmers call the "pudding" or "long pudding" turnip, which is too tender to bear the winter. For a *stock*, a few sorts are taken up and protected from cold like mangold wurzel; and for a general crop the

seed is sown broadcast and not hoed, but suffered to grow like *rapp*. So treated the plants form very small woody sorts, which are capable of enduring frosts. (*J. L.*)

5430. *After the seed has become fully ripened*, it is mostly reaped by cutting off part of the stems, and afterwards tying them up into sheaves, which, when sufficiently dry, are put into long stacks, and kept through the winter, in order to be threshed out about the time when it is wanted. But as in this way much seed is liable to be lost, by its readiness to escape from the pods in which it is contained, it is advised, as a much better practice, to have it immediately threshed out, either upon a cloth in the field where it grew, or in some other convenient place, being then put into bags proper for the purpose and placed in a situation which is perfectly dry. From seed crops of this sort being subject to much injury, and loss in different ways, the quantity of produce must be very different under different circumstances; but it may in general be stated at not less than from twenty to twenty-four bushels the acre. The price of turnip seed being seldom less than seven or eight shillings the bushel, on account of the great demand for it, it may at first appear to be a very advantageous sort of culture; but from the exhausting nature of the crop, the loss sustained in grain, and the quantity of manure afterwards necessary, it is probable that turnip seed can only be grown to advantage in particular circumstances of soil and situation. In most cases it is, however, well for the farmer to raise his own seed, as that of the shops is seldom to be fully depended upon.

5431. *The diseases and injuries to which turnips are liable* are various. At their first appearance their leaves are liable to the attacks of the fly (*Aphis* and *Háltica*), the caterpillar, the slug, and the mildew. Their bulbs and roots are attacked by worms of different kinds; by a singular tendency to monstrosity, known provincially by the name of fingers and toes; by the anbury; by canker, and by wasting or gangrene from water or frost. Of all or most of these injurious diseases it may be observed, that they neither admit of prevention or cure by art. Under favourable circumstances of soil, climate, culture, and weather, they seldom occur; therefore all that the cultivator can do is to prepare and manure his land properly, and in the sowing season supply water when the weather is deficient in showers or the soil in humidity.

5432. *The fly* attacks the turnip when in the seed-leaf, and either totally devours it, or partially eats the leaves and centre-bud, so as to impede the progress of the plants to the second or rough leaves. Whether the eggs of these flies are deposited on the plants or in the soil, does not appear to be ascertained; in all probability they are attached to the former, as in the gooseberry caterpillar, and most cases of flies and insects which feed on plants. Preparations and mixtures of the seed, as already treated of, are all that have yet been done in the way of preventive to this evil.

5433. *The caterpillar* makes its appearance after the plants have produced three or more rough leaves; these they eat through, and either destroy or greatly impede the progress of the plants. There can be little doubt that the eggs of these caterpillars are deposited on the leaves of the plants by a species of moth, as the caterpillar may be detected when not larger in diameter than a hair. As preventives to the moths from fixing on the turnips for a depository for their eggs, it has been proposed to place vessels with tar in different parts of the field, the smell of which is known to be very offensive to moths and all insects; or to cause a thick offensive smoke from straw or weeds to pass over the ground at the time when it is supposed the moths or parent flies were about to commence their operations. To destroy the caterpillar itself, watering with tobacco water, lime water, strong brine, and laying on ashes, barley awns, &c. have been proposed.

5434. *The slug and snail* attack the plants both above and under ground, and eat both the leaves and roots. Rolling, soot, quicklime, awns, &c. have been proposed to annoy them; but the only effectual mode is, immediately after the turnips are sown, to strew the ground with cabbage leaves, or leaves of any of the *Brássica* tribe. On these, especially if sweet from incipient decay, the slugs will pasture, and may be gathered off by women or children every morning. If as many cabbage leaves, or handfuls of decaying pea haulm, or any similar vegetable be procured, as will go over a ridge or two, say at the rate of a leaf to every square yard, a whole field may soon be cleared by picking off the slugs and removing the leaves once in twenty-four hours. This mode we have found most effectual, and it is extensively practised by market and other gardeners. (*Encyc. of Gard.* 2275.)

5435. *The mildew* and blight attack the turnip in different stages of its progress, and always retard its growth. Its effects may be palliated by watering and strewing the leaves with sulphur; but this will hardly be considered applicable to whole fields.

5436. *The worms attack the roots*; and, when they commence their ravages at an early period, impede their growth, and ruin or greatly injure the crop. They admit of no remedy or prevention.

5437. *The forked excrescences*, known as fingers and toes in some places, and as the anbury in others, are considered an alarming disease, and hitherto it can neither be guarded against nor cured. The following account of it is given by William Spence, president of the Holderness Agricultural Society in 1811:—

5438. *In some plants, the bulb itself is split into several finger-like diverging lobes*. More frequently the bulb is externally tolerably perfect, and the tap-root is the part principally diseased; being either wholly metamorphosed into a sort of misshapen secondary bulb, often larger than the real bulb, and closely attached to it, or having excrescences of various shapes, frequently not unlike human toes (whence the name of the disease), either springing immediately from its sides, or from the fibrous roots that issue from it. In this last case, each fibre often swells into several knobs, so as distantly to resemble the runners and accompanying tubers of a potato; and not seldom one turnip will exhibit a combination of all these different forms of the disease. These distortions manifest themselves at a very early stage of the turnip's growth; and plants, scarcely in the rough leaf, will exhibit excrescences, which differ in nothing else than size from those of the full-grown root.

5439. *The leaves discover no unusual appearance*, except that in hot weather they become flaccid and droop; from which symptom the presence of the disease may be surmised without examining the roots. These continue to grow for some months, but without attaining any considerable size, the excrescences enlarging at the same time. If divided at this period with a knife, both the bulb and the excrescences are found to be perfectly solid, and internally to differ little in appearance from a healthy root, except that they are of a more mealy and less compact consistency, and are interspersed with more numerous and larger sap-vessels. The taste, too, is more acrid; and, on this account, sheep neglect the diseased plants. Towards the approach of autumn, the roots, in proportion as they are more or less diseased, become gangrenous and rot, and are either broken (as frequently happens) by high winds, or gradually dissolved by the rain. Some, which have been partially diseased, survive the winter; but of the rest, at this period, no other vestige remains than the vacant patches which they occupied at their first appearance. There is no longer any doubt about the cause of this disease; it is the effect of the deposition of the eggs of a small fly (probably a *Scarabæus*) into the pithy parts of the roots, and the albuminous parts of the bulb, which soon changing to a maggot, and ultimately to a perfect insect, eat their way out.

5440. *For the prevention of this disease*, marl has been recommended by Sir Joseph Banks and others; and where marl cannot be procured, it has been thought that an addition of mould of any kind, that has not borne turnips, will be advantageous; such as a dressing taken from banks, woodlands, ditches, &c. and mixed up with a good dose of lime. But lime alone has been tried in vain; and no great dependence

can be placed upon fresh mould, as this disease has been known to prevail upon lands that had scarcely ever before borne a crop of turnips (*Farmer's Magazine*, vol. xiii.). The only effectual preventive would be to hinder the insect from laying its eggs.

5441. *The canker attacks the roots, and partly the bulbs, of turnips, and is known by the ulcerated appearance it produces.* Some consider it owing to the presence of too much iron in the soil, and recommend liming as a preventive.

5442. *Wasting and putrefaction, from excess of water or frost, are to be prevented by earthing up the bulbs, or taking up and storing.*

SECT. III. *The Carrot.* — *Daucus Carota* L.; *Pentándria Digýnia* L., and *Umbellifera* J. *Carotte*, Fr.; *Gelbe Rübe*, Ger.; *Carota*, Ital.; and *Chirivía*, Span.

5443. *The carrot is a biennial plant, a native of Britain; but though long known as a garden plant, it is comparatively but of recent introduction in agriculture.* It appears to have been cultivated from an early period in Germany and Flanders, and introduced from the latter country to Kent and Suffolk early in the 16th century. As the carrot requires a deep soil, inclining to sand, it can never enter so generally into cultivation as the potato or turnip; but, as observed by a judicious writer, it has been too much neglected on lands where it would have yielded a more valuable product, perhaps, than any bulbous or tap-rooted plant whatever. Several contradictory experiments in its culture have been detailed in a number of publications, from which the practical husbandman will be at a loss to draw any definite conclusion: but, in a recent communication to the Board of Agriculture, from Robert Burrows, an intelligent Norfolk farmer, who has cultivated carrots on a large scale, and with great success, for several years, so accurate an account is presented of the culture, application, and extraordinary value of this root, that carrots will probably soon enter more largely into the rotation of crops on suitable soils. (*Supp. &c.*) This person had more experience than any one; but he, after a few years, discontinued to cultivate carrots so extensively as he did at the time the communication to the Board of Agriculture was made. The consumption of carrot seed in Norfolk had, in 1821, diminished from three or four tons a year to as many cwt.

5444. *The varieties of carrot cultivated in gardens are numerous, and readily increased by the usual means; but the only sort adapted for the field is the long red or field carrot.* New seed is most essential, as it will not vegetate in the second year. Old seed, or a mixture of old and new, and also the mixture of the horn carrot, the seed of which is sent over in large quantities from Holland, ought to be carefully avoided.

5445. *The best soil for the carrot is a deep rich sandy loam; such a soil ought at least to be a foot deep, and all equally good from top to bottom.* On any other the field culture of the carrot will not answer.

5446. *In preparing the soil for the carrot, it is essential to plough it before winter, that it may be pulverised by frost; and to work it well by the plough and cultivator in spring, to at least the depth of a foot.* This deep tillage may be perfectly accomplished either by means of the trench-plough following the common one, or by the common one alone, with a good strength of team; but the former method is to be preferred, wherever the lands are inclined to be stiff or heavy. Three ploughings are mostly found sufficient, where the land has been previously in a state of tillage; but more may in other cases be necessary. The first ploughing should be made to the depth of ten, twelve, or fourteen inches, and be performed when the soil is tolerably dry, about the beginning of October. It may remain in this condition till towards the middle of February, when it should be turned over a second time, but in a cross direction, to nearly the same depths. In March a third ploughing may be given, in order to the putting in of the seed. This may be somewhat lighter than the preceding ones. As soon as the last ploughing has been given in March, the land should be harrowed, and the suriace made as fine as possible.

5447. *In Suffolk the farmers sow carrots after turnips, barley, and peas set upon a ryegrass ley; the crops upon the first have generally been most productive; next to that they prefer the latter.* In the first place, they feed off the turnips by the beginning of February, and then lay the land up in small balks or furrows, in which state it remains till the second week in March, when it is harrowed down, double furrowed to the depth of about twelve inches, and the seed sown.

5448. *The climate most suitable to the carrot is the same as for the turnip; but, from the depth to which their roots penetrate, they will thrive better than the turnip in a dry and warm climate.*

5449. *Manure, according to some, should not be given to carrots the year they are sown, as it is alleged that when the roots meet with it they become forked, scabbed, and wormy.* This, however, is chiefly applicable to cases in which recent unfermented manure has been given, or where other manure has not been properly broken in pieces and spread over the soil or in the drills. The Suffolk and Norfolk farmers, who are the best carrot-growers, always use dung; a suitable proportion of well rotted farmyard dung being constantly turned into the soil at the last ploughing in March: for it has been fully shown, by various trials detailed in *The Annals of Agriculture* and other books on husbandry, that though good crops of carrots may be occasionally grown without the use of manure, it is only by the liberal application of that substance that the greatest produce possible can be obtained; as they are in general found to bear a relative proportion to the quantity that may have been employed.

5450. *Burrows prepares the land with a good dressing of about sixteen cart-loads per acre of rotten farmyard manure or cottager's ashes: the load is about as much as three able horses can draw; and, if bought, costs about four shillings and sixpence per load, besides the carting on the land.* He usually sows

wheat stubbles after clover, ploughing the first time in autumn, and once more in the early part of the month of February, if the weather permits; setting on the manure at the time of sowing, which is about the last week in March, or sometimes as late as the second week in April.

5451. In *Suffolk*, when carrots are intended to be sown after peas, they usually plough the stubble as soon as the harvest is over, in order that the land may clear itself of weeds; in December it is laid up in small balks, to receive the benefit of the frosts; in February it is harrowed down, and manured at the rate of fifteen loads per acre; the manure is ploughed in to the depth of about four inches; and in the month of March the land is double furrowed, and the seed sown. By pursuing this method, they say, the manure lies in the centre of the soil, and not only affords nourishment and support to the carrot in its perpendicular progress, but renders it easy to be turned up by a single ploughing, and greatly promotes the growth of the succeeding crop of barley. In Norfolk it is the practice to sow carrots after a crop of turnips. The manure, after being put on the land in the beginning of March, is first ploughed in with a common plough, and afterwards trench-ploughed about fourteen or fifteen inches deep; it is then harrowed very fine, and the seed sown about the middle of March.

5452. The season preferred by Burrows for sowing the carrot is the last week in March or first in April; but he prefers the first period, having generally found early-sown crops the most productive.

5453. The usual preparation of the seed for sowing, is mixing it with earth or sand, to cause it to separate more freely; but Burrows adds water, turns over the mixture of seeds and moist earth several times, and thus brings it to the point of vegetating before he sows it. "Having weighed the quantity of seed to be sown, and collected sand or fine mould, in the proportion of about two bushels to an acre, I mix the seed with the sand or mould, eight or ten pounds to every two bushels, and this is done about a fortnight or three weeks before the time I intend sowing; taking care to have the heaps turned over every day, sprinkling the outside of them with water each time of turning over, that every part of the sand heaps may be equally moist, and that vegetation may take place alike throughout. I have great advantage in preparing the seed so long beforehand; it is by this means in a state of forward vegetation, therefore lies but a short time in the ground, and, by quickly appearing above ground, is more able to contend with those numerous tribes of weeds in the soil, whose seeds are of quicker vegetation." (*Supp. &c.*)

5454. Crude, the French translator of Von Thac's work, describes in a note (*tom. iv. 237.*) a practice nearly similar to that of Burrows. Crude uses *sciure* (night soil) instead of earth, and waters with the drainings of dunghills. He keeps the mixture in a warm but shady situation for eight days; by that time the seed is nearly ready to vegetate, and he sows it immediately.

5455. The quantity of seed when carrots are sown in rows is two pounds per acre, and for broad-cast sowing five pounds. Burrows sows ten pounds per acre in the broad-cast manner.

5456. The usual mode of sowing the carrot is broad-cast; but a much better mode in our opinion would be to sow them in rows at twelve or fourteen inches' distance; drawing the drills, and hoeing the intervals with any suitable drill and hoe.

5457. The most common practice, when carrots are best cultivated, is the hand or broad-cast method, the seed being dispersed as evenly as possible over the land, after the surface has been reduced to a very fine state of pulverisation by harrowing, in order to provide a suitable bed for it to vegetate in; being then covered in by means of a light harrow. As the seed of the carrot is not of a nature to be deposited with much regularity by the drill, and as the young plants can be easily set out to proper distances in the operation of hoeing, this is probably the most appropriate method of putting such sort of seed into the ground; and an additional proof of it is indeed found in its being that which is almost universally adopted in those districts where carrot-husbandry is practised to the greatest extent. But with the view of having the after-culture of the crops more perfectly performed, and at the same time to save the great expense of hand-labour in hoeing the crop, the drill method has been attempted by some cultivators, but we believe without complete success. The work is finished in equidistant rows at the distance of from twelve to fifteen or eighteen inches from each other, according to the mode of hoeing that is practised. In this business some cultivators do not make use of drill-machines, but strike the land into small furrows by hoes or other implements contrived for the purpose, and then cast the seed over the ground by the hand, covering it in either by slight harrowing, or hoeing in the tops of the ridgelets. It is added, that "in this method, where a drill-machine is used, it has been advised by an intelligent cultivator to deposit the seed to the depth of one inch in the rows, leaving the spaces of fourteen inches between them as intervals; the seed in these cases being previously steeped in rain-water for twenty-four hours, and left to sprout, after which it is mixed with saw-dust and dry mould, in the proportion of one peck and a half of each to a pound of the seed. The land is afterwards lightly harrowed over once. Two pounds of seed in this mode are found, as it has been observed, sufficient for an acre of land."

5458. The after-culture given the carrot consists entirely of hoeing and weeding.

5459. In *Suffolk* they are hoed generally three times in the season. The first time, as soon as the plants can be distinguished from the weeds which surround them. The operation should be performed with three-inch hoes, having handles not above two feet in length; and it requires great attention, as it is extremely difficult to distinguish and separate the young carrots from the weeds. The second hoeing should be given in three or four weeks afterwards, according to the forwardness of the crop; it may be performed with common hoes, care being taken to set out the plants at proper distances. From eight to fifteen or eighteen inches, each way, are the common distances at which they are allowed to stand; and it has been proved, from many years' experience in districts where they are most cultivated, that carrots which grow at such distances always proves a more abundant crop than when the plants are allowed to stand closer together. The third hoeing is commonly given about the middle or end of June; and in this, besides destroying the weeds, another material circumstance to be attended to, is, to set out the carrots at proper distances, and also, wherever any have been left double at the former hoeings, to take the worse of the two plants away.

5460. Carrots sown according to the plan of Burrows are ready to hoe within about five or six weeks. He hoes three and sometimes four times, or until the crop is perfectly clean; the first hoeing is with hoes four inches long, and two and a quarter inches wide. The second hoeing invariably takes place as soon as the first is completed, and is performed with six-inch hoes, by two and a quarter inches wide. By this time the plants are set; the first time of hoeing nothing was cut but the weeds. He leaves the plants nine inches apart from each other; sometimes they will be a foot, or even farther asunder.

5461. *Carrots are taken up* generally in the last week of October. Burrows's practice is to let the work to a man who engages women and children to assist him. The work is performed with three-pronged forks; the children cut off the tops, laying them and the roots in separate heaps, ready for the teams to take away.

5462. "*I take up in autumn* a sufficient quantity to have a store to last me out any considerable frost or snow that may happen in the winter months; the rest of the crop I leave in the ground, preferring them fresh out of the earth for both horses and bullocks. The carrots keep best in the ground, nor can the severest frosts do them any material injury; the first week in March it is necessary to have the remaining part of the crop taken up, and the land cleared for barley. The carrots can either be laid in a heap with a small quantity of straw over them, or they may be laid into some empty outhouse or barn, in heaps of many hundred bushels, provided they are put together dry. This latter circumstance it is indispensably necessary to attend to; for if laid together in large heaps when wet, they will certainly sustain much injury. When selecting such as I want to keep for the use of my horses until the months of May and June, in drawing over the heaps (which should be done in the latter end of April, when the carrots begin to sprout at the crown very fast) I throw aside the healthy and most perfect roots, and have their crowns cut completely off and laid by themselves; by this means, carrots may be kept the month of June out in a high state of perfection." (*Communications to the Board of Agriculture*, vol. vii. p. 72.)

5463. *Storing a whole crop of carrots* may be a desirable practice when winter wheat is to follow them, in which case the same mode may be adopted as for turnips or potatoes, but with fewer precautions against the frost, as the carrot, if perfectly dry, is very little injured by that description of weather.

5464. *The produce of an acre of carrots* in Suffolk, according to Arthur Young, is at an average 350 bushels; but Burrows's crops averaged upwards of 800 bushels per acre, which considerably exceeds the largest crop of potatoes.

5465. *The uses to which the carrot* is applied in Suffolk are various. Large quantities are sent to the London markets, and also given as food to different kinds of live stock. Horses are remarkably fond of carrots; and it is even said, that when oats and carrots are given together, the horses leave the oats and eat the carrots. The ordinary allowance is about forty or fifty pounds a day to each horse. Carrots when mixed with chaff, that is, cut straw, and a little hay, without corn, keep horses in excellent condition for performing all kinds of ordinary labour. The farmers begin to feed their horses with carrots in December, and continue to give them chiefly that kind of provender till the beginning or middle of May; to which period, with proper care, carrots may be preserved. As many of the farmers in that country are of opinion that carrots are not so good for horses in winter as in spring, they give only half the above allowance of carrots at first, and add a little corn for a few weeks after they begin to use carrots.

5466. *The application of the carrot to the feeding of working cattle and hogs* is thus detailed by Burrows:—"I begin to take up the carrot crop in the last week of October, as at that time I generally finish soiling my horses with lucern, and now solely depend upon my carrots, with a proper allowance of hay, as winter food for my horses, until about the first week of June following, when the lucern is again ready for soiling. By reducing this practice to a system, I have been enabled to feed ten cart-horses throughout the winter months for these last six years, without giving them any corn whatever, and have at the same time effected a considerable saving of hay, from what I found necessary to give to the same number of horses, when, according to the usual custom of the country, I fed my horses with corn and hay. I give them to my cart-horses in the proportion of seventy pounds' weight of carrots a horse per day, upon an average; I not allowing them quite so many in the very short days, and sometimes more than that quantity in the spring months, or to the amount of what I withheld in the short winter days. The men who tend the horses slice some of the carrots in the cut chaff or hay, and barn-door refuse; the rest of the carrots they give whole to the horses at night, with a small quantity of hay in their racks; and with this food my horses generally enjoy uninterrupted health. I mention this, as I believe that some persons think that carrots *only*, given as food to horses, are injurious to their constitutions; but most of the prejudices of mankind have no better foundation, and are taken up at random, or inherited from their grandfathers. So successful have I been with carrots, as a winter food for horses, that with the assistance of lucern for soiling in summer, I have been enabled to prove by experiments conducted under my own personal inspection, that an able Norfolk team-horse, fully worked two journeys a day, winter and summer, may be kept the entire year round upon the produce of only one statute acre of land. I have likewise applied carrots with great profit to the feeding of hogs in winter, and by that means have made my straw into a most excellent manure, without the aid of neat cattle; the hogs so fed are sold on Norwich hill to the London dealers as porkers." The profit of carrots so applied he shows in a subsequent statement, together with an experiment of feeding four Galloway bullocks with carrots, against four others fed in the common way with turnips and hay. (*Communications*, &c.)

5467. *In comparing the carrot with the potato*, an additional circumstance greatly in favour of the former is, that it does not require to be steamed or boiled, and it is not more difficult to wash than the potato. These and other circumstances considered, it appears to be the most valuable of all roots for working horses.

5468. *The use of the carrot in domestic economy* is well known. Their produce of nutritive matter, as ascertained by Sir H. Davy, amounts to ninety-eight parts in one thousand, of which three are starch, and ninety-five sugar. They are used in the dairy in winter and spring to give colour and flavour to butter. In the distillery, owing to the great proportion of sugar in their composition, they yield more spirit than the potato: the usual quantity is twelve gallons per ton. They are excellent in soups, stews, and haricots, and boiled whole with salt beef.

5469. *To save carrot seed*, select annually some of the most perfect and best-shaped roots in the taking-up season, and either preserve them in sand in a cellar till spring, or plant them immediately in an open airy part of the garden, protecting them with litter during severe frosts, or earthing them over, and uncovering them in March following. The seed is in no danger of being contaminated by any other plant, as the wild carrot, even should it happen to grow in the neighbourhood, flowers later. In August it will be fit to gather, and is best preserved on the stalks till wanted. This is the most

certain mode of procuring genuine and new seed, but still it will be found advisable to change it occasionally.

5470. *The diseases of carrots* are only those which are common to most plants, such as mildew, insects, &c. The mildew and worms at the root frequently injure crops, and are to be guarded against as far as practicable by a proper choice of soil, season of sowing, and after-culture.

SECT. IV. *The Parsnep.* — *Pastinaca sativa* L.; *Pentándria Digýnia* L., and *Umbellifera* J. *Le Panais*, Fr.; *Pastinake*, Ger.; *Pastinaca*, Ital.; and *Zanahoria*, Span.

5471. *The parsnep* is a biennial plant with a fusiform root like the carrot, and nearly equal in its products of nutritive and saccharine matter. It is a native of most parts of Europe and generally cultivated in gardens, but is only of late and very partial introduction as a field plant. Its culture has been chiefly confined to the Island of Jersey, where it attains a large size, and is much esteemed for fattening cattle and pigs. It is considered rather more hardy than the carrot, and its produce is said to be greater. It may be sown either in autumn or spring, and its seed admits of drilling by machinery. The plants when they come up are more easily recognised than carrots, and consequently their culture is on the whole more simple, less dependent on manual labour, and, therefore, more suited to farming. For the rest, their culture is the same as that of the carrot.

5472. *The variety* best suited for the field is the large Jersey, the seed of which should be procured from the island, as that of the garden parsnep sold by the seedsmen never attains the same size.

5473. *The soil, preparation, and manure* for this plant are the same as for the carrot.

5474. *The quantity of seed* for sowing in drills is from four to five pounds per acre, and for broad-cast six or eight pounds. It must always be new, as two years' seed does not come up freely. It may or may not be prepared by steeping; but it requires no earth or sand, or rubbing, like carrot seed, as it passes freely through the same drill that will sow tarps or peas.

5475. *The time of sowing* is generally about the middle of February; but some sow in September, in which case the seed does not vegetate till early in spring. The latter method, however, is obviously against the culture of the soil, which must thus remain a year in a consolidated state.

5476. *The manner of sowing* is generally in drills at fifteen or eighteen inches' distance; but some sow broad-cast, and harrow in the seed; and in Jersey parsneps and beans are generally cultivated together. The beans are first dibbled in, and afterwards the parsnep seed scattered over the surface and harrowed. It is acknowledged that a good crop of both plants is never obtained; and therefore, though this mode may be found to answer in the mild climate of Jersey, it is not to be imitated in other places. Drills and broad-cast without any intermixture of plants are the only advisable modes.

5477. *The after-culture and taking up* are the same as for the carrot, with this difference, that the parsnep when sown broad-cast is generally thinned out to twelve inches, at an average, plant from plant; and, when in rows eighteen inches apart, to nine inches in the row.

5478. *The produce* is said to be greater than that of carrots; and the economical application the same. In the fattening of cattle it is found equal if not superior, performing the business with as much expedition, and affording meat of exquisite flavour and a highly juicy quality. The animals eat it with much greediness. It is reckoned that thirty perches, where the crop is good, will be sufficient to fatten a perfectly lean ox of three or four years old, in the course of three months. They are given in the proportion of about thirty pounds' weight morning, noon, and night; the large ones being split in three or four pieces, and a little hay supplied in the intervals of those periods. Indeed, the result of experiment has shown that not only neat cattle, but hogs and poultry, become fat much sooner, and are more bulky, than when fed with any other root or vegetable; and that the meat is more sweet and delicate. The parsnep is excellent food for cows; and, with hay during winter, the cows of Jersey and Guernsey yield butter of a fine yellow hue, of a saffron tinge, as excellent as if they had been in the most luxuriant pasture. In these islands beans are cultivated along with parsneps, in double rows, twelve feet asunder, and the beans eighteen inches apart every way. The beans are planted first, and the ground afterwards harrowed, and the parsneps sown broad-cast. (*Com. to B. of Agr.* vol. i. p. 215.)

5479. *Parsnep leaves*, being more bulky than those of carrots, may be mown off before taking up the roots, and given to cows, oxen, or horses, by which they will be greedily eaten.

5480. *The use of the parsnep in domestic economy* is nearly the same as that of the carrot. They are much esteemed to salt fish, and are sometimes roasted for that purpose.

Their produce in nutritive matter is 99 parts in 1000, of which 9 are mucilage and 90 sugar. Gerarde says, that a very good bread was made from them in his time. They afford as much spirit as the carrot, and make an excellent wine.

5481. *To save parsnep seed*, proceed as with the carrot. The parsnep, being more hardy and luxuriant than the carrot, is less liable to the mildew and worms, but equally so to become forked if the soil be not deep and well pulverised, and the manure minutely divided and equally distributed.

SECT. V. *The Field Beet*. — *Bêta L.*; *Pentândria Digÿnia L.*, and *Chenopôdœa J. Betterave Champêtre, Fr.*; *Mangold-würzel, Ger.*; *Bieltola, Ital.*; and *Betarraga, Span.*

5482. *The field-beet*, commonly called the mangold-würzel, and sometimes erroneously the root of scarcity (in German *mangel würzel*), is supposed by Professor Thaer to be a mongrel between the red and white beet. It has a much larger bulb than either, and that bulb, in some varieties, grows in great part above ground. It has been a good deal cultivated in Germany and Switzerland, both for its leaves and roots; the leaves are either used as spinach or given to cattle; and the roots are either given to cattle, used in distillation, or in the manufacture of sugar. The culture of the field-beet in Britain is very recent, and it may be questioned whether it has any advantages over the turnip for general agricultural purposes. It admits, however, of being cultivated on ridgelets and with as little manual labour as the turnip, while it will prosper on a stronger soil, and near large towns it is not liable to the depredations usually committed on turnips or carrots, as the root is unpalatable either raw or boiled.

5483. *The variety preferred in Germany* is one slightly tinged with red for cattle, and the pale yellow variety for the distillery and sugar manufacture. The seed must not exceed a year old, and great care should be taken that the seed of the common red and white beet are not mixed with it. The seed of every variety of beet is very apt to degerate.

5484. *Any soil* will suit this plant provided it is rich: immense crops have been raised on strong clays; but such soils are not easily prepared for this sort of crop, and are also ill adapted for after-culture.

5485. *The preparation* should be exactly the same as for turnips; and the seed should be sown on the ridgelets in the same manner. Some, however, dibble in the seed in order to save the expense of thinning. The season of sowing is the same as for the parsnep, and should not be deferred later than the middle of April. The after culture consists in horse-hoeing, hand-hoeing, and weeding, as in the culture of the turnip, and the plants are thinned out to about the same distance in the rows. Blanks may be filled up by transplanting, or, as in the case of the Swedish turnip, whole crops may be reared in this way; but the produce is never so large. As the transplanting, however, takes place in May, more time is afforded, and drier weather obtained for cleaning the soil. The plants are set by the dibbler along the centre of the ridgelets, which are previously consolidated by rolling.

5486. *The produce is, cæteris paribus*, about the same as that of the Swedish turnip; but the nutritive matter afforded by the beet is 136 parts in 1000, of which 13 are mucilage, 119 sugar, and 4 gluten. According to Von Thaer, they afford ten per cent. of nutritive matter, and are in that respect to hay as 10 to 46, and to potatoes as 20 to 46. An acre would thus appear to afford more nourishment than turnips, carrots, or parsneps.

5487. *Practical men* are not agreed as to the value of this root, compared with the Swedish turnip; but the majority seem to think, that as a food for milk cows, the mangold is to be preferred, more especially as it gives no unpleasant taste to the milk and butter. It has this advantage over turnips, that it thrives better than they do in a dry warm season, being a plant that naturally requires more light and heat than the turnip.

5488. *The application of the field-beet* is almost confined to the fattening of stock, and feeding of milch cows. Near London they are in repute for the latter purpose; and, according to Von Thaer, they cause a great increase of milk, as well as improve its flavour. The tops are first taken off, and given by themselves; and then the roots are taken up, washed, and given raw. The roots are much more easily injured by frost than the turnip, carrot, or parsnep, and are stored with difficulty. The leaves make a very good spinach, but the roots cannot be used in cooking like those of the red beet. In the distillery it is nearly half as productive as the potato; but, according to Von Thaer, it is not likely to yield much profit in the manufacture of sugar.

5489. *The manufacture of sugar from mangold würzel* is still, however, carried on in France, and, although we think it can never ultimately compete with that from the cane, it seems of late years to be on the increase. We shall therefore give a short account of the process, premising that the greatest quantity of sugar is not obtained from the greatest bulk of root, but rather from small roots produced from dry calcareous soils, at the rate of from fifteen to twenty-five tons an acre. One cwt. of sugar is the general produce obtained by the most perfect apparatus from one ton of root. As soon as the leaves begin to turn yellow, the root may be said to have arrived at maturity; and it is time to take up the crop, and to begin the process of sugar-making, an operation which continues from October to February in the larger manufactories. Take the roots up dry, and keep them so; the smaller the heap the better, because the least fermentation will effectually prevent the formation of sugar. The difference in amount and quality of sugar is always in favour of that made at the beginning of the season. The root, in keeping, undergoes a chemical change, often amounting to a total loss of its saccharine matter; although its outward appearance indicates no such change.

5490. *Process of sugar-making*. The roots should first be washed, and then rasped, to reduce them to a state of pulp. Of course, in large manufactories, they are provided with rasping machines; and it is

somewhat difficult to find a substitute on a small scale. I should imagine, though, that a stout iron plate, punched with triangular holes, the rough edges of which are left standing, somewhat after the manner of a nutmeg-grater, might answer the purpose, only that I would have it somewhat concave instead of convex. Upon the rough side of this plate I would rub the roots by hand. If there should be a cider-mill and press within a reasonable distance, it might answer to take the roots thither, slice them, and pass them through the mill. When by these or any other means they are reduced to pulp, the juice should be pressed from the pulp, which is thus done:—It is put into canvass bags, not too fine, so as to impede the running of the juice, nor yet so coarse as to let the pulp through the meshes. The bags should be so fitted as, when pressed, to occupy about an inch in depth. Most manufactories use about twenty-five of these bags at one pressing, but this depends on the power of the press. Between every bag of pulp is laid a sort of osier hurdle, to allow the juice to percolate freely from the press into the juice-cistern below. The operation of pressing should immediately follow that of rasping. This point should be particularly attended to.

5491. *Defecation.* The juice being expressed from the pulp, the next process is the defecation of the juice, and here, too, no time should be lost. This is effected by boiling: a copper boiler should be used. Get up the fire till the thermometer indicates 170° or 178°. Then add sifted lime (quick) previously mixed with water, at the rate of five or six pounds for every 100 gallons of juice. Stir it well up, and skim the liquor. Heat it till the thermometer reaches 200°. Add sulphuric acid in small portions, diluted with six times its bulk of water, to neutralise the effect of the lime, stirring it briskly each time. The proper quantity is ascertained by carefully examining the juice every time the acid is added, with a drop of syrup of violets in a spoon, which ought to turn of a green colour. About thirty ounces of the acid to every 100 gallons of juice will be necessary. This done, the fire is quenched, and the boiler left to settle for half an hour; at the end of which time, the liquor is drawn off: by some, bullock's blood is added when the temperature of the juice reaches 190° in the proportion of two pints and a half to every twenty gallons of juice. Some, too, apply the sulphuric acid to the juice when cold, instead of hot, viz. before the boiler-fire is lighted; and one recommends its being applied to the pulp before it goes into the boiler: but all this practice will decide.

5492. *Concentration.* The next process is concentration of the juice, which means nothing more than evaporating from it the water therein contained. This is effected by flat pans, over a brisk fire, but not so as to burn the syrup, which is the great danger in this operation. When reduced in pan 1 from 4 to 2 inches or so in depth, it is put into a smaller pan (2), and reduced to the same depth, and afterwards into a third pan. These three removals are the work of an hour and a half. If the syrup rises, and threatens to overflow the pan, put in a small lump of butter, which will make it subside.

5493. *Clarification.* This the next operation, and may be carried on in one of the pans used for concentration. Animal charcoal (some have even used wood charcoal) is now applied, at the rate of half a pound for every gallon of syrup, which renders it perfectly black and muddy. In this state, add blood mixed with water (stirred up well with the syrup), in the proportion of about a pint and a half of blood to every twenty gallons of syrup.

5494. *Boil it a short time*, after which it is filtered, and then boiled again, care being taken not to burn the pan. Great care is necessary in examining the state of the syrup from time to time. The thermometer ought to stand as high as 234°; on attaining which, the pan should be emptied: eighteen gallons of syrup will be reduced, by boiling, to eleven gallons. The syrup is next cooled in a suitable vessel to 182° or 190°, and then run into moulds; but the cooling is very gradual. The pan is covered, and the heat kept in by closing the edges with flannel. The syrup is then poured into large earthen moulds cone-shaped, and with a hole at bottom, through which the molasses drains. This hole is temporarily stopped till the mould is full. A mould contains ten or twelve gallons, and requires a month to purge itself. As it cools, it crystalises. The syrup, whilst filling, is at 67° to 77°; but, in the course of purging, it is raised to 120° and even 145°, which expedites the flow of the molasses. Our next process is *turning the moulds*, i. e. setting the cones on their bases, and taking them out of the moulds. The point of the cone is moist and syrupy: this is cut off, and boiled over again with the molasses. Thus far the process of making brown sugar: refining is a different business, and one which there is no occasion to particularise here. It is to be observed, that copper utensils are preferred to those of iron, the latter having a chemical effect on the sugar. (*Gard. Mag.* vol. vi. pp. 150, 151.)

5495. *To save seed*, select the finest specimens, preserve them in sand during winter, and plant them in an airy part of the garden in March. The rest is easy.

5496. *To diseases* no plant is less liable than the beet.

SECT. VI. *The Cabbage Tribe.*—*Brássica L.*; *Tetradynàmia Siliquòsa L.*, and *Cru-cifera J.* *Chou*, Fr.; *Kohl*, Ger.; *Cavolo*, Ital.; and *Col*, Span.

5497. *The cabbage tribe* is of the greatest antiquity in gardens, and most of the species may be cultivated in the fields with success. For the common purposes of farming, however, there can be little doubt that they will afford less profit than any of the plants hitherto treated of in this chapter; but near large towns or sea-ports they may answer the purpose of the farm-gardener. Cabbage culture, Brown observes, is much more hazardous, far less profitable, and attended with infinitely more trouble, than that of turnips; while the advantages to be derived are not, in our opinion, of a description to compensate the extra hazard and trouble thereby incurred.

5498. *The culture of cabbage* has been strongly recommended by several speculative agriculturists, and examples adduced of extraordinary produce and profits; but any plant treated in an extraordinary manner will give extraordinary results; and thus an inferior production may be made to appear more valuable than it really is. One reason why so much has been said in their favour, by Arthur Young and other southern farmers, is, that they compare them with the produce of turnips, which, in the south of England, is averaged at only fifteen tons per acre.

5499. *The variety of cabbage*, cultivated in the fields for cattle, is almost exclusively the large field cabbage, called also the Scotch, Strasburg, drumhead, &c. For the purposes of domestic economy, other varieties of early and late cabbage, as the York, Battersea, sugar-loaf, imperial, &c. are grown; and also German greens, Savoy cabbage, and even Brussels sprouts and broccoli.

5500. *The cow cabbage*, *Cesarean cole*, or *tree cabbage* (*Brássica olerácea L.* var. *acéphala Dec.*; *Chou cavalier*, *Chou à vaches*, *Chou branchu*, *Chou en arbre*, *Chou mille têtes*, Fr.; *Cautet*, Flem.), is much cul-

tivated for milch cows in French Flanders, the Netherlands, and in Jersey and Guernsey; and it has been introduced, at different periods, into this country, without having ever come into general cultivation. The *Chou caulet de Flandre* differs from the French variety in having red leaves; and the *Chou vert branclu*, the *Chou mille têtes du Poiteau*, differs from the first in not growing quite so high, and in forming a somewhat tufted head. No variety among these, and the many that might be named, appears so suitable for field culture in the climate of Britain as the Scotch or drumhead cabbage.

5501. In Jersey the cow cabbage is sown from about the 20th of August to the 1st of September, in a good soil, and planted out from November to January and February in succession, at from twenty to thirty inches' distance, in a good, substantial, well manured soil; as no plant is more exhausting, or requires a better soil; but perhaps no one plant produces so large a quantity of nutriment during its period of vegetation. About the month of April they begin (from the first crop) to strip the under leaves; cut them in small pieces; mix them with sour milk and bran, or other farinaceous substances; and give them as food to ducks, geese, hogs, &c. During the whole summer they continue stripping the plant as above stated, until it attains the height of from six to twelve feet; and it scarcity of herbage prevails, the green leaves form excellent food for cows and oxen, with alternate feeds of hay and straw. The tops and side shoots are excellent at table during winter and spring. The longest of the stalks are frequently used to support scarlet runners and other French beans, and as cross rafters for farm buildings, under thatch, and have been known to last more than half a century, when kept dry, for the latter purpose. (*Gard. Mag.* vol. v.)

5502. Any soil that is rich will suit the cabbage, but a strong loam is preferred. The best mode of preparation for field cabbage is that for potatoes or turnips, the plants being dibbled along the centre of each ridgelet. For early cabbage no ridgelets are required, as the plants are inserted in rows, by a line, at much narrower distances.

5503. The season for planting, for a full crop of field cabbages, is usually March; but cabbages may be planted as late as June, and produce a tolerable crop by November; and in this way they may sometimes be made to succeed an unsuccessful sowing of turnips. The plants used in March should be the produce of seed sown, in an open loamy part of the garden, in the preceding August; but those planted in May or June may be the produce of seed sown in the February or March of the same year.

5504. The preparation given to the plants consists in pinching off the extremity of their tap-root, and any tubercles which appear on the root or stem, and in immersing the root and stem in a puddle, or mixture of earth and water, to protect the fibres and pores of the root and stem from the drought. The plants may then be inserted by the dibber, taking care not to plant them too deep, and to press the earth firmly to the lower extremity of the root. If this last point is not attended to in planting by the dibber, the plants will either die, or, if kept alive by the moisture of the soil or rain, their progress will be very slow. When the distance between the ridgelets is twenty-seven inches, the plants are set about two feet asunder in the rows; and the quantity required for an acre is about 6000 plants. Some recommend sowing as for turnips; but, by this mode, one of the advantages of a green crop is infringed on, viz. the time given to clean the land. Where cabbages are sown, that operation must be performed at least a month sooner than if they were planted; consequently, the best month of the cleaning season is lost. To plant or sow a green crop on land in good heart, that does not require cleaning, will seldom be found good husbandry. It may succeed near large towns, where roots and other green produce sell high, but it can never enter into any general system of farming.

5505. The after-culture consists in horse and hand-hoeing and weeding; and the crop is taken by chopping off the heads with a spade, leaving an inch or two of stalk to each. They may be preserved by housing, but only for a short time. The produce is said to be from thirty-five to forty tons per acre. Sir H. Davy found that 1000 parts of cabbage gave seventy-three of nutritive matter, of which forty-one are mucilage, twenty-four saccharine matter, and eight gluten.

5506. The application of the field cabbage is generally to the feeding of milch cows, and sometimes to the fattening of oxen and sheep. For the former purpose, great care must be taken to remove the outside decaying leaves; otherwise they are apt to give an unpleasant flavour to the milk and butter. Cabbages are also eaten by swine and horses, and are reckoned excellent food for sheep that have newly dropped their lambs, and for calves. A cow will eat from 100 to 150lbs. of cabbage per day, and a sheep ten or twelve pounds, besides a moderate allowance of hay. Some farmers consider that ewes fatten faster on cabbages than on turnips, and that ewes having lambs are much more prolific in milk when so fed. (*Country Times*, Feb. 8. p. 47.) Early or garden cabbages are sold to green-grocers, or to the consumers, or to ships' victuallers for the purpose of being pickled or made into sour crouit.

5507. Salted cabbage, or sauerkraut, is thus prepared in Germany:—Any sort of cabbage or kail, or even turnips and kidneybeans, may be prepared in this way; but white, compact-headed, large cabbages are preferred, and next compact-headed red cabbages. The first process of preparing them is to scoop out the interior part of the stalk, with an iron instrument or scoop; they are then cut into small shreds by a wooden machine, composed of a flat board or tray, which has a ledge on two sides, to steady a box or frame into which the cabbages are put. In the middle of the board are four flat pieces of steel, similar to the steel part of a spokeshave, placed in an oblique direction; and the near edge of each being a little raised up, with small spaces between each, to let the shreds fall down into a tub placed underneath to receive them. The cabbages are then put into the box before described, which is pushed backwards and forwards, when the cabbages, being cut by the steel, fall in small shreds into a tub placed below. A barrel stands by ready to receive them when cut, the sides of which are first washed with vinegar. A man stands on a chair by the barrel, with cleau wooden shoes on, whose business it is to salt and prepare them, which is done in the following manner: the man first takes as much of the cut cabbage as covers about four inches above the bottom; he next stréws upon it two handfuls of salt, one handful of unground pepper, and a small quantity of salad oil; he then gets into the barrel, and treads it down with his wooden shoes till it is well mixed and compact. He next takes another layer of cabbage, and puts salt and pepper on it as before, and treads it again, and so goes on till the barrel is filled. A board is then placed on it, and upon the board some very heavy weights are put; and it remains so ten or fifteen days, when it partially ferments, and a great deal of water swims on the surface: it is then put into the cellar for use. The men

who prepare sauerkraut are Tyrolese, and carry their machine (fig. 767), which has not been invented more than ten or twelve years, on their backs from house to house. This machine contains a cutting tray (a), box into which the cabbages are placed (b), scoop (c), and tub into which the shreds fall (d). (*Gard. Mag.* vol. iii. p. 343.)

5508. Newton's machine for chopping cabbage or other vegetables, roots, or meat (fig. 768), consists of

is screwed to the working bar. The knives are fastened, by bolts passing through them, close under and above the iron plate. The sliding plate is for the purpose of preventing the meat from being scattered; and to this plate are added scrapers, which are screwed underneath, for the purpose of cleaning the knives at every stroke. A spring raises the knives, and enables any person to chop at least twenty times as much meat, in the same time, as can be done by the common mode. The length of the knives being equal to the breadth of the trough, no meat can possibly escape the knives; nor will the meat require so much turning as is usually wanted. When it does require turning, it is easily done by alternately pressing the knives at either end of the trough, sliding them towards the middle. The machine is also applicable for cutting fat, suet, &c. previously to rendering them into tallow; likewise for chopping madder and other roots for calico printers, or as used in their recent state for dyers; and for dividing potatoes, carrots, and other esculent roots, cabbage for sauer kraut, and

roots used in feeding cattle. (*Smith's Mechanic*, vol. ii. p. 360.)

5509. To save cabbage seed, select a few fine specimens, and plant them by themselves where they will be in no danger of being contaminated by others of the *Brássica* tribe when in flower. The seed will keep many years.

5510. The diseases of cabbages are the same as those of the turnip, with the exception of the forked excrescence. On the roots of the plants are frequently found knobs, which, in the preparation for transplanting, should, as we have already observed, be carefully removed.

SECT. VII. *Other Plants which might be cultivated in the Fields for their Roots or Leaves, as Food for Man or Cattle, in a recent State.*

5511. Every hardy garden plant may be cultivated in the fields, and with very little manual labour. Accordingly we find onions, spinach, cress, radishes, and even cucumbers, grown by farmers, or farm gardeners in the neighbourhood of the metropolis, and also in other places. None of these plants, however, can be considered as belonging to agriculture; nor should we notice those which follow, but because they have been tried and recommended by zealous cultivators, and are treated of in some works on farming. No plant can be considered as belonging to agriculture that is not in sufficient demand, or of sufficient general use in feeding stock, as to admit of its frequent occurrence in rotations; and such certainly cannot be said to be the case with the Jerusalem artichoke and lettuce, now about to be noticed.

5512. The Jerusalem artichoke (*Helianthus tuberosus* L.; *Topinambour*, Fr.) is a tuberous-rooted plant, with leafy stems from four to six feet high. It thrives well on soft moist soils, and even, it is said, on moist peat soils; and it is alleged that its tops will afford as much fodder per acre as a crop of oats, or more, and its roots half as many tubers as an ordinary crop of potatoes. (*Agricultural Magazine*, 1807-8.) The soil may be cultivated in all respects like the potato. The tubers, being abundant in the market gardens, are to be had at little more than the price of potatoes. The fibres of the stems may be separated by maceration, and manufactured into cordage or cloth; and this is said to be done in some parts of the north and west of France, as about Hagenuau, where this plant, on the poor sandy soils, is an object of field culture.

5513. *The common Cos lettuce* (*Lactuca sativa L.*) has been grown for feeding pigs, and other purposes. Arthur Young informs us, in his *Calendar of Husbandry*, that he first observed the sowing of lettuces for hogs practised, on a pretty regular system, on the farm of a very intelligent cultivator (not at all a whimsical man) in Sussex. He had every year an acre or two, which afforded a great quantity of very valuable food for his sows and pigs. He adds, that it yields milk amply, and all sorts of swine are very fond of it; and he thinks that the economical farmer who keeps many hogs should take care to have a succession of crops for these animals, that his carts may not be for ever on the road for purchased grains, or his granary opened for corn oftener than is necessary. To raise this sort of crop, the land should have been ploughed before the winter frosts, turning in by that earth twenty loads of rich dung per acre, and making the ridges of the right breadth to suit the drill-machine and horse-hoes, so that in the month of March nothing more may be necessary than to scarify the land, and to drill the seed at one foot equidistant, at the rate of four pounds of seed per acre. Where the stock of swine is large, it is proper to drill half an acre or an acre of lettuce in April, the land having been well manured and ploughed as directed above, being also suffled in February and March, and well harrowed, repeating it before drilling: and at this period, the crop which was drilled in March (a succession being essentially necessary) should be thinned in the rows by hand, to about nine or ten inches asunder. If this necessary attention be neglected, the plants, he says, draw themselves up weak and poor, and will not recover it. Women do this business as well as men. When about six inches high, they should be horse-hoed with a scarifier or scuffier, having the hoe about four inches, or at most five inches in width. With this sort of green food, some kind of meal or other dry meat should be combined, as without it is apt to prove very laxative, &c. This Sussex cultivator is not likely to be followed by any rent-paying farmer who can grow any of the clovers, turnips, or potatoes. The quotation affords a good specimen of Arthur Young's mode of writing on agricultural subjects.

5514. *The chicory, wild endive, or succory* (*Cichorium Intybus L.*; *Chicorée sauvage*, Fr. fig. 769.) has long, thick, perpendicular roots, a tuft of endive or lettuce-looking leaves; and, when it shoots into flower, its stems rise from one to three feet high, rigid, rough, branched, and clothed with leaves and blue flowers. It is found wild in dry calcareous soils in England, and in most parts of Europe of similar or greater temperature. It is cultivated in France as an herbage and pasturage plant, and in Germany and Flanders for its roots, from which a substitute for coffee is prepared. It was first cultivated in this country, about 1780, by Arthur Young, who holds it in very high estimation. It is of such consequence, he says, for different purposes of the farm, that on various sorts of soil the farmer cannot, without its use, make the greatest possible profit. Where it is intended to lay a field to grass for three, four, or six years, in order to rest the land, or to increase the quantity of sheep food, there cannot, he thinks, be any hesitation in using it. There is no plant to rival it. Lucern, he says, demands a rich soil, and will always be kept as long as it is productive; but upon inferior land it is not an equal object. Upon blowing sands, or upon any soil that is weak and poor, and wants rest, there is no plant, he supposes, that equals this. On such sort of blowing poor sandy lands as many districts abound with, especially in Norfolk and Suffolk, it will yield a greater quantity of sheep food than any other plant at present in cultivation. On fen and bog lands, and peat soils, it also thrives to much profit. On all land where clover, from having been too often repeated, is apt to fail, chicory may be substituted to great advantage. It does very well for soiling cattle, both lean and fattening. It is of excellent use for those who keep a large stock of swine; and it does exceedingly well in an alternate system of grass and tillage, as it will last four, five, six, and even more years; but it should

not be sown with any view of making hay in this climate, though it forms a considerable proportion of many of the best meadows in the south of France, and in Lombardy. It has, however, he adds, been objected to, on the ground of its rising and becoming a vivacious weed in succeeding crops; and if this circumstance be not guarded against, it will, he says, happen; but not more than with lucern, nor so much. But who, he asks, ventures to forbid chicory culture on account of this quality, which is really founded on its merit? When the land is ploughed, says he, only use a broad sharp share, and harrow in tares for feeding or soiling, or break it up for turnips, and there is an end of the objection.

5515. *The culture of chicory is the same as of clover.* As the plant is grown in gardens for culinary purposes, the seed may be procured in the seed-shops, gathered in many places from wild plants, or saved by the grower. It is small, flat, black, and resembling that of lettuce; it should be procured fresh; and from eight to twelve pounds an acre are usually sown. The culture of this plant for its roots has been noticed in giving the outline of the agriculture of Flanders, and will be adverted to in a succeeding Chapter.

5516. *The rough comfrey*, (*Symphytum asperrimum L.* fig. 770.), a perennial from Siberia, has been

brought into notice by D. Grant, a nurseryman at Lewisham, and tried by a number of cultivators. Cattle of every kind are said to be fond of this plant; and so great is its produce on good soil, that Mr. Grant thinks an acre might be made to produce thirty tons of green fodder in one year. He has grown it to the height of seven feet as thick as it could stand on the ground. The plant is of easy propagation by seed or division of the roots; the better way would probably be to sow in a garden, and transplant when the plants were a year old. All the symphytums are plants of

great durability, so that this species, if once established, would probably continue to produce crops for many years; and, in that point of view, it would seem to be a valuable plant for the cottager who keeps a cow. (*Gard. Mag.* vol. v. and *Country Times*, May 10th, 1830.)

5517. *The day lily* (*Hemerocallis fulva L.*, fig. 771.) was brought into notice by Mr. Elles, late of Longleat. In the years 1826-7, he observed, accidentally, how extremely fond cattle were of this plant, even eating it down to the roots when an opportunity occurred; and as he knew, from long experience, that it would, even in dry ground, produce herbage in the middle and latter end of

April, equal in quantity to any water meadow, the extreme facility with which it may be propagated and grown in almost any soil and situation, and also its apparently nutritious nature, he was induced to give it a trial in a plot of ground of about twenty rods, attached to the cottage in which he lived. He did so, and after two years' trial found the day lily produce a supply of green food in April and towards the middle of May, when there is little or no pasture grass, and never could detect any unpleasant flavour in the milk or butter, though given in considerable quantities. The day lily, of which there are two species, differing very little in appearance, *H. flava* and *fúlva*, is a perennial of great duration, rapid increase, and of easy propagation by division. It certainly well deserves trial as a permanent herbage plant, especially for the cottager and small farmer. (*Gard. Mag.* vol. v. p. 441.)

CHAP. V.

Culture of Herbage Plants.

5518. *The cultivation of clovers and other herbage plants*, used exclusively as food for live stock, is comparatively a modern improvement. They were known, as we have seen, to the Greeks and Romans, and cultivated from a very early period in the low countries; but do not appear to have attracted much notice in Britain till the sixteenth century, when our frequent intercourse with Holland led to the introduction of some of our best field plants and agricultural practices. At present clovers enter largely into the succession of crops, on all soils, and in every productive course of management. Before they were introduced into cultivation, it was necessary, when land was exhausted by grain crops, to leave it in a state of comparative sterility for several years, before it became either valuable as pasture or again fit for carrying corn: but at present clovers are not only indispensable in the cultivation of white and green crops alternately, upon very rich soils, but are the foundation of convertible husbandry on land that is not so rich as to permit of a constant aration, and which therefore requires two or more years' pasturage at certain intervals. Lucern and saintfoin, though of much less value as general crops, are valuable plants in particular situations; more especially the latter, which will produce good crops on dry chalky and limestone soils, where most other agricultural plants, and even grasses, would barely maintain their existence.

5519. *The characteristic points of culture* of this class of plants are broad-cast sowing, mowing, soiling, and hay-making; and that when cut for the two last purposes, two or more crops may be had in a season from the same roots.

5520. *The nutritive products* of the principal herbage plants are thus given by Sir H. Davy:—

Systematic Name.	English Name.	In 1000 Parts.				
		Whole quantity of soluble or nutritive matter.	Mucilage, or starch.	Saccharine matter, or sugar.	Gluten, or albumen.	Extract, or matter rendered insoluble during evaporation.
<i>Trifolium pratense</i> -	Red clover -	39	31	3	2	3
<i>medium</i> -	Cow clover -	39	30	4	3	2
<i>repens</i> -	White clover -	32	29	1	3	5
<i>Hedysarum Onobrychis</i> -	Saintfoin -	39	28	2	3	6
<i>Medicago sativa</i> -	Lucern -	23	18	1	—	4

SECT. I. *The Clover Family.*—*Trifolium* L.; *Diadelphía Decándria* L., and *Leguminosæ* J. *Trèfle*, Fr.; *Klee*, Ger.; *Trifoglio*, Ital.; and *Trebol*, Span.

5521. *The clovers* (fig. 772.) are a numerous family, chiefly natives of Europe: those selected by the agriculturist are natives of Britain; and one species, the white or creeping clover, is often found in great luxuriance in native pastures. As rye-grass is very generally sown with clovers, it will be necessary to treat of its culture in connection with these plants, reserving, however, the more particular consideration of rye-grass till we treat of the hay grasses. (Chap. VI.) Many intelligent cultivators consider rye-grass as a very severe crop for the soil; and it is alleged that wheat does not succeed well after the herbage with which rye-grass is intermixed in any considerable quantity. Other plants have accordingly been recommended as a substitute for rye-grass, and cock's-foot (*Dáctylis glomerata*) has been tried, apparently with great success, by Coke of Holkham in Norfolk, and others; but this is a very coarse grass when allowed to rise to any height, and the use of it for hay has not yet been ascertained. Donaldson considers the general introduction of clovers, and the cultivated grasses, as one of the greatest improvements in modern husbandry. The commencement of improvements in the different species of live-stock, in the modes of cultivation, and in the superior quality, as well as quantity, of the crops of grain, may all, he thinks, be dated from the period when the sowing of clovers and grass-seeds was first introduced into the different districts of the kingdom.

5522. The species of clover in cultivation are:—

5523. The red clover (*Trifolium pratense*, fig. 772. a), a biennial, and sometimes, especially on chalky soils, a triennial plant, known from the other species by its broad leaves, luxuriant growth, and reddish purple flowers. In its wild state a perennial.

5524. The white, or creeping, or Dutch clover (*T. repens*, b), a perennial plant, known by its creeping stems and white flowers.

5525. The yellow clover, hop-trefoil, or shamrock clover, the black nonsuch of the Norfolk farmers (*T. procumbens*, c), an annual, known by its procumbent shoots and yellow flowers. This species is seldom cultivated; the yellow clover of the seed shops being the *Medicago lupulina*, the lupuline, or *minette dorée* of the French. (fig. 773.)

5526. The meadow clover, cow-clover, cow-grass, or marl-grass, the first the best name (*T. medium*, d), a perennial, resembling the red clover, but of a paler hue, dwarfer habit, with pale red or whitish flowers, and long roots very sweet to the taste. This species is but partially cultivated, and it is extremely difficult to procure the seeds genuine. It comes into flower from twelve to fifteen days later than the common red clover, has a solid stalk, a narrower leaf, and both leaves and flowers have a paler hue. A poor sandy soil, it is said, will produce a good crop of cow-clover that would not produce half a crop of the common red clover; it is also as good the second year as the first. Some farmers sow it because the crop comes in between the first and second cutting of the red clover as green food.

5527. The flesh-coloured clover (*Trifolium incarnatum* Lin.; *Farouche* or *Trefle de Roussillon*, Fr. fig. 774.) has long been cultivated in some of the southern departments of France, and, though an annual, is found very advantageous on dry sandy soils. The Agricultural Society of Nancy have lately recommended it for culture in the province of Lorraine; and a writer in the *Journal des Pays-Bas*, as suitable to many parts of the Netherlands. M. de Dombasle, a theoretical and practical agriculturist in great estimation, sows it, after harvest, in the stubbles, with no other culture than harrowing in. It grows all the winter, and early in spring affords abundant food for sheep; or, if left till May, it presents a heavy crop for the scythe, and may be used for soiling, or making into hay. (*Gard. Mag.* vol. iv. p. 392. and vol. v. p. 734.) It was introduced into England about the year 1824, by Mr. John Ellman, jun. of Southover, near Lewis, who gives directions for sowing it in March without a corn crop, and states that it will be in full bloom and fit to cut by June. He says it is very productive; but should not be sown with corns like other clovers, because it grows so fast as to choke them. (*Farm. Jour.* March 17. 1828.)

5528. *Trifolium Molinèi filiforme* (with yellow flowers), *campêtre* (also with yellow flowers), and *fragiferum*, are cultivated in France; but we believe chiefly on the poorer soils. Seeds of them and of all the other species may be correctly obtained from Vilmorin, Andrieux and Co., seed merchants in Paris.

5529. In the choice of sorts the red or broad clover is the kind most generally cultivated on land that carries corn and herbage crops alternately, as it yields the largest produce for one crop of all the sorts. White and yellow clover are seldom sown with it, unless when several years' pasturage is intended.

5530. The soil best adapted for clover is a deep sandy loam, which is favourable to its long tap-roots: but it will grow in any soil, provided it be dry. So congenial is calcareous matters to clovers, that the mere strewing of lime on some soils will call into action clover-seeds, which it would appear have lain dormant for ages. At least this appears the most obvious way of accounting for the well known appearance of white clover in such cases.

5531. The climate most suitable for the clovers is one neither very hot nor very dry and cold. Most leguminous plants delight both in a dry soil and climate, and warm

temperature, and the clover will be found to produce most seed under such circumstances; but as the production of seed is only in some situations an object of the farmer's attention, a season rather moist, provided it be warm, is always attended by the most bulky crops of clover herbage.

5532. *The preparation of the soil and the manures*, which clover receives in ordinary farm culture, are those destined also for another crop; clover mixed with a certain proportion of rye-grass being generally sown along with or among corn crops, and especially with spring-sown wheat, barley, and the early varieties of oats. Unless, however, the soils on which these crops are sown are well pulverised, and have been some years under tillage, clovers will not succeed in them, it being ascertained that newly broken-up leys or pasture grounds cannot be sown down or restored to clover and grasses till the soil is thoroughly comminuted, and the roots of the former grasses and herbage plants completely destroyed.

5533. *The time of sowing* clover-seeds is generally the spring, during the corn seed time, or from February to May; but they may also be sown from August to October, and when they are sown by themselves, that is, unaccompanied by any corn crop, this will be found the best season, as the young plants are less liable to be dried up and impeded in their progress by the sun, than when sown alone in spring and remaining tender and unshaded during the hot and dry weather of July.

5534. *Some prepare the seed* for sowing by steeping in water or in oil as in Switzerland, and then mixing it with powdered gypsum, as a preventive from the attacks of insects.

5535. *The manner of sowing* is almost always broad-cast. When sown with spring corn, clover and grass-seeds are usually put in immediately after the land has been pulverised by harrowing in the corn-seed, and are themselves covered by one course more of the harrows; or, if the corn is drilled, the small seeds are sown immediately before or after hand-hoeing; and the land is then finished by a course of the harrows. Clover is generally sown by hand, though of late years the broad-cast drill (*fig. 792*) has been used, both in the case of the clovers and the grasses. A lighter harrow is generally employed in covering such seeds, than that used for corn. When the land is under an autumn-sown crop of wheat or other grain, though the clovers and rye-grass are still sown in spring, the proper period must depend both upon the state of the land and the progress of the crops; and it may be often advisable to break the crust formed on the surface of tenacious soils, by using the harrow before the clovers are sown, as well as afterwards to cover them. Sometimes the roller only is employed at this time, and there are instances of clover and rye-grass succeeding when sown, without either harrowing or rolling. But it is commonly of advantage to the wheat crop itself, to use the harrows in spring, and the roller alone cannot be depended on, unless the season be very favourable. In some cases grass-seeds are sown by themselves, either in autumn or spring, but rarely on tillage land. Nature has not determined any precise depth for the seed of red clover more than other seed. It will grow vigorously from two inches deep, and it will grow when barely covered. Half an inch may be reckoned the most advantageous position in clay soil; a whole inch in what is light or loose. It is a vulgar error, that small seed ought to be sparingly covered. Misled by that error, farmers commonly cover their clover seed with a bushy branch of thorn; which not only covers it unequally, but leaves part on the surface to wither in the air.

5536. *In the operation of sowing* some consider it best to sow the clover and rye-grass separately, alleging that the weight of the one seed, and lightness of the other, are unfavourable to an equal distribution of both.

5537. *The quantity of seed* sown on an acre is exceedingly various; not only when more or less white or yellow clover is sown along with grass-seeds and red clover, or when pasturage is intended; but, even when they are the only kinds sown, the quantity is varied by the quality of the soils, and the different purposes of hay, soiling, or one year's pasture, to which the crop is to be applied. When pasture is the object, more seed ought to be allowed than is necessary when the crop is to be cut green for soiling; and for hay, less may suffice than for either of the former. Finely pulverised soils do not require so much seed as clays, on which clover and rye-grass are very frequently sown among autumn or winter-sown wheat, when there is more danger of a part of it perishing from being imperfectly covered. In general, eight or ten pounds may be taken as the *minimum* quantity, though there have been instances of good crops from less; and from that to fourteen pounds or more per English statute acre. Rye-grass, commonly at the rate of a bushel per acre, but in many cases only half, or two thirds of a bushel, is mixed with this weight of clover, and both are sown at the same time. The rye-grass may be either of the perennial or annual variety, as it is understood that the herbage is to be continued for only one year; and the annual is sometimes sown in preference, as producing a bulkier crop than the perennial.

5538. *When it is intended to retain the land in pasture for several years*, the quantity of red clover is diminished, and several kinds of more permanent herbage are added, the most common of which are white and yellow clover, and ribwort. No general rule can be laid down as to the proper quantity of each of these kinds; in some cases red and white clover are sown in equal proportions, and in others the latter is made greatly to predominate. The yellow clover and ribwort are not often sown at the rate of more than two or three pounds per acre. It is scarcely necessary to add, that, in this case, the rye-grass should always be of the perennial sort.

5539. *In the selection of clover and rye-grass seeds* particular attention should be paid to their quality and cleanness; the purple colour of the clover seed denotes that it has been ripe and well saved; and the seeds of weeds may be detected in it by narrow inspection, if there are any; but various noxious weeds are frequently mixed up with the seeds of the rye-grass, which it is difficult either to discover or to separate from them. Between the seeds of the annual and perennial rye-grass the difference is hardly discernible; and therefore, unless it is of his own growth, the cultivator must depend in a great measure on the character of the person from whom he purchases it. Red clover from Holland or France has been found to die out in the season immediately after it has been cut or pastured; while the English seed produces plants which stand over the second, many of them the third, year (*General Report of Scotland*, vol. i. p. 537.); thus remaining in the latter case four summers in the ground from the time of sowing.

5540. *The after-culture* of clover and rye-grass consists chiefly of picking off any stones or other hard bodies which may appear on the surface in the spring succeeding that in which it was sown, and cutting out by the roots any thistles, docks, or other large grown weeds. After this the surface should be rolled once to smooth it for the scythe. This operation is best performed in the first dry weather of March. Some give a top-dressing of soot, gypsum, common lime, peat, or wood-ashes, at this time or earlier:

gypsum has been particularly recommended as a top-dressing for clovers, and the other herbage legumes; because as their ashes afford that substance in considerable quantities, it appears to be a necessary ingredient of their food. Dutch ashes (427.) have been strongly recommended as a top-dressing for red clover, and they also contain gypsum; but where the soil is in good heart, and contains calcareous matter, any description of top-dressing, though it may be of advantage when it does not interfere with the general economy of the farm, cannot be considered necessary. (*Supp. E. Brit. art. Agr.*)

5541. *The taking of the clover, or clover and rye-grass crop*, is either by cutting green for soiling, by making into hay, or by pasturing. It is observed in *The Code of Agriculture*, that it is a most important point to ascertain in what cases cutting, or feeding, is more beneficial. If fed, the land has the advantage of the dung and urine of the pasturing stock; but the dung being dropped in irregular quantities, and in the heat of summer, when it is devoured by insects, loses much of its utility. If the dung arising from the herbage, whether consumed in soiling, or as hay, were applied to the land, in one body, and at the proper season, the operation would be more effectual. The smother of a thick crop, continued for any time upon the ground, greatly tends to promote its fertility; and it has been pretty uniformly found, after repeated trials, upon soils of almost every description, that oats or any other crop taken after clover that has been cut, either for soiling or hay, is superior to the crop taken after clover pastured by sheep.

5542. *Soiling* is a term applied to the practice of cutting herbage crops green for feeding or fattening live stock. On all farms, under correct management, a part of this crop is cut green, for the working horses, often for milch cows, and, in some instances, both for growing and fattening cattle. There can be no doubt of the advantages of this practice, in regard to horses and cows; but for young and for fattening beasts, a sufficient number of experiments are not known to have been yet made with any great degree of accuracy. Young animals require exercise in the open air, and, probably, will not be found to thrive so well in houses or fold-yards, during summer, as on pastures; and though in every case there is a great saving of food, the long, woody, and comparatively naked stems of the plants, with leaves always more or less withered, are perhaps not so valuable in the production of beef on fattening stock as a much smaller weight of herbage taken in by pasturage. Milch cows, however, are so impatient of heat and insects, that this way of feeding them, at least for a part of the day, in warm weather, ought to be more generally adopted; and the convenience of having working horses always at hand, besides that they fill their stomachs speedily, is of not less importance than economy. (See *Communications to the Board of Agriculture*, vol. vii. *Brown's Treatise on Rural Affairs*, vol. ii. *General Report of Scotland*, vols. ii. and iii.)

5543. *In feeding cattle with green clover*, attention must be paid to prevent swelling, or hoving, which is very apt to take place when they are first put on this food, especially if it is wet with rain or dew; and cattle are exposed to this danger, whether they are sent to depasture the clover, or have it cut and brought home to them; though, if the plants are somewhat luxuriant, the danger is greater in the former case. After being accustomed to this rich food for a few days, during which it should be given rather sparingly, the danger is much diminished; but it is never safe to allow milch cows, in particular, to eat large quantities of wet clover.

5544. *The making herbage plants into hay* is a process somewhat different from that of making hay from natural grasses. All the herbage tribe ought to be mown before the seed is formed, and indeed before the plants have fully blossomed, that the full juice and nourishment of the herb may be retained in the hay. By the adoption of this system, the hay is cut in a better season, it can be more easily secured, and it is much more valuable. Nor is the strength of the plant lodged in the seed, which is often lost. The great advantage of converting under-ripe herbage and grass into hay is now beginning to be known. There is much more saccharine matter in it, and it is consequently greatly more nutritious. A crop of clover or saintfoin, when cut in the early part of the season, may be ten per cent. lighter than when it is fully ripe; but the loss is amply counterbalanced, by obtaining an earlier, a more valuable, and more nutritious article; while the next crop will be proportionably more heavy. The hay made from old herbage which has ripened its seed will carry on stock, but it is only hay from herbage cut when young, and soon after it has come into flower, that will fatten them. When the stems of clover become hard and sapless, by being allowed to bring their seeds towards maturity, they are of little more value as provender than an equal quantity of the finer sort of straw of corn.

5545. *The mode of making clover-hay*, and that of all herbage plants, as practised by the best farmers, is as follows:—The herbage is cut as close to the ground and in as uniform and perfect a manner as possible with a sharp scythe. The surface having been in the preceding spring freed from stones and well rolled, the stubble after the mower ought to be as short and smooth as a well shaven grass-lawn. The part of the stems left by the scythe is not only lost, but the after-growth is neither so vigorous nor so weighty, as when the first cutting is taken as low as possible.

5546. *As soon as the swath or row of cut herbage is thoroughly dry above*, it is gently turned over (not tedded or scattered) without breaking it. Sometimes this is done with the hand, or with a small fork; and some farmers are so anxious to prevent the swath from being broken, that they only permit the use of the rake shaft. The grass, when turned over, in the morning of a dry day, is put into cocks in the afternoon. The mode of performing this is very simple and expeditious; and none but women, boys, and girls, under the eye of a confidential servant, are usually employed. If the crop is heavy, a row of cocks is placed in the middle ridge of three, and if light of five ridges. A distinct company of carriers and rakers is allotted to every such number of ridges; and the separate companies proceed each on its own ground, and in the same manner as in reaping grain, which occasions a degree of competition among them for despatch, clean raking, and neat well-built cocks. The carriers gather the hay, and carry it to the ridge where the cock is to be built by one of the most experienced hands. A raker follows the carrier, taking up and bringing to the cocks the remains of the swath. There may be, in general, about five people employed about each row of cocks; a carrier and raker on each side of the ridge on which the cocks are placed, and a person on the ridge, who builds them. But when the crop is not weighty, more rakers are required, as a greater space must be gone over.

5547. *As the cocks are thus placed in a line*, it is easy to put two or more into one afterwards; and the larger cocks may be speedily drawn together, to be put into tramp-ricks, by means of ropes thrown round their bottoms, and dragged along by a horse. It is impossible to lay down any rules for the management of hay, after it is put into cocks; one thing is, however, always attended to, not to shake out, scatter, or expose the hay oftener than is necessary for its preservation. Sometimes the cocks have been put up so large, that they never require to go to a tramp-rick, but are carted to the stack-yard, without ever being broken, and put up in alternate layers with old hay. But where this is attempted, there must not be much clover. The practice of mixing the new with the old hay is, however, a good one, and saves a great deal of time and labour, at the same time that the old hay is much improved by the mixture.

5548. *The best managers disapprove of spreading out the swathes of clover and rye-grass*, though this is often necessary with natural grasses, which are cut and harvested later in the season. The more the swath is kept unbroken, the hay is greener, and the more fragrant.

5549. *Another mode of hay-making*, said to have been originally practised in Lancashire, has been found to answer well in the moist atmosphere of the west of Scotland. This is called tipping or rippling; and if the grass is dry, the operation begins as soon as it is mown. "In making a tippel, a person with his right hand rolls the swath inward, until he has a little bundle; then the same is done by the left, until both meet and form eight to twelve pounds, or nearly so. This bundle is then set up against the legs, or between the feet; a rope is twisted of the grass, while the bundle is supported in this manner, and tied round it near its top; and from the top are drawn up a few straggling stems, which are twisted to make the tippel taper to a point, and give it as much a conical shape as possible. If the crop is strong, there is a row of tippels placed on each swath; if light, two of these are put into one row. After standing a few hours, they become so smooth on the outside, that the heaviest rains seldom wet them through; and when wet, they are soon dried again in good weather. As soon as ready, they are put into the summer-rick, or, if very dry, even into the winter stack, but are never opened out or tedded, to make them dry, as they never require it. By this method, not a blade is lost, and the hay is nearly as green as a leaf dried in a book. In a moderate crop, one woman will tippel to one mower, and a woman will rake to two tippellers, or two swathers. But where the crop is strong, it may require three women to keep pace with two mowers. After the hay is put up in this manner, the crop may be considered secure, though it may continue wet weather for a considerable length of time." (*General Report of Scotland*, vol. ii. p. 11.)

5550. *The making of clover hay*, as practised in Courland, and adopted from that country in Silesia, is said to save not only a number of hands, but the hay is better and more nourishing. The hay is prepared by self-fermentation, whereby it retains its nutritious juices, and only loses its watery particles; it is dried more expeditiously by dissipation of its humidity, and contraction of the sap-vessels, and thus its nutritious juices are concentrated. The process is conducted on the following principle, viz. the sap-vessels are expanded by the circulation of the liquid juices by heat, and the superfluous humidity is exhaled; on cooling, the sap-vessels contract, and thus future intestine fermentation is prevented, and the nutritious quality is preserved.

5551. *The clover intended for hay*, after having been mowed, remains till four o'clock in the afternoon of the following day in swath to dry; it must then be raked together into small coils, and afterwards made into large cocks in the form of a sugar-loaf, and such as it would require six or eight horses to remove. To prevent the air from penetrating these cocks, and to produce a quicker fermentation, they must, whilst forming, be trodden down by one or two men. If it be a still, close, warm night, the fermentation will commence in four hours, and manifest itself by a strong honey-like smell: when proper fermentation is begun, the cocks will, on being opened, smoke, appear brownish, and may then be spread abroad. If in the morning the sun is warm, and a little wind arises, the clover-hay will quickly dry; it may then, towards noon, be turned with the rake or pitch-fork, and about four in the afternoon will be sufficiently dried, so that it may be immediately carted into the barn, without any danger of a second fermentation. By this method of management, the clover will require only three days, from the time of mowing to its being housed, and very little work; whilst, in the common way, even in good weather, it requires six or eight days. In the old method it frequently becomes of a black colour; but in the new method it is only brown, has an agreeable smell, and remains good and unchangeable in the barn. The farmer has also another advantage, that if he has not carts enough to carry it into the barn, he need only, at sun-setting, heap it again into large well trodden cocks, and thatch them with straw, in which state they will remain the whole summer without damage or loss. This clover-hay is not only greedily eaten by sheep and lambs, but also by horses, calves, and cows.

5552. *This new mode of making hay* depends principally upon two circumstances: first, that the mown clover, when brought together in to large heaps, may ferment equally and expeditiously; secondly, that the day succeeding the fermentation be dry, sunny, and windy: on this account it may be proper to point out what should be done when circumstances are unfavourable. Let us suppose, therefore, that the night after the clover-grass has been placed in the great cocks is cold, damp, or rainy, the fermentation will yet take place, although it may require a term of twelve, sixteen, or twenty-four hours to effect it. If it be a second or a third crop, at which season the nights are colder, it may even require from thirty-six to forty-eight hours before the fermentation ensues: it will, however, commence, and may be ascertained from this circumstance, that you can scarcely bear your hand in the interior of the cock. Even if the night be dry, yet if a strong cold wind blows, the cock may not ferment equally, but only in the middle, and on the side opposite to the wind; the other parts may still remain green. In such a case the following rules must be attended to:—

5553. *Rule first.* If the cock has only fermented in the middle, and on that side where the cold wind did not act upon it, the whole heap must nevertheless be opened on the following morning. That which has already fermented must be separated and spread to dry; it must be turned towards noon, and may be carted into the barn in the evening; but that part of the cock which has not fermented must be again put together into large cocks, and fermented in the same manner as the preceding part, after which it may be spread to dry, and brought into the barn.

5554. *Rule second.* In such cases where a small portion of the cock has fermented thoroughly, but not the greater part, the heap must be spread abroad in the morning, but must be again made into a close cock in the evening, in such a manner that the part which has fermented be placed at the top or outside of the cock, and that which has not fermented be inclosed within it; then on the ensuing morning, or, if the weather be cold and rainy, on the morning afterwards, the clover-heap may be again spread abroad, and the clover treated as in the case first mentioned.

5555. *Rule third.* If, in spreading the heap abroad, it be found that nearly the whole of the clover has fermented, it will not be necessary to delay the housing of the whole on account of some small portion; but the clover may be dried and carted into the barn. The small portion which remained unfermented will not occasion any disaster to the other which has fermented; for there is a material difference betwixt hay thus managed, and the meadow-grass which is brought whilst damp, or wet with rain, into the barn, which will grow musty and putrid.

5556. *Rule fourth.* In such instances, where some of the cocks of clover have thoroughly fermented, and it rains on the morning, they ought to be spread abroad, for the clover must be opened and spread, even if it rains violently; since, if it were suffered to remain longer in the heap, it would take fire, or its juices would be injured by too much fermentation; the leaves and stalks would become black, and the clover unfit for food: therefore, if the rain continues, the spread clover must be turned from time to time, but not carted into the barn till dry. This drying takes place, if the rain discontinues for a few hours, much more expeditiously with the clover which has fermented, than with that made in the common way. Besides which, it must be remarked, that the fermented clover remains good, even if it continues some weeks exposed to the rain, provided it is at last suffered to dry before it is put into the barn; otherwise the wet from the rain will render it musty and bad. The clover which has been for so long a time exposed to the rain will not, however, be so nutritious as that which has been well fermented and sooner dried; but it will be far superior to that which has been exposed to the rain, and got up in the common method. (*Klapmeyer in Thacker's Annalen*, &c.)

5557. *Hay is stacked* in circular or oblong stacks, the latter form being most generally approved of, and carefully thatched, as has been already observed in regard to corn. It is never advisable to allow this kind of hay to become heated in any considerable degree, in the stack, though a slight exudation, with a

very gentle warmth, is usually perceptible, both in the field-ricks and in the stacks, for a few days after they are built. But this is a quite different thing from that intentional heating, carried so far, in many instances, as to terminate in conflagration.

558. *The after-growth or second crop of clover* is vigorous or weak, according to the proportion of clover plants to rye-grass, to the time when the first crop was cut, and to the moisture and warmth of the season. When the first cutting has been made early for soiling, there will sometimes be three cuttings in one season. The first of these after-cuttings may be made into hay, and sometimes the second; but in general both are consumed by soiling or pasturing, unless in some dry warm districts, as Norfolk, and parts of Suffolk, Kent, &c., where the second growth is left to ripen its seed. In the northern counties the second crop is seldom made into hay, owing to the difficulty of getting it thoroughly dried at a late period of summer, when other more urgent operations usually employ all the labourers of a farm. If it is cut for this purpose, the best method of saving it is to mix it up with straw, which will absorb a part of its juices. It is often cut green, as a part of the soiling system; or, where a sheep stock is kept, pastures by the old ewes, or other sorts, that are to be fattened the ensuing winter on turnips.

559. *In consuming clover and other herbage plants by pasturing*, or eating down on the spot, three methods have been adopted: tethering, hurdling, and free pasturage.

560. *Tethering* may be considered a rude practice, and is chiefly confined to the north of Scotland and Ireland. In *The Agricultural Report of Aberdeenshire* it is stated, that there are some cases where the plan of tethering can be practised with more profit than even soiling. In the neighbourhood of Peterhead, for instance, they tether milch cows on their grass fields, in a regular and systematic method; moving each tether forward in a straight line, not above one foot at a time, so as to prevent the cows from treading on the grass that is to be eaten; care being always taken to move the tether forward, like a person cutting clover with a scythe, from one end of the field to the other. In this way, a greater number of cows can be kept, on the same quantity of grass, than by any other plan; except where it grows high enough to be cut, and given them green in houses. In one instance, the system was carried to great perfection, by a gentleman who kept a few sheep upon longer tethers, following the cows. Sometimes, also, he tethered horses afterwards upon the same field, which prevented any possible waste; for the tufts of grass produced by the dung of one species of animal will be eaten by those of another kind without reluctance. This system was peculiarly calculated for the cow-feeders in Peterhead; as, from the smallness of their holdings, they could not afford to keep servants to cut, or horses to carry home, the grass to their houses, to be consumed in a green state. (*Code.*)

561. *In hurdling off clovers or herbage crops*, a portion of the field is enclosed by hurdles, in which sheep are confined; and as the crop is consumed, the pen is changed to a fresh place, until the whole is fed off. This practice is very extensively adopted at Holkham, and is peculiarly calculated for light and dry soils. Its advantages are, that the grass is more economically consumed; that the stock thrive better, having daily a fresh bite; and that the dung falls, being more concentrated, is more likely to be of use.

562. *In the common pasturing of clover*, the stock are introduced into the field earlier than in tethering or hurdling, in order to avoid the loss that would be sustained by cattle or sheep treading *ad libitum* on tall herbage. Indeed, the principal advantage of pasturing clovers is, that sheep and lambs may be turned on them more early than on common grass-lands. Sometimes this advantage is taken for a month or six weeks, in the beginning of summer, and the field afterwards shut up for a crop of hay; but more frequently the red clovers are only mown. When white and yellow clovers are sown, the herbage is sometimes not mown at all, but pastured for three years or more; and sometimes a little red clover being sown along with these, a crop of hay is taken the first year.

563. *The produce of clover-hay*, without any mixture of rye-grass, on the best soils is from two to three tons per acre, and in this state in the London market it generally sells 20 per cent. higher than meadow-hay, or clover and rye-grass mixed. The weight of hay from clover and rye-grass varies, according to the soil and the season, from one ton to three tons per English acre, as it is taken from the tramp-ricks; but after being stacked, and kept till spring, the weight is found to be diminished twenty-five or thirty per cent.

564. *The value of clover and rye-grass hay*, in comparison with the straw of beans or peas, may be in the proportion of three to two; and with the finest straw of corn crops, in the proportion of two to one. One acre of red or broad clover will go as far in feeding horses or black cattle as three of ordinary pasture; and when it is cut occasionally, and given to them fresh, it will, probably, go still much farther, as no part of it is lost by being trodden down. With the exception of lucern, and the herbage of rich marshes, there is no crop by which so much stock can be supported as by clover. It may be profitably employed in fattening sheep in spring, and with this food they will soon be ready for the butcher. Afterwards, a crop of hay may be got, and two or three weeks after the hay has been taken off, sheep intended to be fattened on turnips may be turned in, and kept there, until the turnips are ready for them.

565. *The nutritive products of clovers* will be found in the table. (5520.)

566. *The saving of clover seed* is attended with considerable labour and difficulty. Clover will not perfect its seeds, if saved for that purpose early in the year; therefore it is necessary to take off the first growth either by feeding or with the scythe, and to depend for the seed on those heads that are produced in the autumn. Seed-clover turns out to good account in those years when the crops are not injured by the blight, which is often fatal to them, or by the rains in the autumn, which sometimes prove their destruction; for the time of harvesting this seed falling out late when rainy weather may be expected, renders it, on that account, very tedious.

567. *When the first crop is fed off*, it is eaten till about the end of May, frequently by ewes and lambs; and this is understood to be an advantageous practice, because the land is less exhausted, and the green food is of great value for stock in the spring months. It is not uncommon, however, to cut the first growth for a hay crop, and this should be done earlier than usual. The growth thus reserved for seed must be suffered to remain till the husks become perfectly brown, when it is cut and harvested in the usual manner, leaving it on the field till it is very dry and crisp, that the seeds may become more fully hardened; it may then be laid up dry, to be threshed out at the farmer's convenience. Much labour and expense are necessary in separating the seed from the capsule or seed-coat, especially when it is effected by threshing, which seldom costs less than from five to six or seven shillings per bushel. By the use of mills the work may be done much cheaper.

5568. *The management of a crop of clover with a view to saving seed* is thus given by a cultivator in Buckinghamshire. A moderate bulk of haulm is generally found most productive of seed, and a moderately rich, sharp, dry soil is the best for having moderate haulm. The field may be pastured till the middle of May, and then shut up till the ripening is completed. August is generally the ripening month, and the maturity of the seed may be known by the leaves becoming brown and dropping off. Observe the seed from time to time, and when it has changed from a bright yellow to a deep purple, it is then ready for the scythe. After the crop is cut down, disturb it as little as possible by fork or rake. Form it into small cocks not larger than muck heaps. Should favourable weather ensue, nothing more is necessary than to turn these cocks once over, shortly before carting home. And, should the weather prove fickle, these small heaps of withered straw are very soon dried, perhaps in one good day, by turning up the bottom, after the top has become a little dried. After remaining some time in the field, the cocks subside considerably and become caked, by which the flowers adhere together and repel the rain; of course, no loss of top can be sustained by gently turning them to dry. It thus appears, that clover for seed is not so liable to be injured as clover for hay. In general six or ten days of favourable weather render it fit to carry to the rick-yard and stack. It may either be threshed by a light flail, or by threshing machines, having a particular additional cover introduced below the drum or beater for that purpose.

5569. *In threshing*, whether by the flail or machine, the first operation is to separate the heads or spikes of seeds from the haulm. This operation separates none of the seed, which remains firm in the withered florets, and requires to be separated by a course of light thrashing, similar to that used for hummelling barley. When on examination it is found that the seed is all separated, the operations of sifting and winnowing ought to be carried on in the usual manner with appropriate sieves; the clover sieve being well known to the sieve-maker. The average produce per acre is three hundred weight.

5570. *Seed may be saved from a second crop*; that is, after the first crop has been mown for hay; but the sample is seldom so strong or plump as that from a first crop.

5571. *White clover*, and also yellow clover, lucern, and saintfoin, when intended for seed, are treated much in the same manner as red clover. (*Farm. Mag.* vol. xix, p. 276.)

5572. *The produce in seed* may generally be from three to four or five bushels per acre, when perfectly clean, weighing from two to three hundred weight. But there is great uncertainty in the produce of clover seed, from the lateness of the season at which it becomes ripe; and the fertility of the soil is considerably impaired by such a crop. Yet the high value of the seed is a great inducement to the saving of it, in favourable situations. (*Dickson's Practical Agriculture*, vol. ii. p. 863.)

5573. *The diseases of clover* are the blight or mildew, and suffocation or consumption, from insects, slugs, and worms. It often happens that clover, after being repeated at short intervals on the same soil, either fails or does no good; whether that is owing to a disease, or to a defect of some peculiar substance which enters into the food of the plant, does not appear to be clearly ascertained. A top-dressing with ashes or lime is said to be unfavourable to the slug; but where vermin of this sort are very numerous, the most certain remedy is a naked fallow well worked in the hottest months.

SECT. II. *Lucern*. — *Medicago sativa* L.; *Diadélphia Decándria* L., and *Legumindæ* J. *La Lucerne*, Fr.; *Futterklee*, Ger.; *Medica*, Ital.; and *Mielga* Span. (fig. 775.)

5574. *Lucern* is a deep-rooting perennial plant, sending up numerous small and tall clover-like shoots, with blue or violet spikes of flowers. It is a native of the south of Europe, and appears to be acclimated in the warmer parts of England. Lucern or medic is highly extolled by the Roman writers, and also the cytissus, the latter a low evergreen shrub. Lucern is much grown in Persia and Lima, and mown in both countries all the year round; it is also of unknown antiquity in old Spain, Italy, and the south of France. It was introduced to England from the latter country, according to Miller, in 1657. It is mentioned by Hartlib, Blythe, and other early writers, and was tried by Lisle; but it excited little attention till after the publication of Harte's *Essays*, in 1757. It is now only cultivated in a few places, and chiefly in Kent. Columella estimated lucern as the choicest of all fodder, because it lasted many years, and bore being cut down four, five, or six times a year. It enriches, he says, the land on which it grows, fattens the cattle fed with it, and is often

a remedy for sick cattle. About three quarters of an acre of it is, he thinks, abundantly sufficient to feed three horses during the whole year.

5575. *Clover has found no great reception in this country*, though it was so much esteemed by the ancients, and has been long cultivated to advantage in France and Switzerland. If any good reason can be given for this, it is, that lucern is a less hardy plant than red clover, requires three or four years before it comes to its full growth, and is for these and other reasons ill adapted to enter into general rotations. Where the climate and soil suit, perhaps a field of it may be advantageously sown, adjoining the homestead, to afford early cutting or food for young or sick animals, for which it is said to be well adapted; but though it will produce good crops for eight or ten years, yet from the time the farmer must wait till this crop attains its perfection, and from the care requisite to keep it from grass and weeds, we do not think it ever likely to come into general culture. The Highland Society have lately offered premiums for the culture of this plant in Scotland, and crops have been produced in dry sandy soils in the neighbourhood of Edinburgh; the climate, however, and the alternate and convertible system of culture generally pursued in the northern parts of the island, and which seems so well adapted to its agricultural circumstances, forbid the hope that it can ever become general.

5576. *There are no varieties of the lucern deserving the notice of a cultivator.*

5577. *What is called the yellow lucern* is the *Medicægo falcata* (*Lucerne en famille*, or *Lucerne de Suède*, Fr. fig. 776.), a much hardier and coarser plant, common in several parts of England, but not cultivated any where except in some poor soils in France and Switzerland.

776

5578. *Medicægo maculata* and *muricata* are cultivated in France, but to a very limited extent on poor soils. *M. lupulina* (lupuline, or *Minette dorée*, Fr.) resembles our well known hop trefoil, black (from its seeds) nousuch, or yellow clover; but it is seldom cultivated in Britain.

5579. *The soil for lucern must be dry, friable, inclining to sand, and with a subsoil equal to it in goodness. Unless the subsoil be good and deep, it is in vain to attempt to cultivate lucern. According to Young, the soils that suit lucern are all those that are at once dry and rich. If, says he, they possess these two criteria, there is no fear but they will produce large crops of lucern. A friable deep sandy loam on a chalk or white dry marly bottom is excellent for it. Deep putrid sand warp on a dry basis, good sandy loam on chalk, dry marl or gravel, all do well; and in a word, all soils that are good enough for wheat, and dry enough for turnips to be fed on the land, do well for lucern. If deficient in fertility, they may be made up by manuring,*

but he never yet met with any land too rich for it.

5580. *The preparation of the soil consists in deep ploughing and minute pulverisation; and, in our opinion, the shortest way to effect this, is to trench it over by the spade to two or three feet in depth, burying a good coat of manure in the middle or at least one foot from the surface. This is the practice in Guernsey, where lucern is highly prized.*

5581. *The climate for lucern, as we have already hinted, must be warm and dry; it has been grown in Scotland and Ireland, and might probably do well in the southern counties of the latter country, but in the former it has not been found to answer the commendations of its admirers.*

5582. *The season most proper for sowing lucern is as early as practicable in the spring months, as in this way the plants may be fully established before the season becomes too hot. The latter end of March, for the more southern districts, may be the most proper period; and the beginning of the following month for those of the north. When sown late, there is more danger of the plants being destroyed by the fly, as it has been observed by Tull. If the plants are intended to be transplanted out in the garden method, it will also be the best practice to sow the seed-bed as early in the spring as the frosts will admit, in order that they may be strong, and fit to set out about the beginning of August.*

5583. *The manner of sowing lucern is either broad-cast or in drills, and either with or without an accompanying crop of corn for the first year. Broad-cast, with a very thin crop of barley or other spring corn, is generally, and in our opinion very properly, preferred. Arthur Young, who has treated largely on this plant, observes, that "the greatest success by far that has been known is by the broad-cast method, which is nearly universal among the best lucern farmers, even among men who practise and admire the drill husbandry in many other articles. But as they mostly (not all) depend on severe harrowing for keeping their crops clean, which is a troublesome and expensive operation, he still ventures to recommend drilling; but very different drilling from that which has been almost universally practised, viz. at distances of eighteen inches or two feet. Objections to these wide intervals are numerous. If kept clean hoed, the lucern licks up so much dirt, being beaten to the earth by rain, &c., that it is unwholesome, and the plants spread so into these spaces, that it must be reaped with a hook, which is a great and useless expense. For these reasons, as well as for superiority of crop, he recommends drilling at nine inches, which in point of produce, mowing, and freedom from dirt, is the same as broad-cast; and another advantage is, that it admits scarifying once a year, which is much more powerful and effective than any harrowing. These facts are sufficient to weigh so much with any reasonable man, as to induce him to adopt this mode of drilling, as nearer to broad-cast by far than it is to drills at eighteen to twenty-four inches, which open to a quite different system, and a set of very different evils. Nine-inch rows might practically, but not literally, be considered as broad-cast, but with the power of scarifying. And in regard to the material point, of with or without corn, two considerations, he says, present themselves. One is the extreme liability of lucern to be eaten by the fly, which does great mischief to many crops when very young, and against which the growing of corn is some protection. The value of the barley or oats is another object not to be forgotten. It is also gained in the first year's growth of the lucern, which is very poorly productive even if no corn be sown; so that he must own himself clearly an advocate for drilling in among corn, either between the rows of nine-inch barley, or across drilled barley, at a foot, if perhaps the latter is the best method, as there is less probability of the crop being laid to the damage of the lucern. The quantity of seed-corn should also be small, proportioned to the richness of the land, from one bushel to a bushel and a half, according to the fertility of the soil; another security against the mischief of lodging. If these precautions are taken, it would be presumptuous to say that success must follow, that being always, and in all things, in other hands than ours; seed may prove bad, the fly may eat and drought prevent vegetation; but barring such circumstances, the farmer may rest satisfied that he has done what can be done, and if he do succeed, the advantage will be unquestionable."*

5584. *The quantity of seed, when the broad-cast method is adopted, is said to be from fifteen to twenty pounds per acre, and from eight to twelve if drilled. The seed is paler, larger, and dearer than that of clover: it is generally imported from Holland, and great care should be had to procure it plump and perfectly new, as two-years-*

old seed does not come up freely. The same depth of covering as for clover will answer.

5585. *Lucern may be transplanted*, and when the soil is very rich and deep, it is said to produce very large plants; but such plants, from the bulk of their stools, are not likely to be so durable as those of a less size; and on the whole, for this reason and others relative to expense, the plan of transplanting does not seem advisable unless for filling up blanks.

5586. *The after-culture of lucern*, sown broad-cast, consists in harrowing to destroy grass and other weeds; rolling, after the harrowing, to smooth the soil for the scythe; and such occasional top-dressings of manure as the state of the plants may seem to require.

5587. *When lucern is drilled*, horse-hoeing may be substituted for harrowing, which, as already observed, is the only advantage of that mode of sowing. The harrowing may commence the second year, and the weeds collected should always be carefully removed: light harrows may be used at first, and in two or three years such as are heavier. In succeeding years two harrowings may be required, one early in the spring, and the other at the close of the summer. For these, and especially the last, Arthur Young recommends the use of a harrow of weight sufficient for four horses, and which does not cover a breadth of more than four feet. The mode of hoeing, either by the hand or horse-hoe, or of stirring by the drill harrow, requires no description.

5588. *The top-dressings* given to lucern may be either of the saline or mixed manures. Ashes are greatly esteemed, and also gypsum and liquid manure of any kind. Arthur Young advises to apply dung, in the quantity of about twenty tons to the acre, every five or six years. Kent, however, thinks it a better practice to put a slight coat on annually in the spring season. Some recommend a slight top-dressing sown by hand every spring. The farmer will in this, as in every case, exercise his own judgment, and be guided by the wants of the plants, the return they yield for the expense bestowed on them, and the equable distribution of manure among his other crops.

5589. *The taking of lucern* by mowing for soiling, or hay, or by tethering, hurdling, or pasturing, may be considered the same as for clover. Lucern frequently attains a sufficient growth for the scythe, towards the end of April, or beginning of the following month; and, in soils that are favourable for its culture, will be in a state of readiness for a second cutting in the course of a month or six weeks longer, being capable of undergoing the same operation, at nearly similar distances of time, during the whole of the summer season. In this last sort of soil, with proper management, in the drill method, it has been found to rise to the height of a foot and a half in about thirty or forty days, affording five full cuttings in the summer. But in the broad-cast crops, in the opinion of some, there are seldom so many cuttings afforded in the season, three or four being more common, as the growth is supposed to be less rapid than by either of the other modes.

5590. *The application of lucern* is also the same as that of clover. The principal and most advantageous practice is that of soiling horses, neat cattle, and hogs: but as a dry fodder, it is also capable of affording much assistance; and, as an early food for ewes and lambs, may be of great value in particular cases. All agree in extolling it as food for cows, whether in a green or dried state. It is said to be much superior to clover, both in increasing the milk and butter, and improving its flavour. In its use in a green state, care is necessary not to give the animals too much at a time, especially when it is moist, as they may be hoven or blown with it, in the same way as with clover, and other green food of luxuriant growth.

5591. *The produce of lucern*, cut three times in a season, has been stated at from three to five and even eight tons per acre. In soiling, one acre is sufficient for three or four cows during the soiling season; and a quarter of an acre, if the soil be good, or half an acre on a moderate soil, for all sorts of large stock, for the same period. Say, however, that the produce is equal in bulk and value to a full crop of red clover, then, if continued yearly for nine or ten years (its ordinary duration in a productive state), at an annual expense of harrowing and rolling; and a triennial expense of top-dressing, it will be of sufficient value to induce farmers, who have suitable soils and climates, to lay down a few acres under this crop near their homesteads.

5592. *The nutritive product of lucern*, according to Sir H. Davy, is $2\frac{3}{10}$ per cent., and is to that of the clovers and saintfoin as 23 to 39. This result does not very well agree with the superior nutritive powers attributed to lucern.

5593. *To save seed*, the lucern may be treated precisely as the red clover, and it is much more easily threshed, the grains being contained in small pods, which easily separate under the flail, or a threshing machine, or clover mill.

5594. *The diseases of lucern* appear to be the same as those of clover. In Kent, blight and the slug are its greatest enemies.

SECT. III. *Saintfoin*. — *Hedysarum Onobrychis* L.; *Diadélphia Decándria* L., and *Leguminosæ J. Bourgogne, or Esparcette, Fr.; Esparzette, Ger.; Cedrangola, Ital.; and Esparsita, Span. (fig. 777.)*

5595. *Saintfoin* is a deep-rooting perennial with branching spreading stems, compound leaves, and showy red flowers. It is a native of England and many parts of Europe, but never found except on dry, warm, chalky soils, where it is of great duration. It has been long cultivated in France and other parts of the Continent, and as an agricultural plant was introduced from France to England about the middle of the seventeenth century. It has since been a good deal cultivated in the chalky districts; and its peculiar value is, that it may be grown on soils unfit for being constantly under tillage, and which would yield little under grass. This is owing to the long and descending roots of the saintfoin, which will penetrate and thrive in the fissures of rocky and chalky understrata. Its herbage is said to be equally suited for pasturage and for hay, and that eaten green it is not apt to swell or hove cattle like the clovers or lucern. Arthur Young says, that upon soils proper for this grass no farmer can sow too much of it; and in *The Code of Agriculture* it is said to be "one of the most valuable herbage

777

plants we owe to the bounty of Providence."

5596. *There are no varieties of the saintfoin in England, but many other species of the same numerous family might be cultivated, such, for example, as the French honey-suckle, a biennial that might be substituted for red clover on rich soils. The French have a variety which they call *Sainfoin à deux coupes*, and they also cultivated the *Sainfoin d'Espagne* or *Sulla*.*

5597. *The best soil for this plant is that which is dry, deep, and calcareous; but it will grow on any soil that has a dry subsoil. Kent thinks that the soils most suited to the culture of this sort of grass are of the chalky loam, and light sandy or gravelly kinds, or almost any of those of a mixed quality, provided they are sufficiently dry, and have a rocky or hard calcareous bottom to check the roots at the depth of a foot or fifteen inches below the surface, which he conceives necessary, as the plants are apt to exhaust themselves in running down; and for this reason he considers it improper for being sown where there is great depth of mould or soil. It is a plant that is asserted by Marshal to afford a large produce even on those soils which are of the poorest quality, and on such as are of a more rich and friable nature to frequently produce abundant crops. Still, he conceives, that it is only in the calcareous soils, as the dry chalk and limestone, or such as have been well impregnated with that sort of matter, that it succeeds in a perfect manner or becomes durable. The advantages resulting from growing this plant on sandy soils in Norfolk have been already stated. (4744.)*

5598. *The best preparation which any soil fit for this plant can undergo is, unquestionably, trenching; and we have little doubt that in most cases, all things considered, it would be found the cheapest. The usual preparatory culture, however, is the same as for clover, ploughing more deeply than ordinary, either by means of the trench plough, or, what is better because more simple, by the common plough going twice in the same track. Boys (Communications to the Board of Agriculture, vol. iii.) recommends as a preparation for saintfoin: 1st year, pare and burn for turnips, to be eaten on the land by sheep, with the aid of some fodder; 2d, barley, to be sown very early with clover seed; 3d, clover eaten off by sheep; 4th, wheat; 5th, turnips with manure; and, 6th, barley with saintfoin. The corn crops must be carefully weeded, and in particular cleared of charlock. Under this system, the produce has been great, and the ground has been laid down in the highest order with saintfoin, or any other grass calculated for this species of soil.*

5599. *With respect to the season of sowing saintfoin, it may be observed, that the earlier it can be put into the soil in the spring the better, as from the greater moisture of such soils there will be a greater probability of its vegetating in a perfect manner. Where the sowing is executed at a late period, and dry weather succeeds, Bannister thinks that much of the seed is prevented from growing, and that the young plants are more exposed to destruction from the fly; therefore, according to this writer, the sowing of saintfoin seed ought never to be deferred longer than the beginning of March, and it is still better to complete this work in February. Some, however, suppose it may be deferred to the middle of March without injury, and this is soon enough if it is to be sown with barley.*

5600. *The manner of sowing is generally broad-cast; but it may be sown in drills and even transplanted, though neither of these modes can be recommended. Some advise its being sown with about half the quantity of barley usually sown for a full crop, which may shade and keep it moist during the first summer, and at the same time not injure it from the crop being lighter, which is sometimes the case. Where the barley is drilled, the saintfoin may afterwards be put in, in the same manner, but in a contrary direction. If sown over the wheat, it should be harrowed in, and afterwards rolled. In whatever method it is sown, as the seeds are larger than those of many other herbage plants, they should be covered in with more care, and to a somewhat greater depth. By some the ploughing of the seed in with a very thin or shallow*

furrow is recommended. In most cases, especially in all the more light sorts of land in which this sort of crop is grown, the use of the roller may be necessary immediately after the seed is put into the ground. It is the practice in some districts to sow a small portion of clover seed with saintfoin, with the idea of increasing the first year's produce; but as plants of different kinds seldom answer well when grown together, from there being a continual contest in their growth for an ascendancy, it is perhaps a better method to increase the proportion of the seed, without mixing it with that of other sorts. It is, however, supposed by Marshal that such a practice is beneficial in ultimately procuring a fine clean crop of saintfoin upon the land. It is a sort of crop that grows in so perfect a manner in the broad-cast method, that there can seldom be any necessity for having recourse to the drill. It may, however, be cultivated in the latter mode with much success; and, in Norfolk, it is the practice with some cultivators to have it drilled at nine inches across the barley crops which have been sown in the same way.

5601. *The quantity of seed* in the broad-cast method, which is that mostly employed, is about four bushels the acre, though less is frequently given; but on such soils as are proper for this plant it is always necessary to have a full proportion of seed. By some, however, a much smaller quantity is made use of; and where the drill system is had recourse to, a still smaller proportion is used, as from two to two and a half or three bushels. It has been observed, that in Lincolnshire, where this plant is much grown, "the common allowance of seed is five bushels to an acre, and that a gentleman south of Lincoln advises the sowing a small quantity of trefoil with it (about four pounds on an acre)." The reason for this is, that in that exposed country, the young plants suffer more by the sun in summer than by the frost in winter. Of course the trefoil coming to perfection the first year, and living only three, will be a shelter for the young plants during the first year or two, and die off when the saintfoin wants its room.

5602. *In the choice of the seed* the safest practice for the cultivator is to select it from the best and most abiding plants in this particular soil, as that purchased from the seed-shops can rarely be depended upon. A certain method of knowing the goodness of the seed is, by sowing a number of the seeds, and seeing how many plants are produced by them. But the external signs of the seeds being good are, that the husk is of a bright colour, and the kernel plump, of a light grey or blue colour, and sometimes of a shining black. The seed may be good, though the husk be black, as that is owing sometimes to letting it receive wet in the field, and not to its being half-rotted in the heap. If the kernel on being cut across appears greenish and fresh, it is a certain sign that it is good; but if it is of a yellowish colour, and friable, and looks thin and pitted, it is a bad sign. Others observe that the best seed is plump, heavy, bright, and of a yellowish red colour, and that it should always be sown while quite fresh, as old seed, or seed that has been long kept, never vegetates in a perfect manner; seed of this sort is in general from about three to five shillings the bushel.

5603. *The after-culture and management of saintfoin* consists in occasional dressings with manure, and, in the judicious intervention of mowing and pasturing.

5604. *Some farmers do not mow in the first year*, while others do; but in the second year, and in the succeeding summers, a crop of hay may be taken, and the after-grass fed down with any sorts of stock but sheep, till towards December. These should not be permitted to eat it too close, as, from the largeness of the roots, they might by so doing injure the crowns of the plants. In the following autumn there will, however, be less risk in this respect, and sheep as well as cattle stock may be turned in and kept upon the pastures till they are well eaten down, being always careful to shut them up as early as possible in the beginning of the year. This is the opinion of Kent. As this sort of herbage is thought to be improved in its taste by being nipped by the frost, it may be a proper practice not to turn stock upon these leys too early in the autumnal season; perhaps not before the latter end of September, when this sort of rouse or after-grass will be found to have much effect in promoting the flow of milk in cows, as well as in forwarding the condition of fattening beasts; great store of feed being still left for sheep. But with this sort of stock they should not be too closely fed down, nor should the sheep remain too long upon them. It has been suggested that all sorts of cattle stock should be removed by the beginning of the year from these rouens, as much harm might be done by their continuing longer.

5605. *In top-dressing saintfoin* peat-ashes are the best material that can be made use of where they can be procured in sufficient quantity; and other sorts of ashes are likewise found beneficial where these cannot be had. They should be applied so as to form a thin, even, regular dressing over the whole surface of the crop. In this view soot has also been found of great utility when spread evenly over such leys about the beginning of January, in the proportion of about twenty-five or thirty bushels to the statute acre; and malt-dust has been employed in the same way with great success and advantage, as shown by Bamister in his *Synopsis of Husbandry*. It is supposed that where those sorts of top-dressings can be applied every third or fourth year, the saintfoin crops, when well established in the soils, may be preserved in a state of vigorous growth for ten or fifteen years, or more, and the land be considerably improved by the roots striking so deeply into it.

5606. *In taking and using the saintfoin crop*, the same practices may be followed as in taking clover: it may be mown for soiling, hay, or seed; and eaten on the spot by tethering, huddling, or common pasturing.

5607. *In making it into hay*, it is cut immediately on its coming into full blossom, and as it remains but a short time in this state, as much expedition as possible should be employed both in mowing and making the produce into hay. It is remarked by the author of *The Synopsis of Husbandry*, who resides in a district where the culture of saintfoin is frequent, that of all other hay plants, it requires the least pains in making. When the season is favourable, the hay-makers may follow the scythe, and having turned over the swaths, throw them into wind-rows the succeeding day after the crop is mown, when it may be immediately formed into cocks, and the whole crop be fit for carting in a week, sometimes in three days after it is mown. Though it may appear very green, and the stack when made take on or acquire a considerable degree of heat, there is no danger to be apprehended, provided the weather has been fair during the hay-making; as it is so far from taking harm by heating in the stack, that the contrary state is the most to be feared. For this reason great care is necessary not to suffer the fodder to continue long either in the swath or in cocks, lest the sun and wind should dry it up too fast, and by exhaling its juices prevent the heating in the stack, and thereby render it of little value. In order to preserve its succulence, in some places they put a number of these cocks together, so as to form large cocks of a size to contain a load in each, and they finish the stacks out of the cocks. It is likewise a practice with many farmers, where the crop is slight, to turn the swaths, and then run them into cocks with a three-pronged barley fork, following with a wooden dew-rake, the head of which is of sufficient width to cover the ground occupied by three or four swaths, in this manner proceeding with the utmost despatch, and saving a deal of labour and expense in the business.

5608. *In regard to the frequency of cutting saintfoin*, it is probable that on the thinner sorts of soils it can seldom be done more than once; but on those of the deeper sorts two crops may sometimes be taken, in the same manner as with clover, care being taken in these cases that the future growth of the plants be not injured by this means.

5609. *The usual duration of saintfoin*, in a profitable state, is from eight to ten years. It attains its perfect growth in about three years, and begins to decline towards the eighth

or tenth on calcareous soils, and about the seventh and eighth on gravels. There are instances, however, of fields of saintfoin, which had been neglected and left to run into pasture, in which plants have been found upwards of fifty years from the time of sowing. It has been cultivated upwards of a century on the Cotswold Hills, and there roots of it have been traced down into stone quarries from ten to twenty feet in length, and in Germany Von Thier found them attain the length of sixteen feet. In general the great enemy to the endurance of saintfoin is the grass, which accumulates and forms a close turf on the surface, and thus chokes up the plant.

5610. *The quantity of produce* in the state of hay, on a medium of soils and cultivation, may probably be estimated at from about one and a half to two tons the acre; and on the poorer and thinner staple sorts of land it will, perhaps, seldom afford less than from a ton to a ton and a half on the acre.

5611. *The nutritive products of saintfoin* are the same as clover; viz. $3\frac{3}{10}$ being $1\frac{6}{10}$ per cent more than those of lucern.

5612. *In saving seed* from saintfoin, it should remain on the land till the husks become of a somewhat brownish colour, and the seeds are perfectly plump and firm; as by these means they will not only be better in their quality, but be in less danger of being injured in the field, from the very short time that it will be necessary for them to remain, and also less in danger of being hurt by heating when laid up for future use. It has been stated, that it requires some experience to know of what degree of ripeness it is best to cut the seeded saintfoin, because all its seeds do not ripen at the same time. Some ears blossom before others; and every ear begins to blossom at its lower part, and continues to blow gradually upwards for many days; so that before the flower is gone off at the top, the seeds are almost mature at the bottom. From this cause, if the cutting be deferred till the top-seeds are quite ripe, the lower, which are the best, would shed and be lost.

5613. *The best time to cut it* is when the greater part of the seed is well filled, the first blown ripe, and the last blown beginning to be full. The unripe seeds will ripen after cutting, and be in all respects as good as those that were ripe before. Some, for want of observing this, have suffered their saintfoin seed to stand till all of it has shed, and been lost in cutting. Saintfoin should never be cut in the heat of the day, while the sun shines out; for then much, even of the unripe seed, will shed in mowing. The right time for this work is the morning or evening, when the dew has rendered the plants supple. When the weather is fine and clear, the saintfoin will soon dry sufficiently in the swaths, without turning them; but if any rain has fallen, and there is a necessity for turning them, it should be done very gently while they are moist, and not with two swaths together, as in hay made of saintfoin before it has seeded. If the swaths are turned with the handle of the rake, it is best to raise up the ear-sides first, and let the stub-side rest on the ground in turning; but if it is done with the teeth of the rake, let the stub-side be lifted up, and the ears rested on the earth. If it be cocked at all, the sooner it is done the better; because, if the swaths are dry, much of the seed will be lost in separating them, the ears being entangled together. When moist, the seeds stick fast in the ear; but when dry, they drop out with the least touch or shaking. It is, however, the best practice, as soon as the proper degree of maturity has been attained by the crop, to mow it in as short a time as possible, and let it remain exposed in the swath until the upper surface is fully dried, when it must be wholly turned over, but in a very careful manner, so as to prevent the seeds from shedding and being lost. When this side has been rendered perfectly dry and crisp in the same way as the other, the crop should either be threshed out upon cloths in the field where it is grown, or laid up in stacks to be afterwards threshed when the farmer has more leisure and convenience for the work.

5614. *The work of threshing out the seeds* in this kind of crop is much less troublesome and expensive than in the clover kind. In cases where threshing-machines are in use, the business may be executed by them with great ease and facility. It has, however, been observed by a late writer, that "when the season is favourable, the practice of threshing it out in the field is probably the most beneficial, as the stems or haulm may be laid up for the purpose of fodder in the stack."

5615. *As the threshing in the field* cannot be done but in very fine weather, and while the sun shines in the middle of the day, the best manner of performing it is to have a large sheet pegged down to the ground, for two men to thresh on with their flails, while two others bring them fresh supplies in a smaller sheet, and two more clear away the hay that has been threshed. The seed is emptied out of the larger sheet, and riddled through a large sieve, to separate it from the chaff and broken stalks; after which it is put into sacks, and carried into the barn to be winnowed. Care should be taken not to let the hay get wet, as in that case it would be spoiled. It is a very important, but difficult matter, to keep the seed that has been threshed in the field from becoming wet. If it be winnowed immediately, and laid in a heap or put into a sack, it will ferment to such a degree in a few days that the greater part of it will lose its vegetative quality. During that fermentation it will be very hot, and smell sour. Spreading it upon a barn-floor, though but seven or eight inches thick, will answer no end, unless it be frequently and regularly turned until the heating is over: but even this will not make its colour keep so bright as if it were well housed, well dried, and threshed in the winter. Laid up unthreshed it will keep without any danger of spoiling, because it does not lie close enough to heat. The best way to preserve the seed threshed in the field is to place a layer of straw upon a barn-floor, and upon that a thin layer of seed; then another layer of straw, and another layer of seed; and so on. By this means the seed, mixing with the straw, will be kept well, and come out in the spring in as fresh colour as when it was put in.

5616. *In respect to the produce in seed*, it is said to be usually "from about four to five sacks in some districts, but in others it will probably be much less, especially on the shallower sorts of saintfoin soils." But this must obviously be liable to great variation from seasons, &c.

5617. *The diseases of saintfoin* are few, there being little danger of failure after it has escaped the fly, which attacks the clover tribe in germinating.

SECT. IV. *Various Plants (not Gramineæ) which are or may be cultivated as Herbage and for Hay.*

5618. Among the inferior herbage plants which are occasionally cultivated, are burnet, ribwort, furze, and spurry. Those which might be cultivated are very numerous, and includes several species of *Vicia*, *Láthyrus*, *Galèga*, *Lòtus*, *Trifòlium*, *Medicàgo*, and others of the native *Legumindseæ*, or pea-like flowering plants; and *Achillea*, *Alchemilla*, *Cheiránthus*, *Spártium*, *A pium*, and a variety of others of different families. With the exception of the chicory and furze, there are none of these plants that deserve the attention of the professional farmer; ribwort and burnet are occasionally sown; but they are of little value as hay plants, and in most pastures their place might be more advantageously occupied by one or other of the natural grasses. With respect to the other plants enumerated, they have never been tried but by way of experiment, and are only mentioned as resources under peculiar circumstances, and as a field of enquiry and exertion for the amateur cultivator.

5619. The burnet (*Pimpinella grandc*, Fr.; *Potèrium Sanguisòrba L.* fig. 778.) is a native plant, a hardy perennial with compound leaves, blood-coloured flowers, and a long tap-root. It was originally brought into notice by Rogue, a commercial gardener, at Walham green, near London, who found means to procure the patronage of the Dublin and other societies to this plant, which, being a novelty, attracted the attention and called forth the eulogies of Arthur Young, and other leading agriculturists of the day. Miller, however, at the time observed, that whoever will give themselves the trouble to examine the grounds where it naturally grows, will find the plants left uneaten by the cattle, when the grass about them has been cropped to the roots; besides, in wet winters and on strong land, the plants are of short duration, and therefore very unfit for the purpose of pasture or hay, nor is the produce sufficient to tempt any persons of skill to engage in its culture.

5620. Curtis says of burnet, that it is one of those plants which it has for some years past been attempted to introduce into agriculture; but not answering the farmer's expectation, it is now in a great degree laid aside. Cattle are said not to be fond of it; nor is its produce sufficient to answer the expense attending its culture. It is to be lamented that persons do not pay a little attention to the nature of plants before they so warmly recommend them. A small plant, scarcely ever met with but on hilly and chalky ground, and to which cattle in such situations do not show any particular attachment, is not likely to afford better or more copious nourishment than the clovers and other plants already in use.

5621. According to Boys, in *The Agricultural Survey of Kent*, it affords herbage in the winter and spring months, but is not much liked either by cattle or sheep.

5622. Dr. Anderson reports, that burnet retains its verdure pretty well during the winter months, but affords such scanty crops as hardly to be worth the attention of the farmer.

5623. A correspondent in the *Museum Rusticum*, a work very favourable to burnet, confesses with reluctance that it is not deserving of any exalted character, but rather the contrary; and that it is in no degree to be compared to the common clover, which is cultivated at half the expense. It appears from some accounts there that horses will not eat it at all, and that kine frequently will not take it without great reluctance. Its slow growth is also made a great objection: being only about five inches high, and having scarcely one head in flower; whilst lucern, on the same soil, sown the same day and much thicker, was eighteen or twenty inches in height. It is not meant by this, however, to discourage that laudable spirit of improvement which so happily prevails at present; but to caution such as introduce any new plant to make themselves well acquainted with its natural history.

5624. Those who wish to cultivate burnet, as an herbage and hay plant, may treat it exactly as directed for saintfoin: as a pasture plant it is sown among the grasses in the same way as white or yellow clover. A bushel of seed is commonly sown to an acre.

5625. The ribwort plantain (*Plantain des Près*, Fr.; *Plantago lanceolata L.*, fig. 779.) is a hardy native with a tuft of long ribbed leaves springing from the crown of the root, long naked flower-stems, and a long moniliform tap-root. It abounds in dry soils, as do several other species of plantain, especially the *P. mèdeia*. On dry soils it affords little herbage, and is often left untouched by cattle. Curtis, Withering, and other British botanists, speak unfavourably of the ribwort as a pasture herb; but Haller attributes the richness of the milk in the Swiss dairies to the flavour of this plant, and that of the *Alchemilla*, in the mountain pastures. In rich moist or watered lands its herbage is more abundant, and its flavour altered,—a circumstance not uncommon in the vegetable kingdom, but from which it does not always follow that the plant so altered is deserving of culture. In conformity with this observation, though the ribwort is a scanty and rejected herbage, on poor dry soils, it is said by Zappa of Milan to grow spontaneously in every meadow of Lombardy, especially in those which are irrigated. It vegetates early, flowers at the beginning of May, ripens in five weeks, and is cut with the *Poa trivialis*; the height of the leaves is about one foot, and of the stalk a foot and a half; it multiplies itself much by the seed, and a little by the roots, which it continues for some time to reproduce. Ribwort, more especially in a cultivated state, is eaten heartily by every sort of cattle, and in particular by cows, who like it most in May, when it has great influence on the milk, as the hay has on the flesh. In Scotland it is a useful addition to the proper grasses on lands to be pastured by sheep, at the rate of two or three head to the acre. Where kept well fed down by stock, there can be no doubt of its being a very good and nourishing pasture plant for both cattle and sheep; but it is by no means adapted for hay or soiling.

5626. Young says, that he had long before recommended this plant for laying land to grass, and sowed it on his own farm. At the same time, he thinks it extravagant to propose dandelion and sorrel as plants

proper for a cow pasture, and conjectures that those plants, being found among good ones, have qualities given them which do not properly belong to them: he is likewise inclined to make the same conjecture in respect to narrow-leaved plantain, ribwort, or rib-grass, and should even have preferred dandelion and sorrel to it; but he is cautious of opposing theory to practice.

5627. *Dr. Anderson* states, that narrow-leaved plantain or rib-grass is well liked by horses and cattle, and yields a very good crop upon rich ground tending to dampness, if it is at the same time soft and spongy; but that upon any soil which has a tendency to bind, or upon dry ground, it furnishes a very scanty crop. It has been made use of in some parts of Yorkshire as a summer grass. As an article of pasturage for cattle and sheep, it is there in high esteem: it is not, however, well eaten by horses. As an article of hay, it is held to be detrimental to the crop; retaining its sap an unusual length of time, and when fully dry falling into a small compass, or being broken into fragments and left behind in the field.

5628. *The culture of the plantain* is the same as that of clover; its seed is about the same size, and consequently the same proportion of it will sow an acre.

5629. *The whin, furze, or gorze* (*Ajone, Jonc marin, Genet épineux*, Fr.; *Ulex europæa L., fig. 780.*) is a well known shrub, found wild on dry light soils, and in rather hilly situations, in the warmer and more temperate parts of Europe; but not in Sweden, or in Russia or Poland, north of Cracow and Casan. It has been known as a nourishing food for cattle from a very early period, and has been sown in some parts of England for that purpose and for fuel. *Dr. Anderson* knows few plants that deserve the attention of the farmer more than the whin. Horses are peculiarly fond of it; so much so, that some persons think they may be made to perform hard work upon it, without any feeding of grain: but he thinks it tends more to fatten a horse than to fit him for hard labour, and that therefore some grain should be given with it where the work is severe. Cattle, he says, eat it perfectly well when thoroughly bruised, and grow as fat upon it as upon turnips; but unless it be very well bruised for them, they will not eat it freely, and the farmer will be disappointed in his expectations. It has lately been found excellent food for horses in the Highlands of Scotland. (*High. Soc. Trans. vol. v.*) Cows fed upon it yield nearly as much milk as while upon grass, and it is free from any bad taste. The best winter-made butter he ever saw was obtained from the milk of a cow fed upon this plant. This food should be made use of the soon after being prepared. Two bushels, with a proper allowance of hay, have been found to be sufficient for a day for three horses performing the same labour as with corn. It also seemed useful to horses labouring under broken wind and grease. Poor hungry gravelly soils, which would not have let for five shillings an acre, have been rendered worth twenty shillings by sowing them with furze-seed, in places where fuel has been scarce; the furze being frequently used for heating ovens, burning lime and bricks, and also for drying malt: but it is not worth cultivating in countries where fuel of any kind is cheap, or upon such lands as will produce good grass, corn, or other crops employed as the food of animals.

5630. *The culture of the whin* is thus given by the same author:—A field of a good dry loamy land, being well prepared, he sowed, along with a crop of barley, the seeds of the whin in the same way as clover, is usually sown, allowing at the rate of from fifteen to thirty pounds of seed to the acre. The seeds, if harrowed in and rolled with the barley, quickly spring up, and advance under the shelter of the barley during the summer, and keep alive during the winter. Next season, if the field has not a great tendency to run to grass so as to choke them, they advance rapidly after midsummer, so as to produce a pretty full crop before winter. This you may begin to cut with a scythe immediately after your clover fails, and continue to cut it as wanted during the whole of the winter; but it is supposed that, after the month of February, the taste of this plant alters, as it is in general believed that after that time horses and cattle are no longer fond of it. He, however, observes, that never having had a sufficiency of whins to serve longer than towards the middle of February or beginning of March, he cannot assert the fact from his own experience. He has frequently seen horses beating the whins with their hoofs, so as to bruise the prickles, and then eating them, even in the months of April and May; and he says, that sheep which have been used to this food certainly pick off the blossoms and the young pods at that season, and probably the prickles also; so that it is possible the opinion may only be a vulgar error. This is, he thinks, the best way of rearing whins as a crop for a winter food for cattle or horses. But for sheep, who take to this food very kindly when they have once been accustomed to it, less nicety is required; for if the seeds be simply sown broad-cast, very thin (about a pound of seed per acre) upon the poorest soils, after they come up the sheep of themselves will crop the plants, and soon bring them into round close bushes, as this animal nibbles off the prickles one by one very quickly, so as not to be hurt by them. Sheep, however, who have not been used to this mode of browsing do not know how to proceed, and often will not taste them; but a few that have been used to the food will, he observes, soon teach all the rest how to use it.

5631. *Another very economical way of rearing whins*, but which he has seen practised rather than experienced himself, is this:—Let a farm be enclosed by means of a ditch all round, with a bank thrown up on one side, and if stones can be had, let the face of that bank be lined with the stones, from bottom to near the top, this lining to slope backwards with an angle of about sixty or seventy degrees from the horizon. Any kind of stones, even round ones gathered from the land, will answer the purpose very well; upon the top of the bank sow whin-seeds pretty thick, and throw a few of them along the face of the bank. Young plants will quickly appear. Let them grow for two years, and then cut them down by means of a hedge-bill, sloping down by the face of the bank. This mode of cutting is very easy, and as the seeds soon insinuate themselves among the crannies of the stones, the whole face of the bank becomes a close hedge, whose shoots spring up with great luxuriance. If another ditch be made on the other side of the bank, and if this be managed in the same way, and the hedge cut down only once every second year (and in this way it affords very good food for beasts), the inside and outside being cut down alternately, the fence will at all times continue good, as the hedge at the top will at all times be complete. This mode of rearing whins is, he remarks, both convenient and economical. But where stones cannot be obtained for making the facing, the bank very soon moulders down, and becomes unfit for the purposes of a fence. Circumstances have prevented him from ascertaining what is the weight of the crop that may be thus attained, but he thinks he may safely venture to say, that it is at least equal to that of a crop of green clover; and if it be considered, that this affords a green succulent food during winter, on which cattle can be fattened as well as on cut grass in summer, it will, he thinks, be admitted, that it must be accounted even a more valuable crop than clover. After being cut, he also remarks, that it springs up the following season with greater vigour than before, and in this situation acquires a degree of health and succulence very different from what it is ever observed to possess in its natural state. He has seen shoots of one season near four feet in length. The prickles too are so soft, and the stems so tender, that very little bruising is necessary; indeed horses, that have been accustomed to this food, would eat it without any bruising at all; but horned cattle, whose mouths seem to be more tender, always require it to be well bruised. How long crops of this sort may continue to be annually cut over without wearing out, he cannot say, but he believes a long while in favourable circumstances. One thing, however, it is necessary to attend to in

780

order to guard against its being destroyed: as, during the beginning of the season, nature seems to be solely employed about the great work of fructification, and it is not till near Midsummer that the whin begins to push forth its wood-bearing branches, which advance with great luxuriance during the latter part of the season only, it may happen, that if care be not taken to have the grass that springs up on the field, before the whin begins to send out its shoots, eaten close down, that grass will acquire such a luxuriance before the young branches of the whin begin to advance, as to overtop them, and choke them entirely. Whoever, therefore, has a field under this particular crop, must be careful to advert to this circumstance, or, if the field be in good heart, he will infallibly lose it. The field therefore should be kept as

a pasture, bare as possible during the beginning of the season, and the cattle should only be taken from it when the shoots of the whin begin to advance with vigour. Under this management, he presumes, it may be kept for many years, and yield full crops; but, unless the mowers be particularly attentive at the beginning, to cut it as low as possible, it will very soon become impossible to cut the field with a scythe, as the stumps will acquire so much strength as to break the scythe when it happens to touch them.

5632. *The spurry* (*Spergula*, Fr.; *Spérgula arvensis* L., fig. 781.) is a diminutive annual weed, on dry sandy corn-lands, in most parts of Europe. In Germany and the Netherlands, it is sown on the corn stubbles, and in the intervals of time that occur between some crops is fed with sheep. It may be sown and reaped in eight weeks, either in autumn or spring. It is said to enrich the milk of cows, so as to make it afford excellent butter; and the mutton fed on it is preferable to that fed on turnips. Hens eat spurry greedily, and it is supposed to make them lay a great number of eggs. Whether in hay, or cut green, or in pasture, Von Thaer observes, it is the most nourishing, in proportion to its bulk, of all forage, and gives the best flavoured milk and butter. It has been recommended to be cultivated in England; but it ever pay the expense of seed and labour in this country, even on the poorer Martyn observes, we have many better plants for such soils.

5633. *The common broom* (*Genet commun*, Fr.; *Spartium scoparium* L., fig. 782.) is cultivated in the southern parts of France, on the poorer sorts of soil, in the same way as hemp, for the purpose of stripping the bark from it, and converting it into a kind of thread. It is likewise cultivated in these places as a winter-food for sheep, and it is said they eat it with great avidity, preferring it to many other plants. It is, however, liable to produce diseases of the urinary passages, by its diuretic qualities. It has been recommended by Young to be cultivated in England as food for sheep and horses, who are said to eat it after they get accustomed to it; also for thatch, ropes, besoms, food for bees, fuel, and burning on the spot to improve the soil. Its culture is the same as that of the whin; but very peculiar, indeed, must be that situation, where its culture is attempted for any of the above purposes. It is a useful protection of game in plantations, from which source abundance may be had for besoms. The Spanish broom (*S. Juncum* L., fig. 783.) might

781

is not likely that such a plant can poorest soil, or at all events, as Pro

782

be grown perhaps still more advantageously than the common species.

783

5634. *The parsley* (*Persil commun*, Fr.; *Apium Petroselinum* L., fig. 784.) is a well known biennial with a large sweet tap-root. It is a native of Sicily, but endures the British winter like a native plant. It is sown along with clover and grass seeds in some places, and especially in Lincolnshire, as a preventive of the rot in sheep. Fleet, of Hampshire, famous for curing the rot in sheep, cultivates it largely with success: he sows half a bushel to the acre, with a bushel of rye-grass with spring corn; and he finds that it lasts in the ground till it is permitted to seed. He feeds it constantly; it being excellent for sheep, and, when suffered to get a-head, wonderfully fed upon by pigs in the autumn. After September, it will not, he says, run to seed. When it was ploughed up he obtained good oats. The land was poor, and in the next round of the course, the clover was much the better for the parsley having been sown or the clover omitted; for in a field half parsley, half clover, when the clover came again to be sown, it was excellent on the parsley half, but bad on the clover part. In laying down land to grass, Hoyte, in the fourth volume of *Communications to the Board of Agriculture*, advises the sowing with twelve pounds of white clover, two pounds of red clover, two pecks of rye-grass, and two pounds of parsley to the acre, as the parsley stands two years, and by its diuretic qualities prevents the sheep from dying of the red-water, which too luxuriant clovers are apt to produce. In Scotland, also, it has been sown with success, and greedily eaten by horses, cows, and hogs. The seed requires a longer period to germinate than that of any other agricultural plant, and might probably be advantageously prepared by steeping and turning. It must be fresh, as two-year-old seed will not grow. It is easily procured by the pound or bushel, from the seedsman,

784
