EARLY NATURALISTS.

The Early Naturalists. Their Lives and Work (1530–1789). By Dr. L. C. Miall, F.R.S. Pp. xi+396. (London: Macmillan and Co., Ltd., 1912.) Price 10*s.* net.

IN this account of the naturalists who worked and wrote during the period between the commencement of the Protestant Reformation and that of the French Revolution, Prof. Miall has placed under a considerable obligation those who are interested in the advancement of natural knowledge. The period to which the work is in the main limited constitutes perhaps as natural an epoch as may be found in human history. Whether the period be natural or not, the charming introductory sketch of "Natural History down to the Sixteenth Century" fully justifies the selection of the date at which the author's account of scientific progress formally opens, while the closing date adopted is at least convenient. But the work is one that could only have been written with unusually full knowledge of the scientific happenings since the date of Buffon's death, and it is owing to the possession of this knowledge that the author has been able to assess so authoritatively as he does the extent and the value of the permanent additions to biological truth which marked the period he passes under review.

The work, in the main, deals, as its title implies, with the lives and the labours of the naturalists who flourished during the period in question. In his treatment of the subject Professor Miall strikes a happy mean between the methods of the skilled biographer and of the formal historian of human progress. As a result, he succeeds in enabling the reader to acquire a clear conception not only of what was accomplished during the period, but of the character of those by whom the work was done and of the intellectual atmosphere in which they lived. To the personal interest thus aroused is largely due the force of the incisive estimates provided by the author of men like Clusius and Belon, Ray and Leeuwenhoek, Réaumur and Buffon, to mention only a few of the worthies whose lives are discussed. Even in those rare instances in which the reader may feel inclined to differ from Prof. Miall, it will be admitted that his estimates are the result of complete knowledge and judicial thought; any disinclination to accept the verdicts depends not on the facts, but on the point of view from which these facts are regarded.

There is, however, a certain want of unity in the work. In addition to the accounts of individual naturalists which we conclude from the title to be its main subject, the book contains a series of essays of a different type, each of them as self-contained as the character-sketches of which the work is principally composed. One of these, already alluded to, aptly serves as an introduction to these sketches. Another, on "The Natural History of Distant Lands," is interpolated between the accounts of the earlier Continental and the earlier English naturalists, but scarcely serves as a connecting link between the one group and the other. This essay is, however, so interesting in itself that one welcomes it as a digression, which at least does not carry us beyond the later limit of the period discussed, and may be excused for taking us back further than its earlier one.

Two similar essays, equally self-contained, on "The Investigation of the Puss Moth," and on "Early Studies of the Flower," which are not accorded the position of distinct sections, but are incorporated in other sections, deviate more considerably from the plan of the work as a whole; the former brings us down to the present day, while the latter carries us from Theophrastus to the first De Candolle. Still, both essays are germane to the purpose of the book, and add so much to its value that it would be more than ungracious to cavil at their presence among these delightful and informing sketches of the "Early Naturalists."

THE WANDERING OF THE BRONZE AGE POTTERS.

A Study of the Bronze Age Pottery of Great Britain and Ireland, and its associated Grave-goods. By the Hon. John Abercromby. Vol. i., pp. 163+lxi plates. Vol. ii., pp. 128+plates lxii–cx. (Oxford: Clarendon Press, 1912.) Two volumes, price £3 3s. net.

ARCHÆOLOGISTS have long been looking forward to the Hon. Dr. John Abercromby's monograph on Bronze Age pottery, and, as was to be expected, it has proved to be exhaustive and workmanlike. As an indication of the pains which the author has taken, it may be mentioned that there are photographs of 54 Continental beakers, 291 British beakers, 421 food vessels, 570 cinerary urns, numerous photographs of other objects, several plates of details of ornamentation, and a number of valuable maps of distributions. A classified list of the vessels illustrated in the plates would save the reader a great deal of trouble. The purely descriptive matter is as succinct as possible, though all essential information is given, and as there are full references the student knows where to go for further details.

Not only have we data of form, ornamentation, and distribution, but Dr. Abercromby has sought to make them tell a tale by coordinating other finds, such as skulls, implements, beads, &c. He rightly endeavours to give a picture of the life of the people, but some of his speculations on their social condition and religious beliefs are too hypothetical, and are scarcely consistent with the scientific method he adopts when dealing with his immediate subject. His general conclusions may be summarised as follows. About 2000 B.C. it would seem that Britain was invaded by a rugged, enterprising people, mainly of Alpine stock, whose ancestors, perhaps three to four hundred years earlier, had lived beyond the Rhine, not very far north of Helvetia. They had scarcely emerged from the neolithic stage of culture, and perhaps brought no single copper or bronze knife among them, but not long afterwards they possessed such small implements, and perhaps flat axes. Their wealth must have consisted in cattle, sheep, goats, and swine. They were also acquainted with cereals. They were not an inventive people, for they had only two forms of sepulchral pottery, which lasted with small variations for about 500 years, and they never abandoned geometrical ornamentation. Women were buried with as much ceremony as men. They presumably spoke an Aryan language.

The invaders probably landed on the coast of Kent, and in course of time some moved north and others west; these began to cluster on the Wiltshire downs, especially round what is now Stonehenge. About 1880 B.C. the northern branch crossed the Humber into East Riding, where they also found the earlier natives in possession. About this time their influence had reached Hibernia, in the shape of a beaker, though they themselves may not have crossed over so early. Not until about 1600 did they colonise the south coast of Moray Firth, and the extreme north was reached some time later. By 1500 B.C. the direct evidence of the brachycephalic invaders ceases. In the south their ceramic ended, and the skull-type was obliterated by cremation; but they were not exterminated. It is not unlikely that Stonehenge was erected about 300 years after the invasion.

About 1350–1150 there was a remarkable development of material civilisation in south Britain, new forms of small, often beautifully made cups are first met with, and there were skilful artificers in gold; traces of foreign influences are also met with. From about 1150 to 900 B.C. is an obscure period, with diminished material wealth. During the next period (*circa* 900–650), south Britain was entered by new tribes, apparently refugees, who introduced a new form of entrenchment and new forms of pottery, some of which have analogies east of the Rhine, others about the northern base of the Pyrenees. There is no evidence that they spread north of the Thames. During the period beginning *circa* 900, the population increased, and the dead were interred in flat cemeteries, though barrows never fell entirely into disuse; the change was not due to foreign influence, as the contemporary pottery from cemeteries and barrows is identical. The period from 650–400 is obscure; in remote parts like Dorset and Ross-shire, the Bronze Age certainly lasted till about 200 B.C.

This admirable monograph breaks new ground, and will long remain the standard work on the early Bronze Age of the British Islands.

A. C. HADDON.

OUR BOOKSHELF.

The Inter-Relationships of the Bryophyta. By Dr. Frank Cavers. Reprinted from the *New Phytologist.* Pp. vi+203. Cambridge: At the Botany School, 1911. Price 4s.; postage 4d.

WE are a little late in announcing that Dr. F. Cavers's series of articles which appeared on the inter-relationships of the Bryophyta in the *New Phytologist,* vols. ix. and x., 1910–11, has been issued separately. It is a great convenience to have the work in this form, and it certainly deserves this distinction. The classification is mainly that adopted in Engler and Prantl's "Natürlichen Pflanzenfamilien," but as a result of his investigations the author introduces some modifications. His proposed divisions are: (1) Sphærocarpales, (2) Marchantiales, (3) Jungermanniales, (4) Anthocerotales, (5) Sphagnales, (6) Andreæales, (7) Tetraphidales, (8) Polytrichales, (9) Buxbaumiales, and (10) Eu-Bryales.

Dr. Cavers discusses more particularly the question of the old primary division of the Bryophyta into two classes, Hepaticæ and Musci, especially in relation to the Anthocerotales and the Sphagnales. He argues: "If the Anthocerotales are to be made a separate class apart from the Hepaticæ, either Sphagnales should also be considered a separate class apart from the Musci, thus making four primary divisions of Bryophyta —Hepaticæ proper, Anthocerotes, Sphagna, and Musci proper—or the Anthocerotales and Sphagnales might be united to form a class between the Eu-Hepaticæ and the Eu-Musci, thus giving three classes of Bryophyta." But he prefers dividing the Bryophyta into ten groups as designated above.

The account of *Riella capensis* is of special interest, and it is to be followed by a more detailed paper on the genus generally. Until 1902 this singular aquatic genus was only known to inhabit the Mediterranean region and the Lake of Geneva. Since then a species has been discovered in the Grand Canary; another in Texas; a third in Turkestan; and a fourth in South Africa.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Determination of the Epicentre of an Earthquake.

IT has been proved by observation with the Galitzin seismographs, both at Pulkowa and Eskdalemuir, that when the first phase P of an earthquake is sharp, the azimuth of the epicentre from the station is uniquely determined by the observations at that station. It follows that if the azimuth of the epicentre is determined at two independent stations suitably situated, the epicentre can be determined from these two azimuths alone.

We have to-day, as an example, verified by construction and by computation that this principle gives accurately the epicentre of the earthquake that occurred in Monastir on February 18, 1911.

The azimuth observed at Pulkowa was 22° 53′ west of south, while the azimuth observed at Eskdalemuir was 55° 56′ east of south. The resulting epicentre we find to be 40·5° N., 20·3° E.

The epicentre deduced by the Pulkowa observations of azimuth and epicentral distance was 40·5° N., 20·1° E.; while the similar deduction from the Eskdalemuir results was 40·3° N., 20·4° E.

It is clear that in this case the accuracy of determination from the azimuths alone equals that of the determinations from the separate stations, and it is known that the earthquake did occur in the region indicated.

The advantages of this new method based on azimuths alone are:—

(1) That it is quite independent of any time reckoning whatever at the two stations.

(2) That it is independent of the determination of the second phase S on a seismogram (which is frequently difficult to fix with certainty).

(3) That it is independent of any empirical tables for epicentral distance, which are admittedly only approximate.

(4) Although only two stations are used, the determination is unique.

We may observe that for a given case the accuracy of determination depends on a suitable choice of the two stations.

Implements of Man in the Chalky Boulder Clay.

IN NATURE of August 15 Mr. Reid Moir has given us certain interesting facts observed by him in connection with the scratching of flints.

(1) He notes the occasional scratching of what remains of the "cortex" of the original nodule. It does not seem to have occurred to him that such a result may have been produced while the flint was still enclosed in its original chalk matrix. Topley (in his "Geology of the Weald") showed long ago that the chalk strata had in many cases undergone considerable differential movement concomitant with crustal movements; and I have myself seen crushed flints still *in situ* in the chalk cliffs at Ventnor, where there is evidence of intense crustal movement of the strata. So far back as 1880 I noted this, also the extremely fractured and unworn condition of the flints left as a residuum from the solution of the chalk by carbonated rain-water on the top of St. Boniface Downs (see P.G.A., vol. viii., No. 3), and my interpretation of the phenomena there observable has since been confirmed by Dr. A. Strahan, F.R.S., of the Geological Survey. Here we have a sufficient mechanical cause totally independent of anything that may be connoted by the term "glaciation." There seemed, moreover, to be just that slight amount of surface-staining of the fractured surfaces which might be due to meteoric iron-dust.

(2) One fails to see that there is any mystery about the non-striated condition generally of the fracture-surfaces of the flint fragments from the Boulder Clay. How could the soft matrix of the Boulder Clay scratch a flint, or even hold a harder stone with sufficient grip to give it effect as a graving-tool, however great the volume-pressure may have been? When the "glazier" wants to cut glass he does not use putty to hold his "diamond." So much for the talk of "intense glaciation" of hypothetical pre-Crag flints, on which I hope to have shortly more to say.

On the other hand, boulders of the Chalk itself, if at all rounded by the shearing movement of the ice in which they were once embedded, are often scratched and grooved. (See further my paper on the mechanics of glaciers, Q.J.G.S., February, 1883; also NATURE, June 20, 1912.)

I can assure Mr. Reid Moir that the delicate and interesting subject of *patination* presents difficulties to those who (in microscopic and laboratory work) have brought some knowledge of physics and chemistry to bear on the *lithology of the flint*, and that it is not to be dismissed in the easy way he seems to suppose. Nor do I think that even Dr. Sturge (Proc. Prehis. Soc. of E. Anglia) has adequately dealt with the subject or with the possible causes of some phases of "striation." A. IRVING.

Bishop's Stortford, August 22.

THE FIFTH INTERNATIONAL CONGRESS OF MATHEMATICIANS AT CAMBRIDGE.

THE first Mathematical Congress was held at Zurich in 1897, the second at Paris in 1900, the third at Heidelberg in 1904, and the fourth at Rome in 1908. This year's congress met at Cambridge, August 21–28, under the presidency of Sir G. H. Darwin, and was divided into sections as follows:—I, Analysis; II, Geometry; III (*a*), Physical Mathematics; III (*b*), Statistics; IV (*a*), Philosophy and History; IV (*b*), Didactics. Several meetings of the last section were held in connection with the International Commission on the Teaching of Mathematics, which was formed by a resolution of the fourth congress to study and report on the actual state of mathematical teaching in various countries.

Receptions were given by the Chancellor, Lord Rayleigh, in the Fitzwilliam Museum, by Sir G. H. Darwin in St. John's and Christ's Colleges, and by the Master and Fellows of Trinity College. Visits were made to the University observatory and to the works of the Cambridge Scientific Instrument Company. Excursions were arranged to Ely Cathedral, Oxford and Hatfield House. Throughout the week the University and colleges displayed their customary hospitality to the full, and the appreciation of the visitors, both English and foreign, was very evident. The members numbered 572, as compared with 535 at the fourth congress, and included representatives from Brazil, Chile, Egypt, India, Japan, and Mexico. An exhibition organised by the Mathematical Association was arranged in the Cavendish Laboratory, and included English and foreign text-books, examples of school work, models and apparatus, and a most interesting and complete collection of calculating machines. Eight lectures were delivered to the whole congress, and we mention below a few of the less technical points occurring in these, and in the meetings of the didactic section.

Sir G. H. Darwin (Cambridge), in welcoming the congress at the first meeting, referred to the death of Henri Poincaré, whom he described as the one man who alone of all mathematicians might have occupied the position of president of the congress without misgivings as to his fitness. It brought vividly home to him how great a man Poincaré was, when he reflected that, to one incompetent to appreciate fully one half of his work, he yet appeared as a star of the first magnitude.

Prof. E. W. Brown (Yale) lectured on "Periodicity in the Solar System." Newton and his contemporaries aimed at obtaining functions which should express the positions of individual bodies at all epochs. This is now recognised as unattainable; and the position within certain limits of time is expressed by infinite series of terms, some of which are harmonic representing periodic motions, and others expressed as powers of the time representing secular motions. These series are carried to a degree of accuracy exceeding that of the most delicate observation; so that where the calculated positions differ from those observed by a quantity exceeding the possible error of observation, it may be safely assumed that forces are in action other than those postulated in the theory. This is notably the case in the theory of the moon, where the outstanding discrepancy is comparable with the largest of the perturbations due to the planets. Dynamical theory in the case of the asteroids has shown that in the particular case of the problem of four bodies when the mass of one is small, the motion of the latter is unstable for certain ranges of value of the radius vector; and no asteroids have, in fact, been found within these limits. It is possible that an explanation may here be foreshadowed of the dark intervals in Saturn's rings.

Prince B. Galitzin (St. Petersburg) lectured on "The Principles of Instrumental Seismology." The usual seismographic record shows three chief groups of disturbances, due respectively to the longitudinal and transverse waves through the core of the earth, and to the superficial wave round the crust. These, however, are complicated and supplemented by reflections of the deep waves at the surface, and sometimes also by twin earthquakes caused by the primary. The relations between the elastic constants of the core deduced from seismographic observations are in fair agreement with the theory of elasticity of an isotropic medium. But an attempt has been made to construct a more general theory assuming heterogeneity depending on depth. The ideal aim of seismometry must be the determination of the six components of motion of a particle of the earth's crust throughout the whole of a disturbance. Hitherto attention has been confined to the three components of translation. The practical problem of recording the three components of rotation seems to have been solved recently in an apparatus in which induced currents from two pendulums are passed simultaneously in opposite directions through the same galvanometer. There is even reason to believe that the problem of predicting earthquakes is not so hopeless as it would *a priori* seem to be.

Sir W. H. White lectured on "The Place of Mathematics in Engineering Practice." It is matter for surprise that many of the great engineering discoveries of the last century were made by men who had little or no mathematical or scientific training. On the other hand, much good work was done by French mathematicians in the eighteenth century in laying the foundations of naval architecture. The discussions of recent years have tended to the conclusion that the mathematical portion of an engineer's training is best given in the regular manner by a mathematician, rather than in a selected course by an engineer. There can be no doubt as to the value of mathematics, both in indicating the lines along which experiments must be made and in framing a theory from their results. Many problems, such as that of the design of ship propellers, stand urgently in need of the mathematician's help.

At an extra meeting of Section IV, Mr. P. J. Harding lectured on "The History and Evolution of Arithmetic Division." The two methods of calculation prevalent in Europe previous to the introduction of the Arabic numerals were that of the algorists, who used counting-boards ruled with lines representing successive powers of ten on which counters were placed, and that of the abacus. Arabic numerals followed the trend of commerce from India through Arabia and Italy into northern Europe; so far as we know, they first appeared in Italy in 1202. Subtraction was first performed from the left by scratching out the digits successively, a method evolved from the sand-board used in the East, which was small compared with the size of the numerals, so that successive deletion was necessary. From this followed the method of division by scratching, known as the galleon method owing to a fancied resemblance of the resulting disposition of digits to the form of a ship. The modern method of division first appeared in print in Italy in 1494, but it only superseded the galleon method after a struggle which lasted more than a century. In England its ultimate triumph was largely due to the writing-master Cocker, who advocated it to the exclusion of the older method.

At a special meeting of Section III (*a*), Sir J. J. Thomson (Cambridge) gave a lecture illustrated by experiments on "Multiply Charged Atoms," in which he described some recent investigations on positive charges. He explained the parabolic grouping effected by the simultaneous action of electric and magnetic fields, and showed photographs of the parabolic arcs obtained in various particular cases. In the case of mercury atoms, eight such arcs were obtained, due to one or more of the charges originally carried being lost in transit, so that the particles arrived at the screen with their original energy but with reduced charge.

At an ordinary meeting of Section IV, Dr. A. N. Whitehead (London) read a paper on the principles of mathematics in relation to elementary teaching. The only justification for the inclusion of mathematics in a liberal education is the power of abstraction and deductive reasoning fostered thereby. These powers can only be acquired by constant practice, and no short-cuts are possible. But this does not imply that such powers are to be assumed in the pupil from the outset. On the contrary, no generalisation can be made by the pupil until he is familiar with the raw material from which it is to be made. There is no final degree of rigour in deduction, and the degree to be adopted is a matter for the teacher to decide. His personal choice would be approximately the degree of rigour, though not necessarily the content of Euclid's Elements. No compromise is desirable between the purely utilitarian procedure of looking up a formula in an engineering pocket-book and the acquisition of a mathematical habit of mind by years of practice in abstraction and deduction.

Mr. G. E. St. L. Carson (Tonbridge) read a paper on the place of deduction in elementary mechanics. He suggested that, besides the old method of teaching mechanics in which a structure of deduction was raised on a few postulated laws, and the new method in which principles are demonstrated independently by experiment, there is a third method possible in which the logical interdependence of the principles demonstrated is discussed. Not only is this an aid to understanding the foundations of the subject, but they are shown to constitute a broad inductive basis.

A paper by Dr. T. P. Nunn (London) was read on the proper scope and method of instruction in the calculus in schools. He advocated the teaching of integration by means of graphical illustration on the lines originally adopted by Wallis. This should be followed by a consideration of differentiation as the converse geometrical problem. The teacher should avoid all use of such mystic phrases as "infinite" and "ultimately become," keeping carefully to the definition of limit in terms of finite quantities.

At meetings of Section IV (*b*), in conjunction with the International Commission on the Teaching of Mathematics, reports were presented, with a few explanatory remarks, by delegates from twenty-one countries. The reports exceeded 280 in number, forming an aggregate of more than 9000 octavo pages. These may be obtained from Messrs. Georg et Cie., of Geneva; the English reports have recently been issued in two volumes by the Board of Education. The commission was reappointed for a further period of four years, in order that a digest of these reports may be prepared for the use of teachers in each country. The commission has also conducted special investigations, and reports were presented on the results of two of these.

Prof. C. Runge (Göttingen) presented a report on the mathematical training of the physicist in the university. The need for the closer co-operation of the mathematician and the physicist is strongly felt. It would be of benefit not only to the future physicist or engineer, but also to the student of pure mathematics, if in mathematical lectures theoretical solutions were followed up by numerical computations and applications to material problems. It is also felt that mathematical teaching in the university would be improved if the lecturer were assisted by demonstrators who could keep in personal touch with the student, and aid him as difficulties arise. In commenting on this report, Profs. Hobson, Love, and Sir J. Larmor were of opinion that to limit the mathematics of science students to those portions which might be considered of direct utility would destroy that logical unity which is the essential feature of the subject, and relegate it to a subservient position little in keeping with its importance. Sir A. G. Greenhill uttered a warning against the excessive attention engineering pupils are apt to give to descriptive geometry, to the detriment of their studies in the calculus. Sir J. J. Thomson was in favour of physicists learning mathematics from pure mathematicians, if the latter would reserve some of their latest refinements for special lectures.

Prof. D. E. Smith (New York) presented a report on intuition and experiment in mathematical teaching in secondary schools. The object of the inquiry was to ascertain to what extent intuitional methods are at present employed. A general spirit of unrest is apparent. In geometry it may be said that it is the plan of the Teutonic countries to mix the intuitional and deductive work from the outset, while in France, and now in England, the plan is to let an inductive cycle precede a deductive one. The United States is only beginning to talk about the question, whatever tendency there is being towards the Anglo-French plan. The second important movement is the elaboration of the function concept; starting in France within the last twenty years, and vigorously advocated in Germany within the last decade, the movement is, as a whole, too recent to judge of its permanence. A practical form of outdoor mensuration seems to be developing, especially in Austria, Germany, and Switzerland. Geometric drawing and the graphic representation of solids are passing from the hands of the art teacher to the mathematician. Graphic methods of representing functions have become universal in the last generation. The contracted methods of computation that were prominently advocated fifty years ago do not seem to have advanced materially, owing to the feeling that they are not really practical; on the other hand, logarithms have come into general use, and the slide rule is in great favour in technical schools. In general, it may be said that intuitional and experimental methods have made more progress in Austria, Germany, and Switzerland than in England, France, and the United States.

At the final meeting of the congress it was resolved to accept the invitation to Stockholm for the next meeting in 1916. Informal invitations to Budapest and Athens for subsequent meetings were also noted.

THE BRITISH ASSOCIATION AT DUNDEE.

BY the time this issue reaches the reader the British Association will be in full session, and meanwhile there seems to be every prospect of an unusually successful meeting. Dundee is a town of comparatively small population, largely made up of the working classes, but the number of persons resident in the town and neighbourhood who have joined the Association is remarkable. The various towns in which the Association meets are found to differ greatly in this respect, and it occasionally happens that the number of local associates is exceedingly small. Since the year 1901 the Association has held its annual meetings on two occasions abroad and on nine occasions at places within the United Kingdom. The average number of tickets sold at these nine centres before the opening of the reception rooms is 460, and the highest number so sold at any one of the nine was 643; but considerably more than 1100 tickets had already been sold in Dundee by the local committee before the opening of the reception rooms, and by Tuesday evening some 2000 tickets were issued.

This large local addition to the ordinary membership of the Association, together with the unusually large attendance of foreign, American, and Colonial guests, however gratifying it may be to the officers of the Association, renders the task of the local committee a difficult and anxious one. The various halls and Section rooms will be taxed to the utmost, and the various excursions and entertainments will scarcely be sufficient for an attendance so greatly in excess of the estimates that were based on the statistics of recent meetings.

As has already been stated in these columns, the attendance of scientific men from abroad is unusually great, beyond anything indeed that has been seen since the great meeting at Manchester; and this large gathering of foreigners has had its effect in helping to attract the scientific men of our own country. Within the last few days a number of eminent mathematicians, who have attended the recent congress at Cambridge, have made known their intention to be present; geologists are mustering in strength from many countries, tempted to a large extent by the promise of excursions of unusual interest, and a still larger gathering of notable physiologists are coming to do honour to a physiological President.

Every nook and corner of the town is filled almost to overflowing, and members who arrive without having made their arrangements beforehand will have little chance of finding even the simplest houseroom. Private hospitality has provided for between 700 and 800 guests, and every hotel in the town and in the near neighbourhood was filled up many days ago.

It is sometimes said that the British Association is losing ground, but the experience of this meeting shows that the belief is without foundation; not only is the attendance this year fully comparable to the average attendance in the best days of the Association, but there is every prospect also of animated discussion and abundant scientific work. We print this week the inaugural address delivered last night by the president, Prof. E. A. Schäfer, F.R.S., and also the address to be delivered by Prof. H. L. Callendar, F.R.S., before Section A this morning. Other addresses, and reports of the proceedings of the various Sections, will appear in later issues.

INAUGURAL ADDRESS BY PROF. E. A. SCHÄFER, LL.D., D.Sc., M.D., F.R.S., PRESIDENT.

Introductory.

IT is exactly forty-five years ago—to the day and hour—that the British Association last met in this city and in this hall to listen to a Presidential Address. The President was the Duke of Buccleuch; the General Secretaries, Francis Galton and T. Archer Hirst; the General Treasurer, William Spottiswoode; and the Assistant General Secretary, George Griffith, who was for many years a mainstay of the Association. The Evening Discourses were delivered by John Tyndall "On Matter and Force," by Archibald Geikie "On the Geological Origin of the Scenery of Scotland," and by Alexander Herschel "On the Present State of Knowledge regarding Meteors and Meteorites." The Presidents of Sections, which were then only seven in number, were for Mathematics and Physics, Sir William Thomson—later to be known as Lord Kelvin; for Chemistry, Thomas Anderson; for Geology, Archibald Geikie, who now as President of the Royal Society worthily fills the foremost place in science within the realm; for Biology, William Sharpey, my own revered master, to whose teaching and influence British physiology largely owes the honourable position which it at present occupies; for Geography, Sir Samuel Baker, the African explorer, who with his intrepid wife was the first to follow the Nile to its exit from the Albert Nyanza; for Economic Science, Mr. Grant Duff; and for Mechanical Science, Professor Rankine.

Other eminent men present were Sir David Brewster, J. Clerk Maxwell, Charles Wheatstone, Balfour Stewart, William Crookes, J. B. Lawes and J. H. Gilbert (names inseparable in the history of agricultural science), Crum Brown, G. D. Liveing, W. H. Russell, Alexander Williamson, Henry Alleyne Nicholson, William Allmann, John Hutton Balfour, Spencer Cobbold, Anton Dohrn, Sir John Lubbock (now Lord Avebury), William McIntosh, E. Ray Lankester, C. W. Peach, William Pengelly, Hughes Bennett, John Cleland, John Davy, Alexander Christison, Alfred Russel Wallace, Allen Thomson, William Turner, George Busk, Michael Foster (not yet founder of the Cambridge School of Physiology), Henry Howorth, Sir Roderick Murchison, Clements R. Markham, Sir William (afterwards Lord) Armstrong, and Douglas Galton. Many of those enumerated have in the course of nature passed away from us, but not a few remain, and we are glad to know that most of these retain their ancient vigour in spite of the five-and-forty years which separate us from the last meeting in this place.

Selection of Subject of Address.

For the Address with which it is usual for the President to open the proceedings of the annual assembly, the field covered by the aims of the British Association provides the widest possible range of material from which to select. One condition alone is prescribed by custom, viz., that the subject chosen shall lie within the bounds of those branches of knowledge which are dealt with in the Sections. There can be no ground of complaint regarding this limitation on the score of variety, for within the forty years that I have myself been present (not, I regret to say, without a break) at these gatherings, problems relating to the highest mathematics on the one hand, and to the most utilitarian applications of science on the other, with every possible gradation between these extremes, have been discussed before us by successive Presidents; and the addition from time to time of new Sections (one of which, that of Agriculture, we welcome at this Meeting) enables the whilom occupant of this chair to traverse paths which have not been previously trodden by his predecessors. On the last two occasions, under the genial guidance of Profs. Bonney and Sir William Ramsay, we have successively been taken in imagination to the glaciers which flow between the highest peaks of the Alps and into the bowels of the earth; where we were invited to contemplate the prospective disappearance of the material upon which all our industrial prosperity depends. Needless to say that the lessons to be drawn from our visits to those unaccustomed levels were placed before us with all the eloquence with which these eminent representatives of Geology and Chemistry are gifted. It is fortunately not expected that I should be able to soar to such heights or to plunge to such depths, for the branch of science with which I am personally associated is merely concerned with the investigation of the problems of living beings, and I am able to invite you to remain for an hour or so at the level of ordinary mortality to consider certain questions which at any rate cannot fail to have an immediate interest for everyone present, seeing that they deal with the nature, origin, and maintenance of life.

Definition.

Everybody knows, or thinks he knows, what life is; at least, we are all acquainted with its ordinary, obvious manifestations. It would, therefore, seem that it should not be difficult to find an exact definition. The quest has nevertheless baffled the most acute thinkers. Herbert Spencer devoted two chapters of his "Principles of Biology" to the discussion of the attempts at definition which had up to that date been proposed, and himself suggested another. But at the end of it all he is constrained to admit that no expression had been found which would embrace all the known manifestations of animate, and at the same time exclude those of admittedly inanimate, objects.

The ordinary dictionary definition of life is "the state of living." Dastre, following Claude Bernard, defines it as "the sum total of the phenomena common to all living beings."[1] Both of these definitions are, however, of the same character as Sydney Smith's definition of an archdeacon as "a person who performs archidiaconal functions." I am not myself proposing to take up your time by attempting to grapple with a task which has proved too great for the intellectual giants of philosophy, and I have the less disposition to do so because recent advances in knowledge have suggested the probability that the dividing line between animate and inanimate matter is less sharp than it has hitherto been regarded, so that the difficulty of finding an inclusive definition is correspondingly increased.

Life not Identical with Soul.

As a mere word "life" is interesting in the fact that it is one of those abstract terms which has no direct antithesis; although probably most persons would regard "death" in that light. A little consideration will show that this is not the case. "Death" implies the pre-existence of "life"; there are physiological grounds for regarding death as a phenomenon of life—it is the completion, the last act of life. We cannot speak of a non-living object as *possessing* death in the sense that we speak of a living object as *possessing* life. The adjective "dead" is, it is true, applied in a popular sense antithetically to objects which have never possessed life; as in the proverbial expression "as dead as a door-nail." But in the strict sense such application is not justifiable, since the use of the terms dead and living implies either in the past or in the present the possession of the recognised properties of living matter. On the other hand, the expressions *living* and *lifeless*, *animate* and *inanimate*, furnish terms which are undoubtedly

1 "La vie et la mort," English translation by W. J. Greenstreet, 1911, p. 54

antithetical. Strictly and literally, the words animate and inanimate express the presence or absence of "soul"; and not infrequently we find the terms "life" and "soul" erroneously employed as if identical. But it is scarcely necessary for me to state that the remarks I have to make regarding "life" must not be taken to apply to the conception to which the word "soul" is attached.

Problems of Life are Problems of Matter.

The fact that the formation of such a conception is only possible in connection with life, and that the growth and elaboration of the conception has only been possible as the result of the most complex processes of life in the most complex of living organisms, has doubtless led to a belief in the identity of life with soul. But unless the use of the expression "soul" is extended to a degree which would deprive it of all special significance, the distinction between these terms must be strictly maintained. For the problems of life are essentially problems of matter; we cannot conceive of life in the scientific sense as existing apart from matter. The phenomena of life are investigated, and can only be investigated, by the same methods as all other phenomena of matter, and the general results of such investigations tend to show that living beings are governed by laws identical with those which govern inanimate matter. The more we study the manifestations of life, the more we become convinced of the truth of this statement and the less we are disposed to call in the aid of a special and unknown form of energy to explain those manifestations.

Phenomena Indicative of Life: Movement.

The most obvious manifestation of life is "spontaneous" movement. We see a man, a dog, a bird move, and we know that they are alive. We place a drop of pond water under the microscope, and see numberless particles rapidly moving within it; we affirm that it swarms with "life." We notice a small mass of clear slime changing its shape, throwing out projections of its structureless substance, creeping from one part of the field of the microscope to another. We recognise that the slime is living; we give it a name—*Amoeba limax*—the slug amœba. We observe similar movements in individual cells of our own body; in the white corpuscles of our blood, in connective tissue cells, in growing nerve cells, in young cells everywhere. We denote the similarity between these movements and those of the amœba by employing the descriptive term "amœboid" for both. We regard such movements as indicative of the possession of "life"; nothing seems more justifiable than such an inference.

Similarity of Movements in Living and Non-living Matter.

But physicists [2] show us movements of a precisely similar character in substances which no one by any stretch of imagination can regard as living; movements of oil drops, of organic and inorganic mixtures, even of mercury globules, which are indistinguishable in their character from those of the living organisms we have been studying: movements which can only be described by the same term amœboid, yet obviously produced as the result of purely physical and chemical reactions causing changes in surface tension of the fluids under examination.[3] It is therefore certain that such movements are not specifically "vital," that their presence does not necessarily denote "life." And when we investigate closely even such active movements as those of a vibratile cilium or a phenomenon so closely identified with life as the contraction of a muscle, we find that these present so many analogies with amœboid movements as to render it certain that they are fundamentally of the same character and produced in much the same manner.[4] Nor can we for a moment doubt that the complex actions which are characteristic of the more highly differentiated organisms have been developed in the course of evolution from the simple movements characterising the activity of undifferentiated protoplasm; movements which can themselves, as we have seen, be perfectly imitated by non-living material. The chain of evidence regarding this particular manifestation of life—movement—is complete. Whether exhibited as the amœboid movement of the proteus animalcule or of the white corpuscle of our blood; as the ciliary motion of the infusorian or of the ciliated cell; as the contraction of a muscle under the governance of the will, or as the throbbing of the human heart responsive to every emotion of the mind, we cannot but conclude that it is alike subject to and produced in conformity with the general laws of matter, by agencies resembling those which cause movements in lifeless material.[5]

Assimilation and Disassimilation.

It will perhaps be contended that the resemblances between the movements of living and non-living matter may be only superficial, and that the conclusion regarding their identity to which we are led will be dissipated when we endeavour to penetrate more deeply into the working of living substance. For can we not recognise along with the possession of movement the presence of other phenomena which are equally characteristic of life and with which non-living material is not endowed? Prominent among the characteristic phenomena of life are the processes of assimilation and disassimilation, the taking in of food and its elaboration.[6] These, surely, it may be thought, are not shared by matter which is not endowed with life. Unfortunately for this argument, similar processes occur characteristically in situations which no one would think of associating with the presence of life. A striking example of this is afforded by the osmotic phenomena presented by solutions separated from one another by semipermeable membranes or films, a condition which is precisely that which is constantly found in living matter.[7]

Chemical Phenomena accompanying Life.

It is not so long ago that the chemistry of organic matter was thought to be entirely different from that of inorganic substances. But the line between inorganic and organic chemistry, which up to the middle of the last century appeared sharp, subsequently

[2] G. Quincke, "Annal. d. Physik. v. Chem.," 1870 and 1888.

[3] The causation not only of movements but of various other manifestations of life by alterations in surface tension of living substance is ably dealt with by A. B. Macallum in a recent article in Asher and Spiro's "Ergebnisse der Physiologie," 1911. Macallum has described an accumulation of potassium salts at the more active surfaces of the protoplasm of many cells, and correlates this with the production of cell-activity by the effect of such accumulation upon the surface tension. The literature of the subject will be found in this article.

[4] G. F. Fitzgerald (Brit. Assoc. Reports, 1898, and Scient. Trans. Roy Dublin Society, 1898) arrived at this conclusion with regard to muscle from purely physical considerations.

[5] "Vital spontaneity, so readily accepted by persons ignorant of biology, is disproved by the whole history of science. Every vital manifestation is a response to a stimulus, a provoked phenomenon. It is unnecessary to say this is also the case with brute bodies, since that is precisely the foundation of the great principle of the inertia of matter. It is plain that it is also as applicable to living as to inanimate matter."—Dastre, *op. cit.*, p. 280

[6] The terms "assimilation" and "disassimilation" express the physical and chemical changes which occur within protoplasm as the result of the intake of nutrient material from the circumambient medium and its ultimate transformation into waste products which are passed out again into that medium; the whole cycle of these changes being embraced under the term "metabolism."

[7] Leduc ("The Mechanism of Life," English translation by W. Deane Butcher, 1911) has given many illustrations of this statement. In the Report of the meeting of 1867 in Dundee is a paper by Dr. J. D Heaton (On Simulations of Vegetable Growths by Mineral Substances) dealing with the same class of phenomena. The conditions of osmosis *in* cells have been especially studied by Hamburger ("Osmotischer Druck und Ionenlehre," (Wiesbaden, 1902-4).

became misty and has now disappeared. Similarly the chemistry of living organisms, which is now a recognised branch of organic chemistry, but used to be considered as so much outside the domain of the chemist that it could only be dealt with by those whose special business it was to study "vital" processes, is passing every day more out of the hands of the biologist and into those of the pure chemist.

The Colloid Constitution of Living Matter.—Identity of Physical and Chemical Processes in Living and Non-living Matter.

Somewhat more than half a century ago Thomas Graham published his epoch-making observations relating to the properties of matter in the colloidal state: observations which are proving all-important in assisting our comprehension of the properties of living substance. For it is becoming every day more apparent that the chemistry and physics of the living organism are essentially the chemistry and physics of nitrogenous colloids. Living substance or protoplasm always, in fact, takes the form of a colloidal solution. In this solution the colloids are associated with crystalloids (electrolytes), which are either free in the solution or attached to the molecules of the colloids. Surrounding and enclosing the living substance thus constituted of both colloid and crystalloid material is a film, probably also formed of colloid, but which may have a lipoid substratum associated with it (Overton). This film serves the purpose of an osmotic membrane, permitting of exchanges by diffusion between the colloidal solution constituting the protoplasm and the circumambient medium in which it lives. Other similar films or membranes occur in the interior of protoplasm. These films have in many cases specific characters, both physical and chemical, thus favouring the diffusion of special kinds of material into and out of the protoplasm and from one part of the protoplasm to another. It is the changes produced under these physical conditions, associated with those caused by active chemical agents formed within protoplasm and known as *enzymes*, that effect assimilation and disassimilation. Quite similar changes can be produced outside the body (*in vitro*) by the employment of methods of a purely physical and chemical nature. It is true that we are not yet familiar with all the intermediate stages of transformation of the materials which are taken in by a living body into the materials which are given out from it. But since the initial processes and the final results are the same as they would be on the assumption that the changes are brought about in conformity with the known laws of chemistry and physics, we may fairly conclude that all changes in living substance are brought about by ordinary chemical and physical forces.

Similarity of the Processes of Growth and Reproduction in Living and Non-living Matter.

Should it be contended that growth and reproduction are properties possessed only by living bodies and constitute a test by which we may differentiate between life and non-life, between the animate and inanimate creation, it must be replied that no contention can be more fallacious. Inorganic crystals grow and multiply and reproduce their like, given a supply of the requisite pabulum. In most cases for each kind of crystal there is, as with living organisms, a limit of growth which is not exceeded, and further increase of the crystalline matter results not in further increase in size but in multiplication of similar crystals. Leduc has shown that the growth and division of artificial colloids of an inorganic nature, when placed in an appropriate medium, present singular resemblances to the phenomena of the growth and division of living organisms. Even so complex a process as the division of a cell-nucleus by karyokinesis as a preliminary to the multiplication of the cell by division—a phenomenon which would *primâ facie* have seemed and has been commonly regarded as a distinctive manifestation of the life of the cell—can be imitated with solutions of a simple inorganic salt, such as chloride of sodium, containing a suspension of carbon particles; which arrange and rearrange themselves under the influence of the movements of the electrolytes in a manner indistinguishable from that adopted by the particles of chromatin in a dividing nucleus. And in the process of sexual reproduction, the researches of J. Loeb and others upon the ova of the sea-urchin have proved that we can no longer consider such an apparently vital phenomenon as the fertilisation of the egg as being the result of living material brought to it by the spermatozoon, since it is possible to start the process of the ovum and the resulting formation of cells, and ultimately of all the tissues and organs—in short, to bring about the development of the whole body—if a simple chemical reagent is substituted for the male element in the process of fertilisation. Indeed, even a mechanical or electrical stimulus may suffice to start development.

The Question of Vitalism and Vital Force.

Kurz und gut, as the Germans say, vitalism as a working hypothesis has not only had its foundations undermined, but most of the superstructure has toppled over, and if any difficulties of explanation still persist, we are justified in assuming that the cause is to be found in our imperfect knowledge of the constitution and working of living material. At the best vitalism explains nothing, and the term "vital force" is an expression of ignorance which can bring us no further along the path of knowledge. Nor is the problem in any way advanced by substituting for the term "vitalism" "neo-vitalism," and for "vital force" "biotic energy."[8] "New presbyter is but old priest writ large."

The Possibility of the Synthesis of Living Matter.

Further, in its chemical composition we are no longer compelled to consider living substance as possessing infinite complexity, as was thought to be the case when chemists first began to break up the proteins of the body into their simpler constituents. The researches of Miescher, which have been continued and elaborated by Kossel and his pupils, have acquainted us with the fact that a body so important for the nutritive and reproductive functions of the cell as the nucleus—which may be said indeed to represent the quintessence of cell-life—possesses a chemical constitution of no very great complexity; so that we may even hope some day to see the material which composes it prepared synthetically. And when we consider that the nucleus is not only itself formed of living substance, but is capable of causing other living substance to be built up; is, in fact, the directing agent in all the principal chemical changes which take place within the living cell, it must be admitted that we are a long step forward in our knowledge of the chemical basis of life. That it is the *form* of nuclear matter rather than its chemical and molecular structure which is the important factor in nuclear activity cannot be supposed. The form of nuclei, as every microscopist knows, varies infinitely, and there are numerous living organisms in which the nuclear matter is without form, appearing simply as granules distributed in the protoplasm. Not that the form assumed and the

[8] B. Moore, in "Recent Advances in Physiology," 1906; Moore and Roaf, *ibid.*; and "Further Advances in Physiology," 1909. Moore lays especial stress on the transformations of energy which occur in protoplasm. See on the question of vitalism Gley (*Revue Scientifique*, 1911) and D'Arcy Thompson (Address to Section D at Portsmouth, 1911).

transformations undergone by the nucleus are without importance; but it is none the less true that even in an amorphous condition the material which in the ordinary cell takes the form of a "nucleus" may, in simpler organisms which have not in the process of evolution become complete cells, fulfil functions in many respects similar to those fulfilled by the nucleus of the more differentiated organism.

A similar anticipation regarding the probability of eventual synthetic production may be made for the proteins of the cell-substance. Considerable progress in this direction has indeed already been made by Emil Fischer, who has for many years been engaged in the task of building up the nitrogenous combinations which enter into the formation of the complex molecule of protein. It is satisfactory to know that the significance of the work both of Fischer and of Kossel in this field of biological chemistry has been recognised by the award to each of these distinguished chemists of a Nobel prize.

The Chemical Constitution of Living Substance.

The elements composing living substance are few in number. Those which are constantly present are carbon, hydrogen, oxygen, and nitrogen. With these, both in nuclear matter and also, but to a less degree, in the more diffuse living material which we know as protoplasm, phosphorus is always associated. "Ohne Phosphor kein Gedank" is an accepted aphorism; "Ohne Phosphor kein Leben" is equally true. Moreover, a large proportion, rarely less than 70 per cent., of water appears essential for any manifestation of life, although not in all cases necessary for its continuance, since organisms are known which will bear the loss of the greater part if not the whole of the water they contain without permanent impairment of their vitality. The presence of certain inorganic salts is no less essential, chief amongst them being chloride of sodium and salts of calcium, magnesium, potassium, and iron. The combination of these elements into a colloidal compound represents the chemical basis of life; and when the chemist succeeds in building up this compound it will without doubt be found to exhibit the phenomena which we are in the habit of associating with the term "life."[9]

Source of Life. The Possibility of Spontaneous Generation.

The above considerations seem to point to the conclusion that the possibility of the production of life—*i.e.*, of living material—is not so remote as has been generally assumed. Since the experiments of Pasteur, few have ventured to affirm a belief in the spontaneous generation of bacteria and monads and other micro-organisms, although before his time this was by many believed to be of universal occurrence. My esteemed friend Dr. Charlton Bastian is, so far as I am aware, the only scientific man of eminence who still adheres to the old creed, and Dr. Bastian, in spite of numerous experiments and the publication of many books and papers, has not hitherto succeeded in winning over any converts to his opinion. I am myself so entirely convinced of the accuracy of the results which Pasteur obtained—are they not within the daily and hourly experience of everyone who deals with the sterilisation of organic solutions?—that I do not hesitate to believe, if living torulæ or mycelia are exhibited to me in flasks which had been subjected to prolonged boiling after being hermetically sealed, that there has been some fallacy either in the premisses or in the carrying out of the operation. The appearance of organisms in such flasks would not furnish to my mind proof that they were the result of spontaneous generation. Assuming no fault in manipulation or fallacy in observation, I should find it simpler to believe that the germs of such organisms have resisted the effects of prolonged heat than that they became generated spontaneously. If spontaneous generation is possible, we cannot expect it to take the form of living beings which show so marked a degree of differentiation, both structural and functional, as the organisms which are described as making their appearance in these experimental flasks.[10] Nor should we expect the spontaneous generation of living substance of any kind to occur in a fluid the organic constituents of which have been so altered by heat that they can retain no sort of chemical resemblance to the organic constituents of living matter. If the formation of life—of living substance—is possible at the present day—and for my own part I see no reason to doubt it—a boiled infusion of organic matter—and still less of inorganic matter—is the last place in which to look for it. Our mistrust of such evidence as has yet been brought forward need not, however, preclude us from admitting the possibility of the formation of living from non-living substance.[11]

Life a Product of Evolution.

Setting aside, as devoid of scientific foundation, the idea of immediate supernatural intervention in the first production of life, we are not only justified in believing, but compelled to believe, that living matter must have owed its origin to causes similar in character to those which have been instrumental in producing all other forms of matter in the universe; in other words, to a process of gradual evolution.[12] But it has been customary of late amongst biologists to shelve the investigation of the mode of origin of life by evolution from non-living matter by relegating its solution to some former condition of the earth's history, when, it is assumed, opportunities were accidentally favourable for the passage of inanimate matter into animate; such opportunities, it is also assumed, having never since recurred and being never likely to recur.[13]

Various eminent scientific men have even supposed that life has not actually originated upon our globe, but has been brought to it from another planet or from another stellar system. Some of my audience may still remember the controversy that was excited when the theory of the origin of terrestial life by the intermediation of a meteorite was propounded by Sir William Thomson in his Presidential Address at the

9 The most recent account of the chemistry of protoplasm is that by Botazzi ("Das Cytoplasma u. die Körpersäfte") in Winterstein's "Handb. d. vergl. Physiologie," Bd. I., 1912. The literature is given in this article.

10 It is fair to point out that Dr. Bastian suggests that the formation of ultramicroscopic living particles may precede the appearance of the microscopic organisms which he describes. "The Origin of Life," 1911, p. 65.

11 The present position of the subject is succinctly stated by Dr. Chalmers Mitchell in his article on "Abiogenesis" in the "Encyclopædia Britannica." Dr. Mitchell adds "It may be that in the progress of science it may yet be possible to construct living protoplasm from non living material. The refutation of abiogenesis has no further bearing on this possibility than to make it probable that if protoplasm ultimately be formed in the laboratory, it will be by a series of steps, the earlier steps being the formation of some substance, or substances now unknown, which are not protoplasm. Such intermediate stages may have existed in the past." And Huxley in his Presidential Address at Liverpool in 1870 says: "But though I cannot express this conviction" (*i.e.*, of the impossibility of the occurrence of abiogenesis as exemplified by the appearance of organisms in hermetically sealed and sterilised flasks) "too strongly, I must carefully guard myself against the supposition that I intend to suggest that no such thing as abiogenesis ever has taken place in the past or ever will take place in the future. With organic chemistry, molecular physics and physiology yet in their infancy and every day making prodigious strides, I think it would be the height of presumption for any man to say that the conditions under which matter assumes the properties we call "vital" may not, some day, be artificially brought together."

12 The arguments in favour of this proposition have been arrayed by Meldola in his Herbert Spencer Lecture, 1910, pp. 16–24. Meldola leaves the question open whether such evolution has occurred only in past years or is also taking place now. He concludes that whereas certain carbon compounds have survived by reason of possessing extreme stability, others—the precursors of living matter survived owing to the possession of extreme lability and adaptability to variable conditions of environment. A similar suggestion was previously made by Lockyer, "Inorganic Evolution," 1900, pp. 169, 170.

13 T. H. Huxley, Presidential Address, 1870; A. B. Macallum, "On the Origin of Life on the Globe," in Trans. Canadian Institute, VIII.

meeting of this Association in Edinburgh in 1871. To this "meteorite" theory[14] the apparently fatal objection was raised that it would take some sixty million years for a meteorite to travel from the nearest stellar system to our earth, and it is inconceivable that any kind of life could be maintained during such a period. Even from the nearest planet 150 years would be necessary, and the heating of the meteorite in passing through our atmosphere and at its impact with the earth would, in all probability, destroy any life which might have existed within it. A cognate theory, that of *cosmic panspermia*, assumes that life may exist and may have existed indefinitely in cosmic dust in the interstellar spaces (Richter, 1865; Cohn, 1872), and may with this dust fall slowly to the earth without undergoing the heating which is experienced by a meteorite. Arrhenius,[15] who adopts this theory, states that if living germs were carried through the ether by luminous and other radiations the time necessary for their transportation from our globe to the nearest stellar system would be only nine thousand years, and to Mars only twenty days!

But the acceptance of such theories of the arrival of life on the earth does not bring us any nearer to a conception of its actual mode of origin; on the contrary, it merely serves to banish the investigation of the question to some conveniently inaccessible corner of the universe and leaves us in the unsatisfactory position of affirming not only that we have no knowledge as to the mode of origin of life—which is unfortunately true—but that we never can acquire such knowledge—which it is to be hoped is not true.[16] Knowing what we know, and believing what we believe, as to the part played by evolution in the development of terestrial matter, we are, I think (without denying the possibility of the existence of life in other parts of the universe[17]), justified in regarding these cosmic theories as inherently improbable—at least in comparison with the solution of the problem which the evolutionary hypothesis offers.[18]

The Evolutionary Hypothesis as applied to the Origin of Life.

I assume that the majority of my audience have at least a general idea of the scope of this hypothesis, the general acceptance of which has within the last sixty years altered the whole aspect not only of biology, but of every other branch of natural science, including astronomy, geology, physics, and chemistry.[19] To those who have not this familiarity I would recommend the perusal of a little book by Prof. Judd entitled "The Coming of Evolution," which has recently appeared as one of the Cambridge manuals. I know of no similar book in which the subject is as clearly and succinctly treated. Although the author nowhere expresses the opinion that the actual origin of life on the earth has arisen by evolution from non-living matter, it is impossible to read either this or any similar exposition in which the essential unity of the evolutionary process is insisted upon without concluding that the origin of life must have been due to the same process, this process being, without exception, continuous, and admitting of no gap at any part of its course. Looking, therefore, at the evolution of living matter by the light which is shed upon it from the study of the evolution of matter in general, we are led to regard it as having been produced, not by a sudden alteration, whether exerted by natural or supernatural agency, but by a gradual process of change from material which was lifeless, through material on the borderland between inanimate and animate, to material which has all the characteristics to which we attach the term "life." So far from expecting a sudden leap from an inorganic, or at least an unorganised, into an organic and organised condition, from an entirely inanimate substance to a completely animate state of being, should we not rather expect a gradual procession of changes from inorganic to organic matter, through stages of gradually increasing complexity until material which can be termed living is attained? And in place of looking for the production of fully formed living organisms in hermetically sealed flasks, should we not rather search Nature herself, under natural conditions, for evidence of the existence, either in the past or in the present, of transitional forms between living and non-living matter?

The difficulty, nay, the impossibility, of obtaining evidence of such evolution from the past history of the globe is obvious. Both the hypothetical transitional material and the living material which was originally evolved from it may, as Macallum has suggested, have taken the form of diffused ultramicroscopic particles of living substance[20]; and even if they were not diffused but aggregated into masses, these masses could have been physically nothing more than colloidal watery slime which would leave no impress upon any geological formation. Myriads of years may have elapsed before some sort of skeleton in the shape of calcareous or siliceous spicules began to evolve itself, and thus enabled "life," which must already have possessed a prolonged existence, to make any sort of geological record. It follows that in attempting to pursue the evolution of living matter to its beginning in terrestrial history we can only expect to be confronted with a blank wall of nescience.

The problem would appear to be hopeless of ultimate solution if we are rigidly confined to the supposition that the evolution of life has only occurred once in the past history of the globe. But are we justified in assuming that at one period only, and as it were by a fortunate and fortuitous concomitation of substance and circumstance, living matter became evolved out of non-living matter—life became established? Is there any valid reason to conclude that at some previous period of its history our earth was more favourably circumstanced for the production of life than it is now?[21] I have vainly sought for such reason, and if none be forthcoming the conclusion forces itself upon us that the evolution of non-living into living substance has happened more than once—and we can be by no means sure that it may not be happening still.

14 First suggested, according to Dastre, by de Salles-Guyon (Dastre, *op. cit.*, p. 252). The theory received the support of Helmholtz.

15 "Worlds in the Making," transl. by H. Borns, chap. viii., p. 221, 1908.

16 "The history of science shows how dangerous it is to brush aside mysteries—*i.e.*, unsolved problems—and to interpose the barrier placarded 'eternal—no thoroughfare.'"—R. Meldola, Herbert Spencer Lecture, 1910.

17 Some authorities, such as Errera, contend, with much probability, that the conditions in interstellar space are such that life, as we understand it, could not possibly exist there.

18 As Verworn points out, such theories would equally apply to the origin of any other chemical combination, whether inorganic or organic, which is met with on our globe, so that they lead directly to absurd conclusions.—"Allgemeine Physiologie," 1911.

19 As Meldola insists, this general acceptance was in the first instance largely due to the writings of Herbert Spencer: "We are now prepared for evolution in every domain . . . As in the case of most great generalisations, thought had been moving in this direction for many years. . . . Lamarck and Buffon had suggested a definite mechanism of organic development, Kant and Laplace a principle of celestial evolution, while Lyell had placed geology upon an evolutionary basis. The principle of continuity was beginning to be recognised in physical science. . . . It was Spencer who brought these independent lines of thought to a focus, and who was the first to make any systematic attempt to show that the law of development expressed in its widest and most abstract form was universally followed throughout cosmical processes, inorganic, organic, and super-organic."—*Op. cit.*, p. 14.

20 There still exist in fact forms of life which the microscope cannot show us (E. A. Minchin, Presidential Address to Quekett Club, 1911), and germs which are capable of passing through the pores of a Chamberland filter.

21 Chalmers Mitchell (Article "Life," "Encycl. Brit.," eleventh edition) writes as follows: "It has been suggested from time to time that conditions very unlike those now existing were necessary for the first appearance of life, and must be repeated if living matter is to be reconstituted artificially. No support for such a view can be derived from observations of the existing conditions of life."

It is true that up to the present there is no evidence of such happening; no process of transition has hitherto been observed. But, on the other hand, is it not equally true that the kind of evidence which would be of any real value in determining this question has not hitherto been looked for? We may be certain that if life is being produced from non-living substance, it will be life of a far simpler character than any that has yet been observed—in material which we shall be uncertain whether to call animate or inanimate, even if we are able to detect it at all, and which we may not be able to visualise physically even after we have become convinced of its existence.[22] But we can look with the mind's eye and follow in imagination the transformation which non-living matter may have undergone and may still be undergoing to produce living substance. No principle of evolution is better founded than that insisted upon by Sir Charles Lyell, justly termed by Huxley "the greatest geologist of his time," that we must interpret the past history of our globe by the present; that we must seek for an explanation of what has happened by the study of what is happening; that, given similar circumstances, what has occurred at one time will probably occur at another. The process of evolution is universal. The inorganic materials of the globe are continually undergoing transition. New chemical combinations are constantly being formed and old ones broken up; new elements are making their appearance and old elements disappearing.[23] Well may we ask ourselves why the production of living matter alone should be subject to other laws than those which have produced, and are producing, the various forms of non-living matter; why what has happened may not happen. If living matter has been evolved from lifeless in the past, we are justified in accepting the conclusion that its evolution is possible in the present and in the future. Indeed, we are not only justified in accepting this conclusion, we are forced to accept it. When or where such change from non-living to living matter may first have occurred, when or where it may have continued, when or where it may still be occurring, are problems as difficult as they are interesting, but we have no right to assume that they are insoluble.

Since living matter always contains water as its most abundant constituent, and since the first living organisms recognisable as such in the geological series were aquatic, it has generally been assumed that life must first have made its appearance in the depths of the ocean.[24] Is it, however, certain that the assumption that life originated in the sea is correct? Is not the land-surface of our globe quite as likely to have been the nidus for the evolutionary transformation of non-living into living material as the waters which surround it? Within this soil almost any chemical transformation may occur; it is subjected much more than matters dissolved in sea-water to those fluctuations of moisture, temperature, electricity, and luminosity which are potent in producing chemical changes. But whether life, in the form of a simple slimy colloid, originated in the depths of the sea or on the surface of the land, it would be equally impossible for the geologist to trace its beginnings, and were it still becoming evolved in the same situations, it would be almost as impossible for the microscopist to follow its evolution. We are therefore not likely to obtain direct evidence regarding such a transformation of non-living into living matter in nature, even if it is occurring under our eyes.

An obvious objection to the idea that the production of living matter from non-living has happened more than once is that, had this been the case, the geological record should reveal more than one palæontological series. This objection assumes that evolution would in every case take an exactly similar course and proceed to the same goal—an assumption which is, to say the least, improbable. If, as might well be the case, in any other palæontological series than the one with which we are acquainted the process of evolution of living beings did not proceed beyond Protista, there would be no obvious geological evidence regarding it; such evidence would only be discoverable by a carefully directed search made with that particular object in view.[25] I would not by any means minimise the difficulties which attend the suggestion that the evolution of life may have occurred more than once or may still be happening, but, on the other hand, it must not be ignored that those which attend the assumption that the production of life has occurred once only are equally serious. Indeed, had the idea of the possibility of a multiple evolution of living substance been first in the field, I doubt if the prevalent belief regarding a single fortuitous production of life upon the globe would have become established among biologists—so much are we liable to be influenced by the impressions we receive in scientific childhood!

Further Course of Evolution of Life.

Assuming the evolution of living matter to have occurred—whether once only or more frequently matters not for the moment—and in the form suggested, viz., as a mass of colloidal slime possessing the property of assimilation and therefore of growth, reproduction would follow as a matter of course. For all material of this physical nature—fluid or semi-fluid in character—has a tendency to undergo subdivision when its bulk exceeds a certain size. The subdivision may be into equal or nearly equal parts, or it may take the form of buds. In either case every separated part would resemble the parent in chemical and physical properties, and would equally possess the property of taking in and assimilating suitable material from its liquid environment, growing in bulk and reproducing its like by subdivision. *Omne vivum e vivo.* In this way from any beginning of living material a primitive form of life would spread, and would gradually people the globe. The establishment of life being once effected, all forms of organisation follow under the inevitable laws of evolution. *Ce n'est que le premier pas qui coûte.*

We can trace in imagination the segregation of a more highly phosphorised portion of the primitive living matter, which we may now consider to have become more akin to the protoplasm of organisms with which we are familiar. This more phosphorised portion might not for myriads of generations take the form of a definite nucleus, but it would be composed of material having a composition and qualities similar to those of the nucleus of a cell. Prominent among these qualities is that of catalysis—the func-

[22] "Spontaneous generation of life could only be perceptually demonstrated by filling in the long terms of a series between the complex forms of inorganic and the simplest forms of organic substance. Were this done, it is quite possible that we should be unable to say (especially considering the vagueness of our definitions of life) where life began or ended."—K. Pearson, "Grammar of Science," second edition, 1900, p. 350.

[24] For arguments in favour of the first appearance of life having been in the sea, see A. B. Macallum, "The Palæochemistry of the Ocean," Trans. Canad. Instit., 1903–4.

[25] Lankester (Art. "Protozoa," "Encycl. Brit.," tenth edition) conceives that the first protoplasm fed on the antecedent steps in its own evolution. F. J. Allen (Brit. Assoc. Reports, 1896) comes to the conclusion that living substance is probably constantly being produced, but that this fails to make itself evident owing to the substance being seized and assimilated by existing organisms. He believes that "in accounting for the first origin of life on this earth it is not necessary that, as Pflüger assumed, the planet should have been at a former period a glowing fire-ball." He "prefers to believe that the circumstances which support life would also favour its origin." And elsewhere: "Life is not an extraordinary phenomenon, not even an importation from some other sphere, but rather the actual outcome of circumstances on this earth."

tion of effecting profound chemical changes in other material in contact with it without itself undergoing permanent change. This catalytic function may have been exercised directly by the living substance or may have been carried on through the agency of the enzymes already mentioned, which are also of a colloid nature but of simpler constitution than itself, and which differ from the catalytic agents employed by the chemist in the fact that they produce their effects at a relatively low temperature. In the course of evolution special enzymes would become developed for adaptation to special conditions of life, and with the appearance of these and other modifications, a process of differentiation of primitive living matter into individuals with definite specific characters gradually became established. We can conceive of the production in this way from originally undifferentiated living substance of simple differentiated organisms comparable to the lowest forms of Protista. But how long it may have taken to arrive at this stage we have no means of ascertaining. To judge from the evidence afforded by the evolution of higher organisms it would seem that a vast period of time would be necessary for even this amount of organisation to establish itself.

Formation of the Nucleated Cell.

The next important phase in the process of evolution would be the segregation and moulding of the diffused or irregularly aggregated nuclear matter into a definite nucleus around which all the chemical activity of the organism will in future be centred. Whether this change were due to a slow and gradual process of segregation or of the nature of a jump, such as Nature does occasionally make, the result would be the advancement of the living organism to the condition of a complete nucleated cell: a material advance not only in organisation, but—still more important—in potentiality for future development. Life is now embodied in the cell, and every living being evolved from this will itself be either a cell or a cell-aggregate. *Omnis cellula e cellulâ.*

Establishment of Sexual Differences.

After the appearance of a nucleus—but how long after it is impossible to conjecture—another phenomenon appeared upon the scene in the occasional exchange of nuclear substance between cells. In this manner became established the process of sexual reproduction. Such exchange in the unicellular Protista might and may occur between any two cells forming the species, but in the multicellular Metazoa it became—like other functions—specialised in particular cells. The result of the exchange is rejuvenescence; associated with an increased tendency to subdivide and to produce new individuals. This is due to the introduction of a stimulating or catalytic chemical agent into the cell which is to be rejuvenated, as is proved by the experiments of Loeb already alluded to. It is true that the chemical material introduced into the germ-cell in the ordinary process of its fertilisation by the sperm-cell is usually accompanied by the introduction of definite morphological elements which blend with others already contained within the germ-cell, and it is believed that the transmission of such morphological elements of the parental nuclei is related to the transmission of parental qualities. But we must not be blind to the possibility that these transmitted qualities may be connected with specific chemical characters of the transmitted elements; in other words, that heredity also is one of the questions the eventual solution of which we must look to the chemist to provide.

Aggregate Life.

So far we have been chiefly considering life as it is found in the simplest forms of living substance, organisms for the most part entirely microscopic and neither distinctively animal nor vegetable, which were grouped together by Haeckel as a separate kingdom of animated nature—that of Protista. But persons unfamiliar with the microscope are not in the habit of associating the term "life" with microscopic organisms, whether these take the form of cells or of minute portions of living substance which have not yet attained to that dignity. We most of us speak and think of life as it occurs in ourselves and other animals with which we are familiar; and as we find it in the plants around us. We recognise it in these by the possession of certain properties—movement, nutrition, growth, and reproduction. We are not aware by intuition, nor can we ascertain without the employment of the microscope, that we and all the higher living beings, whether animal or vegetable, are entirely formed of aggregates of nucleated cells, each microscopic and each possessing its own life. Nor could we suspect by intuition that what we term our life is not a single indivisible property, capable of being blown out with a puff like the flame of a candle; but is the aggregate of the lives of many millions of living cells of which the body is composed. It is but a short while ago that this cell-constitution was discovered: it occurred within the lifetime, even within the memory, of some who are still with us. What a marvellous distance we have travelled since then in the path of knowledge of living organisms! The strides which were made in the advance of the mechanical sciences during the nineteenth century, which is generally considered to mark that century as an age of unexampled progress, are as nothing in comparison with those made in the domain of biology, and their interest is entirely dwarfed by that which is aroused by the facts relating to the phenomena of life which have accumulated within the same period. And not the least remarkable of these facts is the discovery of the cell-structure of plants and animals!

Evolution of the Cell-aggregate.

Let us consider how cell-aggregates came to be evolved from organisms consisting of single cells. Two methods are possible—viz. (1) the adhesion of a number of originally separate individuals; (2) the subdivision of a single individual without the products of its subdivision breaking loose from one another. No doubt this last is the manner whereby the cell-aggregate was originally formed, since it is that by which it is still produced, and we know that the life-history of the individual is an epitome of that of the species. Such aggregates were in the beginning solid; the cells in contact with one another and even in continuity: subsequently a space or cavity became formed in the interior of the mass, which was thus converted into a hollow sphere. All the cells of the aggregate were at first perfectly similar in structure and in function; there was no subdivision of labour. All would take part in effecting locomotion; all would receive stimuli from outside; all would take in and digest nutrient matter, which would then be passed into the cavity of the sphere to serve as a common store of nourishment. Such organisms are still found, and constitute the lowest types of Metazoa. Later one part of the hollow sphere became dimpled to form a cup; the cavity of the sphere became correspondingly altered in shape. With this change in structure, differentiation of function between the cells covering the outside and those lining the inside of the cup made its appearance. Those on the outside sub-served locomotor functions and received and transmitted from cell to cell stimuli, physical or chemical, received by the organism; while those on the inside, being freed from such functions, tended to specialise in the direction of the inception and digestion of nutrient material; which, passing from them into the cavity of the invaginated sphere, served for the nourishment of all the cells composing the organism. The further course of evolution produced many changes of form and ever-increasing complexity of the cavity thus produced by simple invagination. Some of the cell-aggregates settled down to a sedentary life, becoming plant-like in appearance and to some extent in habit. Such organisms, complex in form but simple in structure, are the Sponges. Their several parts are not, as in the higher Metazoa, closely interdependent: the destruction of any one part, however extensive, does not either immediately or ultimately involve death of the rest: all parts function separately, although doubtless mutually benefiting by their conjunction, if only by slow diffusion of nutrient fluid throughout the mass. There is already some differentiation in these organisms, but the absence of a nervous system prevents any general coordination, and the individual cells are largely independent of one another.

Our own life, like that of all the higher animals, is an *aggregate life*; the life of the whole is the life of the individual cells. The life of some of these cells can be put an end to, the rest may continue to live. This is, in fact, happening every moment of our lives. The cells which cover the surface of our body, which form the scarf-skin and the hairs and nails, are constantly dying and the dead cells are rubbed off or cut away, their place being taken by others supplied from living layers beneath. But the death of these cells does not affect the vitality of the body as a whole. They serve merely as a protection, or an ornamental covering, but are otherwise not material to our existence. On the other hand, if a few cells, such as those nerve-cells under the influence of which respiration is carried on, are destroyed or injured, within a minute or two the whole living machine comes to a standstill, so that to the bystander the patient is dead; even the doctor will pronounce life to be extinct. But this pronouncement is correct only in a special sense. What has happened is that, owing to the cessation of respiration, the supply of oxygen to the tissues is cut off. And since the manifestations of life cease without this supply, the animal or patient appears to be dead. If, however, within a short period we supply the needed oxygen to the tissues requiring it, all the manifestations of life reappear.

It is only some cells which lose their vitality at the moment of so-called "general death." Many cells of the body retain their individual life in suitable circumstances long after the rest of the body is dead. Notable among these are muscle-cells. McWilliam showed that the muscle-cells of the blood-vessels give indications of life several days after an animal has been killed. The muscle-cells of the heart in mammals have been revived and caused to beat regularly and strongly many hours after apparent death. In man this result has been obtained by Kuliabko as many as eighteen hours after life had been pronounced extinct; in animals after days had elapsed. Waller has shown that indications of life can be elicited from various tissues many hours and even days after general death. Sherrington observed the white corpuscles of the blood to be active when kept in a suitable nutrient fluid weeks after removal from the blood-vessels. A French histologist, Jolly, has found that the white corpuscles of the frog, if kept in a cool place and under suitable conditions, show at the end of a year all the ordinary manifestations of life. Carrell and Burrows have observed activity and growth to continue for long periods in the isolated cells of a number of tissues and organs kept under observation in a suitable medium. Carrell has succeeded in substituting entire organs obtained after death from one animal for those of another of the same species, and has thereby opened up a field of surgical treatment the limit of which cannot yet be descried. It is a well-established fact that any part of the body can be maintained alive for hours isolated from the rest if the blood-vessels are perfused with an oxygenated solution of salts in certain proportions (Ringer). Such revival and prolongation of the life of separated organs is an ordinary procedure in laboratories of physiology. Like all the other instances enumerated, it is based on the fact that the individual cells of an organ have a life of their own which is largely independent, so that they will continue in suitable circumstances to live, although the rest of the body to which they belonged may be dead.

But some cells, and the organs which are formed of them, are more necessary to maintain the life of the aggregate than others, on account of the nature of the functions which have become specialised in them. This is the case with the nerve-cells of the respiratory centre, since they preside over the movements which are necessary to effect oxygenation of the blood. It is also true for the cells which compose the heart, since this serves to pump oxygenated blood to all other cells of the body: without such blood most cells soon cease to live. Hence we examine respiration and heart to determine if life is present: when one or both of these are at a standstill we know that life cannot be maintained. These are not the only organs necessary for the maintenance of life, but the loss of others can be borne longer, since the functions which they subserve, although useful or even essential to the organism, can be dispensed with for a time. The life of some cells is therefore more, of others less, necessary, for maintaining the life of the rest. On the other hand, the cells composing certain organs have in the course of evolution ceased to be necessary, and their continued existence may even be harmful. Wiedersheim has enumerated more than a hundred of these organs in the human body. Doubtless Nature is doing her best to get rid of them for us, and our descendants will some day have ceased to possess a vermiform appendix or a pharyngeal tonsil; until that epoch arrives we must rely for their removal on the more rapid methods of surgery!

The Maintenance of the Life of the Cell-aggregate in the Higher Animals.—Coordinating Mechanisms.

We have seen that in the simplest multicellular organisms, where one cell of the aggregate differs but little from another, the conditions for the maintenance of the life of the whole are nearly as simple as those for individual cells. But the life of a cell-aggregate such as composes the bodies of the higher animals is maintained not only by the conditions for the maintenance of the life of the individual cell being kept favourable, but also by the coordination of the varied activities of the cells which form the aggregate. Whereas in the lowest Metazoa all cells of the aggregate are alike in structure and function and perform and share everything in common, in higher animals (and for that matter in the higher plants also) the cells have become specialised, and each is only adapted for the performance of a particular function. Thus the cells of the gastric glands are only adapted for the secretion of gastric juice, the cells of the villi for the absorption of digested matters from the intestine, the cells of the kidney for the removal of waste products and superfluous water from the blood, those of the heart for pumping blood through the vessels. Each of these cells has its individual life and performs its individual functions. But unless there were some sort of cooperation and subordination to the needs of the body generally, there would be sometimes too little, sometimes too much gastric juice secreted; sometimes too tardy, sometimes too rapid an absorption from the intestine; sometimes too little, sometimes too much blood pumped into the arteries, and so on. As the result of such lack of cooperation the life of the whole would cease to be normal and would eventually cease to be maintained.

We have already seen what are the conditions which are favourable for the maintenance of life of the individual cell, no matter where situated. The principal condition is that it must be bathed by a nutrient fluid of suitable and constant composition. In higher animals this fluid is the lymph, which bathes the tissue elements and is itself constantly supplied with fresh nutriment and oxygen by the blood. Some tissue-cells are directly bathed by blood; and in invertebrates, in which there is no special system of lymph-vessels, all the tissues are thus nourished. All cells both take from and give to the blood, but not the same materials or to an equal extent. Some, such as the absorbing cells of the villi, almost exclusively give; others, such as the cells of the renal tubules, almost exclusively take. Nevertheless, the resultant of all the give and take throughout the body serves to maintain the composition of the blood constant in all circumstances. In this way the first condition of the maintenance of the life of the aggregate is fulfilled by insuring that the life of the individual cells composing it is kept normal.

The second essential condition for the maintenance of life of the cell-aggregate is the coordination of its parts and the due regulation of their activity, so that they may work together for the benefit of the whole. In the animal body this is effected in two ways: first, through the nervous system; and second, by the action of specific chemical substances which are formed in certain organs and carried by the blood to other parts of the body, the cells of which they excite to activity. These substances have received the general designation of "hormones" (ὁρμάω, to stir up), a term introduced by Prof. Starling. Their action, and indeed their very existence, has only been recognised of late years, although the part which they play in the physiology of animals appears to be only second in importance to that of the nervous system itself; indeed, maintenance of life may become impossible in the absence of certain of these hormones.

Part played by the Nervous System in the Maintenance of Aggregate Life.—Evolution of a Nervous System.

Before we consider the manner in which the nervous system serves to coordinate the life of the cell-aggregate, let us see how it has become evolved.

The first step in the process was taken when certain of the cells of the external layer became specially sensitive to stimuli from outside, whether caused by mechanical impressions (tactile and auditory stimuli) or impressions of light and darkness (visual stimuli) or chemical impressions. The effects of such impressions were probably at first simply communicated to adjacent cells and spread from cell to cell throughout the mass. An advance was made when the more impressionable cells threw out branching feelers amongst the other cells of the organism. Such feelers would convey the effects of stimuli with greater rapidity and directness to distant parts. They may at first have been retractile, in this respect resembling the long pseudopodia of certain Rhizopoda. When they became fixed they would be potential nerve-fibres and would represent the beginning of a nervous system. Even yet (as Ross Harrison has shown), in the course of development of nerve-fibres, each fibre makes its appearance as an amœboid cell-process which is at first retractile, but gradually grows into the position it is eventually to occupy and in which it will become fixed.

In the further course of evolution a certain number of these specialised cells of the external layer sank below the general surface, partly perhaps for protection, partly for better nutrition: they became nerve-cells. They remained connected with the surface by a prolongation which became an afferent or sensory nerve-fibre, and through its termination between the cells of the general surface continued to receive the effects of external impressions; on the other hand, they continued to transmit these impressions to other, more distant cells by their efferent prolongations. In the further course of evolution the nervous system thus laid down became differentiated into distinct *afferent, efferent,* and *intermediary* portions. Once established, such a nervous system, however simple, must dominate the organism, since it would furnish a mechanism whereby the individual cells would work together more effectually for the mutual benefit of the whole.

It is the development of the nervous system, although not proceeding in all classes along exactly the same lines, which is the most prominent feature of the evolution of the Metazoa. By and through it all impressions reaching the organism from the outside are translated into contraction or some other form of cell-activity. Its formation has been the means of causing the complete divergence of the world of animals from the world of plants, none of which possess any trace of a nervous system. Plants react, it is true, to external impressions, and these impressions produce profound changes and even comparatively rapid and energetic movements in parts distant from the point of application of the stimulus—as in the well-known instance of the sensitive plant. But the impressions are in all cases propagated directly from cell to cell—not through the agency of nerve-fibres; and in the absence of anything corresponding to a nervous system it is not possible to suppose that any plant can ever acquire the least glimmer of intelligence. In animals, on the other hand, from a slight original modification of certain cells has directly proceeded in the course of evolution the elaborate structure of the nervous system with all its varied and complex functions, which reach their culmination in the workings of the human intellect. "What a piece of work is a man! How noble in reason! How infinite in faculty! In form and moving how express and admirable! In action how like an angel! In apprehension how like a god!" But lest he be elated with his physical achievements, let him remember that they are but the result of the acquisition by a few cells in a remote ancestor of a slightly greater tendency to react to an external stimulus, so that these cells were brought into closer touch with the outer world; while, on the other hand, by extending beyond the circumscribed area to which their neighbours remained restricted, they gradually acquired a dominating influence over the rest. These dominating cells became nerve-cells; and now not only furnish the means for transmission of impressions from one part of the organism to another, but in the progress of time have become the seat of perception and conscious sensation, of the formation and association of ideas, of memory, volition, and all the manifestations of the mind!

Regulation of Movements by the Nervous System.—Voluntary Movements.

The most conspicuous part played by the nervous system in the phenomena of life is that which produces and regulates the general movements of the body—movements brought about by the so-called voluntary muscles. These movements are actually the result of impressions imparted to sensory or afferent nerves at the periphery, *e.g.* in the skin or in the several organs of special sense; the effect of these impressions may not be immediate, but can be stored for an indefinite time in certain cells of the nervous system. The regulation of movements—whether they occur instantly after reception of the peripheral impression or result after a certain lapse of time; whether they are accompanied by conscious sensation or are of a purely reflex and unconscious character—is an intricate process, and the conditions of their co-ordination are of a complex nature involving not merely the causation of contraction of certain muscles, but also the prevention of contraction of others. For our present knowledge of these conditions we are largely indebted to the researches of Prof. Sherrington.

Involuntary Movements.

A less conspicuous but no less important part played by the nervous system is that by which the contractions of involuntary muscles are regulated. In normal circumstances these are always independent of consciousness, but their regulation is brought about in much the same way as is that of the contractions of voluntary muscles—viz., as the result of impressions received at the periphery. These are transmitted by afferent fibres to the central nervous system, and from the latter other impulses are sent down, mostly along the nerves of the sympathetic or autonomic system of nerves, which either stimulate or prevent contraction of the involuntary muscles. Many involuntary muscles have a natural tendency to continuous or rhythmic contraction which is quite independent of the central nervous system; in this case the effect of impulses received from the latter is merely to increase or diminish the amount of such contraction. An example of this double effect is observed in connection with the heart, which—although it can contract regularly and rhythmically when cut off from the nervous system and even if removed from the body—is normally stimulated to increased activity by impulses coming from the central nervous system through the sympathetic, or to diminished activity by others coming through the vagus. It is due to the readiness by which the action of the heart is influenced in these opposite ways by the spread of impulses generated during the nerve-storms which we term "emotions" that in the language of poetry, and even of every day, the word "heart" has become synonymous with the emotions themselves.

Effects of Emotions.

The involuntary muscle of the arteries has its action similarly balanced. When its contraction is increased, the size of the vessels is lessened and they deliver less blood; the parts they supply accordingly become pale in colour. On the other hand, when the contraction is diminished the vessels enlarge and deliver more blood; the parts which they supply become correspondingly ruddy. These changes in the arteries, like the effects upon the heart, may also be produced under the influence of emotions. Thus "blushing" is a purely physiological phenomenon due to diminished action of the muscular tissue of the arteries, whilst the pallor produced by fright is caused by an increased contraction of that tissue. Apart, however, from these conspicuous effects, there is constantly proceeding a less apparent but not less important balancing action between the two sets of nerve-fibres distributed to heart and blood-vessels; which are influenced in one direction or another by every sensation which we experience and even by impressions of which we may be wholly unconscious, such as those which occur during sleep or anaesthesia, or which affect our otherwise insensitive internal organs.

Regulation of Secretion by the Nervous System.

A further instance of nerve-regulation is seen in secreting glands. Not all glands are thus regulated, at least not directly; but in those which are, the effects are striking. Their regulation is of the same general nature as that exercised upon involuntary muscle, but it influences the chemical activities of the gland-cells and the outpouring of secretion from them. By means of this regulation a secretion can be produced or arrested, increased or diminished. As with muscle, a suitable balance is in this way maintained, and the activity of the glands is adapted to the requirements of the organism. Most of the digestive glands are thus influenced, as are the skin-glands which secrete sweat.

Regulation of Body Temperature.

And by the action of the nervous system upon the skin-glands, together with its effect in increasing or diminishing the blood-supply to the cutaneous blood-vessels, the temperature of our blood is regulated and is kept at the point best suited for maintenance of the life and activity of the tissues.

Effects of Emotions on Secretion.

The action of the nervous system upon the secretion of glands is strikingly exemplified, as in the case of its action upon the heart and blood-vessels by the effects of the emotions. Thus an emotion of one kind—such as the anticipation of food—will cause saliva to flow—"the mouth to water"; whereas an emotion of another kind—such as fear or anxiety—will stop the secretion, causing the "tongue to cleave unto the roof of the mouth," and rendering speech difficult or impossible. Such arrest of the salivary secretion also makes the swallowing of dry food difficult: advantage of this fact is taken in the "ordeal by rice" which used to be employed in the East for the detection of criminals.

Regulation by Chemical Agents: Hormones.—Internal Secretions.

The activities of the cells constituting our bodies are controlled, as already mentioned, in another way than through the nervous system, viz., by chemical agents (hormones) circulating in the blood. Many of these are produced by special glandular organs, known as internally secreting glands. The ordinary secreting glands pour their secretions on the exterior of the body or on a surface communicating with the exterior; the internally secreting glands pass the materials which they produce directly into the blood. In this fluid the hormones are carried to distant organs. Their influence upon an organ may be essential to the proper performance of its functions or may be merely ancillary to it. In the former case removal of the internally secreting gland which produces the hormone, or its destruction by disease, may prove fatal to the organism.

Suprarenals.

This is the case with the suprarenal capsules: small glands which are adjacent to the kidneys, although having no physiological connection with these organs. A Guy's physician, Dr. Addison, in the middle of the last century showed that a certain affection, almost always fatal, since known by his name, is associated with disease of the suprarenal capsules. A short time after this observation a French physiologist, Brown-Séquard, found that animals from which the suprarenal capsules are removed rarely survive the operation for more than a few days. In the concluding decade of the last century interest in these bodies was revived by the discovery that they are constantly yielding to the blood a chemical agent (or hormone) which stimulates the contractions of the heart and arteries and assists in the promotion of every action which is brought about through the sympathetic nervous system (Langley). In this manner the importance of their integrity has been explained, although we have still much to learn regarding their functions.

Thyroid.

Another instance of an internally secreting gland which is essential to life, or at least to its maintenance in a normal condition, is the thyroid. The association of imperfect development or disease of the thyroid with disorders of nutrition and inactivity of the nervous system is well ascertained. The form of idiocy known as cretinism and the affection termed myxœdema are both associated with deficiency of its secretion: somewhat similar conditions to these are produced by the surgical removal of the gland. The symptoms are alleviated or cured by the administration of its juice. On the other hand, enlargement of the thyroid, accompanied by increase of its secretion, produces symptoms of nervous excitation, and similar symptoms are caused by excessive administration of glandular substance by the mouth. From these observations it is inferred that the juice contains hormones which help to regulate the nutrition of the body and serve to stimulate the nervous system, for the higher functions of which they appear to be essential. To quote M. Gley, to whose researches we owe much of our knowledge regarding the functions of this organ: "La genèse et l'exercice des plus hautes facultés de l'homme sont conditionnés par l'action purement chimique d'un produit de sécrétion. Que les psychologues méditent ces faits!"

Parathyroids.

The case of the parathyroid glandules is still more remarkable. These organs were discovered by Sandström in 1880. They are four minute bodies, each no larger than a pin's head, imbedded in the thyroid. Small as they are, their internal secretion possesses hormones which exert a powerful influence upon the nervous system. If they are completely removed, a complex of symptoms, technically known as "tetany," is liable to occur, which is always serious and may be fatal. Like the hormones of the thyroid itself, therefore, those of the parathyroids produce effects upon the nervous system, to which they are carried by the blood; although the effects are of a different kind.

Pituitary.

Another internally secreting gland which has evoked considerable interest during the last few years is the pituitary body. This is a small structure no larger than a cob-nut attached to the base of the brain. It is mainly composed of glandular cells. Its removal has been found (by most observers) to be fatal—often within two or three days. Its hypertrophy, when occurring during the general growth of the body, is attended by an undue development of the skeleton, so that the stature tends to assume gigantic proportions. When the hypertrophy occurs after growth is completed, the extremities—viz., the hands and feet, and the bones of the face—are mainly affected; hence the condition has been termed "acromegaly" (enlargement of extremities). The association of this condition with affections of the pituitary was pointed out in 1885 by a distinguished French physician, Dr. Pierre Marie. Both "giants" and "acromegalists" are almost invariably found to have an enlarged pituitary. The enlargement is generally confined to one part—the anterior lobe—and we conclude that this produces hormones which stimulate the growth of the body generally and of the skeleton in particular. The remainder of the pituitary is different in structure from the anterior lobe and has a different function. From it hormones can be extracted which, like those of the suprarenal capsule, although not exactly in the same manner, influence the contraction of the heart and arteries. Its extracts are also instrumental in promoting the secretion of certain glands. When injected into the blood they cause a free secretion of water from the kidneys and of milk from the mammary glands, neither of which organs are directly influenced (as most other glands are) through the nervous system. Doubtless under natural conditions these organs are stimulated to activity by hormones which are produced in the pituitary and which pass from this into the blood.

The internally secreting glands which have been mentioned (thyroid, parathyroid, suprarenal, pituitary) have, so far as is known, no other function than that of producing chemical substances of this character for the influencing of other organs, to which they are conveyed by the blood. It is interesting to observe that these glands are all of very small size, none being larger than a walnut, and some—the parathyroids—almost microscopic. In spite of this, they are essential to the proper maintenance of the life of the body, and the total removal of any of them by disease or operation is in most cases speedily fatal.

Pancreas.

There are, however, organs in the body yielding internal secretions to the blood in the shape of hormones, but exercising at the same time other functions. A striking instance is furnished by the pancreas, the secretion of which is the most important of the digestive juices. This—the pancreatic juice—forms the external secretion of the gland, and is poured into the intestine, where its action upon the food as it passes out from the stomach has long been recognised. It was, however, discovered in 1889 by von Mering and Minkowski that the pancreas also furnishes an internal secretion, containing a hormone which is passed from the pancreas into the blood, by which it is carried first to the liver and afterwards to the body generally. This hormone is essential to the proper utilisation of carbohydrates in the organism. It is well known that the carbohydrates of the food are converted into grape sugar and circulate in this form in the blood, which always contains a certain amount; the blood conveys it to all the cells of the body, and they utilise it as fuel. If, owing to disease of the pancreas or as the result of its removal by surgical procedure, its internal secretion is not available, sugar is no longer properly utilised by the cells of the body and tends to accumulate in the blood; from the blood the excess passes off by the kidneys, producing diabetes.

Duodenum.

Another instance of an internal secretion furnished by an organ which is devoted largely to other functions is the "pro-secretin" found in the cells lining the duodenum. When the acid gastric juice comes into contact with these cells it converts their prosecretin into "secretin." This is a hormone which is passed into the blood and circulates with that fluid. It has a specific effect on the externally secreting cells of the pancreas, and causes the rapid outpouring of pancreatic juice into the intestine. This effect is similar to that of the hormones of the pituitary body upon the cells of the kidney and mammary gland. It was discovered by Bayliss and Starling.

Internal Secretions of the Reproductive Organs.

The reproductive glands furnish in many respects the most interesting example of organs which besides their ordinary products, the germ- and spermcells (ova and spermatozoa)—form hormones which circulate in the blood and effect changes in cells of distant parts of the body. It is through these hormones that the secondary sexual characters, such as the comb and tail of the cock, the mane of the lion, the horns of the stag, the beard and enlarged larynx of a man, are produced, as well as the many differences in form and structure of the body which are characteristic of the sexes. The dependence of these so-called secondary sexual characters upon the state of development of the reproductive organs has been recognised from time immemorial, but has usually been ascribed to influences produced through the nervous system, and it is only in recent years that the changes have been shown to be brought about by the agency of internal secretions and hormones, passed from the reproductive glands into the circulating blood.[26]

Chemical Nature of Hormones.

It has been possible in only one or two instances to prepare and isolate the hormones of the internal secretions in a sufficient condition of purity to subject them to analysis, but enough is known about them to indicate that they are organic bodies of a not very complex nature, far simpler than proteins and even than enzymes. Those which have been studied are all dialysable, are readily soluble in water but insoluble in alcohol, and are not destroyed by boiling. One at least—that of the medulla of the suprarenal capsule—has been prepared synthetically, and when their exact chemical nature has been somewhat better elucidated it will probably not be difficult to obtain others in the same way.

From the above it is clear that not only is a coordination through the nervous system necessary in order that life shall be maintained in a normal condition, but a chemical coordination is no less essential. These may be independent of one another; but, on the other hand, they may react upon one another. For it can be shown that the production of some at least of the hormones is under the influence of the nervous system (Biedl, Asher, Elliott); whilst, as we have seen, some of the functions of the nervous system are dependent upon hormones.

Protective Chemical Mechanisms.—Toxins and Antitoxins.

Time will not permit me to refer in any but the briefest manner to the protective mechanisms which the cell-aggregate has evolved for its defence against disease, especially disease produced by parasitic micro-organisms. These, which belong with few exceptions to the Protista, are without doubt the most formidable enemies which the multicellular Metazoa, to which all the higher animal organisms belong, have to contend against. To such micro-organisms are due, *inter alia*, all diseases which are liable to become epidemic, such as anthrax and rinderpest in cattle, distemper in dogs and cats, smallpox, scarlet fever, measles, and sleeping sickness in man. The advances of modern medicine have shown that the symptoms of these diseases—the disturbances of nutrition, the temperature, the lassitude or excitement, and other nervous disturbances—are the effects of chemical poisons (*toxins*) produced by the micro-organisms and acting deleteriously upon the tissues of the body. The tissues, on the other hand, endeavour to counteract these effects by producing other chemical substances destructive to the micro-organisms or antagonistic to their action: these are known as *anti-bodies*. Sometimes the protection takes the form of a subtle alteration in the living substance of the cells which renders them for a long time, or even permanently, insusceptible (immune) to the action of the poison. Sometimes certain cells of the body, such as the white corpuscles of the blood, eat the invading micro-organisms and destroy them bodily by the action of chemical agents within their protoplasm. The result of an illness thus depends upon the result of the struggle between these opposing forces—the micro-organisms on the one hand and the cells of the body on the other—both of which fight with chemical weapons. If the cells of the body do not succeed in destroying the invading organisms, it is certain that the invaders will in the long run destroy them, for in this combat no quarter is given. Fortunately we have been able, by the aid of animal experimentation, to acquire some knowledge of the manner in which we are attacked by micro-organisms and of the methods which the cells of our body adopt to repel the attack, and the knowledge is now extensively utilised to assist our defence.

Parasitic Nature of Diseases.

For this purpose protective serums or antitoxins, which have been formed in the blood of other animals, are employed to supplement the action of those which our own cells produce. It is not too much to assert that the knowledge of the parasitic origin of so many diseases and of the chemical agents which on the one hand cause, and on the other combat, their symptoms, has transformed medicine from a mere art practised empirically into a real science based upon experiment. The transformation has opened out an illimitable vista of possibilities in the direction not only of cure, but, more important still, of prevention. It has taken place within the memory of most of us who are here present. And only last February the world was mourning the death of one of the greatest of its benefactors—a former President of this Association[27]—who, by applying this knowledge to the practice of surgery, was instrumental, even in his own lifetime, in saving more lives than were destroyed in all the bloody wars of the nineteenth century!

Senescence and Death.

The question has been debated whether, if all accidental modes of destruction of the life of the cell could be eliminated, there would remain a possibility of individual cell life, and even of aggregate cell life, continuing indefinitely; in other words, Are the phenomena of senescence and death a natural and necessary sequence to the existence of life? To most of my audience it will appear that the subject is not open to debate. But some physiologists (*e.g.* Metchnikoff) hold that the condition of senescence is itself abnormal; that old age is a form of disease or is due to disease, and, theoretically at least, is capable of being eliminated. We have already seen that individual cell life, such as that of the white blood-corpuscles and of the cells of many tissues, can under suitable conditions be prolonged for days or weeks or months after general death. Unicellular organisms kept under suitable conditions of nutrition have been observed to carry on their functions normally for prolonged periods and to show no degeneration such as would accompany senescence. They give rise by division to others of the same kind, which also, under favourable conditions, continue to live, to all appearance indefinitely. But these instances, although they indicate that in the simplest forms of organisation existence may be greatly extended without signs of decay, do not furnish conclusive evidence of indefinite

[26] The evidence is to be found in F. H. A. Marshall, "The Physiology of Reproduction," 1911.

[27] Lord Lister was President at Liverpool in 1896.

prolongation of life. Most of the cells which constitute the body, after a period of growth and activity, sometimes more, sometimes less prolonged, eventually undergo atrophy and cease to perform satisfactorily the functions which are allotted to them. And when we consider the body as a whole, we find that in every case the life of the aggregate consists of a definite cycle of changes which, after passing through the stages of growth and maturity, always leads to senescence, and finally terminates in death. The only exception is in the reproductive cells, in which the processes of maturation and fertilisation result in rejuvenescence, so that instead of the usual downward change towards senescence, the fertilised ovum obtains a new lease of life, which is carried on into the new-formed organism. The latter again itself ultimately forms reproductive cells, and thus the life of the species is continued. It is only in the sense of its propagation in this way from one generation to another that we can speak of the indefinite continuance of life: we can only be immortal through our descendants!

Average Duration of Life and Possibility of its Prolongation.

The individuals of every species of animal appear to have an average duration of existence.[28] Some species are known the individuals of which live only for a few hours, whilst others survive for a hundred years.[29] In man himself the average length of life would probably be greater than the three-score and ten years allotted to him by the Psalmist if we could eliminate the results of disease and accident; when these results are included it falls far short of that period. If the terms of life given in the purely mythological part of the Old Testament were credible, man would in the early stages of his history have possessed a remarkable power of resisting age and disease. But, although many here present were brought up to believe in their literal veracity, such records are no longer accepted even by the most orthodox of theologians, and the nine hundred odd years with which Adam and his immediate descendants are credited, culminating in the nine hundred and sixty-nine of Methuselah, have been relegated, with the accounted of Creation and the Deluge, to their proper position in literature. When we come to the Hebrew patriarchs, we notice a considerable diminution to have taken place in what the insurance offices term the "expectation of life." Abraham is described as having lived only to 175 years, Joseph and Joshua to 110, Moses to 120; even at that age "his eye was not dim nor his natural force abated." We cannot say that under ideal conditions all these terms are impossible; indeed, Metchnikoff is disposed to regard them as probable; for great ages are still occasionally recorded, although it is doubtful if any as considerable as these are ever substantiated. That the expectation of life was better then than now would be inferred from the apologetic tone adopted by Jacob when questioned by Pharaoh as to his age: "The days of the years of my pilgrimage are a hundred and thirty years; few and evil have the days of the years of my life been, and have not attained unto the days of the years of the life of my fathers in the days of their pilgrimage." David, to whom, before the advent of the modern statistician, we owe the idea that seventy years is to be regarded as the normal period of life,[30] is himself merely stated to have "died in a good old age." The periods recorded for the Kings show a considerable falling-off as compared with the Patriarchs; but not a few were cut off by violent deaths, and many lived lives which were not ideal. Amongst eminent Greeks and Romans few very long lives are recorded, and the same is true of historical persons in mediæval and modern history. It is a long life that lasts much beyond eighty; three such linked together carry us far back into history. Mankind is in this respect more favoured than most mammals, although a few of these surpass the period of man's existence.[31] Strange that the brevity of human life should be a favourite theme of preacher and poet when the actual term of his "erring pilgrimage" is greater than that of most of his fellow creatures!

The End of Life.

The modern applications of the principles of preventive medicine and hygiene are no doubt operating to lengthen the average life. But even if the ravages of disease could be altogether eliminated, it is certain that at any rate the fixed cells of our body must eventually grow old and ultimately cease to function; when this happens to cells which are essential to the life of the organism, general death must result. This will always remain the universal law, from which there is no escape. "All that lives must die, passing through nature to eternity."

Such natural death unaccelerated by disease—is not death by disease as unnatural as death by accident?—should be a quiet, painless phenomenon, unattended by violent change. As Dastre expresses it, "The need of death should appear at the end of life, just as the need of sleep appears at the end of the day." The change has been led gradually up to by an orderly succession of phases, and is itself the last manifestation of life. Were we all certain of a quiet passing—were we sure that there would be "no moaning of the bar when we go out to sea"—we could anticipate the coming of death after a ripe old age without apprehension. And if ever the time shall arrive when man will have learned to regard this change as a simple physiological process, as natural as the oncoming of sleep, the approach of the fatal shears will be as generally welcomed as it is now abhorred. Such a day is still distant; we can scarcely say that its dawning is visible. Let us at least hope that, in the manner depicted by Dürer in his well-known etching, the sunshine which science irradiates may eventually put to flight the melancholy which hovers, bat-like, over the termination of our lives, and which even the anticipation of a future happier existence has not hitherto succeeded in dispersing.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. H. L. CALLENDAR, LL.D., F.R.S., PRESIDENT OF THE SECTION.

My first duty on taking the chair is to say a few words in commemoration of the distinguished members whom we have lost since the last meeting.

George Chrystal, Professor of Mathematics in the University of Edinburgh for more than thirty years, officiated as President of this section in the year 1885, and took a prominent part in the advancement of science as secretary of the Royal Society of Edinburgh since 1901. Of his brilliant mathematical work and his ability in developing the school at Edinburgh, I am not competent to speak, but I well remember as a student his admirable article on "Electricity and

28 This was regarded by Buffon as related to the period of growth, but the ratio is certainly not constant. The subject is discussed by Ray Lankester in an early work: "On Comparative Longevity in Man and Animals," 1870.

29 The approximate regular periods of longevity of different species of animals furnishes a strong argument against the theory that the decay of old age is an accidental phenomenon, comparable with disease.

30 The expectation of life of a healthy man of fifty is still reckoned at about twenty years.

31 "Hominis ævum cæterorum animalium omnium superat præter admodum paucorum."—Francis Bacon, "Historia vitæ et mortis," 1637.

Magnetism contributed to the "Encyclopaedia Britannica," which formed at that time the groundwork of our studies at Cambridge under Sir J. J. Thomson. It would be difficult to find a more complete and concise statement of the mathematical theory at the time when that article was written. One can well understand the value of such a teacher, and sympathise with his university in the loss they have sustained.

John Brown, F.R.S., who acted as local secretary for the Association at Belfast in 1902, will be remembered for his work on the Volta contact effect between metals, which he showed to be in the main dependent on chemical action, and to be profoundly affected by the nature of the gas or other medium in which the plates were immersed. Although the theory of this difficult subject may not yet be completely elucidated, there can be little doubt that his work takes the first rank on the experimental side.

William Sutherland, D.Sc., who at one time acted as Professor of Physics at Melbourne, is best known for his familiar papers on the subject of molecular physics in *The Philosophical Magazine*. His work was always remarkable for its wide range and boldness of imagination. Many of his hypotheses cannot yet be weighed in the balance of experiment, but some have already been substantiated. For instance, his theory of the variation of viscosity of gases with temperature has been generally accepted, and results are now commonly expressed in terms of Sutherland's constant.

Osborne Reynolds, the first Professor of Engineering at Owens College, was President of Section G in 1887, but belongs almost as much to mathematics and physics, in which his achievements are equally memorable. It would be scarcely possible for me to enumerate his important contributions to the science of engineering, which will be more fittingly commemorated elsewhere. His mastery of mathematical and physical methods, while contributing greatly to his success as a pioneer in the engineering laboratory, enabled him to attack the most difficult problems in physics, such as the theory of the radiometer and the thermal transpiration of gases. His determination of the mechanical equivalent of heat is a most striking example of accurate physical measurement carried out on an engineering scale. His last great work, on the "Submechanics of the Universe," is so original in its ideas and methods that its value cannot yet be fully appreciated. While it differs so radically from our preconceived ideas that it fails to carry immediate conviction, it undoubtedly represents possibilities of truth which subsequent workers in the same field cannot afford to ignore.

The present year has been one of remarkable activity in the world of mathematical and physical science if we may measure activity by the number and importance of scientific gatherings like the present for the interchange of ideas and the general advancement of science. The celebration of the 250th anniversary of the foundation of the Royal Society brought to our shores a number of distinguished delegates from all parts of the world, to promote the ever-growing fellowship among men of science which is one of the surest guarantees of international progress. The Congress of Universities of the Empire brought other guests from distant British dominions, and considered, as one of the principal points in its programme, the provision of facilities for the interchange of students between different universities, which will doubtless prove particularly advantageous to the scientific student in the higher branches of research. In the special branches of knowledge more particularly associated with this section, the International Congress of Mathematics at Cambridge, while it affords to Cambridge men like myself a most gratifying recognition of our *alma mater* as one of the leading schools of mathematics in the world, has given us the opportunity of meeting here a number of distinguished foreign mathematicians whose presence and personality cannot be otherwise than inspiring to our proceedings, and will compensate for any deficiency in our own mathematical programme. The Optical Convention held this year in London, by the importance of the papers contributed for discussion, and by its admirable exhibition of British instruments, has revealed the extent of our optical industry and talent, and has done much to dispel the impression, fostered by an unfortunate trade regulation, that the majority of optical instruments were "made elsewhere." The Radio-Telegraphic Conference, held under the auspices of the British Government, has formulated recommendations for regulating and extending the application of the discoveries of modern physics for saving life and property at sea. The work of this Conference will be fittingly supplemented on the scientific side by the discussion on wireless telegraphy which has been arranged to take place in this section in conjunction with Section G.

It would be impossible, even if it were not out of place, for me to attempt to review in detail the important work of these congresses, a full account of which will shortly be available in their several reports of proceedings now in course of publication. In the present age of specialisation and rapid publication it would be equally impossible to give any connected account in the time at my disposal of recent developments in those branches of science which come within the range of our section. The appropriate alternative, adopted by the majority of my predecessors in this chair, is to select some theory or idea, sufficiently fundamental to be of general interest, and to discuss it in the light of recent experimental evidence. It may sometimes be advantageous to take stock of our fundamental notions in this way, and to endeavour to determine how far they rest on direct experiment, and how far they are merely developments of some dynamical analogy, which may represent the results of experiment up to a certain point, but may lead to erroneous conclusions if pushed too far. With this object I propose to consider on the present occasion some of our fundamental ideas with regard to the nature of heat, and in particular to suggest that we might with advantage import into our modern theory some of the ideas of the old caloric or material theory which has for so long a time been forgotten and discredited. In so doing I may appear to many of you to be taking a retrograde step, because the caloric theory is generally represented as being fundamentally opposed to the kinetic theory and to the law of the conservation of energy. I would, therefore, remark at the outset that this is not necessarily the case, provided that the theory is rightly interpreted and applied in accordance with experiment. Mistakes have been made on both theories, but the method commonly adopted of selecting all the mistakes made in the application of the caloric theory and contrasting them with the correct deductions from the kinetic theory has created an erroneous impression that there is something fundamentally wrong about the caloric theory, and that it is in the nature of things incapable of correctly representing the facts. I shall endeavour to show that this fictitious antagonism between the two theories is without real foundation. They should rather be regarded as different ways of describing the same phenomena. Neither is complete without the other. The kinetic theory is generally preferable for elementary exposition, and has come to be almost exclusively adopted for this purpose; but in many cases the caloric theory would have the advantage of emphasising at the outset the importance of fundamental facts which are too often obscured in the prevailing method of treatment.

The explanation of the development of heat by friction was one of the earliest difficulties encountered by the caloric theory. One explanation, maintained by Cavendish and others, was simply that caloric was generated *de novo* by friction in much the same way as electricity. Another explanation, more commonly adopted, was that the fragments of solid, abraded in such operations as boring cannon, had a smaller capacity for heat than the original material. Caloric already existing in the substance was regarded as being squeezed or ground out of it without any fresh caloric being actually generated. The probability of the second explanation was negatived by the celebrated experiments of Rumford and Davy, who concluded that friction did not diminish the capacities of bodies for heat, and that it could not be a material substance because the supply obtainable by friction appeared to be inexhaustible. Rumford also showed that no increase of weight in a body when heated could be detected by the most delicate apparatus available in his time. Caloric evidently did not possess to any marked extent the properties of an ordinary ponderable fluid; but, if it had any real existence and was not merely a convenient mathematical fiction, it must be something of the same nature as the electric fluids, which had already played so useful a part in the description of phenomena, although their actual existence as physical entities had not then been demonstrated. Heat, as Rumford and Davy maintained, might be merely a mode of motion or a vibration of the ultimate particles of matter, but the idea in this form was too vague to serve as a basis of measurement or calculation. The simple conception of caloric, as a measurable quantity of something, sufficed for many purposes, and led in the hands of Laplace and others to correct results for the ratio of the specific heats, the adiabatic equation of gases, and other fundamental points of theory, though many problems in the relations of heat and work remained obscure.

The greatest contribution of the caloric theory to thermodynamics was the production of Carnot's immortal "Reflections on the Motive Power of Heat." It is one of the most remarkable illustrations of the undeserved discredit into which the caloric theory has fallen, that this work, the very foundation of modern thermodynamics, should still be misrepresented, and its logic assailed, on the ground that much of the reasoning is expressed in the language of the caloric theory. In justice to Carnot, even at the risk of wearying you with an oft-told tale, I cannot refrain from taking this opportunity of reviewing the essential points of his reasoning, because it affords incidentally the best introduction to the conception of caloric, and explains how a quantity of caloric is to be measured.

At the time when Carnot wrote, the industrial importance of the steam-engine was already established, and the economy gained by expansive working was generally appreciated. The air-engine, and a primitive form of the internal-combustion engine, had recently been invented. On account of the high value of the latent heat of steam, it was confidently expected that more work might be obtained from a given quantity of heat or fuel by employing some other working substance, such as alcohol or ether, in place of steam. Carnot set himself to investigate the conditions under which motive-power was obtainable from heat, how the efficiency was limited, and whether other agents were preferable to steam. These were questions of immediate practical importance to the engineer, but the answer which Carnot found embraces the whole range of science in its ever-widening scope.

In discussing the production of work from heat it is necessary, as Carnot points out, to consider a complete series or cycle of operations in which the working substance, and all parts of the engine, are restored on completion of the cycle to their initial state. Nothing but heat, or its equivalent fuel, may be supplied to the engine. Otherwise part of the motive power obtained might be due, not to heat alone, but to some change in the working substance, or in the disposition of the mechanism. Carnot here assumes the fundamental axiom of the cycle, which he states as follows:—"*When a body has undergone any changes, and, after a certain number of transformations, it is brought back identically to its original state, considered relatively to density, temperature, and mode of aggregation, it must contain the same quantity of heat as it contained originally.*" This does not limit the practical application of the theory, because all machines repeat a regular series of operations, which may be reduced in theory to an equivalent cycle in which everything is restored to its initial state.

The most essential feature of the working of all heat-engines, considered apart from details of mechanism, is the production of motive power by alternate expansion or contraction, or heating and cooling of the working substance. This necessitates the existence of a difference of temperature, produced by combustion or otherwise, between two bodies, such as the boiler and condenser of a steam-engine, which may be regarded as the source and sink of heat respectively. Wherever a difference of temperature exists, it may be made a source of motive-power, and conversely, without difference of temperature, no motive-power can be obtained from heat by a cyclical or continuous process. From this consideration Carnot deduces the simple and sufficient rule for obtaining the maximum effect:—"*In order to realise the maximum effect, it is necessary that, in the process employed, there should not be any direct interchange of heat between bodies at sensibly different temperatures.*" Direct transference of heat between bodies at sensibly different temperatures would be equivalent to wasting a difference of temperature which might have been utilised for the production of motive-power. Equality of temperature is here assumed as the limiting condition of thermal equilibrium, such that an infinitesimal difference of temperature will suffice to determine the flow of heat in either direction. An engine satisfying Carnot's rule will be reversible so far as the thermal operations are concerned. Carnot makes use of this property of reversibility in deducing his formal proof that an engine of this type possesses the maximum efficiency. If in the usual or direct method of working such an engine takes a quantity of heat Q from the source, rejects heat to the condenser, and gives a balance of useful work W per cycle, when the engine is reversed and supplied with motive-power W per cycle it will in the limit take the same quantity of heat from the condenser as it previously rejected, and return to the source the same quantity of heat Q as it took from it when working direct. All such engines must have the same efficiency (measured by the ratio W/Q of the work done to the heat taken from the source) whatever the working substance, provided that they work between the same temperature limits. For, if this were not the case, it would be theoretically possible, by employing the most efficient to drive the least efficient reversible engine backwards, to restore to the source all the heat taken from it, and to obtain a balance of useful work without the consumption of fuel; a result sufficiently improbable to serve as the basis of a formal proof. Carnot thus deduces his famous principle, which he states as follows:—"*The motive power obtainable from heat is independent of the agents set at work to realise it. Its quantity is fixed* *solely by the temperatures between which in the limit the transfer of heat takes place.*"

Objection is commonly taken to Carnot's proof, on the ground that the combination which he imagines might produce a balance of useful work without infringing the principle of conservation of energy, or constituting what we now understand as perpetual motion of the ordinary kind in mechanics. It has become the fashion to introduce the conservation of energy in the course of the proof, and to make a final appeal to some additional axiom. Any proof of this kind must always be to some extent a matter of taste; but since Carnot's principle cannot be deduced from the conservation of energy alone, it seems a pity to complicate the proof by appealing to it. For the particular object in view, the absurdity of a heat-engine working without fuel appears to afford the most appropriate improbability which could be invoked. The final appeal must be to experiment in any case. At the present time the experimental verification of Carnot's principle in its widest application so far outweighs the validity of any deductive proof, that we might well rest content with the logic that satisfied Carnot instead of confusing the issue by disputing his reasoning.

Carnot himself proceeded to test his principle in every possible way by comparison with experiment so far as the scanty data available in his time would permit. He also made several important deductions from it, which were contrary to received opinion at the time, but have since been accurately verified. He appears to have worked out these results analytically in the first instance, as indicated by his footnotes, and to have translated his equations into words in the text for the benefit of his non-mathematical readers. In consequence of this, some of his most important conclusions appear to have been overlooked or attributed to others. Owing to want of exact knowledge of the properties of substances over extended ranges of temperature, he was unable to apply his principle directly in the general form for any temperature limits. We still labour to a less extent under the same disability at the present day. He showed, however, that a great simplification was effected in its application by considering a cycle of infinitesimal range at any temperature t. In this simple case the principle is equivalent to the assertion that the work obtainable from a unit of heat per degree fall (or per degree range of the cycle) at a temperature t, is some function $F't$ of the temperature (generally known as Carnot's function), which must be the same for all substances at the same temperature. From the rough data then available for the properties of steam, alcohol, and air, he was able to calculate the numerical values of this function in kilogrammetres of work per kilocalorie of heat at various temperatures between 0° and 100° C., and to show that it was probably the same for different substances at the same temperature within the limits of experimental error. For the vapour of alcohol at its boiling-point, 78·7° C., he found the value $F't = 1{\cdot}230$ kilogrammetres per kilocalorie per degree fall. For steam at the same temperature he found nearly the same value, namely, $F't = 1{\cdot}212$. Thus no advantage in point of efficiency could be gained by employing the vapour of alcohol in place of steam. He was also able to show that the work obtainable from a kilocalorie per degree fall probably diminished with rise of temperature, but his data were not sufficiently exact to indicate the law of the variation.

The equation which Carnot employed in deducing the numerical values of his function from the experimental data for steam and alcohol is simply the direct expression of his principle as applied to a saturated vapour. It is now generally known as Clapeyron's equation, because Carnot did not happen to give the equation itself in algebraic form, although the principle and details of the calculation were most minutely and accurately described. In calculating the value of his function for air, Carnot made use of the known value of the difference of the specific heats at constant pressure and volume. He showed that this difference must be the same for equal volumes of all gases measured under the same temperature and pressure, whereas it had always previously been assumed that the ratio (not the difference) of the specific heats was the same for different gases. He also gave a general expression for the heat absorbed by a gas in expanding at constant temperature, and showed that it must bear a constant ratio to the work of expansion. These results were verified experimentally some years later, in part by Dulong, and more completely by Joule, but Carnot's theoretical prediction has generally been overlooked, although it was of the greatest interest and importance. The reason of this neglect is probably to be found in the fact that Carnot's expressions contained the unknown function $F't$ of the temperature, the form of which could not be deduced without making some assumptions with regard to the nature of heat and the scale on which temperature should be measured.

It was my privilege to discover a few years ago that Carnot himself had actually given the correct solution of this fundamental problem in one of his most important footnotes, where it had lain buried and unnoticed for more than eighty years. He showed by a most direct application of the caloric theory that if temperature was measured on the scale of a perfect gas (which is now universally adopted) the value of his function $F't$ on the caloric theory would be the same at all temperatures, and might be represented simply by a numerical constant A (our "mechanical equivalent") depending on the units adopted for work and heat. In other words, the work W done by a quantity of caloric Q in a Carnot cycle of range T to T_0 on the gas scale would be represented by the simple equation:

$$W = AQ(T - T_0).$$

It is at once obvious that this solution, obtained by Carnot from the caloric theory, so far from being inconsistent with the mechanical theory of heat, is a direct statement of the law of conservation of energy as applied to the Carnot cycle. If the lower limit T_0 of the cycle is taken at the absolute zero of the gas-thermometer, we observe that the maximum quantity of work obtainable from a quantity of caloric Q at a temperature T is simply AQT, which represents the absolute value of the energy carried by the caloric taken from the source at the temperature T. The energy of the caloric rejected at the temperature T_0 is AQT_0. The external work done is equal to the difference between the quantities of heat energy supplied and rejected in the cycle.

The analogy which Carnot himself employed in the interpretation of this equation was the oft-quoted analogy of the waterfall. Caloric might be regarded as possessing motive-power or energy in virtue of elevation of temperature just as water may be said to possess motive-power in virtue of its head or pressure. The limit of motive-power obtainable by a reversible motor in either case would be directly proportional to the head or fall measured on a suitable scale. Caloric itself was not motive-power, but must be regarded simply as the vehicle or carrier of energy, the production of motive-power from caloric depending essentially (as Carnot puts it) not on the actual consumption of caloric, but on the fall of temperature available. The measure of a quantity of caloric is the work done per degree fall, which corresponds with the measure of a quantity of water by weight, *i.e.* in kilogrammetres per metre fall.

That Carnot did not pursue the analogy further, and deduce the whole mechanical theory of heat from the caloric theory, is scarcely to be wondered at if we remember that no applications of the energy principle had then been made in any department of physics. He appears, indeed, at a later date to have caught a glimpse of the general principle when he states that "motive-power [his equivalent for work or energy] changes its form but is never annihilated." It is clear from the posthumous notes of his projected experimental work that he realised how much remained to be done on the experimental side, especially in relation to the generation of caloric by friction, and the waste of motive-power by conduction of heat, which appeared to him (in 1824) "almost inexplicable in the present state of the theory of heat."

One of the points which troubled him most in the application of the theoretical result that the work obtainable from a quantity of caloric was simply proportional to the fall of temperature available, was that it required that the specific heat of a perfect gas should be independent of the pressure. This was inconsistent with the general opinion prevalent at the time, and with one solitary experiment by Delaroche and Bérard, which appeared to show that the specific heat of a gas diminished with increase of pressure, and which had been explained by Laplace as a natural consequence of the caloric theory. Carnot showed that this result did not necessarily follow from the caloric theory, but the point was not finally decided in his favour until the experiments of Regnault, first published in 1852, established the correct values of the specific heat of gases, and proved that they were practically independent of the pressure.

Another point which troubled Carnot was that, according to his calculations, the motive-power obtainable from a kilocalorie of heat per degree fall appeared to diminish with rise of temperature, instead of remaining constant. This might have been due to experimental errors, since the data were most uncertain. But, if he had lived to carry out his projected experiments on the quantity of motive-power required to produce one unit of heat, and had obtained the result, 424 kilogrammetres per kilocalorie, subsequently found by Joule, he could scarcely have failed to notice that this was the same (within the limits of experimental error) as the maximum work AQT obtainable from the kilocalorie according to his equation. (This is seen to be the case when the values calculated by Carnot per degree fall at different temperatures were multiplied by the absolute temperature in each case. *E.g.* 1·212 kilogrammetres per degree fall with steam at 79° C. or 352° Abs. $1{\cdot}212 \times 352 = 426$ kilogrammetres.) The origin of the apparent discrepancy between theory and experiment lay in the tacit assumption that the quantity of caloric in a kilocalorie was the same at different temperatures. There were no experiments at that time available to demonstrate that the caloric measure of heat as work per degree fall, implied in Carnot's principle, or more explicitly stated in his equation, was not the same as the calorimetric measure obtained by mixing substances at different temperatures. Even when the energy principle was established its exponents failed to perceive exactly where the discrepancy between the two theories lay. In reality both were correct, if fairly interpreted in accordance with experiment, but they depended on different methods of measuring a quantity of heat, which, so far from being inconsistent, were mutually complementary.

The same misconception, in a more subtle and insidious form, is still prevalent in such common phrases as the following: "We now know that heat is a form of energy and not a material fluid." The experimental fact underlying this statement is that our ordinary methods of measuring quantities of heat in reality measure quantities of thermal energy. When two substances at different temperatures are mixed, the quantity remaining constant, provided that due allowance is made for external work done and for external loss of heat, is the total quantity of energy. Heat is a form of energy merely because the thing we measure and call heat is really a quantity of energy. Apart from considerations of practical convenience, we might equally well have agreed to measure a quantity of heat in accordance with Carnot's principle, by the external work done in a cycle per degree fall. Heat would then not be a form of energy, but would possess all the properties postulated for caloric. The caloric measure of heat follows directly from Carnot's principle, just as the energy measure follows from the law of conservation of energy. But the term *heat* has become so closely associated with the energy measure that it is necessary to employ a different term, *caloric*, to denote the simple measure of a quantity of heat as opposed to a quantity of heat energy. The measurement of heat as caloric is precisely analogous to the measure of electricity as a quantity of electric fluid. In the case of electricity, the quantity measure is more familiar than the energy measure, because it is generally simpler to measure electricity by its chemical and magnetic effects as a quantity of fluid than as a quantity of energy. The units for which we pay by electric meter, however, are units of energy, because the energy supplied is the chief factor in determining the cost of production, although the actual quantity of fluid supplied has a good deal to do with the cost of distribution. Both methods of measurement are just as important in the theory of heat, and it seems a great pity that the natural measure of heat quantity is obscured in the elementary stages of exposition by regarding heat simply as so much energy. The inadequacy of such treatment makes itself severely felt in the later stages.

Since Carnot's principle was adopted without material modification into the mechanical theory of heat, it was inevitable that Carnot's caloric, and his solution for the work done in a finite cycle, should sooner or later be rediscovered. Caloric reappeared first as the "thermodynamic function" of Rankine, and as the "equivalence-value of a transformation" in the equations of Clausius; but it was regarded rather as the quotient of heat energy by temperature than as possessing any special physical significance. At a later date, when its importance was more fully recognised, Clausius gave it the name of *entropy*, and established the important property that its total quantity remained constant in reversible heat exchanges, but always increased in an irreversible process. Any process involving a decrease in the total quantity of entropy was impossible. Equivalent propositions with regard to the possibility or impossibility of transformations had previously been stated by Lord Kelvin in terms of the dissipation of available energy. But, since Carnot's solution had been overlooked, no one at the time seems to have realised that entropy was simply Carnot's caloric under another name, that heat could be measured otherwise than as energy, and that the increase of entropy in any irreversible process was the most appropriate measure of the quantity of heat generated. Energy so far as we know must always be associated with something of a material nature acting as carrier, and there is no reason to believe that heat energy is an exception to this rule. The tendency of the kinetic theory has always been to regard entropy as a purely abstract mathematical function, relating to the distribution of the energy, but having no physical existence. Thus it is not a quantity of anything in the kinetic theory of gases, but merely the logarithm of the probability of an arrangement. In a similar way, some twenty years ago the view was commonly held that electric phenomena were due merely to strains in the æther, and that the electric fluids had no existence except as a convenient means of mathematical expression. Recent discoveries have enabled us to form a more concrete conception of a charge of electricity, which has proved invaluable as a guide to research. Perhaps it is not too much to hope that it may be possible to attach a similar conception with advantage to caloric as the measure of a quantity of heat.

It has generally been admitted in recent years that some independent measure of heat quantity as opposed to heat energy is required, but opinions have differed widely with regard to the adoption of entropy as the quantity factor of heat. Many of these objections have been felt rather than explicitly stated, and are therefore the more difficult to answer satisfactorily. Others arise from the difficulty of attaching any concrete conception of a quantity of something to such a vague and shadowy mathematical function as entropy. The answer to the question "What is caloric?" must necessarily be of a somewhat speculative nature. But it is so necessary for the experimentalist to reason by analogy from the seen to the unseen, that almost any answer, however crude, is better than none at all. The difficulties experienced in regarding entropy as a measure of heat quantity are more of an academic nature, but may be usefully considered as a preliminary in attempting to answer the more fundamental question.

The first difficulty felt by the student in regarding caloric as the measure of heat quantity is that when two portions of the same substance, such as water, at different temperatures are mixed, the quantity of caloric in the mixture is greater than the sum of the quantities in the separate portions. The same difficulty was encountered by Carnot from the opposite point of view. The two portions at different temperatures represented a possible source of motive-power. The question which he asked himself may be put as follows:—"If the total quantity of caloric remained the same when the two portions at different temperatures were simply mixed, what had become of the motive-power wasted?" The answer is that caloric is generated, and that the quantity generated is such that its energy is the precise equivalent of the motive-power which might have been obtained if the transfer of heat had been effected by means of a perfect engine working without generation of caloric. The caloric generated in wasting a difference of temperature is the necessary and appropriate measure of the quantity of heat obtained by the degradation of available motive-power into the less available or transformable variety of heat energy.

The processes by which caloric is generated in mixing substances at different temperatures, or in other cases where available motive-power is allowed to run to waste, are generally of so turbulent a character that the steps of the process cannot be followed, although the final result can be predicted under given conditions from the energy principle. Such processes could not be expected *a priori* to throw much light on the nature of caloric. The familiar process of conduction of heat through a body the parts of which are at different temperatures, while equally leading to the generation of a quantity of caloric equivalent to the motive-power wasted, affords better promise of elucidating the nature of caloric, owing to the comparative simplicity and regularity of the phenomena, which permit closer experimental study. The earliest measurements of the relative conducting powers of the metals for heat and electricity showed that the ratio of the thermal to the electric conductivity was nearly the same for all the pure metals, and suggested that, in this case, the carriers of heat and electricity were the same. Later and more accurate experiments showed that the ratio of the conductivities was not constant, but varied nearly as the absolute temperature. At first sight this might appear to suggest a radical difference between the two conductivities, but it results merely from the fact that heat is measured as energy in the definition of thermal conductivity, whereas electricity is measured as a quantity of fluid. If thermal conductivity were defined in terms of caloric or thermal fluid, the ratio of the two conductivities would be constant with respect to temperature almost, if not quite, within the limits of error of experiment. On the hypothesis that the carriers are the same for electricity and heat, and that the kinetic energy of each carrier is the same as that of a gas molecule at the same temperature, it becomes possible, on the analogy of the kinetic theory of gases, to calculate the actual value of the ratio of the conductivities. The value thus found agrees closely in magnitude with that given by experiment, and may be regarded as confirming the view that the carriers are the same, although the hypotheses and analogies invoked are somewhat speculative.

When the electrons or corpuscles of negative electricity were discovered it was a natural step to identify them with the carriers of energy, and to imagine that a metal contained a large number of such corpuscles, moving in all directions, and colliding with each other and with the metallic atoms, like the molecules of a gas on the kinetic theory. If the mass of each carrier were 1/1700 of that of an atom of hydrogen, the velocity at 0° C. would be about sixty miles a second, and would be of the right order of magnitude to account for the observed values of the conductivities of good conductors, on the assumption that the number of negative corpuscles was the same as the number of positive metallic atoms, and that the mean free path of each corpuscle was of the same order as the distance between the atoms. The same hypothesis served to give a qualitative account of thermo-electric phenomena, such as the Peltier and Thomson effects, and of radiation and absorption of heat, though in a less satisfactory manner. When extended to give a consistent account of *all* the related phenomena, it would appear that the number of free corpuscles required is too large to be reconciled, for instance, with the observed values of the specific heat, on the assumption that each corpuscle possesses energy of translation equal to that of a gas molecule at the same temperature.

Sir J. J. Thomson has accordingly proposed and discussed another possible theory of metallic conduction, in which the neutral electric doublets present in the metal are supposed to be continually interchanging corpuscles at a very high rate. Under ordinary condition these interchanges take place indifferently in all directions, but under the action of an electric field the axes of the doublets are supposed to become more or less oriented, as in the Grotthus-chain hypothesis of electrolytic conduction, producing a general drift or current proportional to the field. This hypothesis, though fundamentally different from the preceding or more generally accepted view, appears to lead to practically the same relations, and is in some ways preferable, as suggesting possible explanations of difficulties encountered by the first theory in postulating so large a number of free negative corpuscles. On the other hand, the second theory requires that each neutral doublet should be continually ejecting corpuscles at the rate of about 10^{15} per second. There are probably elements of truth in both theories, but, without insisting too much on the exact details of the process, we may at least assert with some confidence that the corpuscles of caloric which constitute a current of heat in a metal are very closely related to the corpuscles of electricity, and have an equal right to be regarded as constituting a material fluid possessing an objective physical existence.

If I may be allowed to speculate a little on my own account (as we are all here together in holiday mood, and you will not take anything I may say too seriously), I should prefer to regard the molecules of caloric, not as being identical with the corpuscles of negative electricity, but as being neutral doublets formed by the union of a positive and negative corpuscle, in much the same way as a molecule of hydrogen is formed by the union of two atoms. Nothing smaller than a hydrogen atom has yet, so far as I know, been discovered with a positive charge. This may be merely a consequence of the limitations of our experimental methods, which compel us to employ metals to so large an extent as electrodes. In the symmetry of nature it is almost inconceivable that the positive corpuscle should not exist, if only as the other end of the Faraday-tube or vortex-filament representing a chemical bond. Prof. Bragg has identified the X or γ rays with neutral corpuscles travelling at a high velocity, and has maintained this hypothesis with brilliant success against the older view that these rays are not separate entities, but merely thin, spreading pulses in the æther produced by the collisions of corpuscles with matter. I must leave him to summarise the evidence, but if neutral corpuscles exist, or can be generated in any way, it should certainly be much easier to detach a neutral corpuscle from a material atom or molecule than to detach a corpuscle with a negative charge from the positive atom with which it is associated. We should therefore expect neutral corpuscles to be of such exceedingly common and universal occurrence that their very existence might be overlooked, unless they happened to be travelling at such exceptionally high velocities as are associated with the γ rays. According to the pulse theory, it is assumed that all γ rays travel with the velocity of light, and that the enormous variations observed in their penetrative power depend simply on the thickness of the pulse transmitted. On the corpuscular theory, the penetrative power, like that of the α and β rays, is a question of size, velocity, and electric charge. Particles carrying electric charges, like the α and β rays, lose energy in producing ions by their electric field, perhaps without actual collision. Neutral or γ rays do not produce ions directly, but dislodge either γ rays or β rays from atoms by direct collisions, which are comparatively rare. The β rays alone, as C. T. R. Wilson's photographs show, are responsible for the ionisation. Personally, I have long been a convert to Prof. Bragg's views on the nature of X rays, but even if we regard the existence of neutral corpuscles as not yet definitely proved, it is, I think, permissible to assume their existence for purposes of argument, in order to see whether the conception may not be useful in the interpretation of physical phenomena.

If, for instance, we assume that the neutral corpuscles or molecules of caloric exist in conductors and metallic bodies in a comparatively free state of solution, and are readily dissociated into positive and negative electrons owing to the high specific inductive capacity of the medium, the whole theory of metallic conduction follows directly on the analogy of conduction in electrolytic solutions. But, whereas in electrolytes the ions are material atoms moving through a viscous medium with comparatively low velocities, the ions in metallic conductors are electric corpuscles moving with high velocities more after the manner postulated in the kinetic theory of gases. It is easy to see that this theory will give similar numerical results to the electronic theory when similar assumptions are made in the course of the work. But it has the advantage of greater latitude in explaining the vagaries of sign of the Hall effect, and many other peculiarities in the variation of resistance and thermoelectric power with temperature. For good conductors, like the pure metals, we may suppose, on the electrolytic analogy, that the dissociation is practically complete, so that the ratio of the conductivities will approach the value calculated on the assumption that all the carriers of heat are also carriers of electricity. But in bad conductors the dissociation will be far from complete, and it is possible to see why, for instance, the electric resistance of cast-iron should be nearly ten times that of pure iron, although there is comparatively little difference in their thermal conductivities. The numerical magnitude of the thermoelectric effect, which is commonly quoted in explanation of the deviation of alloys from the electronic theory, is far too small to produce the required result; and there is little or no correspondence between the thermo-electric properties of the constituents of alloys and the variations of their electric conductivities.

One of the oldest difficulties of the material theory of heat is to explain the process of the production of heat by friction. The application of the general principle of the conservation of energy leads to the undoubted conclusion that the thermal energy generated is the equivalent of the mechanical work spent in friction, but throws little or no light on the steps of the process, and gives no information with regard to the actual nature of the energy produced in the form of heat. It follows from the energy principle that the quantity of caloric generated in the process is such that its total energy at the final temperature is equal to the work spent. If a quantity of caloric represents so many neutral molecules of electricity, one cannot help asking where they came from, and how they were produced. It is certain that in most cases of friction, wherever slip occurs, some molecules are torn apart, and the work spent is represented in the first instance by the separation of electric ions. Some of these ions are permanently separated as frictional electricity, and can be made to perform useful work; but the majority recombine before they can be effectively separated, leaving only their equivalent in thermal energy. The recombination of two ions is generally regarded simply as reconstituting the original molecule at a high temperature, but in the light of recent discoveries we may perhaps go a step further. It is generally admitted that X or γ rays are produced by the sudden stoppage of a charged corpuscle, and Lorentz, in his electron theory of radiation, has assumed that such is the case however low the velocity of the electron. A similar effect must occur in the sudden stoppage of a pair of ions rushing together under the influence of their mutual attraction. Rays produced in this way would be of an exceedingly soft or absorbable character, but they would not differ in kind from those produced by electrons except that their energy, not exceeding that of a pair of ions, would be too small to produce ionisation, so that they could not be detected in the usual way. If the X rays are corpuscular in their nature, we cannot logically deny the corpuscular character even to the slowest moving rays. We know that X rays continually produce other X rays of lower velocity. The final stage is probably reached when the average energy of an X corpuscle or molecule of caloric is the same as that of a gas molecule at the same temperature, and the number of molecules of caloric generated is such that their total energy is equal to the work originally spent in friction.

In this connection it is interesting to note that Sir J. J. Thomson, in a recent paper on ionisation by moving particles, has arrived, on other grounds, at the conclusion that the character of the radiation emitted during the recombination of the ions will be a series of pulses, each pulse containing the same amount of energy and being of the same type as very soft X rays. If the X rays are really corpuscular, these definite units or quanta of energy generated by the recombination of the ions bear a close resemblance to the hypothetical molecules of caloric.

It may be objected that in many cases of friction, such as internal or viscous friction in a fluid, no electrification or ionisation is observable, and that the generation of caloric cannot in this case be attributed to the recombination of ions. It must, however, be remarked that the generation of a molecule of caloric requires less energy than the separation of two ions; that, just as the separation of two ions corresponds with the breaking of a chemical bond, so the generation of one or more molecules of caloric may correspond with the rupture of a physical bond, such as the separation of a molecule of vapour from a liquid or solid. The assumption of a molecular constitution for caloric follows almost of necessity from the molecular theories of matter and electricity, and is not inconsistent with any well-established experimental facts. On the contrary, the many relations which are known to exist between the specific heats of similar substances, and also between latent heats, would appear to lead naturally to a molecular theory of caloric. For instance, it has often been noticed that the molecular latent heats of vaporisation of similar compounds at their boiling-points are proportional to the absolute temperature. It follows that the molecular latent caloric of vaporisation is the *same* for all such compounds, or that they require the same number of molecules of caloric to effect the same change of state, irrespective of the absolute temperatures of their boiling-points. From this point of view one may naturally regard the liquid and gaseous states as conjugate solutions of caloric in matter and matter in caloric respectively. The proportion of caloric to matter varies regularly with pressure and temperature, and there is a definite saturation limit of solubility at each temperature.

One of the most difficult cases of the generation of caloric to follow in detail is that which occurs whenever there is exchange of heat by radiation between bodies at different temperatures. If radiation is an electro-magnetic wave-motion, we must suppose that there is some kind of electric oscillator or resonator in the constitution of a material molecule which is capable of responding to the electric oscillations. If the natural periods of the resonators correspond sufficiently closely with those of the incident radiation the amplitude of the vibration excited may be sufficient to cause the ejection of a corpuscle of caloric. It is generally admitted that the ejection of an electron may be brought about in this manner, but it would evidently require far less energy to produce the emission of a neutral corpuscle, which ought therefore to be a much more common effect. On this view, the conversion of energy of radiation into energy of caloric is a discontinuous process taking place by definite molecular increments, but the absorption or emission of radiation itself is a continuous process. Prof. Planck, by a most ingenious argument based on the probability of the distribution of energy among a large number of similar electric oscillators (in which the entropy is taken as the logarithm of the probability, and the temperature as the rate of increase of energy per unit of entropy), has succeeded in deducing his well-known formula for the distribution of energy in full radiation at any temperature; and has recently, by a further extension of the same line of argument, arrived at the remarkable conclusion that, while the absorption of radiation is continuous, the emission of radiation is discontinuous, occurring in discrete elements or quanta. Where an argument depends on so many intricate hypotheses and analogies the possible interpretations of the mathematical formulæ are to some extent uncertain; but it would appear that Prof. Planck's equations are not necessarily inconsistent with the view above expressed that both emission and absorption of radiation are continuous, and that his *elementa quanta*, the energy of which varies with their frequency, should rather be identified with the molecules of caloric, representing the conversion of the electro-magnetic energy of radiation into the form of heat, and possessing energy in proportion to their temperature.

Among the difficulties felt, rather than explicitly stated, in regarding entropy or caloric as the measure of heat quantity is its awkward habit of becoming infinite, according to the usual approximate formulæ, at extremes of pressure or temperature. If caloric is to be regarded as the measure of heat quantity, the quantity existing in a finite body must be finite, and must vanish at the absolute zero of temperature. In reality there is no experimental foundation for any other conclusion. According to the usual gas formulæ it would be possible to extract an infinite quantity of caloric from a finite quantity of gas by compressing it at constant temperature. It is true that (even if we assumed the law of gases to hold up to infinite pressures, which is far from being the case) the quantity of caloric extracted would be of an infinitely low order of infinity as compared with the pressure required. But, as a matter of fact, experiment indicates that the quantity obtainable would be finite, although its exact value cannot be calculated owing to our ignorance of the properties of gases at infinite pressures. In a similar way, if we assume that the specific heat as ordinarily measured remains constant, or approaches a finite limit at the absolute zero of temperature, we should arrive at the conclusion that an infinite quantity of caloric would be required to raise the temperature of a finite body from 0° to 1° absolute. The tendency of recent experimental work on specific heats at low temperatures, by Tilden, Nernst, Lindemann, and others, is to show, on the contrary, that the specific heats of all substances tend to vanish as the absolute zero is approached, and that it is the specific capacity for caloric which approaches a finite limit. The theory of the variation of the specific heats of solids at low temperatures is one of the most vital problems in the theory of heat at the present time, and is engaging the attention of many active workers. Prof. Lindemann, one of the leading exponents of this work, has kindly consented to open a discussion on the subject in our section. We are very fortunate to have succeeded in securing so able an exponent, and shall await his exposition with the greatest interest. For the present I need only add that the obvious conclusion of the caloric theory bids fair to be completely justified.

A most interesting question, which early presented itself to Rumford and other inquirers into the caloric theory of heat, was whether caloric possessed *weight*. While a positive answer to this question would be greatly in favour of a material theory, a negative answer, such as that found by Rumford, or quite recently by Profs. Poynting and Phillips, and by Mr. L. Southerns working independently, would not be conclusively against it. The latter observers found that the change in weight, if any, certainly did not exceed 1 in 10^8 per 1° C. If the mass of a molecule of caloric were the same as that generally attributed to an electron, the change of weight, in the cases tested, should have been of the order of 1 in 10^7 per 1° C., and should not have escaped detection. It is generally agreed, however, that the mass of the electron is entirely electro-magnetic. Any such statement virtually assumes a particular distribution of the electricity in a spherical electron of given size. But if electricity itself really consists of electrons, an argument of this type would appear to be so perfectly circular that it is questionable how much weight should be attached to it. If the equivalent mass of an electron in motion arises slowly from the electromagnetic field produced by its motion, a neutral corpuscle of caloric should not possess mass or energy of translation as a whole, though it might still possess energy of vibration or rotation of its separate charges. For the purpose of mental imagery we might picture the electron as the free or broken end of a vortex filament, and the neutral corpuscle as a vortex ring produced when the positive and negative ends are united; but a mental picture of this kind does not carry us any further than the sphere coated with electricity, except in so far as either image may suggest points for experimental investigation. In our ignorance of the exact mechanism of gravity it is even conceivable that a particle of caloric might possess mass without possessing weight, though, with the possible exception of the electron, nothing of the kind has yet been demonstrated. In any case it would appear that the mass, if any, associated with a quantity of caloric must be so small that we could not hope to learn much about it by the direct use of the balance.

The fundamental property of caloric, that its total quantity cannot be diminished by any known process and that it is not energy but merely the vehicle or carrier of energy, is most simply represented in thought by imagining it to consist of some indestructible form of matter. The further property, that it is always generated in any turbulent or irreversible process, appears at first sight to conflict with this idea, because it is difficult to see how anything indestructible can be so easily generated. When, however, we speak of caloric as being generated, what we really mean is that it becomes associated with a material body in such a way that we can observe and measure its quantity by the change of state produced. The caloric may have existed previously in a form in which its presence could not be detected. In the light of recent discoveries we might suppose the caloric generated to arise from the disintegration of the atoms of matter. No doubt some caloric is produced in this way, but those corpuscles that are so strongly held as to be incapable of detection by ordinary physical methods require intense shocks to dislodge them. A more probable source of caloric is the æther, which, so far as we know, may consist entirely of neutral corpuscles of caloric. The hypothesis of a continuous æther has led to great difficulties in the electromagnetic theory of light and in the kinetic theory of gases. A molecular, or cellular-vortex, structure appears to be required. According to the researches of Kelvin, Fitzgerald, and Hicks, such an æther can be devised to satisfy the requirements of the electromagnetic theory without requiring it to possess a density many times greater than that of platinum. So far as the properties of caloric are concerned, a neutral pair of electrons would appear to constitute the simplest type of molecule, though without more exact knowledge of the ultimate nature of an electric charge it would be impossible to predict all its properties. Whether an æther composed of such molecules would be competent to discharge satisfactorily all the onerous functions expected from it, may be difficult to decide, but the inquiry, in its turn, would probably throw light on the ultimate structure of the molecule.

Without venturing too far into the regions of metaphysical speculation, or reasoning in vicious circles about the nature of an electric charge, we may at least assert with some degree of plausibility that material bodies under ordinary conditions probably contain a number of discrete physical entities, similar in kind to X rays or neutral corpuscles, which are capable of acting as carriers of energy, and of preserving the statical equilibrium between matter and radiation at any temperature in virtue of their interchanges with electrons. If we go a step further and identify these corpuscles with the molecules of caloric, we shall certainly come in conflict with some of the fundamental dogmas of the kinetic theory, which tries to express everything in terms of energy, but the change involved is mainly one of point of view or expression. The experimental facts remain the same, but we describe them differently. Caloric has a physical existence, instead of being merely the logarithm of the probability of a complex ion. In common with many experimentalists, I cannot help feeling that we have everything to gain by attaching a material conception to a quantity of caloric as the natural measure of a quantity of heat as opposed to a quantity of heat energy. In the time at my disposal I could not pretend to offer you more than a suggestion of a sketch, an apology for the possibility of an explanation, but I hope I may have succeeded in conveying the impression that a caloric theory of heat is not so entirely unreasonable in the light of recent experiment as we are sometimes led to imagine.

NOTES.

DR. G. T. BEILBY, F.R.S., has been appointed a member of the Royal Commission on Oil Fuel in succession to the late Dr. H. Owen Jones.

THE death is announced, at eighty years of age, of Prof. T. Gomperz, of the University of Vienna, distinguished by his studies in philology and philosophy, and well known by his work "Greek Thinkers," of which an English translation appeared several years ago.

As previously announced, the autumn meeting of the Institute of Metals will be held in London on Wednesday and Thursday, September 25 and 26. The following are among the papers that are expected to be submitted:—Autogenous welding by means of oxygen and acetylene of copper and its principal alloys, and of aluminium, Prof. F. Carnevali; the effect of other metals on the structure of the beta constituent in copper-zinc alloys, Prof. H. C. H. Carpenter; the effect of temperatures higher than atmospheric on tensile tests of copper and its alloys, Prof. A. K. Huntington; the influence of oxygen on the properties of metals and alloys, E. F. Law; the annealing of coinage alloys, Dr. T. Kirke Rose; intercrystalline cohesion in metals (with an appendix on the formation of twinned crystals in silver), Dr. W. Rosenhain and D. Ewen; oxygen in brass, Prof. T. Turner.

WE regret to announce that Prof. T. Winter, professor of agriculture in University College of North Wales, Bangor, died on Sunday, September 1, at forty-six years of age. Prof. Winter was educated at Darlington Grammar School and Edinburgh University, where he graduated in arts. He afterwards became assistant lecturer on agriculture at the University College of North Wales. Later he was appointed lecturer in agriculture at the University of Leeds; and in 1894 he returned to the University College of North Wales as head of the agricultural department. He took an active part in agricultural matters in Wales, and was widely known and respected throughout the country.

WE are glad to see that progress is gradually being made with the synchronisation of clocks, thanks largely to the enterprise of private companies. Last year a committee of the British Science Guild presented a valuable report upon the position of the subject and the system employed by the General Post Office, and an instructive account of synchronisation and the importance of correct time is given by Major O'Meara in an address printed in this year's report of the Guild. The committee recommended that, as a beginning, it would probably be well to have a few large public clocks in London synchronised, and that these should be set apart and considered as "standard time clocks." An electric clock which may be used for the purpose suggested by the committee has just been built by the Silent Electric Clock Co., 192 Goswell Road, London, E.C., on the new mills of the Hovis Bread Co., Vauxhall Bridge Road. We understand that this electric clock, with its four faces each 9 ft. 6 in. diameter, is not only the largest electric clock in London, but is also to be controlled by a master clock directly synchronised from Greenwich. The clock thus represents an up-to-date form of public timekeeper which is likely to be extensively adopted in the future.

A LOCAL society which possesses such a creditable record of work as the Royal Cornwall Polytechnic Society does well to commemorate worthies who were members of their body. In the first part of its Proceedings for 1912 it publishes portraits and lives of three of its most eminent members, Sir C. Lemon, F.R.S., first president (1833–67), who did good service to science by his attempt to found a school of mines at Truro, a project which was in advance of the times when it was proposed, but has been since realised; Lord de Dunstanville, first patron, scholar and politician; and last, but not least, Davies Gilbert, who succeeded Sir Humphry Davy as president of the Royal Society, an accomplished botanist and distinguished in other branches of science. In the annual report the council takes occasion to congratulate the Rev. Philip Carlyon, a former vice-president of the society, on attaining the age of a hundred years in December last.

VOLUME xi. of the Zoological Publications of the Field Museum is devoted to an account of the mammals of Illinois and Wisconsin, comprising 502 pages of text and a large number of illustrations. "Keys" to the various genera and their species are given.

IN the report of the Field Museum of Natural History, Chicago, for 1911, the director refers to the acquisition by the trustees of a site for a new building in Jackson Park, immediately to the north of the present structure. The plans for the new building have been approved, and the specifications for the contracts drawn up. The report is illustrated with photographs of bird groups and other interesting exhibits recently added to the museum.

THE Meteorological Service of Canada has issued a very useful pamphlet on the comparison of the Ångström pyrheliometer and the Callendar sunshine recorder, and the determination of the proportion of heat received on a horizontal surface from the diffuse radiation from the sky to that received from the sun. The International Union for Cooperation in Solar Research at its Oxford conference recommended (1) the adoption of the former instrument, and (2) comparisons between it and other standard instruments, but except at laboratories and the larger observatories little is yet generally known about its working. The paper in question, prepared by Mr. J. Patterson, under the direction of Mr. R. F. Stupart, gives a very clear idea of the construction and action of both the above instruments. The following are among the noteworthy features shown by their comparison: (1) the maximum intensity of radiation measured by the Ångström instrument occurred at apparent noon, and by the Callendar recorder about forty minutes later. (2) The Ångström instrument gave slightly higher values in the afternoon than in the morning, and the Callendar recorder much higher values. (3) In the early morning and late afternoon the Callendar instrument gave higher readings than the Ångström. (4) Excluding the morning readings the greatest percentage difference occurred between 9h. and 10h. a.m.; from about 1h. to 3h. p.m. the change in percentage was very slight.

SIR T. L. HEATH has now supplied an English edition (Cambridge Press, 2*s.* 6*d.*) of the "Method" of Archimedes, discovered by Heiberg in 1906. This tract is of very great interest, because it gives mechanical discussions of geometrical problems based upon the principle of the lever. Thus we have the rule for the quadrature of a parabolic segment which Archimedes elsewhere proves by the method of exhaustion. Archimedes expressly says that the "Method" does not supply demonstrations; he does not give any reasons, but no doubt he had in mind what we should call the theory of infinitesimals of different orders. For example, a triangular lamina may be roughly, but not exactly, replaced by a set of parallel rectangular strips; to find the centroid of the triangle we must find the *limiting* position of the centroid of the system of strips. Among other noteworthy points it may be observed that Archimedes arrived at the formula for the volume of a sphere before he discovered that for its area; and that he attributes to Democritus the discovery of the theorem that pyramids of equal bases and altitudes are of equal volume. The first proof, allowed to be rigorous, he assigns (as elsewhere) to Eudoxus. As usual, the editor's task is performed with great learning and thoroughness; his introduction in particular will be found extremely useful by those who are not familiar with Greek mathematics beyond the elementary stage.

The Central—the journal of the City and Guilds Engineering College—for August contains an article advocating the use of direct rather than alternating currents in electric traction by Mr. L. Calisch, an account of some recent improvements in vacuum evaporation by Mr. W. A. Davis, and a description of the Boncourt system of gaseous combustion by one of its inventors, Mr. C. D. McCourt. The feature of the system is the combustion of the gas and air mixture as it is passing with the requisite velocity through the interstices of a granular refractory material. A steam boiler fired in this way evaporates 16 lbs. of water per hour per square foot of heating surface. The old student notes occupy fifteen pages. Referring to work in the drawing office of a French engineering firm, Mr. K. C. Barnaby writes:—". . . there is the delightful metric system. I cannot imagine anyone who has worked and calculated in a Continental office who would not wish our antiquated system of weights and measures—well, where parallels meet."

The fifty-seventh annual exhibition of the Royal Photographic Society, which was opened last Monday, will remain open until the 21st inst. at the Gallery of the Royal Society of British Artists, Suffolk Street, Pall Mall. In the scientific and technical sections four exhibits have been awarded medals. The first consists of examples of a new photo-mechanical process by Mr. A. E. Bawtree, who has found a method of transferring the pigment of an impression from an engraved plate, whether it is old or new, to a sheet of glass, so producing a more perfect transparency than any camera method can yield. He claims that not a grain of the pigment is lost. From this transparency copies of the original may be made by various photographic or photo-mechanical methods as is well known. He can then retransfer the pigment from the glass to paper without the loss of even the finest detail. The method of transfer is so easy that the author does not yet describe it, because it enables facsimiles of bank-notes and such documents to be prepared with a very moderate outlay for apparatus. Dr. D. H. Hutchinson's series of photomicrographs of the ova of the Mexican Axolotl show the development of the embryo from the first day after the egg has been laid up to the time of its escape from the egg. This, and Mr. Farren's series of photographs of the little egret, and Mr. G. Busby's autochrome landscape, well deserve the medals that have been awarded them. Among the numerous other exhibits we may perhaps direct special attention to the radiographs of Dr. Hall-Edwards, which show the effect of bismuth salts and iodoform in indicating details with great clearness, Dr. Thurstan Holland's "plastic" radiographs, Dr. T. W. Butcher's high-power photomicrographs, and Dr. Rodman's stereo-photomicrographs of the scales on the wings of moths and butterflies and the hairs on the leaves of plants, though it seems almost invidious to do so where so much good work is shown illustrating many different branches of work.

Parts ii. and iii. of the Subject List of Works on Mineral Industries in the Library of the Patent Office have just been published at the office, 25 Southampton Buildings, Chancery Lane, W.C., price sixpence each. Part ii. contains classified titles of works on iron manufacture, alloys, and metallography, and part iii. those relating to metallurgy (non-ferrous and general), assaying, and fuel combustion. The lists, like others in the same series, are most helpful guides to the contents of a very valuable library.

OUR ASTRONOMICAL COLUMN.

The Spectrum of Brooks's Comet, 1911c.—Some excellent spectrograms of comet 1911c are reproduced and their special features discussed by MM. de la Baume Pluvinel and Baldet in the September number of *L'Astronomie*. The spectrographs employed were mounted at the Juvisy Observatory, and an examination of the complete series of plates shows very markedly the spectral changes which took place as the comet approached the sun; between August and the end of October a number of "unknown" radiations between λ 4100 and λ 4000 suffered a considerable diminution of intensity as compared with other radiations. The wave-lengths of these lines, considered precise to 1 Å, are 4099, 4074, 4065, 4051, 4041, 4032, and 4016. These radiations were peculiar to the nucleus of the comet, being found neither in the coma nor the tail, and as they became fainter the tail radiations became strong; it was also noted that in the later spectra the tail radiations extended well to the front of the comet's head, showing that in active comets, such as this one and Morehouse's, the tail matter is expelled in all directions. In Kiess's comet it appeared to escape from one point only. Altogether 47 monochromatic images of the nucleus were counted on the Juvisy plates, but the kathode spectrum of nitrogen was not recognised among them.

The Corona at the Total Solar Eclipse of April 17.—A drawing of the corona, made by Señor J. Comas Solá, at Barco de Valdeorras (Galicia), on April 17, appears in No. 4597 of the *Astronomische Nachrichten*. Although observers at other stations were uncertain as to the definite apparition of the corona, Señor Comas Solá saw it well extended, and on his drawing depicts it extending equatorially to about $2\frac{1}{2}$ solar diameters on either side of the sun. The drawing, given principally to show the general form, represents a corona distinctly of the minimum type. The same observer also describes his spectrum observations, while many others give the results of observations of the contacts, &c.

The Diameter of Neptune.—An interesting paper by Dr. G. Abetti, discussing the various measures of Neptune made since 1846, appears in No. 8, vol. i. (second series), of the *Memorie della Società degli Spettroscopisti Italiani*. He shows that the measured diameter has, in general, tended to become less as the aperture and magnification employed have increased. Using only the results from apertures of more than 40 c.m. and magnifications greater than 620, the mean values being 76 c.m. and 794 respectively, the diameter at unit distance comes out as $69{\cdot}04''$ for the mean aperture, and $68{\cdot}98''$ for the mean power; other considerations show that the true value differs but little from $69''$. Using this value, he then calculates the true diameter as 5×10^4 km., the density (earth = 1) as 0·29 or (water = 1) 1·6, and the superficial gravity as 1·12, that at the earth's equator being taken as 1·0. As seen from the earth, the apparent diameter ranges between $2{\cdot}39''$ and $2{\cdot}20''$.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—The University has suffered a severe loss by the death of the Vice-Chancellor, Alderman Charles Gabriel Beale, at the early age of 69. Alderman Beale, who was a graduate of Trinity College, Cambridge, was one of the most prominent citizens of Birmingham, having been elected to the mayoral chair no fewer than four times. He was mainly instrumental in carrying to a successful conclusion the great scheme for supplying the city with water from the Welsh mountains. He was, from the outset, a most energetic supporter of the movement for establishing a University in Birmingham, and was largely responsible for the working-out of the scheme, for which his legal training and experience qualified him in an unusual degree. When the University became an accomplished fact in 1900, his services to the cause were fittingly recognised by his appointment as the first Vice-Chancellor. His ideas were on a large scale, and he believed in the importance of associating the University with buildings which by their imposing size and appearance should appeal to local patriotism and serve to keep before the inhabitants of a great industrial centre the claims of higher education. Within the University he was known to the undergraduates for his special interest in their social welfare.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 26.—M. A. Bassot in the chair.—Edouard **Heckel**: The cultural bud mutation of *Solanum tuberosum*. An account of experiments in the cultivation of wild potato plants from Chile, Bolivia, and Peru. The tubers produced from the cultivated plants were edible, and contained a greater amount of starch than the wild plants. The tubercles from Bolivia showed the characters of mutation; those from other sources appeared to be in course of mutation.—W. H. **Young**: The summability of a function of which the Fourier's series is given.—B. **Bianu** and L. **Wertenstein**: An ionising radiation, attributable to the radio-active recoil, emitted by polonium. It was found to be necessary to use a polonium film in these experiments not exceeding $10\mu\mu$ in thickness. The curves obtained with a silver disc covered with this thin polonium layer, in presence of a transversal magnetic field of 1100 units, were analogous with those obtained in the case of radium C, and show clearly the existence of an absorbable radiation.—J. **Bougault**: Benzylpyruvic acid. The acid was prepared by the action of alkaline solutions on phenyl-α-oxycrotonamide. The yields of benzylpyruvic acid were good. The condensation products of this acid with itself and with acetone were also studied.—H. **Vincent**: The active immunisation of man against typhoid fever. Details of five cases are given which show that inoculations of typhovaccin have a preventive power not only against subsequent absorption of typhoid cultures, but also against a recent infection anterior to the inoculation.—Charles **Nicolle**, L. **Blaizot**, and E. **Conseil**: The conditions of transmission of recurrent fever by the flea. The evidence is against the assumption of hereditary transmission in the flea. Details are given of studies in the necessary conditions for infection.—J. **Wolff**: The stimulating action of alkalies and of ammonia in particular on peroxydase.—P. **Chaussé**: The vitality of the tubercle bacillus tested by inoculation and by inhalation.

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2237, Vol. 90] THURSDAY, SEPTEMBER 12, 1912 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

THURSDAY, SEPTEMBER 12, 1912.

THERMODYNAMICS OF THE ATMOSPHERE.

Thermodynamik der Atmosphäre. By Dr. A. Wegener. Pp. viii+331. (Leipzig: J. A. Barth, 1911.) Price 11 marks.

THE progress of a science depends upon the intellectual calibre of the men who pursue it: that determines what shall be written for them as well as by them. It is therefore significant for meteorology that a text-book on the thermodynamics of the atmosphere should be added to a collection recently enriched by treatises on meteorological optics and on the foundations of dynamical meteorology. Special phases of the subject have been treated at some length by Helmholtz, Hertz, von Bezold, and others, but their papers are scattered among different scientific journals, rarely accessible in a single library. Dr. Wegener's treatise, which has been written with the object of giving a systematic account of the existing knowledge and methods, should therefore be generally welcomed.

In an introductory chapter the author deals with the constitution of the atmosphere, and discusses in interesting fashion the extreme heights at which ...us optical phenomena, aurora, meteors, and ...liacal light appear. He finds that in all cases the values lie roughly between 70 and 100 km., or in the layer in which the nitrogen atmosphere is changing to the hydrogen atmosphere. After an account of the thermodynamics of an ideal gas and its application to a consideration of the precise proportions in which different gases exist at different heights, he indulges in some speculation about the existence of a hypothetical gas, geocoronium, above the hydrogen atmosphere. Such speculation is out of place in a text-book, and the same criticism applies to the statement that the stratosphere extends from 11 to 70 km. There is no evidence as to the upper limit of the temperature conditions characteristic of the stratosphere.

In the third section the different phases of water vapour, the condensation on nuclei, and the formation of crystals are discussed thoroughly and comprehensively.

The fourth and fifth sections, which comprise rather more than two-thirds of the book, are undoubtedly the most valuable parts of the work. In them the author treats of the thermodynamics of adiabatic changes and of the physics of clouds respectively. The effect of the condensation of water vapour in diminishing the vertical temperature gradient for air rising adiabatically is important both in the general circulation and in local disturbances, and it is usually put forward as the explanation of the Föhn. The cooling of the air which rises on the windward side of the mountains is influenced by the condensation and precipitation of the water which it contains. This air descends on the lee side, where there is no moderating effect on the vertical temperature gradient, and is consequently hot and dry. Dr. Wegener deduces, from the fact that the average vertical gradient is less than that corresponding to the adiabatic gradient either for saturated or for dry air, that the rising of the air on the windward side actually exerts a moderating influence on the Föhn.

A very full account is given of "inversions," *i.e.* cases in which the temperature remains constant or increases with increasing altitude. Their connection with waves and wave-clouds is discussed at length, and the form of the surface between currents of different densities and velocities is made the subject of mathematical investigation. A chapter is devoted to the stratosphere. The different types of the temperature-height curve between the troposphere and stratosphere are illustrated by an excellent diagram derived by Schmauss from a consideration of the results obtained at Munich. In the discussion of the meteorological conditions in the stratosphere itself it is assumed that the relative humidity at the base of the stratosphere, the region of minimum temperature, is 50 per cent. As there is no process by which the nitrogen-oxygen atmosphere is "dried" except by the precipitation of water condensed by cooling, it is not easy to see how a relative humidity of 50 per cent. could be obtained at the place of minimum temperature, where diffusion and convection would both tend to produce saturation.

The discussion of clouds is excellent. It includes a note on the rate of fall of drops and its connection with the passage from cloud to rain. The photographs of the different forms of clouds, some of which were taken from balloons above the clouds, are well reproduced, and add considerably to the educational value of the descriptive matter and the theoretical discussion.

Dr. Wegener has performed a signal service in producing a good book on a branch of the subject which had not previously been dealt with systematically. The work as a whole loses by the deliberate exclusion of radiation, which is fundamentally and indissolubly connected with the application of thermodynamic considerations to the problems which confront the meteorologist every day. The author regards it, however, as a subject for separate treatment.

THE STORY OF "EIGHT DEER."

The Story of "Eight Deer" in Codex Colombino. By J. Cooper Clark. Pp. 33+plates A–J (coloured). (London: Taylor and Francis, 1912.) Price 21*s.* net.

AMONG the papers presented to the International Congress of Americanists during the session held in London at the end of last June was a pamphlet by Mr. J. Cooper Clark entitled "The Story of 'Eight Deer' in the Codex Colombino." This is an attempt to throw some light into the obscurity of the pre-Columbian American manuscripts.

Mr. Cooper Clark commenced his researches with a careful examination of the Codex Colombino, a picture-writing painted on prepared deerskin, folded like a screen, and measuring 6·80 metres in length when spread open, now preserved in the National Museum in the City of Mexico. In this manuscript Mr. Cooper Clark traced the history of a warrior chieftain named "Eight Deer." All the personages identified by Mr. Cooper Clark in this codex are named after days of the month, and the name "Eight Deer" is expressed by a deer's head with the numeral eight (that is, by eight round discs) attached to it, a deer's head (Maçatl) being one of the twenty day signs of the Nahua month, and according to the Nahua method of noting time, this date would occur only once in a cycle of fifty-two years. It is not, however, explained why this particular day was chosen as the name of the warrior, although it is stated that it was not the day of his birth.

The life-history of Eight Deer is most ingeniously traced through the pages of the codex, but the most interesting fact established by Mr. Cooper Clark is that the history of the same individual is also told in five of the other extant pre-Columbian codices, namely, the Zouche (British Museum), the Vienna, the Bodleian, the Baker, and the Selden. By a careful comparison of these codices, Mr. Cooper Clark has not only been able to show that in part they tell the same story, but to supply incidents in the history of Eight Deer which are missing from the Codex Colombino owing to the destruction of a part of the manuscript.

Mr. Cooper Clark has further come to the conclusion that Eight Deer can be identified as the glyph attached to the figure of a warrior carved on one of the stone slabs from Monte Alban in Oaxaca (in the Zapotec country), now exhibited in the National Museum of Mexico, and from this he argues that the codices dealing with the story of Eight Deer must be of Zapotec and not Aztec origin, adding, "Not many Nahua codices are likely to have survived the destruction by Archbishop Zumárraga of the temple libaries of Tenochtitlan, Texcoco, and the other cities around the lakes, whereas, warned by the example of Mexico, the Zapotecs would have had ample time to secrete their records."

There is no difficulty in fixing the dates mentioned in the Codex Colombino within the fifty-two year cycle; the difficulty arises in determining in which cycle of fifty-two years the dates occur. If the events depicted are placed in the next cycle before the arrival of the Spaniards, the birth of Eight Deer would have taken place in the year 1491 A.D.; but Mr. Cooper Clark thinks that it more probably took place in the previous cycle, when the date would correspond to 1439 A.D.

The pamphlet is illustrated with plates most carefully drawn and coloured from the original manuscripts, showing how the same events in the life of Eight Deer are depicted in the Colombino, Zouche, Bodleian, and Becker codices.

Mr. Cooper Clark is to be heartily congratulated on his most painstaking achievement. The pamphlet was written for the few who are interested in ancient American civilisations, and can only be fully appreciated by those who have access to copies of the codices discussed; but even to the general reader it must be of interest as showing a native American method of recording historical events, and, moreover, as demonstrating how, by careful and intelligent examination and comparison, order and meaning may be evolved from the most obscure and unpromising material.

SUBMERGED RIVER-VALLEYS.

Monograph on the Sub-Oceanic Physiography of the North Atlantic Ocean. By Prof. Edward Hull, F.R.S. With a Chapter on the Sub-Oceanic Physical Features off the Coast of North America and the West Indian Islands, by Prof. J. W. W. Spencer. Pp. viii+41+xi plates. (London: E. Stanford, 1912.) Price 21*s.* net.

THIS is a folio publication with eleven excellent maps and nine short chapters of explanatory text, and an additional chapter by Prof. J. W. Winthrop Spencer. The author has based the work on a detailed study of the Admiralty charts showing the soundings over the continental shelf and the upper part of the continental slope off the western coasts of Europe and Africa, and this leads up to a statement of his views as to the cause of the Glacial Period.

It is pointed out that there are two principal schools of geographical evolution, the one believing that the ocean basins and the position of the chief continental areas retain traces of their primeval structure and have undergone only slight modification, the other, to which the author belongs, believing that land and sea have changed places at various geological periods. The latter view, he considers, is upheld by a consideration of the distribution of geological formations on both sides of the North Atlantic.

A detailed description is then given of the submerged river-valleys occurring off western Europe and Africa and in the Mediterranean as traced from the soundings shown on the charts. These were formed not only by rivers, the greater part of the course of which is visible on land, such as the Loire and the Congo, but also by rivers which rose on land now completely submerged, such as the "Irish Channel River" and the "English Channel River." They all indicate a former great uplift of land. The Norwegian fjords also are regarded as river-valleys of great geological age.

Professor Spencer shows that the continental shelf off the east coast of America is likewise cut up by submarine river-valleys and that there was a land connection between the West Indies and the American continent, and he upholds the view that great changes of level, amounting in some cases to thousands of feet, have taken place in recent geological times.

In the final chapter Prof. Hull gives his explanation of the cause of the Glacial Period. As shown from a study of the submerged river-valleys, a general elevation of the earth's crust took place all round the North Atlantic, the date of which is concluded to be about the close of the Tertiary Period. This brought about a much colder climate and at the same time a great change in the direction and temperature of the Gulf Stream. When the Antilles were directly connected with the American continent this current could not enter the Caribbean Sea, where at present it gains about 13° Fahrenheit of temperature; hence arose an additional cause for decreased temperature along all the coasts of the North Atlantic. The combined effect of these two factors, viz., the increased elevation of land on both sides of the Atlantic and the decrease of temperature in the Gulf Stream, would be sufficient, the author considers, to call into existence a rigorous glacial climate over the northern parts of America and Europe, which in its turn would affect a great part of the rest of Europe and western Asia, and more or less the entire northern hemisphere. Thus Dr. Hull shows that he belongs to those who regard purely terrestrial factors as the cause of the Glacial Period, in contrast to those who explain it on an astronomical basis. The book is useful to all who are interested in physical geography, whether they can agree with Dr. Hull's conclusions or not.

OUR BOOKSHELF.

The Elements of Statistical Method. By Willford I. King. Pp. xvii+250. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1912.) Price 6*s.* 6*d.* net.

IN this volume Mr. King has endeavoured "to furnish a simple text in statistical method for the benefit of those students, economists, administrative officials, writers, or other members of the educated public who desire a general knowledge of the more elementary processes involved in the scientific study, analysis, and use of large masses of statistical data." After a brief historical introduction, he outlines the uses and sources of statistical data, and then gives a few short chapters on "the gathering of material"; the third part, forming the bulk of the book, deals with "analysis," *i.e.*, tabulation, averages, dispersion, correlation, and so forth.

The writing of a satisfactory elementary work on such a subject—a work that can be placed in the hands of the junior student with confidence that he will not have to unlearn at a later stage some of the notions that he has gathered—is an exceedingly difficult feat, much more difficult in many respects than the writing of a work for more advanced students, and we cannot say that, in our opinion, Mr. King has altogether succeeded. The style is simple enough, but some matters are very insufficiently explained—probable errors, for example—and in other cases, notably in the chapters dealing with correlation, extensive revision and correction are required. A coefficient "of concurrent deviations" suggested on p. 208 does not fulfil the fundamental condition of becoming equal to zero if the deviations are independent. The student, in dealing with correlation, is repeatedly told to divide deviations by the mean, and the graph of regression obtained when the deviations have been divided by their respective means is termed the "Galton graph." What Sir Francis Galton did was to divide deviations by their respective quartile deviations—not their means—and he obtained the correlation coefficient graphically in that way. The relation of regression to correlation is never clearly exhibited, and Mr. King's use of the term is not in accordance with general usage. As it at present stands, the book cannot be recommended as a completely trustworthy guide.

Anthropologie Anatomique. Crâne—Face—Tête sur le Vivant. By Dr. Georges Paul-Boncour. Pp. xix+396. (Paris: Octave Doin et Fils, 1912.) Price 5 francs. (Encyclopédie Scientifique.)

THE enterprising publishers of the "Encyclopédie Scientifique" have arranged for the issue of a series of forty-eight volumes dealing with anthropology, the editorship of the series being assigned to Prof. Papillault, of l' cole d'Anthropologie, Paris. This volume, by Dr. Georges Paul-Boncour, forms the first of the series, and if its successors maintain an equally high standard, the "Bibliothèque d'Anthropologie" is destined to become a standard work.

Dr. Paul-Boncour's task is limited to a systematic study of the cranium, the facial part of the cranium, and the head of the living; his volume gives an accurate reflection of the methods and conclusions of the French school of anthropologists. The nature of his book is best indicated by a bare recitation of the subject-matter of its chapters.

The volume commences with a discussion on the growth and evolution of the skull, and then passes on to a description of its various parts. The succeeding chapters are devoted to the formation of the cranial cavity, to the methods of measurement and estimation of indices and of angles. The mandible and brain cavity are the subject-matter of special chapters. The second part—the more valuable—is devoted to the methods employed in registering the racial and individual characters as seen in living people—the form of the head, the development of muscles, the colour of the skin, the shape of the eyes, contour of the nose, form of ear, mouth, hair, and chin.

Dr. Paul-Boncour's volume is a simple, explicit, and methodical presentment of methods and opinions which have been perfected by the three generations of men who have made Paris the Mecca of anthropologists.

Science of the Sea. Edited by Dr. G. Herbert Fowler. Pp. xviii+452. (London: John Murray, 1912.) Price 6*s*. net.

THERE is a large though scattered body of people interested in oceanography or fascinated by marine biology, but prevented from making any advance by the want of practical direction and assistance: not only explorers and yachtsmen, but officers in the Navy with time on their hands in port or in foreign stations, medical officers on board ship or on coastal stations, and gentlemen who have retired from active service. To all such who wish to learn the methods of oceanographic inquiry, this book will be gladly welcomed, for it brings together instructions that otherwise are hard to find, given with the greatest care, and tested by the practical experience of many lives. The handbook is, in fact, the collective wisdom of the most active members of the Challenger Society, a body that has met quarterly in an unobtrusive fashion in London for some years, and now expresses its interest in oceanographic research by this publication.

The book begins with a chapter on meteorology by Dr. Mill and Capt. Wilson Barker, whose names, like those of the succeeding contributors, are guarantees of soundness and fulness of knowledge, and then proceeds to a well-illustrated account of hydrography, the joint work of Prof. H. N. Dickson and Mr. D. J. Matthews, of Plymouth. A very interesting and practically helpful account of tropical shore-collecting and outfit is given by Prof. Stanley Gardiner, whose methods, with a little adaptation, are applicable to similar work in temperate seas. Then follow four chapters on marine biology, including one by Sir John Murray on oceanic deposits and the organisms of the sea-floor. Fishing, whaling, and sealing are referred to in a rather summary fashion. Finally, the editor gives valuable counsel on methods of note-taking, whilst yacht-equipment, dredging, trawling, and the preservation of specimens are dealt with in a most helpful manner by the Director of the Marine Biological Association and others.

We congratulate the editor, Dr. Fowler, on the manner in which he has correlated and brought together such a valuable elementary compendium, and we can recommend this handbook as a trustworthy and practical guide to travellers, and not less a book of great interest to all biologists.

F. W. G.

LETTERS TO THE EDITOR.

Practical Mathematics.

I WAS particularly sorry to be absent from the meetings of the International Mathematical Congress at Cambridge, because an address was expected from me upon the teaching of practical mathematics, and because Sir Wm. White, in his address on the relation of mathematics to engineering practice, referred to practical mathematics in a most contemptuous way.

Twenty years ago mathematics continued to be taught in what may be called the orthodox way, a way that succeeded fairly well with students who were fond of abstract reasoning, 3 per cent. of all students, and quite failed with the other 97 per cent. At the British Association discussion of 1901 (verbatim report published by Messrs. Macmillan), most of the great mathematicians and teachers of mathematics spoke or sent remarks in writing. In opening that discussion, I published my proposed Science and Art Department syllabus on practical mathematics. There was essential agreement with my views; there was scarcely one dissentient remark. A committee was formed, and recommended methods of teaching which are now extensively adopted. It is perhaps a pity that I gave such a misleading name as practical mathematics to the reformed methods, but I wanted to differentiate them from the orthodox methods of twenty years ago, and I did not dream that the new methods would be adopted so quickly. They are in use now in all the public schools where natural science is taught; they are in use in all science colleges and in all engineering colleges.

In evening schools it used to be that when a class of thirty apprentices was started in elementary mathematics, the attendance dwindled to ten in November, and in May it was usual to find only one or two faithful students. Now, in such schools, there is almost no teaching of the kind we used to call orthodox, but some hundred thousand apprentices study practical mathematics. The class of thirty formed in September remains in good attendance all the winter, and remains an excited and interested class of thirty in May. The new method suits the boy of great mathematical promise, but it is really arranged to give the average boy a love for computation and the power to use mathematical reasoning with pleasure and certainty. It recognises that every boy, every man, already possesses the fundamental notion of the infinitesimal calculus, and that it is quite easy to develop this notion so that he can use the methods of the calculus in his reasoning and computation. The subject was first recognised by the Science and Art Department in 1899; the number of students has increased year by year by the compound interest law, and it is now the most important science subject of the Board of Education.

When I was appointed professor of mathematics and mechanics, seventeen years ago, at the Royal College of Science, it was known that I would adopt that experimental method of teaching mechanics and applied mechanics and engineering science with which my name had become identified at the Finsbury College of the City Guilds. It is the method now in use in nearly all polytechnics and engineering colleges. It went hand in hand with the practical mathematics which it was also understood that I should establish at Kensington. My books describing these methods have been translated into many languages, and the methods have been largely adopted in America, Germany, and other foreign countries. Much of my time has been spent in showing foreign visitors how my methods of teaching were carried out in practice.

I feel sure that few of the men listening to Sir Wm. White, even of the foreigners, were ignorant of these facts. It is known that the most elementary class at the college, attendance at which is compulsory on all students of the Royal School of Mines and the chemical and other students, was taught on the lines laid down for all evening classes in practical mathematics, the work being made interesting for the average student, and including the elementary methods of the calculus. Not only here, but in the very highest mathematical work of the college, a competent person will see that the study is exceedingly different from what used to be the study of the mere mathematician on the same subjects. All our syllabuses and methods of teaching have been highly praised by most eminent judges, like the late Lord Kelvin, and they are now in no way different from what they were seventeen years ago.

According to the report in *The Times*, Sir Wm. White said that in the teaching of engineering students, some authorities now favoured special courses in practical mathematics; others believed that engineers should be taught by professional mathematicians because this method must lead to broader views and greater capacity for original investigation. His experience led him to rank himself with the supporters of the latter, and he said that this view is now adopted at the Imperial College of Science and Technology.

I know that Sir William contemplates great changes at the Imperial College, and no doubt great changes will rapidly take place, as I have been asked to retire, and Prof. Henrici has already retired. An attempt will, no doubt, be made to give up those methods to which I gave the misleading name practical mathematics, and in all probability the places of Prof. Henrici and myself will be taken by more orthodox persons. It is also probable that a "professional mathematician" will be put in charge of the teaching of mechanics. As I am still on the staff of the college I do not think that I can criticise the actions of the governing body. It is, however, my duty to deny a hurtful statement about my own department, and to oppose what I consider to be a wrong opinion, expressed at a public meeting by one of the forty members of the governing body.

I wish to observe that no change has yet been made. The syllabus and methods of teaching are exactly as they have been for seventeen years, and when Sir William says that his view is now adopted at the Imperial College he really means that he himself has adopted this view.

This is a most important matter. Sir William White's remarks may influence the action of the governing bodies of the other engineering colleges of the country. In England, if a man is a great lawyer it is assumed that his views about Tibet must be right; if he is a great chemist it is held that his views about women's suffrage must not be disputed; and if he is a great designer of ships it is assumed that he is an authority on technical education.

It used to be that colleges were governed by a council of the professors, but now the opinions of the professors are of no account, and the staff dare not even suggest to the governors that it is possible for honest, sensible, diligent, self-sacrificing shopkeepers, merchants, and manufacturers to be so misled that they may ruin technical education for the next ten years. Such ruin will only be temporary, it is true, but when I think of our competition with the foreigner I look with great dismay on the possibility that Sir William White's opinions may have too much weight with the persons who have charge of technical education.

The old engineering college did not compel its students to have more than the most elementary mathematical knowledge, because only civil engineering was taught, and the average civil engineer needs no mathematics. When mechanical engineering and shipbuilding students began to be taught, the mathematics standard was only slightly raised. But modern high-speed machinery has made it necessary for mechanical engineers to understand the effects of vibration, critical speeds of shafts, &c., and to pursue numerous studies which require a knowledge of higher mathematics even in the average student. And nowadays we have the electrical engineer requiring a knowledge of the methods of very advanced mathematics. Sir Wm. White thinks of the requirements of the civil engineer or shipbuilder of his youth; we teachers have to think of the requirements of the student of to-day. Now I affirm that the average student cannot be taught this necessary advanced work unless by the reformed methods. He cannot be carried beyond the most elementary things, and these he does not understand.

I have now expressed my opinion in regard to Sir William's remark about practical mathematics. In weighing our opinions it must be remembered that Sir William's practical experience as an engineer has been in naval architecture only, and as a teacher it lay also in naval architecture only, and a considerable time ago.

Sir William says that all the mathematical teaching of engineers should be by what he calls professional mathematicians, and he evidently means by this that these teachers shall not be engineers or men acquainted with engineering science. He means that they shall be mere mathematicians. Well, this has been tried often enough, and it has always been found that the one or two good students take a distaste to practical engineering, and the average student is never brought beyond the driest elementary work, and he hates the appearance of a mathematical symbol all his life after. The average student cannot understand abstract reasoning; his teacher has no knowledge of him, and pursues his serenely ignorant way, wondering how it is that so many students are stupid, or else he wonders that he and a few other men should be so supremely clever. He never studies his pupil. There are men who can train almost any animal; they study its habits of thought; they are kind and sympathetic. The poor average English boy is never studied by the professional mathematician.

Polymorphism in a Group of Mimetic Butterflies of the Ethiopian Nymphaline Genus Pseudacræa.

A LITTLE more than two years ago Dr. Karl Jordan informed me that he had been studying the male genital armature of the Pseudacræas, and that he could not find any difference between the "species" of a large group made up of Linné's *eurytus* and its numerous allies on the west coast, of Neave's *hobleyi, terra,* and *obscura* in Uganda, of Trimen's *rogersi* of the Mombasa district and his *imitator* of Natal. All these forms possess patterns mimetic of species of the Acræine genus Planema. The conclusion was a very startling one. If each mimetic Pseudacræa had been confined to a single area and had interbred on its margin with the Pseudacrææ of surrounding areas with different mimetic patterns, we should have been confronted with a more remarkable and complex example than any as yet known (except perhaps *Papilio dardanus*), but one that raised no special difficulty. Dr. Jordan's discovery, however, involved far more than this: it led to the remarkable conclusion that the sexually dimorphic *P. hobleyi,* mimicking the sexually dimorphic *Planema macarista* in the Entebbe district, was the same species as the two monomorphic Pseudacræas flying in the same forests with it, viz. *P. terra* and *P. obscura*, mimicking respectively the sexually monomorphic *Planema tellus* and *P. paragea.*

Dr. Jordan communicated his discovery to the First International Entomological Congress, meeting at Brussels in 1910, and at the same meeting I brought forward the results of researches in 1909 by Mr. C. A. Wiggins, D.P.M.O. of the Uganda Protectorate, upon the Pseudacræas and other mimetic butterflies of the forests near Entebbe. The preparation of this latter paper afforded the opportunity of testing Dr. Jordan's conclusions by the careful study of a splendid mass of material.

Out of the long series of Pseudacræas, two specimens yielded strong support: (1) a male *P. terra* with a pattern approaching the male of *P. hobleyi*; (2) a female *P. hobleyi* bearing the mimetic colours of its own male. Nevertheless, I felt, and stated in the paper published in the Proceedings of the Congress, that conclusions so far-reaching ought not to be finally accepted until they had been tested by breeding.

Mr. Wiggins has continued his fruitful study of mimicry in the forest butterflies of Uganda from the point reached in the Brussels paper up to the present time.

There was, however, a break in 1911, when he came home and worked with me upon his material in the Oxford museum, preparing a tabular statement for the Second International Congress which has just met at Oxford. The results which have been gained from his enthusiasm and energy will throw far more light on the proportions of mimics and models at different seasons and in different years than has been shed by any other naturalist in any part of the world. A few more intermediate Pseudacræas, and one or two more male-coloured females of *P. hobleyi,* appeared in the wonderful series obtained by him, but the collection as a whole shows that in the forests within a few miles of Entebbe two out of these three mimetic Pseudacræas, viz. *hobleyi* and *terra,* are wonderfully constant and sharply marked off, and that the sexual dimorphism of one of them is nearly always pronounced. In the Entebbe district the third form, *P. obscura,* is so much rarer than the others that it is at present impossible to speak with any certainty of its constancy.

While Mr. Wiggins was continuing his researches on the mainland, Dr. G. D. H. Carpenter, a member of the Royal Society's Sleeping Sickness Commission, began to study Pseudacræas in the intervals of his work on the tsetse-flies of the islands in the north-west of the Victoria Nyanza. During a large part of 1911 Dr. Carpenter was on Damba Island, on the Equator, about twenty miles south-east of Entebbe. Early in the present year he moved to Bugalla, one of the Sesse islands, to the south-west of Damba. In both these islands he found the Planema models rare as compared with their mimics. The Planemas are apparently more exclusively forest butterflies than the Pseudacræas, and the forested areas on the islands may not be extensive enough for them to establish themselves freely. Furthermore, the proportions of the three forms of Pseudacræas are very different.

On the adjacent mainland *hobleyi* is by far the commonest form, and *obscura* much the rarest. Although on the islands the exact proportions have not been ascertained, it is clear that *terra* is by far the commonest, and *obscura* quite abundant. Male-coloured females of *hobleyi* are rare, although apparently less rare than in the Entebbe district; but the chief interest of the island Pseudacræas lies in the extraordinary number of transitional forms—between *terra* and *obscura,* between *terra* and the female *hobleyi,* between *terra* and the male *hobleyi,* between *obscura* and the female *hobleyi.* Dr. Carpenter has also observed on Bugalla the male of *hobleyi* pursuing the female of *terra,* the male of *terra* the female of *hobleyi,* and the male of *obscura* the female of *terra.*

All these facts offer the most convincing support to Dr. Jordan's conclusions, as well as to an interpretation of mimicry based on natural selection. Where the models—which are different species sharply cut off from one another—are predominant the mimetic forms of an interbreeding community are also sharply cut off, and intermediates are rare; where the models —although all of them exist—are in a small minority, the forms of the mimetic community tend to run into one another. The results here summed up were communicated to the Entomological Society, and will be found in the Proceedings for 1911 (pp. xci.–xcv.) and 1912 (pp. xix.–xxiii., and later pages as yet unpublished).

Finally, my friends Mr. Guy A. K. Marshall, scientific secretary of the Entomological Research Committee of the Colonial Office, and Mr. S. A. Neave have given me the opportunity of studying the collections made in 1911–12 by the latter over a wide area in the Uganda Protectorate —from the Mount Elgon district far to the north-east of Entebbe, to Buddu in the south, and Ankole, Unyoro, and Toro, as far as Ruwenzori and the Semliki Valley, to the west. As yet only a few of the specimens have been "set," so that it has been impossible to study the patterns in detail, but one important conclusion has emerged, viz. that male-coloured females of *P. hobleyi* were relatively far commoner outside the Entebbe district than we know them to be within it. The most remarkable manifestation of this tendency was encountered (August 13, 1911) on the Siroko River (3600 ft.), near the western foot of Mount Elgon, when Mr. Neave collected ten males of *P. hobleyi,* eight male-coloured females, and four normal females. This change in the proportion of the females corresponds with a change in that of the models, *Planema poggei,* with both sexes resembling the male of *P. macarista,* being commoner and *P. macarista* rarer outside than they are within the Entebbe district, so well investigated by Mr. C. A. Wiggins. Mr. Neave never saw the latter species near Mount Elgon, in Kavirondo, or indeed anywhere to the east of the Nile at Jinja.

We now come to the evidence furnished by breeding, which indeed is the object of the present letter. Ever since the Brussels Congress I have tried to induce

African naturalists to settle this question. In Natal Mr. G. F. Leigh, the late Mr. A. D. Millar, and Miss Fountaine have been successful in breeding the two Pseudacræas, *lucretia* and *imitator*, but the latter, which is the only Natal member of Dr. Jordan's group, appears in a single form mimetic of *Planema aganice*, and is therefore incapable of supplying the desired test. I attempted to induce both Miss Fountaine and Mr. Millar to travel to Entebbe in order to decide the question. My friend Mr. W. A. Lamborn, who has done such splendid work in breeding Lepidoptera in the Lagos district, has reared *P. lucretia* and also *P. semire*—the latter, I believe, for the first time—but has not yet been successful in finding the larvæ or in obtaining the eggs of any local form of *P. eurytus*.

Lately, however, I have felt confident that success would be achieved by Dr. Carpenter, with his wide experience of breeding and residence in an exceptionally favourable locality. He first succeeded in finding and rearing the larvæ of *P. lucretia*, and then made many attempts to obtain eggs from captured females of the *hobleyi* group. Discouraged by many failures, he was beginning to despair when, some weeks past, he observed in the Bugalla forest a female *obscura* "with a touch of *hobleyi*" settling in an unusual position on a leaf of the food-plant of *lucretia*—almost certainly a Sapotaceous plant. The butterfly escaped, but Dr. Carpenter found the egg on the leaf, and hoped to rear the perfect insect before or during the meeting of the Second International Congress at Oxford (August 5–10), and he promised that if the offspring turned out to be *terra* or *hobleyi*, he would cable the result. He wrote that he anticipated *terra*, because this form is much the commonest on Bugalla.

Unfortunately the eagerly-expected butterfly did not emerge until after the meeting, but on August 19 I received a cable from Entebbe with the word "terra." Furthermore, Dr. Carpenter has now succeeded in obtaining eggs laid by known parents upon enclosed branches of the food-plant in the forest, so that we shall not have to wait long for evidence that is tolerably certain to afford direct proof of Dr. Jordan's conclusions as regards all the forms of the *hobleyi* group on the island, and is likely to establish the genetic relationship between them.

Dr. Jordan, Mr. Wiggins, Mr. Neave, and Dr. Carpenter are all to be warmly congratulated on the parts they have played in solving a bionomic problem of extraordinary interest and complexity.

E. B. Poulton.

St. Helens, Isle of Wight, August 28.

Wireless Telegraphy and Terrestrial Magnetism.

The report in *The Times* of the discussion on wireless telegraphy at the British Association meeting in Dundee mentions the hypothesis—introduced apparently by Dr. Eccles—that several of the phenomena of the propagation of electric waves round the earth are largely influenced by the existence of an ionised layer in the atmosphere. The hypothesis seems analogous to, if not identical with, one made by several magneticians independently, with the object of explaining phenomena exhibited by the diurnal variation of the magnetic elements. This diurnal variation is now generally regarded as most probably due to electric currents in the upper atmosphere, and it has been suggested that the fact that the magnetic changes are normally larger by day than by night is due to an increased ionisation of the atmosphere due to sunshine.

The regular diurnal magnetic variations are much larger in years of many than of few sun-spots. The difference between the size of the day and night movements is relatively reduced in years of sun-spot maximum, and in all years during large magnetic storms. Again, the diurnal variation is much larger in high latitudes—where aurora abounds—than elsewhere, and the difference between day and night phenomena is there much reduced. Finally, it has been recently found that a substantial part of the magnetic sun-spot relationship may be explained by a direct connection between the amplitude of the diurnal magnetic range and the spotted area of the sun some four days previously. These phenomena, or at least some of them, have been ascribed to corresponding changes in the ionisation of the upper atmosphere.

The natural inference, in short, is that the ionisation is much enhanced in years of sun-spot maximum and during magnetic storms, and is substantially influenced by the sun-spot area four days previously. Also one would infer that in high latitudes the upper atmosphere is normally much more highly ionised than elsewhere. If wireless telegraphy is largely dependent on an ionised layer, then unless this layer is distinct from that which influences terrestrial magnetism, we should expect wireless phenomena to show peculiarities corresponding to those just described in terrestrial magnetism. My object in writing this note is to direct the attention of those in control of wireless installations to the field of research which is thus suggested. Wireless telegraphy may yet lend itself to the direct experimental investigation of the causes of a variety of the phenomena of terrestrial magnetism.

On the Structure of the Stromatoporoid Skeleton, and on Eozoon.

I have pointed out (Annals. Mag. Nat. Hist., September, 1912) that Stromatoporoids are Foraminifera, but I did not give an explanation of the structure of the skeleton. I now find that the clue to this structure lies in the "astrorhizæ" or stellate patterns on the surface of many of these fossils.

Each astrorhiza consists of a spiral series of chambers formed round a central and a circumambient chamber, and the existence of a number of astrorhizæ is due to budding—as in corals. Anyone who has been bewildered—as I have been—at the apparent complexity of Stromatoporoid structure will at once appreciate—I cannot forbear saying—the beautiful simplicity of this solution of a difficult problem, and will realise that these organisms have at last come to rest in their proper place. I am publishing in the October number of the Annals a revised classification of the group.

Eozoon canadense likewise is a colony-forming Foraminiferan, the unit in this case being a coiled Nummulitid shell. Convincing evidence for this statement also will be given in the October number of the Annals Mag. Nat. Hist.

In view of a possible recrudescence of the Eozoon controversy, it is very fortunate that the evidence in favour of the theory of organic origin is now so overwhelming that the former opponents of that theory will readily change their views. R. Kirkpatrick.

British Museum (Nat. Hist.).

The Striation of Stones in Boulder Clay.

In Nature of September 5, Dr. A. Irving, in criticism of statements by Mr. Reid Moir, asks "how could the soft matrix of the Boulder Clay scratch a flint, or even hold a harder stone with sufficient grip to give it effect as a graving-tool?"

It is true that one may see flints emerging from arctic glaciers unscratched and unrounded, while softer rocks are reduced to strongly striated boulders; but Dr. Irving seems to conceive the Boulder Clay as something distinct from the ice-sheet in which it originated, and as merely pressed on by superincumbent ice. It cannot be too strongly urged that the lower portions of glaciers of the continental or ice-sheet type consist largely of stones and mud and abrading sand-grains, and that these materials are held in the grip of the ice and are moved against one another as it flows. The ice-sheet is, in fact, a conglomerate with an ice cement; the Boulder Clay is an essential part of it, and remains as its representative when the portion that can melt has yielded before climatic change. GRENVILLE A. J. COLE.

Royal College of Science, Dublin, September 6.

Boulder Clay in Essex.

YOUR correspondent Dr. Irving, in his letter entitled "Boulder Clay in Essex" (NATURE, August 22), states that he has made a keen but futile search for a human artefact in the Boulder Clay, and, I presume, infers that these relics do not occur therein.

I have had no opportunity of carefully examining the Boulder Clay of Essex, but for the last six years I have been able to search that of Suffolk, and know that the occurrence of humanly flaked flints in this latter deposit is capable of unassailable demonstration. As until the notification of a human skeleton having been found beneath the Boulder Clay no search had been made in the clay for worked flints, and as that notification was made only a few months ago, I think that perhaps further and more prolonged search in the Essex deposits will reveal some of the type of implements which are found in Suffolk.

But even if this is not so, it cannot be brought as an argument against man's presence here before the deposition of the Boulder Clay. It would be as foolish to argue that because palæolithic implements are not found in a certain section of river-gravel, they do not occur in any other portion of the same deposit.

J. REID MOIR.

12 St. Edmund's Road, Ipswich.

The "Titanic."

YOUR article (NATURE, August 29, 1912) on the report of the Advisory Committee having emphasised the contention from the first of some of us (students of science and old naval commanders) as to the insanity of high speed "at night in the known vicinity of ice," it behoves surely men of science to ask the question whether we have not reached the imperative limits of that false security which the "practical man" is wont to feel in his contempt for scientific "theory"; and, further, whether the time has not therefore come for legislation requiring commanders of the largest ocean-going steamers to hold a diploma, guaranteeing such a systematic course of study (say in a class at Greenwich or Kensington) in marine physiography and the elementary laws of mechanics as would quicken their imagination as to the uncertainty and the magnitude of the risks to be run in an abnormally ice-drifted sea. Lord Mersey's report may whitewash the facts, but the facts *en évidence* remain; and the chain of cause and effect in the lamentable and tragic loss of the *Titanic* leads us in the last resort to the notorious contempt for scientific acquaintance with the facts and laws of nature on the part of the "practical man." A. IRVING.

Hockerill, Bishop's Stortford, September 2.

STUDIES OF AURORA.[1]

ONE or two photographs of aurora seem to have been taken before, but Prof. Störmer is the first to meet with marked success. In the earlier of the volumes before us he describes with full detail the apparatus and methods employed in photographing aurora during a stay of some months at Bossekop, in the extreme north of Norway, early in 1910. Photographs were taken by Störmer and an assistant from the two ends of a base of about $4\frac{1}{4}$ kilometres, simultaneity of exposure being secured by telephonic signal. Using special plates, satisfactory photographs were obtained with a few seconds' exposure. One or more prominent stars were always included in the photograph, and the time was carefully noted. From the known coordinates of the stars, it was thus possible to fix the position of the aurora. The base was long enough in general to give a parallax which could be measured with sufficient accuracy to determine the approximate position and height of selected prominent points. The heights calculated for the different auroras varied from 36 to 461 kilometres. Fig. 1 shows a photograph—from the original

FIG. 1.—Reproduction of a photograph of an aurora: original size.

negative—taken with 3 seconds' exposure; Fig. 2 is an enlargement, the original of which had a 5 seconds' exposure.

The second of the two volumes referred to below repeats some of the information given in the first, but is mainly theoretical. Störmer was apparently first attracted to the subject of aurora and magnetic storms by the work of his well-known colleague at Christiania, Prof. Kr. Birkeland, but the views he now holds are independent.

An electrified particle projected in a uniform magnetic field H describes with uniform velocity a helix about the lines of magnetic force. If projected perpendicular to the lines of force, it describes a circle of radius ρ. If m be the mass, e the charge, v the velocity of the particle, and V the velocity of light, then, according to Störmer, $H\rho=(m/e)v(1-v^2/V^2)^{-\frac{1}{2}}$. This differs from the usual formula in English books unless $(v/V)^2$ be

[1] "Bericht über eine Expedition nach Bossekop zwecks photographischer Aufnahmen und Höhenmessungen von Nordlichtern. By Carl Störmer. (Utgit for Fridtjof Nansens Fond.) Pp. 112+88 plates. (Kristiania: Jacob Dybwad, 1911.) Extract from Videnskap. Skrift. Mat. Natur. Klasse, 1911

"Sur les Trajectoires des Corpuscles électrisés dans l'espace sous l'action du Magnétisme Terrestre avec application aux Aurores boréales (second Mémoire). By Carl Störmer. Pp. 163+10 plates. Extrait des Archives des Sciences physiques et naturelles, Geneva, 1912.

negligible, which is far from the case in some of the hypothetical cases dealt with by Störmer. $H\rho$ may for mathematical purposes be regarded as the characteristic constant for a definite species of ray.

In his earliest work, Störmer treated the earth as a uniformly magnetised sphere, of moment $8{\cdot}52 \times 10^{25}$ C.G.S. Assigning to $H\rho$ values ordinarily conceded to kathode rays and β-rays of radium, he found that no electrified particle coming from the sun could reach the earth's atmosphere except in the immediate vicinity of a magnetic pole. If, for instance, $H\rho$ is 1000, the greatest angular distance from the pole is only $3{\cdot}8°$, and to increase the angle to $22°$—which answers roughly to the position of maximum aurora—one must assign to $H\rho$ the enormous value 10^6. To account for the observed occurrence of aurora in low latitudes, Prof. Birkeland has had to assume no less a value than 7×10^6, which implies a very close approach in v to the velocity of light.

Prof. Störmer sets out in quest of another explanation. His first idea was to substitute for the field of a uniformly magnetised sphere that derived from the earth's Gaussian potential, based ultimately on the work of Carlheim Gyllensköld. The mathematical difficulties were thereby much increased, while the physical difficulties showed no abatement. Störmer's next idea was suggested apparently by experiments of Birkeland's, which showed that kathode rays in a vacuum tube containing a magnetised sphere can form a luminous ring in the magnetic equator. Störmer supposes a gigantic ring of kathode rays to form and persist for some time in the plane of the earth's magnetic equator, and the auxiliary magnetic field thus produced is believed to render access to low latitudes possible to other kathode rays coming from the sun.

In the absence of a ring, as already remarked, rays require $H\rho$ to equal 10^6 to permit of their getting as far as $22°$ from the magnetic pole, but this becomes possible to rays the $H\rho$ of which is only 1000, provided there is an equatorial ring of 140 times the earth's radius, carrying a current of about 60 million amperes. The rays forming the ring are supposed to be quite distinct. Their value of $H\rho$ increases from 100 when the ring's radius is 1400 times the earth's to 10^6 when the former radius is 14 times the latter. For a given size of ring, the distance from the magnetic pole which rays coming from the sun can attain increases with the current in the ring. In the case of the largest angular distance considered in detail, $41{\cdot}6°$, the rays forming the ring and those coming from the sun have both 10^6 for their value of $H\rho$, and the

FIG. 2.—Enlargement of a photograph of an aurora on February 28, 1910.

current required in the ring is 100 million amperes. The magnetic field due to this current at the earth's surface is given as 681γ, which represents a magnetic storm of the first order.

In considering how the question is affected by the presence of the earth's atmosphere, Störmer inclines to the views of Wegener (while not committing himself to the existence of a gas, "geocoronium," of one-fifth the density of hydrogen). At altitudes above 100 kilometres there is supposed to be no trace of anything but the lighter gases, especially hydrogen (and geocoronium, if it exists). In agreement with Lenard, Störmer concludes that ordinary kathode rays coming from space would be absorbed in the upper hydrogen atmosphere before reaching the 100 kilometres level, that β-rays of radium would be absorbed in the nitrogen atmosphere at heights of 50 to 70 kilometres—a common altitude for the lower border of auroral "curtains"—and that the rays forming the lowest aurora he has measured must have a greater penetration than β-rays. Fairly substantial evidence has been advanced by Paulsen and others that auroras in the auroral belt, especially in Greenland, sometimes come much below the lowest height, 36 kilometres, observed by Störmer at Bossekop. This tends to support Birkeland's latest views as to an enormously high velocity in the rays if they originate in the sun. On the other hand, there seems reason to accept Störmer's view that auroras seen in low latitudes are usually at considerably greater heights than those seen in the Arctic. Thus aurora in low latitudes would seem to arise from rays of less, not of higher, penetration than those in high latitudes, which seems inconsistent with Birkeland's hypothesis.

Störmer's mathematical work, like Birkeland's, assumes the motion of the individual corpuscle to be unaffected by the presence of other corpuscles. This is one of the principal criticisms urged by Prof. Schuster,[2] who concluded that the scattering inevitably produced is fatal to Birkeland's theory, so far at least as magnetic storms are concerned. The same criticism would seem to apply, with at least equal force, to Störmer's theory. It would thus be of great interest to have Prof. Störmer's views on the validity of Prof. Schuster's criticisms. Meantime, considering the calibre of the protagonists, the prudent course seems to be to "wait and see." But whatever the fate of Störmer's theoretical work may be, his photographs of aurora clearly constitute a fundamental advance towards exact knowledge. In temperate and southern Europe, aurora and large magnetic storms are both rare events, and their coincidence of occurrence seems the rule rather than the exception. A total absence of physical connection between the two phenomena seems thus almost inconceivable. The careful intercomparison of measurements of aurora—rendered possible by Störmer's work with contemporaneous records from magnetic observatories is clearly one of the most promising methods of getting at the root of the matter.

C. CHREE.

[2] Roy. Soc. Proc., A. 85, 1911, p. 44.

PROF. THOMAS WINTER.

PROF. THOMAS WINTER, of the University College of North Wales, Bangor, whose death we recorded in our last issue, was the son of Mr. Thomas Winter, of Lotherton Park, Aberford, Leeds. Born in 1866, he was educated at the Darlington Grammar School under Dr. Wood, and afterwards proceeded to the University of Edinburgh, where in 1888 he graduated in arts with honours in natural science. On leaving the University he became a master at a Scarborough school, and later at the Norfolk County School at Dereham. The son of a successful practical farmer, and equipped with a university training in natural science, he was naturally attracted to the development of schools of agriculture in the provincial colleges and universities which marked the later decades of the last century. In 1891 he was appointed assistant lecturer in agriculture at the University College of North Wales, Bangor. In 1892 he accepted a similar appointment at the Yorkshire College, Leeds, as it then was, but returned in 1894 to Bangor as head of the department of agriculture, a post which he occupied for the next eighteen years. It is thus in North Wales that his life-work chiefly lay, and where the stimulus which he gave to the cause of agricultural education will be longest felt.

The work of a school of agriculture has its internal and external sides. On the internal side courses of instruction have to be provided with a view to certificates, diplomas, and degrees. On the external side the agricultural community within the area served by the school has to be considered, and extension lectures, field experiments, and instruction in dairy-work have to be provided for the benefit of those who cannot reach the college. In both these aspects of the work of his chair, Prof. Winter achieved a rare success. Within the University of Wales his sound judgment contributed to the framing of the existing scheme of instruction for the degree in agriculture and rural economy, the marked feature of which is the requisition of an adequate acquaintance with the pure sciences, prior to the study of their applications to agriculture. It was also to Prof. Winter's fostering care that the chair of forestry was established at Bangor.

In the external work of the department his gift of organisation and his tact and good sense have greatly contributed to the removal of the distrust of agricultural education among old-fashioned farmers. Not the least contribution to this end was his successful management of a college farm, where experiments in cropping and breeding have been carried out, and where the visits of farmers and their sons and daughters have always been welcomed. Prof. Winter's death while still in the prime of life will be greatly deplored by his colleagues on the senates of his college and university, by his former pupils scattered in many parts of the world, and not least among the farmers of the North Welsh counties.

THE BRITISH ASSOCIATION AT DUNDEE.

IT is often pointed out that the meetings of the British Association can never be so important in the future in the estimation of the public as they were in the past. First, because there used to be only one yearly congress attracting general attention; now there are many, and any such meeting is a great expense to a town. Secondly, the most important function of the meeting, the temporary creation of an interest in natural science, is less wanted, because everybody now takes an interest in science, and almost every city now visited has a science college where evening lectures are given. Thirdly, the disappearance of the pioneers of the Huxley type, whose names were well known outside scientific circles. Fourthly, the death of that interest which used to be excited by the quarrel between science and religion.

The Dundee meeting shows that the British Association excites as much interest, not merely among scientific men, but in the general public, as it has ever done in the past. In the hotels here there is still hanging a notice of some weeks ago referring to the expectation that the membership of this meeting may reach 1200 in number. As I write, the number is more than 2460, a number greater than that of the members of the Dundee meeting of forty-five years ago, which is often referred to as a great meeting.

There has been a little grumbling that there were some hundreds of members who could not get seats for the president's address and some of the evening lectures. Naturally, the local secretaries are blamed, but they have the valid excuse that nobody could have expected the meeting to be so successful as to numbers, and they were probably afraid that the hall provided might actually be too large. Much of the success of a British Association meeting is due to the recognition by the local authorities that some one man of great energy and knowledge and tact and good humour must devote himself to its organisation for eighteen months beforehand. Large subscriptions of money are wanted; enthusiasm must be created and maintained in an army of hard-working members of committees. Nobody denies that it is to Prof. D'Arcy Thompson that the enormous success of this meeting is due. Everybody knows the grumbling which in some irritable members is sometimes very loud, when they meet with slight inconveniences. Whether it is that the arrangements are more perfect than usual or that members are in better temper, I do not know, but there is certainly less than the usual amount of complaint.

Almost everybody expected the weather to be bad. Except that we had rather windy weather for a day, and some occasional threats of rain which came to nothing, the weather has been very good. The hotel accommodation is not great for so important a town, but there is much private hospitality, and on the whole the physical comforts of the visitors are better looked after than a person acquainted with Dundee could have anticipated.

At every meeting of the British Association it is found by the visitors that most of the good reserved seats for the presidential address are booked by local people before the first day of the meeting. It is probable that the pressure of the local desire for seats is always too great for the resistance of the local secretaries. The consequent heartburning has been greater than usual this year, because the number of members so largely exceeds all expectation.

The success of a meeting depends greatly on the attention paid to certain details some of which might seem unimportant. First, the reception room should be large, and should have such ample accommodation of many kinds that members, when there, shall feel almost as if they were in a club. It ought to be in a central position, as near as possible to the most frequented section. It is essential that the meetings of the council and general committee and the committee of recommendations should be held in some neighbouring place, if not in the same building. Secondly, there are now twelve sections, and meeting rooms must be provided for each of them, each with its committee room, and sometimes one section may split up into two or three. These rooms must all be large and conveniently arranged, because changes cannot be made near the time of the meeting, and any of the sections may turn out to be exceedingly popular, and be unexpectedly well attended. Thirdly, although there are many members who wish to attend only one section, and the Recorders try to keep papers of one particular kind of interest to one section, on any one day, a member always finds that there are papers interesting to him in two or more sections, and he desires to hear them.

It is therefore important to have facilities for getting rapidly from one section to another. I am now speaking of the scientific members. But besides these, the non-scientific people must be thought about, the people who divide their attention over all the sections, and who desire to hear as many interesting papers as possible on quite diverse subjects. It is evident that the best of all cities for a British Association meeting is one which can house all the twelve sections and reception room in one great building or in a few large buildings which are close together. But as this is generally impossible, the best compromise is to place the sections near one another in groups of allied subjects. It is evident that great attention has been paid to this most important idea at Dundee, and, considering the accommodation of the town, it is impossible to suggest a change for the better.

The sections for mathematics and physics, chemistry and engineering, are in the University College buildings, not too easily reached from the reception room, a fifteen minutes' walk or by infrequent tram-car; with these we have zoology and physiology. The College buildings are well away from the other groups. One other such group is of geology, botany, and agriculture;

another is geography and anthropology; another is economics and education, and, except the College group, they are all quite near the reception room. No matter what arrangements had been made, there must have been inconvenience for some members. It is now difficult for a man whose chief interest is in physiology to hear a botany paper, or for a man interested in mathematics or physics or chemistry to hear an education paper, but I have heard much less complaint about such matters than I have ever heard before at a British Association meeting.

The presidential address is usually rather a disappointment to a general audience, many of whom cannot hear, and the subject is often of only special interest to some scientific people. On this occasion the voice of the president was low but penetrating, and I never remember an occasion since the time of Tyndall when one felt so strongly that there was subdued but intense feeling in the audience. When at length the Lord Provost sprung upon the meeting the hitherto carefully hidden fact that Dr. Caird had made us a gift of 10,000*l.*, there was a thrill through the audience which made itself immediately manifest. Satisfaction and delight were to be expected on the faces of the visitors, but it might have been expected that Dundee people would not altogether like to see so large a benefaction leaving their town. But, as a matter of fact, the pride already felt by the local people in the acknowledged success of the meeting was augmented in a wonderful manner, and there was only delighted satisfaction in their faces and congratulation in their language. The feeling of the more permanent members of the association is soberly expressed in the remarks of the treasurer when he proposed the vote of thanks to Dr. Caird at the meeting of the general committee.

As for the scientific work, I can only speak as one member attending sections A and G. The presidents' addresses and the reading of papers have so far been well attended by mathematicians, physicists, and engineers, as well as by the ordinary members. A joint discussion between these sections on unsolved problems in wireless telegraphy was so well maintained and so interesting that when Lord Rayleigh was speaking, one thought at once of the possible return of the older times when Kelvin or Fitzgerald suddenly illuminated our proceedings. From men attending the other sections I have heard so far only of successful sectional meetings. There is no doubt that much more than the average number of members capable of speech and interested in the scientific work of the Association are present at this meeting of the British Association.

JOHN PERRY.

At the meeting of the general committee on Friday, September 6, it was unanimously resolved "That the best thanks of the British Association be expressed to Dr. J. K. Caird for his most generous gift to the Association." Speaking to the motion, Prof. Perry, the general treasurer, said:—"This is the only gift of money that the British Association has ever received. It is greatly needed. In my eight years of office as treasurer the nominal assets of our Association have neither increased nor diminished. I have made the fat years of our visits to large cities make up for the lean years of our visits to smaller towns. But although our nominal wealth is the same, our actual wealth is less because of the depreciation of Consols and our other investments.

"There are two great functions of the British Association. One is to stir up all the people of this Empire occasionally to take an interest in scientific discovery and research of all kinds; the other is less known. It is perhaps the treasurer of the British Association who knows better than anybody else the enormous importance of the work that is done every year by the committees appointed by the various sections to make scientific researches during the ensuing year.

"Groups of men of the highest scientific attainments and reputation give their time and enthusiasm to the work, and they only ask that quite a small part of their out-of-pocket expenses shall be paid. I know of no work in the world that is so important or that is so little known.

"Every year your treasurer meets the Committee of Recommendations, each section strong in its reason for getting money, and yet the aggregate amount asked for is so much above our means. It really goes to my heart every year to limit the supply of money, and my colleagues here, the secretaries, blame me every year because I give more money than I ought. I particularly feel for the biological committees. I know nothing of biology, but I know of the enormous importance of the work done by the biological committees; and these biological people can get no outside money. If I want money for any important scientific object relating to physics or engineering, I know at once where to apply for a few hundreds or even many hundreds of pounds, and I get it readily, for men have become rich through engineering. But the biological people seem to have no outside pecuniary resources. I am, however, glad to think that this gift is not earmarked in any way. It is generous and unconditional.

"Gentlemen, your treasurer assures you that this splendid gift of Dr. Caird will return him more interest than all the other benefactions."

At the same meeting of the general committee, Sir William White, K.C.B., F.R.S., was elected President for the meeting of the Association to be held at Birmingham next year from September 10 to September 17. The following have been appointed Vice-Presidents of this meeting:—The Right Hon. the Lord Mayor of Birmingham, the Lord Lieutenant of Warwickshire (the Most Hon. the Marquess of Northampton), the High Sheriff of Warwickshire, the Lord Lieutenant of Worcestershire (the Right Hon. the Earl of Coventry), the Lord Lieutenant of Staffordshire (the Right Hon. the Earl of Dartmouth, V.D.), the Right Rev. the Lord Bishop of Birmingham, the Chancellor of the University of Birmingham (the Right Hon. J. Chamberlain, M.P.), the Vice-Chancellor of the University of Birmingham, the Principal of the University of Birmingham (Sir Oliver Lodge, F.R.S.), the Hon. President of the Birmingham Chamber of Commerce (the Right Hon. Jesse Collings, M.P.), Alderman the Right Hon. William Henrick, J.P., the Deputy Lord Mayor of Birmingham, Prof. J. H. Poynting, F.R.S., Prof. C. Lapworth, F.R.S.

Local officers:—Treasurers, Alderman Sir G. H. Kenrick and Councillor Neville Chamberlain, J.P.; secretaries, Prof. F. W. Gamble, Mr. Howard Heaton, Mr. John Humphreys, and Mr. W. Byng Kenrick.

SECTION B.

CHEMISTRY.

Opening Address by Prof. A. Senier, Ph.D., M.D., D.Sc., President of the Section.

I am sure it will be agreeable to the feelings of the members of this section that, before beginning my address, I should refer to the great losses we have sustained by death since our gathering last year at Portsmouth.

An active member and past-president has passed away in the death of Edward Divers, after a serious operation, undergone at his advanced age with characteristic fortitude. His devotion of his long life, in this country and Japan, to the advancement and diffusion of science is indelibly inscribed in its records. But Divers was more than an investigator and teacher; he was a beloved centre of our social life, and was particularly happy when he could bridge over the distance between the young beginner in research and the older experienced master. He understood and had the sympathy of both.

In Henry Forbes Julian, one of the victims of the awful disaster to the *Titanic,* we have lost a valued contributor to our proceedings; though he was best known as a geologist and metallurgical engineer. It was, however, by chemistry, under the inspiring influence of Sir Henry Roscoe, that his first enthusiasm for science was aroused. Forbes Julian was a leading technical adviser in mining undertakings, and his advice was much sought after, especially in South Africa, and even in Germany.

Another tragedy, from the shock of which we have not yet recovered, has deprived science of the young and promising inquirer, Humphrey Owen Jones. We know the dreadful details—he and his young wife—how they became sacrifices to the treacherous crags and snows of Mont Blanc.

And this, alas, is not all. On the very day of the fatal accident to Humphrey Jones, another young and promising chemist—John Wade—passed from us from the effects of a cycling accident. He was an inquirer of singular ability, and found time also to give us one of our deservedly most popular manuals of organic chemistry.

Part I.

The Nature and Method of Chemistry.

Perhaps there is no intellectual occupation which demands more of the faculty of imagination than the pursuit of chemistry, and perhaps also there is none which responds more generously to the yearnings of the inquirer. It is surely no commonplace occurrence that in experimental laboratories day by day the mysterious recesses of Nature are disclosed and facts previously quite unknown are brought to light. The late Sir Michael Foster, in his presidential address at the Dover meeting, said:—"Nature is ever making signs to us, she is ever whispering the beginnings of her secrets." The facts disclosed may have general importance, and necessitate at once changes in the general body of theory; and happily, also, they may at once find useful application in the hands of the technologist. Recent examples are the discoveries in radio-activity, which have found an important place as an aid to medical and surgical diagnosis and as a method of treatment, and have also led to the necessity of our revising one of the fundamental doctrines of the theory of chemistry—the indivisibility of atoms. But the facts disclosed may not be general or even seem important; they may appear isolated and to have no appreciable bearing on theory or practice—our journals are crowded with such—but he would be a bold man who would venture to predict that the future will not find use for them in both respects. To be the recipient of the confidences of Nature; to realise in all their virgin freshness new facts recognised as positive additions to knowledge, is certainly a great and wonderful privilege, one capable of inspiring enthusiasm as few other things can.

While the method of discovery in chemistry may be described, generally, as inductive, still all the modes of inference which have come down to us from Aristotle, analogical, inductive and deductive, are freely made use of. A hypothesis is framed which is then tested, directly or indirectly, by observation and experiment. All the skill, all the resource the inquirer can command, is brought into his service; his work must be accurate; and with unqualified devotion to truth he abides by the result, and the hypothesis is established, and becomes part of the theory of science, or is rejected or modified. In framing or modifying hypotheses imagination is indispensable. It may be that the power of imagination is necessarily limited by what is previously in experience—that imagination cannot transcend experience; but it does not follow, therefore, that it cannot construct hypotheses capable of leading research. I take it that what imagination actually does is—it rearranges experience and puts it into new relations, and with each successive discovery it gains in material for this process. In this respect the framing of a hypothesis is like experimenting, wherein the operator brings matter and energy already existing in Nature into new relations, new circumstances, with the object of getting new results. The stronger the imaginative power, the greater must be the chance of success. *The Times*, in a recent leading article on Science and Imagination, says:—"It has often been said that the great scientific discoverers . . . see a new truth before they prove it, and the process of proof is only a demonstration of the truth to others and a confirmation of it to their own reason." While never forgetting the essentially tentative nature of a hypothesis, still, until it has been tested and found wanting, there should be some confidence or faith in its truthfulness; for nothing but a belief in its eventual success can serve to sustain an inquirer's ardour when, as so often happens, he is met by difficulties well-nigh insuperable. In a well-known passage Faraday says:—"The world little knows how many of the thoughts and theories which have passed through the mind of a scientific investigator have been crushed in silence and secrecy by his own severe criticism and adverse examination; that in the most successful instances not a tenth of the suggestions, the hopes, the wishes, the preliminary conclusions have been realised."

But a hypothesis to be useful, to be admitted as a candidate for rank as a scientific theory, must be capable of immediate, or at least of possible, verification. Many years ago, in the old Berlin laboratory in the Georgenstrasse, when our imaginations were wont, as sometimes happened, to soar too far above the working benches, our great leader used to say:—"I will listen readily to any suggested hypothesis, but on one condition—that you show me a method by which it can be tested." As a rule, I confess we had to return to the workaday world, to our bench experiments. No one felt the importance of the careful and correct employment of hypotheses more than Liebig. In his Faraday lecture Hofmann says of Liebig:—"If he finds his speculation to be in contradiction with recognised facts, he endeavours to set these facts aside by new experiments, and failing to do so he drops the speculation." Again, he gives an illustration of how on one occasion, not being able to divest himself of a hypothesis, he missed the discovery of the element bromine. While at Kreuznach he made an investigation of the mother-liquor of the well-known salt, and obtained a considerable quantity of a heavy red liquid which he believed to be a chloride of iodine. He found the properties to be different in many respects from chloride of iodine; still, he was able to satisfy all his doubts, and he put the liquid aside. Some months later he received Balard's paper announcing the discovery of bromine, which he recognised at once as the red liquid which he had previously prepared and studied. Thus, though imagination is indispensable to a chemist, and though I think chemists should be, and let us hope are, poets, or at least possess the poetic temperament, still, little can be achieved without a thorough laboratory training; and he who discovers an improved experimental method or a new differentiating reaction is as surely contributing to the advancement of science as he who creates in his imagination the most beautiful and promising hypothesis.

It may never be possible to trace in civilisation's early records the exact period and place of the origin and beginnings of our science, but the historical student has been led, it appears to me, by a sure instinct to search for this in such lands of imaginative story as ancient Egypt and Arabia. For is there anything more fittingly comparable with the marvellous experiences of a chemical laboratory than the wonderful and fascinating stories that have come down to us in "The Arabian Nights"? Those monuments of poetic building of which Burton, in the introduction to his great translation, says that in times of official exile in less-favoured lands, in the wilds of Africa and America, he was lifted in imagination by the jinn out of his dull surroundings, and was borne off by him to his beloved Arabia, where under diaphanous skies he would see again "the evening star hanging like a golden lamp from the pure front of the western firmament; the after-glow transfiguring and transforming as by magic the gazelle-brown and tawny-clay tints and the homely and rugged features of the scene into a fairyland lit with a light which never shines on other soils for seas. Then would appear," &c. I cannot help thinking that the study of such books as this, the habit of exercising the imagination by reconstructing the scenes of beauty and enchantment which they describe, might do much to strengthen and sharpen the imaginative faculty, and greatly increase its efficiency as an indispensable tool in the hands of the pioneer who seeks to extend the boundaries of knowledge. *The Times,* in the leading article already quoted, says that, as with a Shakespeare, "it is the same with imaginative discoverers in science. . . . But the faculty is not merely a fairy gift that can be exercised without pains. As the sense of right is trained by right action, so the sense of truth is trained by right thinking and by all the labour which it involves. That is as true of the artist as of the man of science; and one of the greatest achievements of science has been to prove this fact and so to justify the imagination and distinguish it from fancy."

Again, let it not be forgotten that chemistry in its highest sense—that is, in its most general and useful sense—is purely a world of the imagination, is purely conceptual. And in addition to this, moreover, it is based, like all science, on the underlying assumption of the uniformity of Nature, an assumption incapable of proof. If we think of the science as a body of abstract general theory, and exclude for the moment from our purview its innumerable practical applications, and also all special individual facts not yet known to be related to general theory, then what remains are the more or less general facts or laws. These it is which give the power of prediction in newly arising cases of a similar character; the power of foresight by which the claim of chemistry to its position as a science is justified. Chemistry, as such, is a complicated ideal structure of the imagination, a gigantic fairy palace, and, be it noted, can only continue to exist so long as there are minds capable of reproducing it. Think of all the speculation—and speculation too of the highest utility when translated into concrete applications—about the internal structure of molecules. I venture to say that the most magnificent creations of the world's greatest architects are not more elaborate or more beautiful or more fairylike than the chemist's conception of intramolecular structure and the magical transformations of which molecules are capable; and yet no one has had direct sensuous experience of any molecule or atom, or possibly ever will. It is well from time to time to recall these truths and realise where we are. But although the conceptual nature of science is unquestionable, it certainly contains truth in some form as tested by deductive concrete realisation, by correctness of prediction, and during the last century or two has undoubtedly given to man a mastery over Nature never before dreamt of.

A Brief Historical Retrospect.

The foundations of chemistry, as we now know it, were laid under the influence, the guidance, of three great theories: first, the theory of the alchemists of the transmutation of metals by means of the philosopher's stone; second, the theory of phlogiston, connected so much with the names of Becher and Stahl, which held sway for some two centuries; third, the theory of combustion, the quantitative period of chemistry, inaugurated by the great Scottish chemist Black by his introduction of the balance. How this led to a veritable renascence of chemistry in the hands of Lavoisier and the other giants of that stirring period—the close of the eighteenth and commencement of the nineteenth centuries—is well known. Looking back at the warfare which was waged about these older theories, for and against them, one realises now that there were elements of truth on both sides; for have we not in the work of Sir William Ramsay and others the revival of transmutation, and does not the essential truth of phlogiston survive in the modern doctrine of heat? In one of Dr. Johnson's letters to Boswell there is a curious reference to transmutation. He says that a learned Russian had at last succeeded, but, fearing the consequences to society, he had died without revealing the secret.

After the discovery of oxygen and the beginnings of quantitative chemistry, the science was ready for Dalton's great discoveries respecting combination by weight; the corresponding discoveries by Gay-Lussac on combination of gases by volume, and, through the latter, for Avogadro's famous hypothesis. Dalton had indeed, by reviving an old Greek suggestion, proposed to explain his discoveries by his atomic theory, but neither this nor our molecular theory, though the latter was inherent in the laws of gaseous combination of Gay-Lussac and in Avogadro's hypothesis, was finally put upon its present basis until Cannizzaro took up the subject half a century later. Meanwhile Dulong and Petit had completed their studies of atomic heat, and Mitscherlich had pointed out the relation between isomorphism and molecular structure. When it is considered how little is known of solid or liquid structure, and that our present knowledge of molecules is only of gaseous molecules, it is fortunate that these methods of study of solids are available. The same may be said of the results of the work of Kopp and his successors on molecular volumes. Of other aids to fixing our conception of molecules and atoms I need only refer to the periodic law, the studies of the properties of dilute solutions, of electrolytic dissociation, and of surface tension of liquids.

Liebig, in his first inquiry, begun before he went to Gay-Lussac in Paris, proved that silver fulminate and silver cyanate, though distinct substances, had exactly the same composition; thus was opened that great chapter in the history of chemistry which Berzelius named isomerism. Perhaps nothing in chemistry has given rise in recent years to more intellectual and practical activity than isomerism. Wöhler's classical synthesis of urea, by the metastasis of ammonium cyanate, added another instance of isomerism, and Berzelius soon afterwards announced the isomerism of tartaric and racemic acids. Wöhler's synthesis of urea, followed, as it was, by numerous other laboratory syntheses, showed that substances which occur in living organisms are not different from those which may be prepared artificially, and the old distinction between inorganic and organic chemistry disappeared there is, of course, only one chemistry. The words, it is true, have survived, but only for reasons of practical convenience.

After isomerism the next great step forward in the study of intra-molecular structure was the discovery of groups partially individualised which are capable of remaining intact through many reactions. Gay-Lussac had previously noticed the cyanogen group as common to cyanides; but it was the celebrated paper by Wöhler and Liebig on the radical of benzoic acid which finally established the existence of compound radicals or groups such as benzoyl, and obtained for the theory of compound radicals the position in chemistry it now holds. Bunsen followed somewhat later with the discovery of cacodyl, and now such groups are almost innumerable. In many respects, by the experimental skill which it shows, the clearness of its logical method, and the beauty of its form and diction, this memoir is a model of what a scientific communication should be. I will read the opening paragraph, using Hofmann's translation:—"When a chemist is fortunate enough to encounter, in the darksome field of organic nature, a bright point affording him guidance to the true path by following which he may hope to explore the unknown region, he has good reason to congratulate himself, even though he may be conscious of being still far from the desired goal." Of this memoir Berzelius, in a letter quoted by Hofmann (Faraday lecture), says:—"The facts put forward by you give rise to such considerations that they may well be regarded as the dawn of a new day in vegetal (organic) chemistry."

The history of the advance of chemistry since the days of the Giessen laboratory is bewildering in its extent. This has been largely due to the Giessen laboratory itself, which sent trained investigators, each carrying with him some touch of its master's magic, into all civilised lands. I cannot attempt to even catalogue the results here. One thing may be said, that chemistry is not worked out, as some have thought; but rather the opportunities of discovery seem greater and more promising than at any previous period.

PART II.

Sub-atoms, Atoms, Molecules, Molecular Aggregates; Valency.

Whether in the light of recent researches it may become necessary to give up that portion of Dalton's theory of atoms in which he regards them as undecomposable and indivisible; or whether we may consider them, as Prout suggested a hundred years ago, as different aggregates of sub-atoms of a uniform kind of matter; or whether they must be regarded as complexes built in the manner supposed by the electron hypothesis; also what should be our attitude towards the related problem of transmutation—all this I pass over, the more willingly that these subjects were discussed so recently by so high an authority as Sir William Ramsay in his address to the Association last year at Portsmouth.

I assume that we are fairly satisfied with our present atoms and their respective weights, and this no matter how the atoms are constructed, and that we shall be satisfied with them so long as they disport themselves in chemical changes as indivisible entities. And further, I assume that we are satisfied with our molecules and their respective weights, as determined by the application of Avogadro's hypothesis. Whether the molecular weight is obtained by direct determination of gaseous density or by taking advantage of the properties of dilute solutions, in either case the molecular weight which results is the weight of a supposed gaseous molecule, for the latter method depends for its justification on the former. All our molecular weights are weights of molecules in the gaseous state or are supposed to be; they are not necessarily applicable to liquids, and much less to solids: solids and liquids may well consist of far more complex particles.

Gradually the central problem of chemistry has become more and more the study of internal structure of molecules—of gaseous molecules. The enormous number and variety of the compounds of carbon, with which so many workers have enriched the science during the last hundred years, and the special adaptability of these compounds to the experimental study of molecular structure, have led investigators to make use of them rather than of the so-called inorganic compounds: thus out of inquiries into the intramolecular structure of these compounds arose and were developed the theories of types of Gerhardt, Williamson, and Kekulé. These are now, however, looked upon more as aspects of the general problem. More fruitful has been the study of the compound radicals or individualised groups of Wöhler and Liebig. But gradually these molecular structures have been regarded, in agreement with the views of Dumas, as complete wholes; like fairy temples, which from different points of view show different parts in relief, accentuating, it may be, this or that column or frieze or pediment. Kekulé's brilliant and suggestive theory of chain compounds and ring compounds did more than any other theory to guide and stimulate research in chemistry in recent times. Like Gay-Lussac's theory of gaseous combination, though built in the first place only upon a few facts, this theory has proved true of the thousands of others with which we have since become acquainted; there seems indeed to be a need of a new psychology to account for such truly marvellous foresight as is here exhibited. The atoms forming these varied structures were, however, regarded as being arranged in a plane, until the great discoveries of Pasteur made it necessary for chemists to extend their conceptions and to frame hypotheses of three dimensions. Thus have arisen in the hands of Le Bel and van't Hoff and others our modern theories of stereo-chemistry. When isomerism occurs in an element Berzelius names it allotropy. It seems to me that now, when molecules of the elements do not differ essentially from molecules of compounds, there is no longer any distinctive meaning in the term, and that it might well be abandoned. I would like also to make another suggestion respecting nomenclature: that when we distinguish ring compounds as *cyclic* we might appropriately adopt the word *hormathic* (from the Greek word for a chain or a row) for chain compounds.

But in order to understand the linking of atoms in these molecular edifices some combining value had to be assigned to the different atoms. This idea of valency of the atoms was, no doubt, implied in Gerhardt's theory of types; but it did not gain much attention until later, when Frankland and Kolbé formulated an empirical theory of variable valency. Kekulé thought that atoms could not vary in their valency; but the alternative formulæ which he put forward to explain cases of difficulty would appear to be, rather, an attempted explanation of variable valency. It might be more correct to say that Kekulé's formulæ constitute an anticipation of Werner's theory of auxiliary valencies, the theory which seems to find most favour at the present day. Fixed valency can scarcely now be defended, in view of the existence of such compounds, for example, as the two fluorides and the two chlorides of phosphorus; the two oxides of carbon, ammonia and ammonium chloride; and, for example, the two series of compounds respectively of iron, mercury, and copper. Variable valency of atoms is, empirically at least, an establish fact.

By the latest conceptions of variable atomic valency and its extension almost without limit—so that, for example, oxygen may be regarded as quadrivalent and even sexivalent—no doubt the existence of numerous compounds which previously presented difficulties can be explained. There are, however, others long known to chemists, such as double salts and the combination of water with salts, formerly called "molecular compounds," definite and individual, in which these views do not assist us. These compounds do not exist as gases, and unless they admit of experimental study by the methods of dilute solution, even their gaseous molecular weights cannot be ascertained.

It is noteworthy that in most of the instances recently investigated where variable valency has been assumed the compounds studied have been easily decomposable solids or liquids, and for one reason or another their gaseous molecular weights could not be determined. Many of these compounds, indeed, only exist at low temperatures. As instances of work of this kind I may mention Collie and Tickle on quadrivalent oxygen in dimethylpyrone derivatives; Gomberg on triphenylmethyl; Landolf on acetone dihydrofluoride; Thiele and Peter on methyl-iododichloride; and similar studies by Kehrmann, Willstatter and Iglauer, Bülow and Sicherer, Baeyer and Villiger, Archibald and McIntosh, Chattaway, Pfeiffer and Truskier, and others.

Another most interesting class of solids which are capable of existing in two isomeric forms distinguished from each other by such physical properties as density or colour are the Schiff's basis or anils. Some of these were studied by Hantzsch, who proposed to explain their existence by the Hantzsch-Werner stereo hypothesis:—

$$\begin{array}{c} HO.C_6H_4.CH \\ \| \\ NR' \end{array} \qquad\qquad \begin{array}{c} HC.C_6H_4OH \\ \| \\ NR' \end{array}$$

But since only a few, and these not very satisfactory, compounds show this isomerism, which do not contain the hydroxyl group, other suggestions have been put forward to account for the isomerism, by Anselmino and by Manchot.

In my own laboratory, associated with Mr. F. G. Shepheard and also with Miss Rosalind Clarke, I have made a study of various Schiff's bases for the purpose of investigating the remarkable property which some of these bases exhibit of *phototropy*. By phototropy is meant the capability of reversible change of colour in solids depending upon the presence or absence of light. Incidentally, too, I wished to study another physical property which many Schiff's bases possess, in common with other substances, of reversible change of colour with raising or lowering of temperature. This property we have called *thermotropy*, and many old instances will be remembered of substances of simpler constitution which exhibit it: thus, when subjected to the temperature of solid carbon dioxide, ordinary sulphur becomes colourless, red oxide of mercury becomes yellow, vermilion becomes scarlet, and on return to the ordinary temperature the original colours reappear.

As has been pointed out in a recent communication by Biilman, it is most important in these discussions that we should be perfectly clear in the use of terms. I take it for granted that *isomerism* is a general term for compounds differing in some respect but having the same composition. If the molecules (gaseous) have the same weights they are *metamerides*; if of different weights they are *polymerides*. When solids crystallise in more than one form they are *polymorphous*. Now it does not seem reasonable to suppose that reversible colour changes such as those exhibited by phototropes or thermotropes involve such violent intra-molecular changes as the breaking and reconnecting of atomic linkages. For example, take the three bases, salicylidene-*m*-toluidine, which in the dark or immediately it is exposed to light is yellow, but on continued exposure to light quickly becomes orange, and changes back again to its original colour in the dark; salicylidene-*m*-aminophenol, which at ordinary temperatures is orange, but is much paler at the temperature of solid carbon dioxide, on raising the temperature to nearly the melting-point (128·9°) becomes orange red, and these changes take place in the reverse order again on cooling; salicylidene-*p*-aminobenzoic acid, studied by ourselves and by Manchot and Furlong independently, shows a wider range of thermotropic change between bright yellow and blood-red, and is also phototropic. To explain such changes as these and the others of a similar nature previously referred to, I think some less drastic hypothesis should be sought than intra-molecular breaking, and consequent metastasis or polymerisation. Though doubtless the hypothesis of Hantzsch and Werner could be invoked, or the modified hypotheses of Manchot or Anselmino, I think there should be some simpler explanation. Someone suggests polymorphism. Now polymorphism means that a change of crystalline form takes place which might doubtless connote change of colour. If one watches phototropic crystals changing colour under the influence of light from yellow to red, and notices that after remaining in the dark the same crystals have changed back to the original colour, and, remember, that these changes can be repeated with the same crystals apparently without limit, it will not be considered likely that this phenomenon depends on a reversible change of crystalline form. In a communication to the Chemical Society some three years ago Mr. Shepheard and I put forward the following suggestion:—"Evidence is accumulating of reversible isomeric reactions, like those described in this paper, which are indicated by physical differences, such as changes of colour. It is possible that these may be explained by hypotheses, similar to that of Hantzsch and Werner, assuming intra-molecular rearrangement; but in the case of phototropy and thermotropy it should not be forgotten that the substances exhibiting these phenomena are solids. No one will doubt, however, that these differences of colour depend on isomeric change of some kind, but in the case of solids we know practically nothing of their molecules, not even of their relative molecular weights. The molecules of solids are probably far more complex than those of liquids or gases; indeed, they may be rather complex groups or aggregates of ordinary gaseous molecules, which would give rise to far more numerous possibilities of isomerism. It appears to us that phototropic and thermotropic reactions are more probably due to isomeric changes affecting the aggregation of molecules in solids than to intra-molecular change of molecules derived from a study of gases."

It seems to me that just as atoms may be structures built of sub-atoms of some kind, and just as molecules of gases are built of atoms variously linked together, it is reasonable to conceive that molecules might combine to form aggregates, particularly when constituting solids; that as the sub-atoms may be conceived to have a combining valency—and the atoms are already accredited with this property, and in addition, as is supposed with Thiele's partial or Werner's auxiliary valencies—molecules may have valencies also whereby to combine into molecular aggregates. It may be presumed that such aggregates are more complicated in structure, and thus may give rise to greater variety of isomerides, and be more readily transmutable than gaseous molecules. If such aggregates of gaseous molecules exist they might explain not only the easily changed isomerides recently studied, but also the large class of "molecular compounds" of the older chemists. I imagine someone saying that in suggesting this hypothesis—which by the way is not new, for it is mentioned in Ostwald's "Outlines"—I am violating the canon to which I have myself subscribed, as a condition of a scientific hypothesis, that it should be verifiable. Perhaps we carry our critical faculty sometimes too far. It is most highly scientific to doubt, but doubt which is merely destructive has little value; rather, with Descartes, it should lead on to construction, for he who builds even imperfectly is better than he who simply destroys. And I do not doubt that some way will be found to study solids and obtain data that will lead to the determination of their molecular aggregate weights. The study of molecular volumes of solid solutions; the remarkable results obtained by Pope and Barlow; Tutton's work on crystallography, and much besides, induce the hope that some day solids, like gases, will find their Avogadro.

Part III.

Pursuit of Chemistry Justified by its Useful Applicability.

In the pursuit of all this abstract theory, and still more so in the bewildering multitude of undigested individual facts, there is danger that important and fundamental, even moral, considerations may be lost sight of. For example, take the fundamental question: Why should we pursue chemistry? No doubt it is considered by its votaries, those who seek in our laboratories to advance the science, that they are entitled to have provided for them, and will be rewarded by the provision of, the ordinary means of livelihood; but these, it will scarcely be denied, could generally be far better assured by other pursuits. It is suggested that intellectual discipline is a reason; but, I ask, for what purpose? Will anyone pretend that intellectual discipline without utilitarian object, without the possibility of using it for the betterment of society, is a worthy pursuit? I think not. But, in any case, none of us have devoted ourselves to chemistry merely for the sharpening of our wits. Again, someone suggests that chemistry and learning generally should be pursued for their own sake. In a recent most interesting and inspiring academic address[1] Prof. Sir Walter Raleigh commends "those who seek nothing from knowledge but the pleasure of understanding." If such a statement bears its most obvious meaning then, I venture to think that, in common with intellectual discipline without the intention of applying to a useful object the intellect so trained, such a reason is selfish, inadequate, and unworthy, and does not justify the pursuit of anything. No; research in chemistry apart from the possibility of applying it to the advantage of humanity cannot be defended. The mastery of the seemingly unlimited resources of Nature which chemistry achieves more and more and its use to alleviate the misery and add to the happiness of mankind are the only worthy and effective defence. And that this is the underlying ideal, in point of fact, that leads the chemist onward, not necessarily that he is always conscious of it, but always when he reflects, I think cannot be doubted. But, of course, no narrow idea of utility must be aimed at. Practically any chemical inquiry may lead to results of material advantage. Certainly nothing could be more mischievous than to make a narrow immediate utility the test. It would be easy to illustrate all this from the records of science, but instances in point are so well known that it is unnecessary.

On the other hand, it should not be forgotten that in making use of the manifold advantages derived from the growth of science, humanity, on its part, owes a great debt to scientific inquirers, and ought to feel it a sacred duty to do in return all in its power by support and encouragement to further scientific research. As Sir Walter Raleigh, in the address already referred to, says:—"It is so easy to use the resources of civilisation that we fall into the habit of regarding them as if they were ours by right. They are not ours by right; they come to us by free gift from the thinkers."

Some Concrete Applications of the Science.

That this advantage to civilisation has been, and is, the result of the pursuit and consequent advance of chemistry is happily a truth that is well known. There is scarcely an industry or a profession that has not been materially influenced or even created by the discoveries of chemistry, and therefore the welfare of nations is most intimately concerned in promoting its advancement. Now, it is common knowledge that no country has appreciated this to the same degree as Germany. It will, therefore, be worth our while to consider a moment the inauguration in Berlin, a year ago, of an entirely new institution, the Kaiser Wilhelm Institut, for the promotion and organisation of chemical research. This research is to be effected throughout the German Empire, in the universities, the technical high schools, or in works, and it is supported mainly, at least at first, by subscriptions of the chemical manufacturers. An address of very great importance was delivered at its opening by Prof. Emil Fischer, than whom, perhaps, no one living has added more to the progress of chemistry. A translation of this address appeared in Nature, and, with additions, has since been published in a convenient book form.[2] In this address an authoritative account is given of the main contributions of chemistry to the national welfare, which even to those familiar with the subject must be astonishing in their importance, variety, and universality. It includes the applications of the science to problems of nourishment, to agriculture, and food supply; to engineering, metallurgy, cements; to clothing, artificial silk, or to colouring—dyes; to indiarubber production, both natural and artificial; to perfumery—artificial violet and other artificial floral perfumes, even that of the rose; to synthetic camphor; to drugs and synthetic materia medica, including the recent arsenic and selenium organic compounds which promise so much in the treatment of cancer and other fatal diseases; to radio-activity, to therapeutics, to the destruction of pathogenic microbes; to methods of sewage disposal; to the preparation of efficient ex-

1 "The Meaning of a University." (Clarendon Press, 1911.)

2 "Chemical Research in its Bearings on National Welfare." (London, 1912.)

plosives; and to many other useful objects. In connection with the manufacture of explosives the public should know that the ability to wage war is becoming more and more dependent on the work of chemists. When the supply of mineral nitrates is exhausted, or even before that event, the requisite nitrogen compounds will have to be provided in some other way, and almost certainly they will be obtained synthetically from the atmospheric gases which even now are becoming a commercial source.

The Time-spirit and Science.

But students of history know that there are certain periods that for some unexplained reason are specially fruitful in certain departments of intellectual or artistic development. Prof. Sir Walter Raleigh, for instance, a high authority on this subject, says:—"The human body, so far as we know, has not been improved within the period recorded by history; nor has the human mind, so far as we can judge, gained anything in strength or grace." Further, regarding literature:—"The question is not by how much we can excel our fathers, but whether with toil and pains we may make ourselves worthy to be ranked with them." Again:—"In the beautiful art which models the human figure in stone or some other enduring material, who can hope to match the Greeks? In the art of building who can look at the crowded confusion of any great modern city, with all its fussy and meaningless wealth of decoration, like a pastrycook's nightmare, and not marvel at the simplicity, the gravity, the dignity and the fitness of the ancient classic buildings? How can the seasoned wisdom of life be better or more searchingly expressed than in the words of Virgil or Horace, not to speak of more ancient teachers?" Thus all things are not progressing. The time-spirit now, and for some two centuries past, seems to have chosen to take under its particular guardianship the physical and natural sciences, their cultivation and applications, rather than philosophy or architecture or sculpture, or painting or literature. We shall do well to recognise this, and not waste our resources in striving to fight against it.

Present Indiscriminate Elementary Teaching and Neglect of Research.

Large sums of money are expended in this country on the diffusion of some knowledge of chemistry among all classes of scholars and students; in fact, scarcely anyone escapes from a smattering, largely undigested if not indigestible, either forced on them by regulations or by allurements of bribes in the form of prizes, scholarships, or academic laurels. And if this is not good for scholars and students, it is worse for masters or professors. Our professors work "whole time" at this "stall-feeding" process, and if they happen to be strong men mentally and physically they may be able when weary with work to devote any overtime to—what I submit is far the more important matter for the State—the advancement of science by research. But this pursuit requires, for its successful prosecution, for resource and initiative to be at their best, that all the faculties should be in readiness in their fullest strength, freedom, and adaptability. How many, alas! are not strong men, and in their praiseworthy endeavours, notwithstanding, to contribute something to the achievements of their time succumb as martyrs to their devotion. The truth of this statement, I fear, is too well known to many of us here. In Germany this strain of elementary teaching is more recent, and is only now being felt. Prof. Emil Fischer in his address (*loc. cit.*) says of it: "During the last ten years a scheme of practical education of the masses has developed." "But this very education of the masses tends mentally to exhaust the teacher, and to a great extent, certainly to a higher degree than is desirable or indeed compatible with the creative power of the investigator, there prevails in modern educational laboratories a condition of overstrained activity." And again, "In the harassing cares of the day the teacher too readily loses that peace of mind and broad view of scientific matters necessary for tackling the larger problems of research." Laboratories, he says, are wanted "which should permit of research in absolute tranquillity, unencumbered by the duties of teaching." I have given these quotations from Prof. Fischer's address as indicating the matured judgment of a highly competent authority, communicated in the presence of the German Emperor on an historic occasion. His words are words of great weight, and no country which regards its future welfare can afford to ignore them.

Sir Walter Raleigh (*loc. cit.*) says that every university is bound to help the poor . . . but that does not mean that a university is doing good if it helps those who have no special bent for learned pursuits to acquire with heavy labour and much assistance—just so much as may enable them to pass muster; on the contrary, it is doing harm. I would like to invite the attention of all who are seriously interested in the country's welfare to reconsider the present policy in the teaching of chemistry; and this applies also to other sciences. For the advancement of civilisation, for the increased welfare of the race by the technical applications of our science, it is not the indiscriminate teaching of the masses and the multiplication of examinations that is wanted, but the training of the few, of capable investigators. I do not propose necessarily that we should interfere with, or much less abandon, much of our present elementary teaching, and I know that elementary, largely technical, training in chemistry is needed for medicine and engineering; but I do propose that our first endeavour should be to secure under present conditions in the present college or works laboratories, or in laboratories to be specially provided, that capable men, of whom we have many, should be able to devote themselves to research without the worry of teaching and examining or of providing the ways and means of livelihood. There is, happily, reason to believe that this vital need is to some extent becoming known; for there have been several recent instances where a particular investigator has been afforded the means, financially, of prosecuting his particular researches in tranquillity. The diversion of endowments to such purposes, instead of their going to the foundation of additional school or undergraduate scholarships, cannot be too highly commended.

We may learn a lesson which bears on this from that remarkably prolific period of our science, the close of the eighteenth and the beginning of the nineteenth centuries. It was then no easy matter to pass the precincts of a chemical laboratory; only the fittest survived the ordeal. At the beginning of the nineteenth century the traditions of Berthollet and Lavoisier in Paris were kept alive by Gay-Lussac; in England those of Cavendish and Priestley by Davy; and Berzelius in Sweden worthily maintained the older school of Bergmann and Scheele. By a happy fate the interest of Alexander v. Humboldt was the means of both Liebig and Dumas being admitted to the intimacy of Gay-Lussac; and in Sweden Wöhler was fortunate to gain the confidence of Berzelius; and in London, Faraday that of Davy. The achievements of these men—Liebig, Dumas, Wöhler, and Faraday—are part of the history of science. To me it contains a lesson, in point, of great importance. The opportunity offered them was beset with difficulties. No bribes such as scholars or students expect to-day were offered them; they knew no examinations, and their available apparatus and laboratory equipment were of the smallest and crudest description; but they were eager students with whom the master was in sympathy, and it is common knowledge that they completed the foundations of our science. Now I ask, considering the thousands of students whom we teach and examine to-day, are we doing as well in the interest of the country as our predecessors a century ago? Who can confidently answer in the affirmative? No; whatever else is done, the country needs the provision of men whose untrammelled energy should be devoted to original chemical research. Even as intellectual discipline the value of research is of the highest importance. In his address to the British Association at Winnipeg, Prof. Sir J. J. Thomson bears testimony to this. He says: "I have had considerable experience with students beginning research in experimental physics, and I have always been struck by the quite remarkable improvement in judgment, independence of thought, and maturity produced by a year's research. Research develops qualities that are apt to atrophy when the student is preparing for examinations, and, quite apart from the addition of new knowledge to our store, is of the greatest importance as a means of education."

And the object and ideal are wrong also in our system of technical training. We aim too much at giving elementary instruction to artisans, which, though important in itself, can never take the place of the higher education of leaders or managers of industrial works. This is different in Germany, where, although the training of artisans is by no means neglected, the chief energy is directed to the training and teaching of the smaller class of managers. There is, too, in Germany a far more intimate relation between academic and industrial work, and the leaders in each often interchange posts. In one respect we have an advantage over Germany; it is important that this should be understood. The higher technical instruction across the Rhine has not been undertaken by the universities, but is carried out in separate institutions. With us the universities have gradually undertaken, in addition to the older technical subjects, theology, medicine, and law, the various branches of engineering and agriculture, and even commerce. This, it is to be hoped, will be extended so that the highly trained technologist may have the advantage of the undoubted humanising influence of the university.

Conclusion.

I have not attempted in this address any complete survey of chemistry, either its growth in the past or its present condition, but I have endeavoured to give some account of the sort of thing chemistry is—of its method—and to maintain three theses: (1) That the logical method by which chemistry advances is not a simple one, and requires as one essential element the use of a highly developed imagination. To render this more efficient I have advocated special training. (2) Without violating, I hope, the canons of the proper use of hypothesis, I have proposed, in order to account for certain isomeric and other phenomena, the conception of solid molecular aggregates, although I am not able at present to indicate precise methods for its further investigation. These molecular aggregates are supposed to be formed by the combination of gaseous molecules just as the latter are formed by the combination of atoms. (3) As a matter of vital interest to the continued well-being of this country I have insisted strongly that our educational resources devoted to chemistry should be directed, in the first place and chiefly, to the highest possible training of promising students in the prosecution of research, and that the giving to the many of elementary instruction should be at least a secondary consideration.

Now I do not wish to dictate how this last proposition could be best carried into effect. I think we should distinguish three classes of chemists, or technical chemists, whose domains would more or less overlap. Occasionally there will be a man, like the late Sir William Perkin, who would combine all three. The three classes are: first, the pure chemist, devoted to scientific discovery only; second, the technical chemist, who prepares the discoveries of the pure chemist for the technologist, and has to determine such questions as economical production and, for example, the conversion of colours into dyes; third, the technologist or works manager. These three classes should be in close relation to one another. By such a scheme we should probably overcome by education one of our most serious present difficulties—the ignorance of owners of works of the value of science.

It is a matter deserving most earnest consideration whether, under the propitious influence of our own time-spirit, it would be possible to organise research and develop it without interfering with its essential freedom and initiative, and this in each of the three classes I have mentioned, either by means of some of our existing institutions, or by the inauguration here of such an organisation as the Kaiser Wilhelm Institut in Berlin.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY B. N. PEACH, LL.D., F.R.S., PRESIDENT OF THE SECTION.

The Relation between the Cambrian Faunas of Scotland and North America.

Introduction.

EVER since the announcement made by Salter in 1859 that the biological affinities of the fossils found in the Durness Limestone are more closely linked with American than with European forms, the relation between the older palæozoic faunas of Scotland and North America has been a subject of special interest to geologists. The subsequent discovery of the *Olenellus* fauna in the north-west Highlands furnished striking confirmation of Salter's opinion. This intimate relationship raises questions of prime importance bearing upon the sequence and distribution of life in Cambrian time in North America and north-west Europe, on the probable migration of forms from one life-province to another, and on the palæogeographical conditions which doubtless affected these migrations.

On this occasion, when the British Association revisits the border of the Scottish Highlands, it seems appropriate to refer to some of these problems. With this object in view I shall try to recapitulate briefly the leading features of the life-history of Cambrian time in Scotland and North America, to indicate the relation which these life-provinces bear to each other, and, from these data, to draw some inferences regarding the probable distribution of land and sea which then obtained in those regions.

The two great rock groups in Scotland that are universally admitted to be older than Cambrian time are the Lewisian Gneiss and the Torridon Sandstone. The Lewisian Gneiss, as mapped by the Geological

Survey, consists mainly of igneous rocks, or of gneisses and schists of igneous origin. But, in addition to these materials, we find, in the Loch Maree region, schists o sedimentary origin, comprising siliceous schist, mica-schist, graphite-schist, limestone, chert, and other sediments. The association of graphite-schist with limestone and chert suggests that we are here dealing with rocks that were formed at or near the extreme limit of sedimentation, where the graphite, the limestone, and the chert were probably accumulated from the remains of plankton. But this assemblage has been so completely altered into crystalline schists that all traces of original organic structure in them have been destroyed.

The Torridonian strata were evidently accumulated under desert or continental conditions, and could therefore furnish little or no evidence bearing upon the development of marine life. That life existed, however, is clear from the presence of phosphatic nodules, containing remains of cells and fibres of organic origin, in the upper division of the system, and from the presence of worm burrows and casts in the Diabaig beds (Lower Torridon).

Geologists are familiar with the fact that the Cambrian faunas all over the globe present highly specialised types belonging to most of the great groups of marine invertebrate life. Scotland is no exception to this general rule. For the fossils prove that their ancestors must have had a long history in pre-Cambrian time.

The Cambrian Fauna of Scotland.

Beginning with the false-bedded quartzites forming the basal sub-division of the Cambrian strata in the north-west Highlands, we find no traces of organic remains in them, except at one locality, where worm casts (*Scolithus linearis*) were obtained. In the upper subdivision of the quartzites—the pipe-rocks—the cylinders of sand are so numerous that the beds have been arranged in five subzones, based on a definite order of succession of different forms probably of specific value. One of them, *Arenicolites* of Salter, may be of generic importance. Worms of this habit are confined to comparatively shallow water, and therefore near the shore line. Their occurrence helps to confirm the belief that the quartzites were laid down on an ancient shelving shore line during a period of gentle subsidence. Their presence also indicates the existence of plankton, from which they derived nourishment. Besides the relics of these burrowing annelids, one of the subzones of the pipe-rock has yielded specimens of *Salterella* (*Serpulites Maccullochii*)—a tubicolar annelid, which becomes more abundant in the overlying fucoid beds, serpulite grit, and basal limestone, where it is associated with *Olenellus* and other typical Lower Cambrian forms.

The fucoid beds, which immediately overlie the pipe-rocks, consist chiefly of shales and brown dolomitic bands, with intercalations of grit locally developed. This type of sedimentation indicates that the mud line was superimposed on the shore line by subsidence. With this change of conditions there is a change of organisms, for though the burrowing forms (*Scolithus*) are still to be found in the sandy layers, the most characteristic types are those occurring along the bedding planes, known under the name of *Planolites* (Nicholson). They are very varied forms, and were probably produced by many types of errant annelids. The tubicolar annelids are represented by *Salterella, Coleoloides*, and *Hyolithes*—an organism which perhaps links the worms with the hingeless brachiopods. This suggestion gains additional support from the researches of Dr. Walcott in the Middle Cambrian rocks of Canada. It is interesting to note that small annelids seem to have bored the spines of dead trilobites. Walcott has found similar borings in the chetæ of annelids in the Middle Cambrian rocks of Canada.[1]

The researches of Dr. Walcott have proved beyond doubt that representatives of nearly all the divisions of the annelids are entombed in the Middle Cambrian rocks of Mount Stephen, in British Columbia. We may therefore reasonably infer that the worm casts of *Scolithus* type found in the north-west Highlands are due to annelids. He has also shown that wormlike holothurians are to be found in the same beds.[2] In this connection it may be observed that some of the recent holothurians have much the same habit of obtaining nourishment from the sands and silts containing organic matter.

Fragments showing the characteristic microscopic structures of the plates and ossicles of echinoderms have been found in the fucoid beds. These are possibly Cystidean. Hingeless forms of brachiopods also occur, among which may be mentioned *Paterina labradorica* and *Acrothele subsidua*. The type of *Acrothele* suggests a genetic descent from such a tubicolar worm as *Hyolithes*. Of the gasteropods, only one specimen, belonging to a subgenus of *Murchisonia*, has been obtained at one locality in Skye. *Helenia bella*, a curved calcareous tube, open at both ends, doubtfully referred to the *Dentalidae* by Walcott, is comparatively plentiful. It occurs also in the *Olenellus* zone in Newfoundland.

But the organic remains that render the fucoid beds of exceptional interest and importance are the trilobites, because they clearly define the horizon of this zone in the Cambrian system and display strong affinities with American types. They are represented by five species and varieties of *Olenellus*, very closely resembling the forms in the Georgian terrane, or *Olenellus* zone, on the east and west sides of the North American continent. The genus *Olenelloides* has also been recorded from these beds. The crustacea are represented by phyllocarids, among which we find *Aristozoe rotundata*, likewise characteristic of the *Olenellus* zone of North America.

Next in order comes the serpulite grit, which indicates a recrudescence of the pipe-rock conditions of deposition, and presents the *Scolithus* type of annelid borings. From the diameter of the pipe and the depth of the burrow it is probable that the worm may have belonged to a different species from any of those the casts of which are to be found in lower horizons. This large variety is associated with smaller and more irregular worm casts which have often weathered out and leave the rock honeycombed with hollow casts. The characteristic form from which the zone takes its name is *Salterella* (*Serpulites Macculochii*). It occurs abundantly along certain calcareous layers that mark pauses in the deposition of the sand. This calcareous type culminates at the top of the zone, where there is a thick, carious, weathering band, crowded with specimens of *Salterella*, forming a passage bed into the calcareous shales at the base of the Durness dolomites. At one locality near Loch an Nid, Dundonnell Forest, Ross-shire, thin shales, intercalated in the serpulite grit, yielded a fine carapace of *Olenellus Lapworthi*—a form of frequent occurrence in the underlying fucoid beds. Prof. Lapworth recorded the finding of *Orthoceras* and linguloid shells in the top part of this zone at Eireboll.[3]

Immediately above the serpulite grit in Eireboll and Assynt we find a few feet of dark calcareous shale, with iron pyrites, probably deposited at the limit of

[1] Smithsonian Miscell. Collect., vol. lvii., No. 5, p. 125, 1911.

[3] *Geol. Mag.*, vol. x., new series, p. 126, 1883.

sedimentation. This layer, which is singularly devoid of organisms, ushers in the great succession of dolomites and limestones, upwards of 1500 feet in thickness—perhaps the most remarkable type of sedimentation among the Cambrian rocks of the north-west Highlands. The Geological Survey has divided this calcareous sequence into seven well-marked groups, some of which have as yet yielded no fossils beyond worm casts. Attention will presently be directed to the absence of calcareous forms in many of the bands of dolomite and to the probable cause of their disappearance.

The thin calcareous shale just referred to is followed by dark blue dolomite limestone, forming the basal portion of the Ghrudhaidh group. It contains sparsely scattered, well-rounded sand grains, with a bed about three feet thick, near the bottom, charged with *Salterella pulchella* and *S. rugosa*. In the overlying twenty feet of dolomite the sand grains gradually disappear, and the rock assumes a mottled character, due to innumerable worm casts of the *Planolites* type, Here a second layer, yielding *S. pulchella* and *S. rugosa*, supervenes, both forms occurring in the *Olenellus* zone of North America.

The brief summary of the palæontological evidence which has just been given clearly shows that the strata ranging from the middle of the pipe-rock zone to the upper *Salterella* band of the Durness dolomites represent in whole or in part the *Olenellus* zone of North America. Owing to the absence of fossils we have no means of deciding more definitely the base and top of the Lower Cambrian rocks of the north-west Highlands. All the quartzites lying below the middle of the pipe-rock, notwithstanding the absence of zonal forms, have been included in the Lower Cambrian division. This correlation receives some support from the remarkable discovery of Dr. Walcott, who found primitive trilobites several thousand feet beneath the beds yielding *Olenellus Gilberti*, the form closely allied to the Highland trilobites.

On the other hand, when we pass upwards for a certain distance from the *Salterella* bands the evidence is insufficient to establish the stratigraphical horizon of the beds. For in the overlying strata, comprising the remainder of the Ghrudhaidh group, the whole of the Eilean Dubh group, and the lower part of the Sail Mhor group, and consisting of dolomites, limestones, and cherts, with little or no terrigenous material, the only fossils that can be shown to be due to organisms are worm casts of the nature of *Planolites*, although the limestone and chert may have originated from the débris of the calcareous and siliceous organisms of the plankton. A noticeable feature of the Ghrudhaidh and Eilean Dubh groups is the occurrence in them of bands of brecciated dolomite on several horizons, which do not imply any break in the continuous sequence of deposits. The total thickness of this portion of the Durness dolomites and limestones, yielding no fossils beyond worm casts, amounts to 350 feet.

But in the upper part of the Sail Mhor group siliceous and calcareous organisms of a higher grade make their appearance. Among the former we find the *Rhabdaria* of Billings. The calcareous forms are represented by (1) gasteropods, including a single specimen of a murchisonid, two species of a pleurotomarid (*Euconia Ramsayi* and *E. Etna*) of a type occurring in the calciferous rocks of Newfoundland and Canada; (2) cephalopods, comprising two slightly bent forms with closely set septa and wide endogastric siphuncles, showing affinities with those of *Endoceras* and *Piloceras*; (3) arthropods, represented by the epitome of a large asaphoid trilobite resembling that of *Asaphus canalis* of Conrad. This evidence is insufficient to determine the exact horizon of these beds, but clearly indicates that we are no longer dealing with Lower Cambrian strata. The cephalopods are like those found in the Ozarkic division of Ulrich (Upper Cambrian), in North America. According to Schuchert, the cephalopods with closely set septa are of Cambrian type and older than those of the Beekmantown terrane of American geologists. On the other hand, the asaphoid type of trilobite is suggestive of a somewhat higher horizon.

No fossils have been found in the overlying Sangomore group, about 200 feet thick, which consists mainly of granular dolomite, with bands of chert, some being oolitic, together with thin fine-grained limestones near the top.

Above this horizon, at a height of more than 800 feet above the top of the *Olenellus zone*, we encounter the great home of the fossils peculiar to the Durness limestone in the Balnakeil and Croisaphuill groups. The former consists mostly of dark limestones, with nodules of chert, and, with a few alternations, of white limestone bands. A few thin layers are charged with worm casts. The overlying group is more varied, the lower part being composed of dark grey limestones full of worm casts, and with some small chert nodules arranged in lines; the middle portion, of dark granular and unfossiliferous dolomite; and the upper part, of massive sheets of fossiliferous limestone full of worm casts. The total thickness of these two groups in Durness is about 550 feet.

These two subdivisions have yielded more than twenty genera and about one hundred species. In Durness sixty-six species have been obtained from the Balnakeil group alone, fifteen of which have not as yet been found in the overlying Croisaphuill group, thus leaving fifty-one species common to both divisions. The Ben Suardal limestones in Skye, which were mapped by the Geological Survey as one division, are regarded, on palæontological grounds, as the equivalents of both these groups. Owing to the number of species common to both subdivisions, the fauna will be here referred to as a whole.

Both siliceous and calcareous organisms are present in this fauna. Among the former we find *Archaeoscyphia* (Hinde), described by Billings as *Archaeocyathus*, an early Cambrian coral, but shown by Hinde to be a siliceous sponge.[4] The genus *Calathium* is represented by four species. Other genera and species of sponges occur, so that the siliceous nodules, which are very common in both groups, may be in great part due to them. In this connection it may be mentioned that Hinde obtained sponge spicules from some of the nodules. Hinged brachiopods have also been collected from these beds, and include *Nisusia* (*Orthosina*) *festinata*, *N. grandaeva*, and Camarella.

But the characteristic feature of the fauna is the assemblage of calcareous mollusca comprising lamellibranchs, gasteropods, and cephalopods, showing a wide range of variation, and consequently a long ancestry. The lamellibranchs, though represented only by two genera, *Euchasma* and *Eopteria* of Billings, with several intermediate forms, are of extreme interest, as they are only known to occur elsewhere in Newfoundland and eastern Canada. The gasteropods, however, furnish the largest number of species —about 48 per cent. of the whole. The primitive euomphalids, *Maclurea* and *Ophileta*, are most characteristic. The former genus has a large number of species, many of which are to be found in the Beekmantown limestone of Newfoundland and eastern North America. Only one of the species (*Maclurea Peachi*) is peculiar to Durness. Several species of

[4] Quart. Jour. Geol. Soc., vol. xlv., p. 125, 1889

Ophileta are found, some of which likewise occur in the Beekmantown limestone. Euomphalus has also been recorded, while several forms belonging to the nearly allied family of the Turbinidæ, and placed in Lingström's genus *Oriostoma*, are also met with in the Beekmantown limestone.

Murchisonids and Pleurotomarids number twenty-seven species and show a very wide range of variation. The chief subgenera of the former are *Hormotoma* and *Ectomaria*, many species of which occur with remarkable variations. All the types of variation found in Durness are to be found in North America, and several of the species are common to both regions. The pleurotomarids vary in a similar manner, the chief genera being *Raphistoma* and *Euconia*, and a form resembling *Hormotoma*, only with a shorter spire. Species belonging to each of these subgenera are likewise common to both areas, while some are only known from the north-west Highlands.

The cephalopods are of equal interest. They are also of primitive type, and, at the same time, show a wide range in form. The prominent feature in the straighter specimens is the great width of the laterally placed siphuncle, which is generally furnished with endocones and organic deposits. The genus *Piloceras* is the most characteristic type and shows this peculiar feature best. It has only been recorded from Scotland, Newfoundland, Canada, and the eastern States of North America. The following additional genera are represented, viz. *Endoceras*, chiefly by siphuncles in great variety; *Actinoceras*, *Cyrtoceras*, and, doubtfully, *Orthoceras*. Several forms have been attributed to *Orthoceras* which, on re-examination have been found to be the siphuncles of other genera, resembling American types described by Hall and Whitfield.

The whorled nautiloids provisionally classed with the genus *Trocholites* of Conrad are represented by several distinct forms as yet unnamed.

The trilobites are of rare occurrence in these two groups of dolomite and limestone. They are fragmentary and poorly preserved. This is doubtless one of the disappointing features connected with this remarkable assemblage of organic remains, for the presence of a zonal form would have helped to define the horizon of these beds. Only one species, *Bathyrus Nero* (Billings) has been identified, which also occurs in the Beekmantown limestone of Newfoundland. The other trilobite remains, though poorly preserved, leave a Cambrian facies characteristic of North America.

In connection with this fauna certain features have been observed which throw some light on the absence of calcareous organisms from thick zones of the Durness dolomite and limestone. In my detailed description of the palæontology of the Cambrian rocks of the north-west Highlands in the Geological Survey Memoir I stated that "in most cases the septa and walls of chambered shells have been wholly or in part dissolved away, so as to leave only the more massive structures of the siphuncles, and worm castings are often found within the chambers where the septa have been preserved. These features seem to indicate that the accumulation of the calcareous mud in which the fossils were embedded was so slow that there was time for the solution of part of an organism before the whole of it was covered up."[5] There is good reason to believe that many organisms wholly disappeared by this process, so that it is reasonable to conclude that the fossils obtained from the Durness dolomites cannot be regarded as furnishing a complete life-history of the forms that originally existed in that sequence of deposits. Attention has already been directed to the fact that beneath the two subdivisions now under consideration there are groups of dolomite and limestone which so far have yielded no organic remains beyond worm castings. And even in the important Croisaphuill group, with its fossiliferous zones, there are thick groups of dolomite which have furnished no calcareous organic remains. Obviously the palæontological record in this instance is glaringly incomplete, for we have no reason to suppose that the life of the time flourished in some of the calcareous zones and not in others.

The highest subdivision of the Durness limestone, measuring about 150 feet in thickness (Durine group), has yielded two species of *Hormotoma*—viz. *H. gracilis* and *H. gracillima*—both of which occur in the two underlying groups. *H. gracilis* occurs in the Beekmantown, the Chazy, and the Trenton limestones of America.

Before assigning any stratigraphical horizons to the fauna of the Durness dolomites, it is desirable, owing to the American facies of the fossils, to recapitulate the evidence bearing upon the life of Cambrian time in North America. But the Cambrian life-history of Scotland would be incomplete without a brief reference to the recent discovery of fossils along the eastern border of the Highlands.

In 1911 Dr. Campbell announced in *The Geological Magazine* that fossils had been found in the Highland border series north of Stonehaven, and, during this year, Dr. Jehu made a similar discovery in rocks belonging to this series near Aberfoyle. Papers on these subjects will be communicated to this section. For my present purpose it will be sufficient to indicate the nature of the fossils and the lithological characters of the rocks containing them.

The Highland border series north of Stonehaven and near Aberfoyle includes sheared igneous rocks, both lavaform and intrusive, with black shales, cherts, and jaspers. North of Stonehaven the fossils occur in thin, dark, flinty pyritous shale, while at Aberfoyle they have been found in shaly films at the edge of the chert bands. Several years ago radiolaria were detected in the cherts between Aberfoyle and Loch Lomond. From time to time these Highland border rocks have been carefully searched for fossils, but until recently with little success, owing to the intense movement to which they have been subjected, resulting in marked flaser structure in all except the most resistant bands.

The fossils consist chiefly of horny, hingeless brachiopods, phyllocarid crustacea, worm-tubes, and the jaws and chetæ of annelids. The genera of brachiopods comprise *Lingulella*, *Obolus*, *Obolella*, *Acrotreta*, and *Linarssonia*. The association of these brachiopods with phyllocarid crustaceans resembling *Hymenocaris* and *Lingulocaris* is suggestive of an Upper Cambrian horizon—an inference which is supported by the absence of graptolites.

In the published Geological Survey maps these Highland border rocks are queried as of Lower Silurian age. This correlation was based partly on their resemblance to the Arenig volcanic rocks and radiolarian cherts of the Southern Uplands, and partly because, as shown by Mr. Barrow, they are overlain by an unconformable group of sediments, termed by him the Margie series. The cherts, the green schists, and the Margie series have shared in a common system of folding, and are unconformably surmounted by Downtonian strata near Stonehaven. Though the original correlation may not be strictly correct, it is probable, in my opinion, that representatives of both the Arenig and Upper Cambrian formations may occur in the Highland border series, and, further, that Upper Cambrian strata may yet be found in the Girvan area, as originally suggested by Professor Lapworth in correspondence with Dr. Horne.

The Cambrian Fauna of North America.

The classification of the Cambrian fauna found in North America is based on the researches of a band of distinguished palæontologists, comprising among the older investigators Billings, Hall, and Whitfield, and among modern workers Walcott, Ulrich, Schuchert, Brainerd, Seely, Ruedemann, Matthew, Clarke, and Grabau. Prominent among these investigators stands Dr. Walcott, alike for his original and exhaustive contributions to this branch of inquiry and for his complete mastery of the sequence and distribution of life in Cambrian time in North America. Indeed, geologists all over the world owe him a deep debt of gratitude for the services which he has rendered to Cambrian palæontology.

Throughout the greater part of Cambrian time there existed in North America two distinct life provinces. The eastern one ran along the Atlantic coast from the north of Newfoundland to a point south of New York, extending only a short distance inland, with a faunal facies resembling that of north-west Europe, exclusive of the north-west Highlands of Scotland. The western province lay to the north-west of that just described, and ranged from northern Newfoundland, south-westwards to Central North America and the Pacific Ocean. On the east side of the Rocky Mountains it swept northwards to British Columbia, perhaps as far as the Arctic Ocean. The remarkable feature of the life of the western province is its essentially American facies.

Geologists are familiar with the triple classification of the Cambrian system by means of the trilobites in North America, as in Europe. The Lower Cambrian division represents the *Olenellus* epoch of Walcott, characterised by some form of Olenellid, or, to use the name now given to the family by that investigator, the *Mesonacidae*. The western life-province contains the true *Olenellus* of which *O. Thompsoni* is the type. The strata yielding this fauna extend over such a wide area of North America that within this same province we find a western and an eastern facies. The western facies is found in Nevada and California, where *Olenellus* is represented by such specific forms as *O. Gilberti* and *O. Freemonti*. But it is noteworthy that these forms occur near the top of the Lower Cambrian series, and are soon followed by *Zacanthoides* and *Crepicephalus*, trilobites of Middle Cambrian affinities. Towards the lower part of the sequence of deposits, which there consist mainly of limestone, and extend downwards for a distance of more than 4000 feet beneath the beds containing the true *Olenellus*, Walcott found specimens of *Holmia Rowei* and *Nevadia Weeksi*. The latter form is regarded by him as the most primitive of all the *Mesonacidae* yet known. Near the base the limestones have yielded the primitive corals, *Archaeocyathus* and *Ethmophyllum*; and the brachiopods *Mickwitzia* and *Trematobolus*. The other forms found on this horizon belong to the following genera: (trilobites) *Protypus* and *Microdiscus* (brachiopods) *Kutorgina*, *Swantonia*, *Nisusia*, *Billingsella*, and (tubicolar annelids) *Hyolithellus* and *Salterella*. The eastern facies of the western life-province is best known from the region of Georgia, in Vermont. It is the home of the type species of *Olenellus* (*O. Thompsoni*). It is associated with *Mesonacis vermontana*, which has now given the name to the whole family, with *Elliptocephalus asaphoides*, one of the earliest known trilobites of the family, and with other forms such as *Bathynotus*, *Holopygia*, *Protypus*, and *Microdiscus*. The tubicolar worms are represented by *Hyolithellus* and *Salterella*, the brachiopods by *Nisusia*, *Swantonia*, *Kutorgina cingulata*, and *Paterina labradorica*. There can be no doubt that the assemblage of organic remains found in this Georgian terrane is merely the counterpart of that found in the *Olenellus* zone of the north-west Highlands.

Proceeding now to the eastern life-province, we find that the Lower Cambrian rocks are characterised by the trilobite genus *Callavia*, belonging to the family of the *Mesonacidæ*, and bearing a close resemblance both to *Holmia* and *Nevadia*. In southern Newfoundland two species of *Callavia* occur, of which *C. Bröggeri* is the type. It is accompanied by *Microdiscus*, *Hyolithellus*, *Paterina labradorica*, and *Helenia bella*. In New Brunswick the *Protolenus* fauna, with *Protolenus* as the characteristic trilobite, probably represents the upper part of the *Olenellus* zone. In this connection the recent discovery of the *Protolenus* fauna by Mr. Cobbold, in Shropshire, in strata associated with *Callavia*, and overlain by beds yielding *Paradoxides*, is of special importance, as it shows the close relation between the Lower Cambrian fauna of Wales and that of the Atlantic or eastern province of North America.[6]

The Middle Cambrian division of the western life-province is characterised chiefly by the trilobite genus *Olenoides*; indeed, the western part of it is the home of *Olenoides* and the large-tailed trilobites. The characteristic genera of this group to be found in that region are *Kootenia*, *Zacanthoides*, *Bathyuriscus*, *Asaphiscus*, *Neolenus*, *Dorypygella*, *Dorypyge*, *Damesella*, and *Ogygopsis*.

In this region the Middle Cambrian limestones and shales occurring on Mount Stephen, in British Columbia, have yielded a magnificent series of trilobites, eurypterids, limuloids, crustacea ranging from congeners of the brine shrimps to phyllocarid nebalids, annelids belonging to most of the still extant families, holothurians, medusae, and other organic remains. For the most part many of these forms are so fragile that only their tracks remain as indications of their existence in palæozoic deposits. Not till we reach the Solenhofen slates in Jurassic time do we find similar favourable conditions for the entombment and preservation of their highly modified successors. The remarkable evidence bearing on the evolution of groups of organisms furnished by this assemblage of fossils from Mount Stephen has been admirably described and illustrated by Walcott in his series of papers published in the Smithsonian Miscellaneous Collections.

In the New Brunswick portion of the eastern or Atlantic life-province the strata yielding *Paradoxides* follow those bearing the *Protolenus* fauna. Six species of Paradoxides have been obtained from this horizon, including *P. davidis*, together with the following genera: *Agnostus*, *Agraulos*, *Liostracus*, *Conocoryphe*, and *Ctenicephalus*. Schuchert points out that this fauna is "closely allied to the *Paradoxides* faunas of Wales and Sweden, but less so with that of Bohemia."[7]

In southern Newfoundland Walcott showed that the base of the Middle Cambrian division is marked in Manuel's Brook by a conglomerate containing fossils of the lower or Georgian terrane, thus indicating elevation and erosion of the Lower Cambrian rocks. Higher up the strata yielded *Paradoxides davidis* and *P. bennetti*.

Important evidence pointing to the conclusion that the *Paradoxides* fauna of the eastern or Atlantic province encroached to some extent on the eastern part of the western life-province has been obtained by Walcott at St. Albans, Vermont. But the suggestion has been made by Schuchert that their present position is there due to north-westerly thrusting.[8]

6 Quart. Jour. Geol. Soc., vol. lxvii., p. 296. 1911.
7 Bull. Geol. Soc. of Amer., vol. xx. (1910), p. 522.
8 *Ibid.*

It should be borne in mind that in Middle Cambrian time the eastern and western parts of the western life-province were evidently separated from each other by a land barrier, owing to crustal movement, which was probably connected with the elevation of the Lower Cambrian rocks in the region where they were subjected to erosion.

In the upper division of the Cambrian system in North America there is a marked change in the fauna. Its characteristic features are thus clearly summarised by Schuchert: "In a general way it may be said that the Ozarkic period of Ulrich (Upper Cambrian) begins with the trilobite genus *Dikelocephalus* and the first distinct molluscan fauna. . . . The trilobites and inarticulate brachiopods (greatly reduced in species) are still Cambrian in aspect, while the new faunal feature consists in a rapid evolution, in form and size, of the coiled gasteropods, and of both straight and coiled cephalopods. The latter are distinguished from those of subsequent periods by the exceedingly close arrangement of the septa."[9]

The distinctive trilobite genus of the Upper Cambrian strata of the western life-province is *Dikelocephalus*, where it is associated with an American facies of fossils. The eastern or Atlantic province is characterised by Olenids, though *Dikelocephalus* also occurs, and by typical European forms. In Minnesota and Wisconsin, where the strata consist of sandstones, dolomites, and shales, two species of *Dikelocephalus* have been obtained, together with other genera of trilobites such as *Agnostus* and *Illaenurus;* the limuloid *Aglaspis*; and the gasteropods *Holopea*, *Ophileta*, and *Raphistoma*.

In certain areas this period is characterised by a great succession of calcareous deposits, comprising parts of the Shenandoah limestone and Kittatinny dolomite in New Jersey, portions of the Knox dolomite in Tennessee, and of the dolomite and limestone in Oklahoma. In some of these localities, at least, the lower portions of this calcareous series are grouped with the Upper Cambrian sediments, while the upper parts are classed with Lower Silurian or Ordovician strata. The researches of American palæontologists have shown that in certain areas there is a mixed Cambrian and Ordovician fauna in some of the beds, as in the Tremadoc rocks of Wales. This commingling of faunas is exemplified in the case of the Beekmantown limestone, which is grouped with the Ordovician (Lower Silurian) rocks by most American geologists. Ulrich and Schuchert, on the other hand, regard it as a formation (the Canadic) distinct from the overlying Ordovician system.

The type areas of the Beekmantown limestone are Lake Champlain, the Mingan Islands, and Newfoundland, where the strata consist mainly of a succession of limestones and dolomites more than 1000 feet thick. The fossils are chiefly molluscan, comprising lamellibranchs, gasteropods, and cephalopods. The lamellibranchs are represented, among others, by the genera *Euchasma* and *Eopteria*; the gasteropods by *Ophileta, Maclurea, Euomphalus, Holopea, Hormotoma, Ectomaria, Murchisonia, Lophospira, Euconia, Raphistoma, Helicotoma*; the cephalopods by *Orthoceras, Cyrtoceras, Gomphoceras, Piloceras, Trocholites*. Of the foregoing genera many of the species are common to this region and the north-west Highlands of Scotland.

The trilobites associated with this fauna comprise the genera *Dikelocephalus, Bathyrus, Asaphus, Harpes*, and *Nileus*.

In northern Newfoundland, in zones F to N of Billings, this fauna, with localised species, is found in great development in limestones and dolomites resembling those of Durness. Its upper limit is there clearly defined, for the limestones and dolomites are overlain by dark shales containing graptolites of undoubted Arenig age.

A careful comparison of the faunas of the Durness and Beekmantown limestones shows that the assemblage of fossils in the Balnakeil and Croisaphuill groups of Durness is practically identical with that in the zones F to N of Billings, as developed in Newfoundland. These groups must therefore be older than the Arenig rocks of Wales, and must represent at least the Welsh Tremadoc strata, if not part of the Lingula Flags, both of which, according to the English classification, are grouped with the Cambrian system.

But even in the purely European province of North America, in New Brunswick, where the Beekmantown calcareous fauna is entirely absent, and where the faunal sequence and type of sedimentation are almost identical with those of North Wales, the basal Ordovician or Lower Silurian rocks of American geologists include the *Peltura scarabaeoides* and the *Parabolina spinulosa* zones, which, in Wales, are classed with the Lingula Flags. It is obvious, therefore, that the boundary-line between the Cambrian and Ordovician (Lower Silurian) systems is not drawn at the same stratigraphical horizon by American and British geologists. In fixing the age of the Durness dolomites and limestones the English classification has been adopted.

The palæontological evidence now adduced regarding the relation of the Cambrian fauna of the north-west Highlands to that of North America leads to the following conclusions:—

1. The Lower Cambrian fauna of the north-west Highlands, distinguished by the genus *Olenellus* and its associates, is almost identical in character with that of the Georgian terrane of the western life-province of North America, and essentially different from the Lower Cambrian fauna of the rest of Europe.

2. No forms characteristic of the Middle Cambrian division, either of Europe or North America, have as yet been found in the north-west Highlands; but this division may be represented by the unfossiliferous dolomites and limestones of the Ghrudhaidh, Eilean Dubh, and the lower Sail Mhor groups.

3. The fossiliferous bands of the Sail Mhor group may be the equivalents of the lower part of the Upper Cambrian formation.

4. The Balnakeil and Croisaphuill groups of the Durness dolomites and limestones contain a typical development of the molluscan fauna of the Beekmantown limestone, belonging to the western life-province of North America. As the Beekmantown limestone is succeeded by shales, with Arenig graptolites, it follows, in accordance with British classification, that these groups must be of Upper Cambrian age.

5. The highest subdivision of the Durness limestone (Durine) has not yielded fossils of zonal value, and the members of this group are not overlain in normal sequence by graptolite-bearing shale or other sediments.

Cambrian Palaeogeography between North America and North-West Europe.

In attempting to restore in outline the distribution of land and sea in Cambrian time between North America and north-west Europe reference must be made to various investigators whose researches in palaeogeography are more or less familiar to geologists. Among these may be mentioned Suess, Dana, De Lapparent, Frech, Walcott, Ulrich, Schuchert, Bailey Willis, Grabau, Hull, and Jukes Browne. The

[9] *Op. cit.*, p. 524.

views now presented seem to me to be reasonable inferences from the palæontological evidence set forth in this address.

In the north-west Highlands there is still a remnant of the old land surface upon which the Torridonian sediments were laid down. There is conclusive evidence that the pre-Torridonian land was one of high relief. As the Torridonian sediments form part of a continental deposit it may be inferred that the Archæan rocks had a great extension in a north-westerly direction. The increasing coarseness of the deposits towards the north-west suggests that the land may have become more elevated in that direction. At any rate, the pile of Torridonian sediments points to a subsidence of the region towards the south-east, and probably to a correlative movement of elevation towards the north-west.

The sparagmite of Scandinavia is an arkose resembling the dominant type of the Torridon sandstone; is of the same general age, and has evidently been derived from similar sources in the Scandinavian shield. In eastern North America coarse sedimentary deposits form part of the newer Algonkian rocks, which are still to be found rising from underneath the Cambrian strata in the region of the great lakes. These materials were obtained from the great Canadian shield, which must have formed a large continental area during their deposition.

It is reasonable to infer that these isolated relics of old land surfaces were united in pre-Torridonian time, thus forming a continuous belt from Scandinavia to North America. During the period which elapsed between the deposition of the Torridon sandstone and the basement members of the Cambrian system a geosyncline was established which gave rise to a submarine trough, trending in an east-north-east and west-south-west direction, both in the British and North American areas. In the latter region it extends from Newfoundland to Alabama, its south-eastern limit being defined by the old land surface of Appalachia. The extension of this Appalachian land area in a north-east direction beyond the limits of Nova Scotia and Newfoundland was postulated by Dana and other American writers. This geosyncline remained a line of weakness throughout palæozoic time, both in Britain and North America, which resulted in the Caledonian system of folding in Britain, and in the Taconic, Appalachian, and Pennsylvanian systems in North America. Hence it is manifest that the original shore-lines of this trough are now much nearer each other than they were in Cambrian time.

The Cambrian rocks of the north-west Highlands were laid down along the north-west side of this trough during a period of subsidence, for the great succession of Durness dolomite and limestone, with little or no terrigenous material, is superimposed on the coarser sediments of that formation. On the other hand, the Cambrian strata of Wales seem to have been deposited along the southern limit of this marine depression. The Archæan rocks that now constitute the central plateau of France may have formed part of its southern boundary. The extension of this land area towards the north-east may have given rise to the barrier that separated the Baltic life-province from that of Bohemia, Sardinia, and Spain. In my opinion this southern land area in Western Europe was continuous across the Atlantic with Appalachia. For the life sequence found in the Cambrian rocks of New Brunswick is practically identical with that of Wales and the Baltic provinces, thus showing that there must have been continuous intercourse between these areas. Along this shore-line the migration of forms seems to have been from Europe towards America. On the other hand, along the northern shore the tide of migration seems to have advanced from America towards the north-west Highlands. The question naturally arises, what cause prevented the migration of the forms from one shore of this trough to the other? American geologists are of opinion that this is probably due to the existence of land barriers; but, in my opinion, it can be more satisfactorily accounted for by clear and open sea, aided by currents.

The south-western extremity of the American trough in Lower Cambrian time opened out into the Mississippian sea, which was connected with the Pacific Ocean, and stretched northwards towards the Arctic regions. Reference has already been made to Walcott's discovery in Nevada of the primitive trilobite *Nevadia Weeksi*, from which he derives both branches of the *Mesonacidae*, one branch linking *Nevadia*, through *Callavia*, *Holmia*, and *Wanneria*, with *Paradoxides*, the other connecting *Nevadia* with *Olenellus*, through *Mesonacis*, *Elliptocephalus* and *Paedumias*.

In Nevada the genus *Holmia*, as already shown, is associated with the primitive type *Nevadia*. *Wanneria* is found in Nevada, in Alabama, and in Pennsylvania, thus showing that this genus is common to the Missisippian sea and to the long trough north-east of Alabama. *Mesonacis* has been obtained in the submarine depression at Lake Champlain, at Bonne Bay, Newfoundand, and at the north side of the Straits of Belle Isle. *Elliptocephalus* has been recorded from the New York State. *Olenellus* has been found in Nevada, in Vermont, and in the north-west Highlands. All the genera now referred to may have migrated along the north-western shore of this trough.

As regards the distribution of the genus *Callavia*, this form has been met with in Maine, in Newfoundland, and in derived pebbles in a conglomerate in Quebec. Two species have been recorded in Shropshire. These forms probably moved along the southern shore of this sea from Wales to North America.

Reference has already been made to the fact that, in the interval between Lower and Middle Cambrian time, in certain areas in North America the Lower Cambrian rocks were locally elevated and subjected to erosion. During this interval the southern end of the trough seems to have had no connection with the Mississippian sea, for in Middle Cambrian time, as already indicated, the *Paradoxides* fauna is found in the trough on the east side of North America, whereas on the west side it is represented by the *Olenoides* fauna.

In Upper Cambrian time a great transgression of the sea towards the north supervened. The *Dikelocephalus* fauna is found on both sides of America, thus showing that the previous land barrier had been submerged. While this genus occurs in Wales and the Baltic provinces, it has not as yet been recorded from the north-west Highlands, but I quite expect that this discovery may be made at some future time.

Along the northern side of the American trough clear water conditions prevailed, owing to the northward recession of the shore-line, which led to the accumulation of a great succession of calcareous deposits, including the Beekmantown limestone, to which reference has already been made. Schuchert, as already stated, has pointed out that, in the lower part of the Ozarkic (Upper Cambrian) system, in Minnesota and Wisconsin, the gasteropod genera *Hoopea*, *Ophileta*, and *Raphistoma* are associated with two species of *Dikelocephalus*. This molluscan fauna is evidently the precursor of that of the Beekmantown limestone. It was probably from this central region of America that the calcareous fauna of Beekmantown migrated to the submarine trough in the typical Champlain region, and through Newfoundland to the north-west Highlands of Scotland.

The section at St. John, New Brunswick, where the Baltic and Welsh types of the *Olenus* fauna occurs, shows that the southern shore line of the trough must then have occupied much the same relative position as in Lower and Middle Cambrian time. In the same region the strata containing this fauna, with *Peltura scarabaeoides* and *Dictyonema flabelliforme*, are overlain by dark shales with Arenig graptolites. These graptolite-bearing terrigenous deposits eventually extended across the trough northwards, until, in Newfoundland, they came to rest on the Beekmantown limestones.

In the Lake Champlain region, in the Chazy limestone, which there immediately succeeds the Beekmantown limestone without the intervention of the Arenig graptolite shale, there is a survival of the Beekmantown molluscan fauna with only such slight modifications as to indicate genetic descent. In the same trough the descendants of this fauna are to be found in the Trenton limestone.

In this connection it is worthy of note that the molluscan fauna and the corals of the Stinchar and Craighead limestones of Upper Llandeilo age in the Girvan district of the Southern Uplands have an American facies, as first suggested by Nicholson. The appearance of American types in these limestones may be accounted for in the following manner: attention has already been directed to the divergent types of sedimentation presented by the Upper Cambrian strata of the north-west Highlands, and of the south-east Highlands, at Stonehaven and Aberfoyle. In the former case there is a continuous sequence of dolomites and limestones, while in the latter we find a group, comprising radiolarian cherts and black shales, associated with pillowy spilitic lavas and intrusive igneous rocks, indicating conditions of deposition at or near the limit of sedimentation. But, notwithstanding the different types of sedimentation and the divergent faunas in the two areas, I believe that during the Upper Cambrian period, and probably for some time thereafter, continuous sea extended from the north-west Highlands to beyond the eastern Highland border. The Upper Cambrian terrigenous sediments which we now find at Stonehaven and Aberfoyle must have been derived from land to the south. In Llandeilo time the Arenig and Lower Llandeilo rocks of the Girvan area were elevated and subjected to extensive denudation. On this highly eroded platform, as first proved by Prof. Lapworth, coarse conglomerates, composed of the underlying materials, were laid down in association with the Stinchar and Craighead limestones. In my opinion the appearance of the American forms in these limestones is connected with the movement that produced this unconformability in the Girvan area. This local elevation was probably associated in some form with the great crustal movements that culminated in the overthrust of the north-west Highlands and caused the intense folding and flaser structure of the rocks along the Highland border. By these movements shore-lines may have been established between the north side of the old Palæozoic sea and the Girvan area, which permitted the southern migration of the American forms.

Note.—Since writing the above my attention has been directed to the recent work of Bassler on "The Early Palæozoic Bryozoa of the Baltic Provinces," published by the Smithsonian Institution in 1911. In his introduction the author has shown that the Ordovician (Lower Silurian) and Gothlandian (Upper Silurian) rocks of the Baltic provinces contain a larger percentage of bryozoan species, in common with the Black River, Trenton, and Niagara limestones of the same relative age in eastern North America. This fact suggests that during Lower and Upper Silurian time the old lines of migration were still open, and that the Bryozoa, being of clear-water habit, were able to cross the old trough from side to side.

NOTES.

FROM a Press cutting just received from Sydney we learn that Mr. Fisher, Prime Minister, Australia, referred to the forthcoming visit of the British Association in 1914 in his Budget speech on August 1. He said:—"We have been advised that about half as many more members of that association are likely to visit the Commonwealth than was anticipated when our invitation was accepted. This will entail an increase in the amount of money which I propose to give towards their expenses; and, speaking for this Parliament and country, I say that no greater compliment could be paid to Australia than the fact that our visitors are to be increased in number. It is usual a year or eighteen months before the visit is made to send a representative man of the same class as themselves to get into communication with them. We propose to incur that expenditure pending the expenditure of a larger amount to cover their expenses."

THE Chancellor of the Royal Prussian Ordre pour le Mérite has, through the German Embassy, informed Sir William Turner, K.C.B., F.R.S., vice-chancellor and principal of the University of Edinburgh, that the German Emperor has appointed him to be knight of the Order in the department of science. The number of those on whom this Order is conferred is strictly limited, and since 1885, when Lord Lister was appointed, Sir John Murray, Sir Joseph D. Hooker, Lord Avebury, Lord Rayleigh, the Right Hon. James Bryce, Sir David Gill, and Sir Wm. Ramsay have been its recipients. The death of Lord Lister having caused a vacancy, his Majesty the Emperor has been pleased to confer the Order on Sir Wm. Turner, in recognition of the contributions which he has made to anatomical science.

THE fourteenth meeting of the Australasian Association for the Advancement of Science will be held in Melbourne in January, 1913.

THE Royal Aero Club has decided to award its gold medal to Mr. S. F. Cody in recognition of his victory in the recent War Office aeroplane trials.

MR. T. H. MOTTRAM has been appointed to succeed the late Mr. Pickering as divisional inspector of mines in charge of the Yorkshire and North Midlands District. Mr. J. R. Wilson, of Leeds, will fill the position vacated by Mr. Mottram.

WE regret to see the announcement of the death, on September 4, of Dr. Stanley Dunkerley, formerly professor of engineering, Manchester University, and the Royal Naval College, Greenwich, and the author of a standard work on "Hydraulics."

THE departmental committee appointed by the Home Office to consider the best methods of testing miners' safety lamps reports that the official tests for flame safety lamps should be mechanical and photometric, and should be made by means of an explosive mixture. For the mechanical test they suggest that a lamp should be dropped from a height of 6 ft. on a wooden floor.

THE annual general meeting of the Society of Chemical Industry was held in New York last week under the presidency of Dr. R. Messel, F.R.S. The society's medal, awarded once in every two years for conspicuous service rendered to applied chemistry by research, discovery, invention, or improvements in processes, has this year been awarded to Sir William Crookes, O.M., F.R.S., for his discoveries in physical chemistry and the rare metals. It has been decided to hold the next annual meeting of the society in Liverpool.

ACCORDING to *The Lancet*, the following sums have been bequeathed by Madame Jonglart for the furtherance of science in France:—50,000 francs to the Collège de France; 95,000 francs to the faculty of science of the Sorbonne, of which amount 55,000 francs is to be devoted to the zoological laboratory; 95,000 francs to the museum; 50,000 francs to the Faculty of Medicine; 70,000 francs to the School of Advanced Studies; 150,000 francs to be divided between the Geographical and Anthropological Societies and the Association for the Advancement of Science, and 139,000 francs to various scientific and charitable institutions.

THE Board of Agriculture and Fisheries desires to direct attention to the fact that the employment, from time to time, in the newspaper Press and elsewhere, of the phrase "cattle plague" in connection with the recent outbreaks of foot-and-mouth disease in this country has given rise to considerable apprehension in Continental countries, and is calculated to be prejudicial to the interests of British stockowners. The Board wishes, therefore, specifically to state that no case of cattle plague (*Peste bovine, Rinderpest*) has recently occurred in the United Kingdom, which has been absolutely free from that disease since the year 1877, that is for more than thirty-five years past.

BY the will of Mr. A. O. Hume, C.B., an obituary notice of whom appeared in our issue of August 8, his collection of heads and horns of Asiatic and other animals is left to the trustees of the British Museum, provided that an undertaking be given by the trustees that the collection be preserved in an undivided condition. The testator confirmed a settlement dated January 10, 1907, by which he gave a sum of 10,000*l*. Two-and-a-Half per Cent. Consolidated Stock for the endowment of the South London Botanical Institute, and also the provisions of an indenture dated September 29, 1911, by which he gave his premises, 323, Norwood Road, for the purposes of the institute, and he left all his botanical books and books on ornithology and dictionaries upon trust for the institute, to encourage the study of botany (especially British botany) in the county of London south of the River Thames, and also all parts of his herbaria not already transferred to the institute. Subject to the payment of certain annuities, Mr. Hume left the residue of his property to the South London Botanical Institute.

THE council of the Institute of Chemistry is making an endeavour to raise a fund for new buildings for the institute. There can be no doubt that the institute has steadily raised the standard of education in chemical science in the British Empire, and by its means the practice of chemistry, as a profession, has become firmly established and honourably maintained for the public good. From a perusal of the papers relating to the appeal issued to the fellows and associates, it appears that owing to alterations which the London County Council propose to carry out by the widening of Southampton Row, at the rear of the present premises of the institute, 30 Bloomsbury Square, it will not be possible to effect a renewal of the present lease. The council of the institute wishes, therefore, to take this opportunity to secure more suitable and permanent headquarters. It is reckoned that with real economy, adequate provision for the work of the institute can be obtained for about 15,000*l*. The appeal has now been issued nearly three years, and the amount promised to date is about 10,000*l*. As the council will proceed to select a site and prepare plans at the close of this year, it is very desirous of being assured that the full sum of 15,000*l*. will be available, and it is hoped, therefore, to raise the 5000*l*. which is still required before the end of October. Contributions may be forwarded to the president at 30 Bloomsbury Square, London, W.C., or may be sent direct to the account of the Institute of Chemistry (Buildings Fund), with the London County and Westminster Bank, Ltd., 214 High Holborn, London, W.C.

IN the September issue of *Man* Mr. A. R. Brown has compiled from his own personal knowledge and information gathered from some published literature a useful map of Western Australia, showing the distribution of several of the native tribes. The map also marks the division between the tribes which practise circumcision and subincision on the east, and those on the west among whom these rites are unknown.

MAJOR A. J. N. TREMEARNE publishes in the September issue of *Man* selections from a diary written in the years 1843–48 by his great-uncle, the late Rev. John Martin, a Wesleyan missionary to the West Coast of Africa, which possess a special interest because they supply a record of a remarkable type of fetish practices before anthropologists had begun to interest themselves in such matters. The natives in his day, he says, had some confused ideas about metempsychosis, which to a reader of our time suggests totemism. Thus, when a child was carried off by a wild beast, it was believed that some deceased member of the family, annoyed at the neglect of his relatives, had entered the animal and caused the attack, and for this reason they would not kill such animals. The living sacred snake, Dagwe or Dagbi, used to get loose, enter houses and kill poultry until he was finally captured by his priest. The insolent and outrageous conduct of the fetish priests and priestesses during their processions through the towns is specially noteworthy.

THE Field Museum established at Chicago in 1893 has issued a well-illustrated catalogue of a valuable collection of antiquities from Boscoreale, in South

Italy, which has been recently presented. It is the work of Mr. De Cou, who was killed by Arabs while conducting excavations at Cyrene in north Africa in March, 1911. Mr. Tarbell, professor of classical archæology at Chicago, has now edited the work of his friend, with some additions. Nearly the whole collection comes from a villa at the foot of Mount Vesuvius which shared the fate of Pompeii in the eruption of 79 A.D. It contains some curious frescoes and a number of bronze articles, of which the most remarkable is a fine bronze table, the legs shaped in the form of a lion's feet. This was found in a room with the skeletons of two men and a woman, who had apparently perished in the attempt to remove to safety the more valuable property of the house. Two bronze bathing-tubs, which have counterparts in the Naples Museum from Pompeii, are interesting on account of their comparative rarity.

THE movement in favour of the protection and conservation of scenery, antiquities, and the native flora and fauna has made considerable progress in Germany and Switzerland, as well as in other parts of the Continent, during the last few years. A recent number of the *Naturwissenschaftliche Wochenschrift* (No. 27, 1912) is occupied by a series of four articles dealing with the scenic, geological, botanical, and zoological aspects of the question, and contributed by Profs. W. Bock, F. Wahnschaffe, P. Graebner, and M. Braess respectively. In each case the writer describes, with numerous concrete examples, the melancholy results of various acts of vandalism and destruction—the spoiling of otherwise beautiful scenery by huge advertisement hoardings, the erection of painfully conspicuous buildings on hillsides and on the shores of lakes, the conversion of fine lakes into unsightly marshes owing to the construction of waterworks in the neighbourhood, the building over of interesting or even unique geological outcrops, the rooting-up of rare plants, the threatened extinction of rare animals, &c. Righteous indignation is expressed at the wanton or careless mischief done by those responsible for such acts; but it is gratifying to note that vigorous steps are being taken by the State and by private organisations to protect beautiful and interesting natural objects, animate and inanimate, from continued vandalism, and to undo wherever possible the harm already done.

AN article in *The Scientific American* of August 10 discusses the proposal of Prof. Etchegoyen to flood a portion of the Sahara with sea-water by means of a channel from the Mediterranean and thereby to create an inland sea, which, as he claims, would favourably affect the climate, make for conditions of fertility, and for possibilities of colonisation, and provide a channel of communication. Quite apart from the possibility or desirability of the scheme itself, a considerable number of crimes seem to have been committed in the name of physical geography by opponents of the scheme, who have foreseen that the new subtropical area thus created would so far affect the climate of more northern lands as to bring the arctic belt southward to Denmark, and they even seriously discuss the probability of the upsetting of the earth's equilibrium by the displacement of so great a body of sea-water. The writer of the article is at pains to calm these fears, shows that the total area of the Sahara capable of flooding from the sea is no large proportion of the whole, and appears to welcome the idea as much for its own romantic sake as for any benefits which it might confer. He is not concerned to remark upon the ultimate condition of a practically stagnant pond of sea-water, with only a long narrow channel connecting it with the general marine circulation.

THE second volume of Dr. G. Linck's "Fortschritte der Mineralogie, Kristallographie und Petrographie" is now issued (Jena: G. Fischer, 1912. Price 10.50 marks). This annual of the German Mineralogical Society contains original memoirs, and also useful reviews of current work, in which a number of papers are brought together and compared. J. H. L. Vogt (p. 24) summarises his views on the production of ore-deposits by magmatic differentiation; A. Ritzel (p. 62) treats of plasticity in crystals; and both these papers have considerable geological interest. H. Stremme (p. 87) discusses what is known as to the chemistry of kaolin, and papers follow on petrography and on meteorites. The aim of the publication, like that of the *Geologische Rundschau*, is to correlate recent work in the interests of those engaged in teaching and research. The individuality imparted by the authors to their reviews makes an annual of this type far more interesting than a collection of ordinary abstracts.

DISEASES of the respiratory and digestive organs among apes and monkeys in confinement are discussed by Mr. W. R. Blair in vol. i., No. 9, of *Zoologica*. Among other items in the report, it may be noted that orang-utans and chimpanzees in the New York Gardens were infected in 1901 by an outbreak of ulcerating dysentery due to the presence of *Balantidium coli*. The source of the infection was traced to Galapagos giant tortoises in an adjacent enclosure, the colons of which swarmed with the parasite, although the health of the reptiles was unaffected.

DR. ANNANDALE has sent us a copy of the report of a lecture on recent advances in our knowledge of the fresh-water fauna of India, published in vol. viii. of the Journal and Proceedings of the Asiatic Society of Bengal. During the last five years Dr. Annandale has devoted great attention to this fauna, with special regard to the biological relations between different groups of fresh-water organisms, seasonal changes in the life-cycles of the lower invertebrates, and the effect of environment on sponges and other plastic groups. The geographical distribution of the fresh-water fauna as a whole is reserved for future investigation.

SELF-FERTILISATION in the fresh-water snail *Limnaea columella* forms the subject of an article by Mr. H. S. Colton in the May issue of the Proceedings of the Philadelphia Academy. As the result of investigation, it appears that the eggs, when isolated, are self-fertilised, and that the generation-period lasts only two or three months. When more than one species of pond-snail inhabit the same area, hybridisation may occur. *L. columella* seems to present some of the factors necessary for the investigation of a "pure-line" development, that is to say, a line formed by the descendants of a single "homozygotic" organism propagating by self-fertilisation.

THE annual report of the Marine Biological Association of the West of Scotland for 1911 shows that the marine station at Millport is being more largely used by competent investigators, and the amount of first-class scientific work which is being carried out is highly creditable to those who have charge of its organisation. The report contains summaries of the work of Dr. J. F. Gemmill on the anatomy and development of starfishes, of Prof. MacBride's researches on Echinus and Echinocardium and their hybrids, and of Dr. Valentin Dogiel's studies on the development of Pycnogonida. The most unsatisfactory feature of the report is the statement that the steam yacht *Mermaid* has been laid up from want of funds to run her. The use of an adequate steamboat for collecting work is a matter of vital importance to every marine station, and it is to be hoped that in such a wealthy district as that in which the station is situated this defect may soon be remedied by local enterprise.

To the *Naturwissenschaftliche Wochenschrift* of August 18, 1912, Dr. O. Antonius contributes an article on the tarpan of eastern Europe and its relationship to the wild Mongolian horse. The wild horses seen by Pallas in some part of Mongolia are considered to represent a race of the latter; the name *Equus ferus*, Pallas (shown by Mr. Lydekker to be invalid), being adopted for the Mongolian horse, which Hamilton Smith identified years ago as the true tarpan, although this is not referred to by the author. On the other hand, the Russian tarpans obtained in 1853, 1862, and 1866, and described by Schatilow and Radde, are regarded as a truly wild and distinct species, for which the name *E. gmelini* is proposed. The third of these, which was gelded soon after its capture, was acquired in 1884 by the Zoological Gardens at Moscow, where it died a few years later, and was the last representative of its kind. It may be added that these Russian tarpans are generally regarded as half-breds, to which category belongs the animal figured by the author as Przewalski's horse of Mongolia. The domesticated ponies of Bosnia are considered to represent the tarpan type.

THE fifth volume of Notes from the Royal Botanic Garden, Edinburgh, has just been completed by the issue of part xxv., containing an index to the volume and various items of information concerning the garden, together with a somewhat bald key-plan—plenty of blank space is left which might with advantage be utilised in indicating the outdoor plants grown in the garden, as is done in the case of Kew. The most important contents of the present volume are the articles dealing with the plants, including many new species, collected by George Forrest in Yunnan and Eastern Tibet, and described by various distinguished systematists.

THE seismological observatory of Rocca di Papa, near Rome, is one of the oldest in Italy. That it is also one of the most efficient is shown by the summary of the records of the last twelve years recently issued by the director, Dr. G. Agamennone, and his assistant, Mr. A. Cavasino. From this it appears that the average yearly number of earthquakes recorded is 186. Of these, 44, or one-quarter of the total number, originated at distances of less than 100 km., the extinct Latial volcanoes being the seat of a considerable number; while 85 originated at distances greater than 5000 km.

THE report on rainfall registration in Mysore for the year 1910, which has recently reached us, shows that the number of official stations was then 227, in addition to which a few coffee-planters maintain private stations on their estates. Compared with the district averages for the forty years, 1870–1909, the rainfall was in excess by about 8 inches, or 22 per cent. Some heavy falls in twenty-four hours were recorded in each of the eight districts into which the province is divided, the heaviest being 10·8 inches at Nagar and 10·5 inches at Aralagode in the Shimoga district early in July.

THE first report of the Meteorological Observatory in connection with the College of Nuestra Señora de Montserrat, Cienfuegos, Cuba, has just been issued. The volume has been prepared by the Rev. Simon Sarasola, S.J., director, and contains details of the establishment of the observatory, together with notes upon the meteorological observations taken at the college from 1886, and upon cyclones and their prognostication. The position of the observatory is an important one, especially with regard to the Panama Canal, and the results obtained will probably prove of great interest. The instrumental equipment is excellent, including nine self-recording instruments. The tables for 1911, printed in the report, include observations made every two hours, from 6 a.m. to 8 p.m., of barometer, temperature, vapour tension, relative humidity, and direction and force of wind, with cloud observations four times daily and notes on the weather. The tables are not arranged on the international system, although the international symbols are used in the weather columns. It is a matter for regret that the daily maxima and minima of temperature are not printed instead of the highest and lowest of the bi-hourly readings. The absolute extremes of temperature of each month are, however, given in one of the yearly tables.

THE Meteorological Office has commenced the issue of a series of geophysical memoirs, the first of which is by Commander Hepworth, and deals with the effect of the Labrador current on the surface temperature of the North Atlantic, and of the latter on the air temperature and pressure over the British Isles. The author shows from the records of the last eight years that abnormally low temperatures in the North Atlantic are due to the current of cold water from the coast of Labrador and not to the ice which that current brings with it. The low temperature of the water lowers the temperature of the air over these islands by cooling the winds from seawards, by influencing the paths of depressions, and by diminishing cloudiness. When the north-eastern arm of the

North Atlantic is colder than usual, the centres of depressions pass almost directly over the British Isles and produce excessive cloudiness and rain.

The Builder for August 30 has an illustrated article on the reconstruction of the campanile of St. Mark's, in Venice. Preserving the old foundations as a nucleus, a strong enclosure of Istrian stone has been constructed around them; the old foundations had a superficies of 222 square metres, and the present foundations cover 407 square metres, nearly double the surface. As the tower began to rise, a movable framework was employed; for the carrying up of the materials a Steigler elevator was used, which also lifted the bells into position. The bells weigh respectively 3625, 2556, 1087, 1366, and 1011 kilograms, and the angel 1300 kilograms. The tower itself from outside the ground to its summit weighs 8,900,000, and with its foundation included about 12,970,000 kilograms. The Loggetta of Sansovino has also been successfully restored. The loggia had been completely crushed by the campanile in its fall. All the fragments of sculpture were carefully collected before commencing the work of reconstruction; in the group of the Virgin and Child alone there were no fewer than 1600 separate pieces. The new campanile was opened on April 25 of this year.

"THEORIES OF SOLUTIONS," by Svante Arrhenius, director of the Nobel Institute of the Royal Swedish Academy of Science, Stockholm, is being published this week by Mr. Frowde for the Yale University Press. The volume constitutes the eighth of the series of Silliman Memorial Lectures at Yale.

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A COMET.—A telegram from the Kiel Centralstelle announces the discovery of a comet by Mr. Gale, of New South Wales, on September 9. The position at 7h. 24·8m. (Sydney M.T.) on that date was:—R.A. = 13h. 37m. 1s., decl. = 36° 31′ 2″ South.

THE MARKINGS OF JUPITER.—A valuable summary of the phenomena attending the various prominent markings on Jupiter is contributed by Mr. Denning to No. 452 of *The Observatory*. He first deals with the large dusky marking discovered by Major Molesworth, in the same latitude as the red spot, in February, 1901. This remarkable object, which can be seen well with a 3-in. refractor, has exhibited some extraordinary variations in length, having, for example, decreased from 115° in June, 1911, to 63° recently. It has also exerted a marked influence on the red spot, the motion of the latter being considerably accelerated at the conjunctions of the two features in 1902, 1904, 1906, 1908, and 1910. For the period 1894–1910 the rate of rotation of the red spot was 9h. 55m. 40·63s., exactly that adopted for system ii., but then a rapid acceleration set in, and for the two succeeding years the period was 9h. 55m. 37·5s. This drifting westward was at the rate of about 22,000 miles per year, but recent observations indicate that it is temporarily suspended.

OBSERVATIONS OF NOVA GEMINORUM NO. 2.—A number of observations of Nova Geminorum No. 2 are discussed in No. 4598 of the *Astronomische Nachrichten*, chiefly dealing with determinations of position and magnitude. Dr. H. E. Lau, from observations made between March 14 and May 18, finds secondary maxima on the light-curve on March 14, 23, and 31, April 18, and May 1. At first the period appeared to be about eight days and the amplitude 1·0 magnitude, but later the period lengthened and the amplitude decidedly decreased. Most of the observations indicate that the magnitude became fairly stationary about the end of May, its value being about 8·0, but Prof. Eginitis records an apparent augmentation from 8·0 on June 4 to 7·4 on June 7.

Prof. Newall states that spectroscopic observations by Messrs. Stratton and Brunt on August 13 showed the nebula line, 501$\mu\mu$, to be much the strongest line in the visible spectrum; other lines observed were at $\lambda\lambda$464 (?), 486 (Hβ), 496, 531 (?), and 575. The magnitude, difficult to estimate, was probably a little brighter than 9·0.

Prof. Strömgren records the magnitude as 7·70, on the PD system, on August 24, while, in No. 452 of *The Observatory*, Mr. Harold Thomson gives it as 7·7 on August 20, on the scale employed by the Variable Star Section of the B.A.A.

THE ORBIT OF ξ PERSEI.—The star ξ Persei is one of those interesting binaries in which the radial velocity as determined from the H and K lines of calcium differs from that determined from the other lines. Its spectrum is of the Oe 5 B class, according to Miss Cannon, and shows lines of H, He, Ca, and Fe, but the H and He lines are generally too diffuse to give trustworthy results for the velocity.

Using the H and K lines only, Mr. Cannon, of the Ottawa Observatory, has derived an orbit from his own measures and those made at the Yerkes Observatory, which he publishes in No. 3, vol. vi., of the Journal of the R.A.S., Canada. He finds the period to be 6·951 days, the range of velocity 15·7 km., and the velocity of the system 15·4 km. The diameter of the projected semi-major axis of the orbit is 751,800 km. An attempt was also made to determine the velocity from the broad lines, other than calcium, but nothing more definite can be said than that they show a much higher positive velocity than do the H and K lines.

CATALOGUE OF STELLAR PARALLAXES.—No. 24 of the Publications of the Astronomical Laboratory at Groningen contains a wealth of information concerning the parallaxes, probable intrinsic luminosities, &c., of 365 stars. The table has been made up from many sources, and relative weights are given to the different values. There are eleven stars with parallaxes greater than +0·300″, the five nearest, with their adopted parallaxes, being: α Centauri (+0·759″), Sirius (+0·376″), Piazzi, oh. 130 (+0·360″), τ Ceti (+0·334″), and Procyon (+0·324″). Ten stars have computed luminosities greater than one hundred times that of the sun, the five most luminous being: β Centauri (520), Regulus (423), Achernar (350), Capella (300), and Arcturus (230); the values in brackets are the computed luminosities, that of the sun being taken as unity.

THE ORBITS OF COMETS.—In No. 4598 of the *Astronomische Nachrichten*, Prof. Strömgren points out, in reference to a recent note by Prof. W. Pickering on the fundamental form of cometary orbits, that Prof. Pickering has misconstrued the sense of his conclusions. The final contention of Prof. Strömgren's (not Prof. Kobold's, as was inadvertently stated in our previous note on August 15) was that if the effects of Newtonian gravitation be strictly taken into consideration it is probable that all the cometary orbits yet considered would prove to be *elliptical*.

AMERICAN MINERAL STATISTICS.[1]

THE annual report of the production of minerals in the United States has been issued for 1910 by the United States Geological Survey in the form of two bulky volumes dealing with metallic and non-metallic products respectively. Most of the statistical information had been already published in the special pamphlets issued from time to time by the Geological Survey, so that the present volumes contain no new facts, although they add a great quantity of important and interesting details, whilst the study of the subject is, of course, greatly facilitated by the collection and juxtaposition of all the various items.

The total value of the mineral production is given as a little more than 2,000,000,000 dollars, an increase of 6·2 per cent. over that of 1909. This figure is quite comparable with the values of output of the United States for previous years, but is not comparable with those for other countries, because of a number of inexactitudes due to the method in which the returns are presented. As has more than once been pointed out, the grand total contains a number of reduplications, in spite of the statement in the report itself that "all unnecessary duplication has been excluded." The report directs attention to the fact that the value of the coke produced, practically 100,000,000 dollars, is excluded from the total, because "the quantity and value of the coal used in its manufacture are included in the statistics of coal production." It neglects the equally important fact that practically the whole of this coke is consumed in the production of metals, such as pig-iron, copper, and lead, and as the value of these metals is given, and not merely that of the ores from which they are extracted, the cost of the coke is really included in the value assigned to the metals. If the total value assigned to mineral products is to be correct, the value of all the fuel used for metallurgical purposes, and for burning clay products, lime, cement, &c., should be deducted from the grand total; this is by no means a trifling correction, for it would probably mean a diminution of the total by something like 10 per cent.

Care has been taken in this report to include only metals produced from domestic ores as far as possible; this brings out the very interesting fact that the recovery of metals from residues, by-products, waste materials, &c., is assuming very important dimensions. Thus in 1910 the production of zinc, here called "primary spelter," direct from domestic ores amounted to 252,479 tons, and that of zinc from imported—chiefly Mexican—ores to 16,705 tons, whilst the quantity of so-called "secondary zinc" recovered from waste and scrap materials of various kinds was no less than 68,723 tons, or about a quarter of the production of primary spelter. In the case of tin the figures are still more striking; the quantity of tin obtainable direct from ores is not stated, but appears to be of the order of some 40 tons, whilst the recovery of secondary tin from scrap of all kinds amounted to no less than 13,903 tons. It is calculated that the recovery of secondary tin throughout the world is only 27,000 tons, so that one-half of this production takes place in the United States. Seeing that the world's output of primary tin was about 115,920 tons in 1910, the recovery of tin from scrap is assuming very important dimensions.

Amongst the non-metallic minerals, coal is, of course, by far the most important, the output for 1910 exceeding 500 millions of tons, this being the first time that this figure has been attained. The mineral output shows steady and progressive development in practically all directions, and these volumes afford conclusive evidence of the prominent position that the mineral riches of the United States hold amongst the sources of national wealth. It should, however, in all fairness be added that these two fine volumes of mineral statistics are not unworthy of the flourishing industries, the progress of which they chronicle. Is it too much to hope that we may have some day in this country a record of mineral statistics that might worthily sustain comparison for accuracy and completeness with that issued by the United States Geological Survey?

H. L.

[1] "Mineral Resources of the United States, Calendar Year, 1910." Part i., Metals. Pp. 796+plate. Part ii., Non-metals. Pp. 1005+plates. Washington: Government Printing Office, 1911.)

INCOME OF AMERICAN COLLEGES OF UNIVERSITY RANK.

THE second volume of the report of the United States Commissioner of Education for the year ended June 30, 1911, has now been received from Washington. It is chiefly devoted to statistical details concerning the development and present provision of educational facilities in institutions of all the grades included in the American system of education. Especially interesting are the facts which may be gathered respecting education of university rank.

The total receipts of the universities in the United States are given as 18,934,410*l.*, derived from a variety of sources, as shown in the following table:—

Total Receipts of Universities and Colleges for the year ended June 30, 1911.

	£
Tuition and other educational fees ...	3,698,600
Room rent	381,700
Board and other non-educational fees ...	1,218,970
Productive funds	2,658,700
State or city for increase of plant	932,430
,, ,, current expenses	2,941,450
United States Government	1,175,040
Private benefactions for increase of plant ..	1,144,700
,, ,, endowment ...	2,753,970
,, ,, current expenses ...	693,950
All other sources	1,334,900
Total receipts	18,934,410

More detailed information is provided as to the benefactions given during the year under review, which exceeded four and a half millions sterling, or 4,592,620*l.* to be precise. We notice, for example, that the total is more by 845,200*l.* than was received during 1909–1910. Fifty universities and colleges each received gifts amounting to more than 20,000*l.*, and, as the following table shows, seven universities and colleges were fortunate enough to benefit to the extent of 100,000*l.* or more.

Universities and Colleges receiving 100,000l. or more in Benefactions during 1910–11.

	£
Columbia University	507,010
Harvard College, Massachusetts	349,090
University of Chicago	271,790
Yale University	226,880
New York University	185,690
Dartmouth College, New Hampshire ...	156,890
Amherst College, Massachusetts	101,950

A separate chapter in the report deals with agricultural and mechanical colleges, but the Commissioner is careful to point out that some of them are also included under universities and colleges, so that overlapping occurs. The following table shows the total income of the agricultural and mechanical colleges for the year under consideration. Grants for experiment stations, farmers' institutes, and other means for extending agricultural education are not included in the amounts shown.

Income of Agricultural and Mechanical Colleges for 1910–11.

	£
Income from State endowment	22,890
Appropriations for current expenses ...	1,004,990
Tax levy ,, ,, ...	575,820
Appropriations for increase of plant ...	558,410
Tax levy ,, ,, ...	100,440
Total State aid ...	2,262,550
From land grant of 1862	156,670
From other land grants	47,090
Additional endowment	450,000
Total Federal aid ..	653,760
From other endowment funds	149,800
Tuition and incidental fees	487,310
Other sources	562,500
Total income ...	4,115,920

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. R. G. MCKERRON has, with the approval of the King, been appointed professor of midwifery in the University of Aberdeen, in succession to Prof. W. Stephenson, who has resigned.

THE foundation stone of a new college for the training of teachers at Dundee was laid on Thursday last by Lord Camperdown. The cost of the building will be 60,000*l.*, and provision will be made for 400 students.

PROF. J. LORRAIN SMITH, F.R.S. (at present professor of pathology and pathological anatomy in the University of Manchester) has been appointed to the chair of pathology in the University of Edinburgh, in succession to Prof. W. S. Greenfield, who is retiring from the position.

THE sum of 5000*l.* has been given by the Lord Lieutenant of Berkshire, Mr. J. H. Benyon, towards the new buildings of University College, Reading. The donor has apportioned his gift between the new hall, the Letters Buildings, the Agricultural Buildings, and the new St. Patrick's Hall.

THE Board of Agriculture has issued a scheme under which the University College of North Wales, Bangor, will undertake advisory work in forestry for the whole of Wales. Prof. F. Story, professor of forestry at the College, has been appointed to the position of advisory officer for all Wales under this scheme. Prof. Story will retain his professorship, but Mr. Thomson Thomson has been appointed assistant lecturer under him.

THE Senate of the projected University of Western Australia recently advertised eight professorships, and the Agent-General for the State reports that the response has been of a character justifying the belief of good appointments being made. The Senate now invites applications for lectureships in veterinary science and mental and moral philosophy. It is stated that Crawley Park, near Perth, which contains spacious grounds, is likely to be selected as the site of the new institution.

THE fourth international congress of physical education is to be held in Rome on October 24 to 27. Discussions are to take place on the organisation of physical education as a preparation for military service; a rational method of physical training in primary, middle, and secondary schools; the value of sports in physical education, and their physiological limitations; the physical education of woman in relation with her function in the family and in society; respiratory gymnastics and choral singing in schools; open-air schools; the physical exercises suitable for the prophylaxis of tuberculosis.

THE following are the arrangements for the opening of the winter session of certain of the medical schools:—That of St. Bartholomew's Hospital will be inaugurated on October 1 by an old students' dinner; at Charing Cross Hospital the prizes will be distributed on October 2 by the Bishop of Peterborough and Lady Mary Glyn; at St. George's Hospital the prizes will be distributed on October 1, and an address delivered by Mr. H. B. Grimsdale on "The present Duty of the Medical Citizen"; at Guy's Hospital there will be a conversazione on October 4 by the Pupils' Physical Society, the session commencing on October 1; at the London Hospital the Schorstein memorial lecture will be delivered on October 1 by Prof. T. W. Griffith; at the London School of Medicine for Women an address on "Common Sense" will be given on October 1 by Dr. Jane Walker; King's College Hospital will hold a dinner on October 1; at the Middlesex Hospital the prizes will be distributed on October 1 by Sir Charles Wyndham, and an address delivered by Dr. W. S. Lazarus-Barlow on "The Genius of the Infinitely Little"; at St. Mary's Hospital on October 1 the Lord Mayor of London will deliver an address and distribute the prizes; in connection with St. Thomas's Hospital there will be an old students' dinner on October 1; the Westminster Hospital School will have a dinner on October 3; a dinner, on October 2, will inaugurate the new session of the University College Hospital School; there will be a conversazione on October 1 in connection with the University of Birmingham; an address will be given on October 1 at the University of Manchester by Dr. H. D. Rolleston on "Universities and Medical Education," and at the University of Leeds an address will be delivered on October 1 by Sir Alfred Keogh, K.C.B.

THE new session of the Sir John Cass Technical Institute, Aldgate, E.C., which is especially devoted to technical training in experimental science and in the artistic crafts, will commence on Monday, September 23. The instruction in experimental science provides systematic courses in mathematics, physics, and chemistry for London University examinations, in addition to the courses on higher technological instruction, which form a special feature of the work of the institute. In connection with the latter, several new departures are being made for the coming session. The curriculum of the fermentation industries has been much developed, and now includes courses of instruction on brewing and malting, on bottling and cellar management, and power and mechanical plant in the brewery, on the microbiology of the fermentation industries, and on the chemistry and technology of hops, in addition to courses in chemistry and physics for those who have not sufficient previous knowledge of these subjects. In the department of physics and mathematics a special course of lectures and demonstrations will be given on colloids, which will deal with the methods employed in their investigation and their relation to technical problems; also a special course of lectures on the theory and application of mathematical statistics, in which the application of modern mathematical methods of dealing with statistical data in social, educational, economic, and physical problems will be discussed and opportunity given to students to investigate problems on their own account. In the metallurgy department, in addition to the ordinary courses of instruction in general metallurgy, several special courses of an advanced character are provided. The special courses on liquid, gaseous and solid fuel have also been extended, and in addition to a course of lectures, will include laboratory work on fuel analysis, and on technical gas analysis. It is also of interest to note that included amongst the language classes is a course on scientific and technical German.

A long resolution embodying the oft-repeated education demands of the Trade Union Congress was adopted unanimously at a meeting of the congress at Newport (Mon.) on September 4. The main points are as follows:—(1) A national system of education under full public control, free from the primary school to the university; (2) The adequate maintenance of school children; (3) Scientific physical education with annual individual medical inspection, and records showing the physical development of each child; (4) that secondary and technical education be an essential part of every child's education, and secured by such a reform and extension of the scholarship system as will place a maintenance scholarship within the reach of every child, and thus make it possible for all children to be full-time day pupils up to the age of sixteen; (5) That the best intellectual and technical training be provided for the teachers of the children, that each educational district shall be required to train the number of pupil teachers demanded by local needs, and to establish training colleges, preferably in connection with universities or university colleges; (6) that the provision of educational buildings and facilities be obligatory upon the local authority, which shall always retain administrative control of the buildings and facilities so provided; (7) that the cost of education be met by grants from the Imperial Exchequer, and by the restoration of misappropriated educational endowments. The congress placed on record its emphatic disapproval of the refusal of Ministers of Education to grant the demand for a Royal Commission to inquire into such endowments; and instructed the Parliamentary Committee once more to press for the appointment of such a Royal Commission, which shall inquire into: (*a*) The finances of the universities and of the great public schools; and to issue a report containing a statement of the history and present value of those endowments which were originally intended for the poor; (*b*) the conditions of scholarships and other aids in universities and public schools; (*c*) the relations with lower education institutions; (*d*) the government of universities and public schools, and to bring forward recommendations showing how these institutions may be brought under full public control.

Secondary education in New South Wales has now been organised completely, and Mr. Board, the director of education, in announcing at the beginning of July last a series of appointments to the high schools, described the character of the system which has now been inaugurated. We learn from *The Sydney Morning Herald*, that Mr. Board claims for the New South Wales scheme of secondary education that it assigns a definite time for the studies of a secondary school, making four years the minimum which any student should spend on these studies. Another good point is the certificating system, which connects the secondary school with the primary school on one hand and the university on the other, and also leads definitely to certain well-marked types of career —for example, the technical or the commercial. Attached to the scheme of certificates is the system of examination. The examinations are, in the first place, school examinations as well as tests of individual attainments. In the second place, the results of the examination will be modified by consideration of the school record of the pupil, and, again, the examination can only follow upon the completion of a specific programme of studies that has occupied a definite period of time, and in the last place the examinations for the certificates are closely associated with the thorough inspection of the schools. A specially constituted board of examiners, representing both the University and the Education Department, will determine the award of all certificates. In a few years there will be a large number of efficient high schools under the control of the Department of Public Instruction, and it is hoped that a leaving and intermediate examination will be carried on somewhat on the lines of that in Scotland. The alternative scheme, which was not adopted, was a system of inspection and examination by the University of Sydney. That is not, however, the true function of a university. Sydney has acted wisely in not undertaking it, though the University may assist, as it has done, to strengthen the State Education Department, and get it to organise secondary education as well as primary and technical.

SOCIETIES AND ACADEMIES.

Calcutta.

Asiatic Society of Bengal, August 7.—R. K. **Bhide**: Two more new species of Gramineæ from Bombay. Two new species of grasses are described, (1) *Chloris quinquesetica*, collected by Mr. G. A. Gammie, and subsequently by the author, from Bassein, and (2) *Sporobolus scabrifolius*, collected by the author from Rannebennur.—Manindra Nath **Banerjee**: A measure of chemical affinity. The chemical activity of an element bears a simple relation to its density; if its atomic volume be divided by its density, the figure obtained, for which the name "specific extensity" is suggested, gives a measure of the chemical activity of the element. For instance, platinum, which is a very inactive element, is near one end of the scale with a specific extensity of 0·42; hydrogen, a very active one, is near the other end with a specific extensity of 127·25. There are a number of exceptions to the rule, the most obvious being the inactive gases found in the atmosphere.—Rev. H. **Hosten**: The mouthless Indians of Megasthenes. According to Megasthenes, there lived near the sources of the Ganges a tribe of people, the Astomoi, who had no mouth, but merely orifices through which they breathed. They ate and drank nothing. When they went on a distant journey, they took with them certain roots and flowers or wild apples, on the perfumes of which they subsisted. "Should they inhale very foul air death is inevitable." The tribe is found mentioned in conjunction with the Trispithami (men of three spans long), the Pygmies, and the Scyritæ or Scyratæ (Kirātas), tribes whose characteristic features are distinctly Mongolian or Himālayan. A number of texts are quoted to prove that the "foul air" against which the Astomoi had to protect themselves represents the phenomenon known as *mal-de-montagne*, or breath-seizure, and that the "wild apples" they used as antidote were onions, dried apples, and apricots, nostrums employed in the Himālayas wherever breath-seizure prevails. The fact that some hill tribes used in their travels fruits of which they inhaled the perfume, lest the "foul air" should kill them, seems then to have led to the idea that they subsisted on nothing else. From this to the belief that they needed no mouth, and, in fact, had none, or "instead of mouths had orifices through which they breathed," the inference was easy.—Rev. Fr. Nicholas Krick: Account of an expedition among the Abors in 1853. The recent expedition among the Abors gives renewed interest to Fr. Krick's visit to them in 1853. His "Relation d'un voyage au Thibet en 1852 et d'un voyage chez les Abors en 1853" (Paris, 1854) has become scarce; hence we are under obligations to Rev. Fr. A. Gille, S.J., for having translated that part which concerns the Abors. Fr. Krick's remarks on their manners and customs are as applicable to-day as they were nearly sixty years ago.

CHEMICAL TECHNOLOGY.

(1) *Bleaching and Dyeing of Vegetable Fibrous Materials.* By Julius Hübner. With an Introduction by Prof. R. Meldola, F.R.S. Pp. xxiii+434. (London: Constable and Co., Ltd., 1912.) Price 14*s.* net.

(2) *German Varnish-making.* By Prof. Max Bottler. Authorised Translation with Notes on American Varnish and Paint Manufacture. By A. H. Sabin. Pp. vii+363. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1912.) Price 15*s.* net.

(3) *Allen's Commercial Organic Analysis.* Edited by W. A. Davis and S. S. Sadtler. Fourth edition. Entirely re-written. Vol. vi. Pp. ix+726. (London: J. and A. Churchill, 1912.) Price 21*s.* net.

(1) THIS is a practical manual intended for the use of students and junior employees. The purely scientific aspect of bleaching and dyeing is not within the scope of the work. As Prof. Meldola remarks in an interesting introduction, Mr. Hübner knows the theoretical side of the industry as well as anybody does . . . but his present treatment of his subject is not intended to supersede but to superadd to the scientific treatment. About one-third of the book is devoted to the description of bleaching operations, including some preliminary sections dealing with the materials employed, namely, the textile fibres, water, chemicals, and mordants. After a few pages on mercerising, the rest of the space is allotted to the discussion of dyestuffs and dyeing procedure. Practical directions for carrying out the operations are given, and frequently different methods of applying the same dyestuffs are adduced for purposes of comparison. There are numerous illustrations, chiefly of sections of machinery; and a feature of these is that in many cases they are made much more intelligible than usual by the use of a two-colour device to show the course of the fabric through the machine. The book can be cordially recommended as a concise and up-to-date compilation of practical information.

(2) Mr. Sabin is an enthusiast on the subject of paints and varnishes, and his translation of Prof. Bottler's book is far from being dry reading. The original is too concise and brief, in the translator's opinion; he has therefore added a number of notes *en passant.* These are printed distinct from the main text, and include useful bibliographical references, explanatory comments, and extensions of matters mentioned in the original or suggested by it. For example, when resenes are first referred to (as constituents of copal and other resins), Mr. Sabin interpolates a brief account of their properties, with a reference and a criticism. Hence the work may be looked upon as giving the German practice in varnish-making, annotated from the American point of view. But in addition to the running notes, Mr. Sabin contributes whole chapters also; one upon miscellaneous points in the manufacture of varnish, and one on the nature and constitution of paint; there is, further, a useful appendix of notes and references on analytical methods employed in the examination of varnishes. It is worthy of remark that, according to the translator, "our (*i.e.*, the American) methods are based upon English practice, and the English alone among foreign nations are still able to sell varnish here against our best makers."

(3) The general characteristics of the new edition of Allen's "Commercial Organic Analysis" are now tolerably familiar to users of the work, and in this connection it need only be noted that the sixth volume follows much the same lines as its predecessors. It is concerned with the chief organic bases and the alkaloids. All the latter, however, are not dealt with, some being relegated to the succeeding volume. The amines, anilines, naphthylamines, and their allies are discussed by Messrs. Davis, Sadtler, and Glover respectively. In dealing with the alkaloids, the plan has been to have first a general description of the vegetable alkaloids (this is contributed by Dr. Henry), and then to have the various groups of these products dealt with by special contributors.

It is perhaps invidious to single out any sections where all appear to be well done, but mention may be made of the articles on the volatile alkaloids and the opium group by Mr. F. O. Taylor; those on the aconite alkaloids and on atropine and its allies by Mr. F. H. Carr; and that on the cinchona group by Mr. Oliver Chick. The section on caffeine, tea, and coffee, by Messrs. Fox and Sageman, is a very useful contribution, as is also that on cocoa and chocolate by Mr. Whymper; the former is illustrated with photographs of leaves said to have been used as adulterants of tea, and by some diagrammatic sketches showing the microscopic structure of tea, coffee, and chicory.

The descriptions of the theoretical chemistry of the various products dealt with in the book appear to be trustworthy, and it is a convenience to have them in conjunction with the analytical working details. A little more careful proof-reading would have detected a number of misprints.

THE GOLDEN BOUGH.

The Golden Bough: A Study in Magic and Religion. By Prof. J. G. Frazer, D.C.L. Third edition. Part v.: "Spirits of the Corn and of the Wild." In 2 vols. Vol. i., pp. xvii + 319. Vol. ii., pp. xii + 371. (London: Macmillan and Co., Ltd., 1912.) Price, 2 vols., 20*s.* net.

AT the conclusion of his elaborate study of "Spirits of the Corn," Prof. Frazer observes that "while the fine flower of the religious consciousness in myth, ritual, and art is fleeting and evanescent, its simpler forms are comparatively stable and permanent, being rooted deep in those principles of common minds which bid fair to outlive all the splendid but transient creations of genius. It may be that . . . simple folk will still cherish the simple faiths of their nameless and dateless forefathers. . . ." In his feeling for the system he has studied so long and so minutely, the Darwin of religion resembles Ernest Renan, who came to regard affectionately the Christian and Pauline subjects of his analysis.

But a more interesting point is the suggestion that superstition "springs eternal in the human breast." If there is anything in the suggestion, it is that what we know as superstitious tendencies, crystallising into religious forms, are part of the mechanical workings of the human brain. For undoubtedly these multiple variations of a few simple ideas persist, just as they first developed, in subconscious or unconscious thought. It is only the primitive explanations of belief and ritual that show conscious exercise of the brain. From a similar point of view, Adolf Bastian has remarked the deplorable sameness and the small number of the conceptions of the human mind.

Such views and such prognostications seem to forget that mental action is relative to its object, that it varies in form as its knowledge of the object, and, consequently, that science can alter, and has altered, the "principles of common minds." And, after all, this rich crop of myth, ritual, and religion, so carefully harvested in "The Golden Bough," is but the chaff of man's imagination, however persuaded he may be that it is golden grain. For the true seeds of the mind are scientific; during countless ages they were garnered in absolute unconsciousness, fancy playing meanwhile with the flying chaff.

The mistake of regarding these recurrent and multitudinous expressions of man's mental "play" as the foundation of his individual and social achievements will not be made by the synthetic sociologist of the future. He will take the logical mechanism of the mind in its relation with increasing knowledge as the foundation, and relegate the iridescent play of religion and superstition to the sphere of the imagination, as a part of æsthetics. But this "play," simultaneous with, or preceding, or following, mental adaptation to reality will be of value in determining the nature and quality of that adaptation. And the social psychologist needs no further material than that supplied in "The Golden Bough" and in "Totemism and Exogamy" for understanding the tendencies of the mind when free from scientific relations.

The discussion of "Spirits of the Corn and of the Wild" is the main stem of "The Golden Bough." Mannhardt's studies, which inspired it originally, have found a multiplex reincarnation. Besides the general extension of material there are interesting and valuable episodes, such as the connection of the Pleiades with agriculture, woman's part in agriculture, games in agriculture. A delightful essay on Empedocles as a pioneer of evolution and in comparison with Herbert Spencer shows the author's style at its best.

A. E. Crawley.

SOME PHYSIOLOGICAL MONOGRAPHS.

(1) *Schutzfermente des tierischen Organismus.* By Emil Abderhalden. Pp. xii + 110. (Berlin: Julius Springer, 1912.) Price 3.20 marks.

(2) *Les Parathyroïdes.* By L. Morel. Pp. iii + 344. (Paris: A. Hermann et Fils, 1912.) Price 10 francs. (Questions Biologiques Actuelles.)

(3) *Le Goût et l'Odorat.* By J. Larguier des Bancels. Pp. x + 94. Paris: A. Hermann et Fils, 1912.) Price 3.50 francs. (Questions Biologiques Actuelles.)

(4) *The Physiology of Protein Metabolism.* By Dr. E. P. Cathcart. Pp. viii + 142. (London: Longmans, Green and Co., 1912.) Price 4*s.* 6*d.* net. (Monographs on Biochemistry.)

(1) PROF. EMIL ABDERHALDEN is probably about the busiest physiological investigator at the present day; he is certainly the most prolific writer. Not only do original papers flow in a steady stream from his laboratory, but he has also the time and energy to edit and write books. The work mentioned above is one of the most recent of these, and in it he collates the results of his own work and that of others on one of the most interesting developments of recent biochemical study. It deals with the protective mechanisms of the body, and especially with the part played by enzymes in resisting the effects of introducing foreign material into it. This is only part of the large subject included under the general heading of Immunity, but it is an important part. It is, for instance, well known that if "peptone"

is introduced into the blood-stream a very serious train of symptoms results which may terminate fatally. Healthy blood contains no enzymes capable of splitting peptone into its simpler and more harmless constituents. But by educating an animal by gradually introducing successively increasing doses of the poison, the blood acquires the property of dealing with it, owing to the genesis of peptolytic enzymes. This is only one example of the sort of thing which is continually occurring; many others are given, which the reader must discover for himself. The little book is valuable also because it deals clearly with the methods, especially the so-called "optical method," which have been elaborated by the author for the detection of the enzymes in question.

(2) The parathyroid glands were only discovered in 1880, and their importance in the life of the organism was not recognised until some years later. Removal of the thyroid body produces results analogous to those which occur when this organ is the seat of disease. Now that its neighbours, the parathyroids, have been recognised, much controversy has centred around the question as to how much of the effect is due to removal or disease of the latter bodies rather than of the thyroid itself. Much difference of opinion still prevails, but it is pretty generally admitted that what is known as tetany is a symptom rather of parathyroid than thyroid insufficiency. The main facts and views are set out with admirable lucidity in the second book mentioned above, and Dr. Louis Morel, the author, is to be congratulated, not only on having written such an interesting book, but on having added to it a valuable bibliography of the subject. This extends over nearly twenty closely printed pages in double columns, and seeing the recent date of our knowledge even of the existence of these little organs, we have an illustration of the industry of modern physiological and pathological investigators.

(3) The next monograph on our list is published in the same series, which is being published under the editorship of Prof. Dastre. In it, Dr. des Bancels gives the most up-to-date information regarding the two special senses, taste and smell.

(4) Dr. Cathcart's contribution to the biochemical monographs which Messrs. Longmans are publishing deals with the important subject of protein metabolism. This also is enriched with an excellent bibliography. Although one must admire the way in which the author has placed before his readers all the latest information on the complex problems involved, one is naturally disappointed to find how many of these still continue in an uncertain state. That, however, is not Dr. Cathcart's fault, and we must rejoice that he has himself done so much in the way of research to illuminate the dark places of scientific knowledge. It can only be a question of time and hard work before our difficulties in the interpretation of facts will disappear. W. D. H.

OUR BOOKSHELF.

Die Radiumkrankheit tierischer Keimzellen. Ein Beitrag zur experimentellen Zeugungs- und Vererbungslehre, by O. Hertwig. Pp. iii + 164 + Taf. i–vi. (Bonn: F. Cohen, 1911.) Price 8 marks.

The author has planned and carried out a comprehensive series of experiments with a view to ascertain the effect of exposing to radium the ova and spermatozoa of animals, and of exposing the normal embryo in various stages of its development.

The axolotl and the frog (*Rana fusca*) were used in the experiments. The results show that exposure to radium leads, at every stage, to imperfect development of the embryo; numerous illustrations (in the text and in six special plates) show that inhibition of development and abnormal development are readily produced.

The book is divided into three parts; the first and second parts deal with experiments on amphibian ova and embryos; the third part with those of echinoderms.

The first part describes the results of irradiating fertilised ova at the beginning of segmentation, and the male reproductive cells before fertilisation. The second part describes the changes following exposure of the normal embryo at the several characteristic stages, such as the gastrula stage, the development of the nerve-plate, and of the spinal cord.

A number of microscopical sections are included in the illustrations to show the far-reaching nature of the changes produced by exposure to the rays of radium.

Antropologia Generale. Lezioni sull' Uomo secondo la Teoria dell'Evoluzione. By Prof. Enrico Morselli. 671 figs. + 1 plate + 3 maps. (Turin: Unione Tipografica, Editrice Torinese, 1901–1911.)

From 1887 until 1908 Prof. Morselli, who is by profession a physician, devoting himself to the study and cure of mental diseases, has been in the habit of delivering free courses of lectures on anthropology. The lectures, which have been in the course of publication, by instalments, for a number of years past, have now been completed, and form a work which represents a monument of patient and painstaking industry. In its conception and execution this work resembles the treatises which are so often produced by men attached to German universities.

Prof. Morselli's personality is never obtrusive: he seeks to express the facts as seen and rendered by others; he keeps his own opinions in the background. In the preface he acknowledges his indebtedness to Haeckel. "Antropologia Generale," however, is even wider in its scope than the "Natural History of Creation." The opening lectures are devoted to a historical account of the various hypotheses which have been formulated regarding man's origin and evolution, and to the bearing of Darwin's work on the modern problems of anthropology. The following chapters have even a wider sweep; they deal with life, the conditions of life, as far back in the world's history as human imagination can reach. Embryology, growth, anatomy, and all the various kinds of knowledge which have even a remote bearing on the human body are woven into the subject-matter of Prof. Morselli's lectures.

The chapters dealing with extinct and past forms of men are very complete. One is rather surprised to observe that he accepts in good faith all the discoveries of ancient man which have been made in South America in recent years. The concluding lecture pictures the man of the future as a form of Greek god. The numerous illustrations, although they have often little connection with the part of the text in which they appear, are well executed, and have been selected from many standard works and original papers.

The work is so ambitious in aim and so wide in its scope that it is impossible for any single man to obtain a first-hand knowledge of all its parts; few could have completed so successfully the task which Prof. Morselli imposed on himself.

An Outline of the Russo-Japanese War, 1904, 1905. By Col. Charles Ross, D.S.O. Vol. i., Up to, and including, the Battle of Liao-Yang. Pp. xxv+490+14 maps. (London: Macmillan and Co., Ltd., 1912.) Price 10*s*. 6*d*. net. (Military Text-Books.)

THIS account of the latest of the great campaigns of modern history takes the story up to the close of the first stage of the Japanese advance into Manchuria, which was marked by the complete and final severance of the field army under Kuropatkin from the troops interned in Port Arthur.

Naturally in so comparatively short a work it has been impossible for the author to enter into any discussion of tactical problems or to refer to the doings of the smaller units, whether in action or during the various strategical movements of the campaign. He has succeeded, however, in giving a very clear view of the earlier phases of the war, and of the numerous influences that guided the actions of the opposing commanders.

The chapters dealing with the war itself are exceedingly clearly written, and the contrast between the divided counsels that confused the Russian strategy and the impassive unanimity that ruled the movements of the Japanese is well brought out. As one would expect from an author bearing the name of Ross, not only are the facts clearly stated but the lessons to be learnt from them are philosophically discussed. The book should be read by all who desire to get a clear view of the campaign, unencumbered by technical detail, or to realise the effect on the art of war of modern scentific advances. C. H. M.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Practical Mathematics.

IT is surely rather a pity that Prof. Perry concluded his letter with such a violent attack on the "professional mathematician." If he had attached a little less importance to Sir William White's address and a little more importance to the proceedings of, and reports presented to, the Educational Section of the Congress, I think he would find ample justification for withdrawing, or at least qualifying, his statement that the teacher "never studies his pupil," or that "the poor average English boy is never studied by the professional mathematician."

One of the main changes that is taking place at the present time consists in the introduction of the calculus at a much earlier stage in our mathematical curricula than was ever dreamt of fifteen years ago. Surely this and many other equally important changes owe their inception largely to what has often been described as the "Perry movement." After all, only a small percentage of the boys who study mathematics at school intend to qualify for the engineering profession. It is in connection with the education of the large body of pupils who learn mathematics as part of a general education that the introduction of the practical element is producing the most beneficial results. G. H. BRYAN.

Weather and the Ultra-violet Radiations of the Sun.

I WAS rather astonished by Dr. Carl Ramsauer's second letter in NATURE of June 13, which has just reached me, and although "the weather of 1911" is rapidly becoming ancient history, and I have much reluctance in pursuing the discussion of it, it is hoped that the long distance which separates me from the editorial room will be sufficient apology for asking your indulgence at this late day in order to register a protest against the conclusions enunciated in that letter.

I regret having to acknowledge that, to me, the letter appears of the nature of a *lucus a non lucendo*. If Dr. Ramsauer advances as a theory, well substantiated by experiment, that ultra-violet solar radiation is the chief source of condensation nuclei in the atmosphere, and cites in support of his theory diminished ultra-violet radiation and a hot and dry summer, with clear skies, in the northern hemisphere during 1911; and if, upon learning that, simultaneously with the existence of drought conditions in the north, there was excessive precipitation in the southern hemisphere, he can conclude that his theory is thereby fortified, in fact, universally confirmed, then he surely owes it to science to support this conclusion by convincing evidence. This should be something more than a mere supposition that the aqueous vapour which diffused into the hot summer atmosphere of the north, not encountering in the free air proper vehicles (provided by solar ultraviolet waves) for returning to the earth's surface, thereupon rushed to the southern hemisphere, where, in lieu of condensation nuclei provided by solar ultraviolet waves, it was pleased to avail itself of the facilities afforded by the ordinary laws governing gaseous bodies in order to get back to *terra firma*. According to what Dr. Shaw has written, it is evident that the laws of gases operated with full vigour in the northern hemisphere during the summer of 1911.

If, as Dr. Ramsauer contends, ultra-violet solar radiation is the *chief source* of condensation nuclei, and if normal ultra-violet radiation is a necessary condition for normal precipitation of aqueous vapour from the atmosphere, and if during periods of diminished activity in this part of the solar spectrum we are to expect the heaviest precipitation over one-half of the world, then it logically follows that the existence *in excess* of condensation nuclei produced by ultra-violet solar rays is a preventive of rain.

Not to pursue farther for the moment this function of ultra-violet radiation, it may be confidently stated that orthodox meteorologists will view with suspicion the simple conception of rapid and general distribution of vapour through the atmosphere embraced in Dr. Ramsauer's supposition. According to a well-established law of physics, the quantity of vapour which may exist in a given space is conditioned upon the temperature of the vapour and the pressure exerted upon it; consequently, in speaking of the aqueous vapour of the atmosphere, it may be said, without widely deviating from the truth, that the temperature of a given volume of air is the controlling factor determining the quantity of vapour which may exist therein. It has been well established by observation that the spontaneous diffusion of vapour in the air is a rather slow process, and that its general distribution through the atmosphere is chiefly effected by the winds and the currents of the general planetary circulation.

Dr. Ramsauer suggests no explanation as to the manner in which the vapour from the northern was translated to the southern hemisphere. The assumption that it was by the process of diffusion implies supersaturation in the upper air; and as to that condition we must hold, with Dr. Shaw, "that it has never been demonstrated." Numerous observations in the lofty atmosphere made in practically all parts of the world, by means of balloons and kites, show that the quantity of vapour decreases in nearly a geometrical progression as the elevation above the surface increases arithmetically, so that even at a moderate height a region is reached in which the water equivalent of its vapour content may conveniently be expressed in barrels instead of billions of tons—a quantity inadequate to account for excessive rains over a large portion of the earth. With such free distribution of vapour in the atmosphere as Dr. Ramsauer suggests, it would be difficult to account for the arid regions of the earth; since atmospheric overturnings are most frequent and most violent over such regions, enough vapour would be condensed to convert them into fertile regions. Indeed, the arid regions furnish evidence of the most conclusive kind that the lowest stratum of the atmosphere constitutes the "physical laboratory where rains and dense clouds are made," since they are all flanked to windward by mountain barriers which abstract the life-giving vapour from the air.

It is highly probable that during the earth's dawn the vapour of the atmosphere was saturated, as it is supposed to be now on Venus, but the irregularities introduced by continental upheavals have been the means of draining the moisture to such an extent that the air over all continental interiors and in all regions high aloft is now prevailingly dry.

If it be assumed that a mere preponderance of vapour over a given region would cause a rapid outflow to regions where the air is less charged, then there might arise a number of complicated conditions much more difficult to explain than the "weather of 1911." For instance, to cite an extreme case, the mean vapour tension over the desert of Sahara is about the same as that over central Europe and southern England; consequently it must be in excess over the desert during probably half the time, and it might therefore be concluded that much of the rain and verdure of central Europe and England is due to the vapour coming to those regions from the heart of the African desert. The relative conditions over Europe and the desert are chronically similar to those which characterised the weather of Europe and South America during 1911.

If the semi-annual exchange of vapour between the hemispheres really took place, as suggested by Dr. Ramsauer, it would probably cause disaster throughout the northern half of the world during periods of diminished ultra-violet radiation. For while the southern hemisphere might easily accommodate the vapour emanating from the limited water surfaces during the northern summer, six months later, with the boundless southern oceans seething under the perihelion sun, the quantity of vapour sent across the equator would quickly impart a decidedly martian aspect to the northern hemisphere.

In discussions of summer weather, an important physical fact is generally overlooked, one which is rarely referred to with proper stress even in treatises on meteorology, viz. the remarkable increase in the tension of saturated aqueous vapour after passing the temperature of 30° C. The energy of solar rays falling upon the ocean surfaces, the chief source of vapour supply, is almost wholly used up in converting the water into a gaseous state, so that the temperature of the water surface varies but slightly during a season; whereas the energy of the rays falling on land areas is chiefly exhausted in heating the soil and dust particles suspended in the air, and thus indirectly heating the air in contact with those solid bodies and causing land temperatures in the lower atmosphere to vary through wide limits. So, while the ocean gives off a nearly constant supply of vapour at a uniform and relatively low temperature during the summer, the so-called capacity of the continental air for vapour increases enormously once the midsummer temperatures are reached, making it increasingly difficult for atmospheric overturnings to bring about condensation unless rains have been sufficiently distributed over the land during the late spring and early summer to compensate for this large saturation deficit which would otherwise be caused by intense solstitial insolation.

This relation between temperature and vapour tension sufficiently explains the barren islands of tropical mid-oceans, as well as the clear skies and "dry spells" of the great majority of summers; and it also points to the red end as the portion of the solar spectrum chiefly responsible for "the weather of 1911."

I have no desire to question the statement that ultra-violet rays do produce condensation nuclei; the portion of Dr. Ramsauer's first letter which struck me as open to debate is the statement that ultra-violet solar radiation is the *chief source* of condensation nuclei in the atmosphere. One of the ablest investigators of the day has recently said, in treating of another branch of terrestrial physics, "it is in any case to observation that we must turn as the touchstone by which to try theory." During the past nine years I have made many observations of the relative intensity of ultra-violet solar radiation in the northern hemisphere, on the ocean, and in the southern hemisphere, with the hope of witnessing some phenomenon in nature that might furnish evidence of this power of ultra-violet rays so conclusive as the results obtained in laboratory experiments. Only once have I had reason to think (for a short time) that my efforts were being rewarded.

Although Dr. Ramsauer concludes that ultra-violet solar radiation was at a minimum phase during 1911, during the first half of March of that year I obtained the highest values for all the years of my measurements. About 10 a.m., March 11, just after the highest maximum had been recorded, a surprisingly sudden decrease in intensity was indicated by the actinometer; no cause for the change was discernible in the deep blue of a perfectly clear sky, and observations were repeated as rapidly as possible until 10.45 a.m., when the intensity had become very weak and filmy clouds could be seen in the zenith in an incipient stage of formation; by 11.30 the whole sky was overcast with an alto-stratus formation. During this time no change was registered in the brisk, warm, northerly wind which had been blowing since early morning, and the pressure, though slightly below normal, showed the normal variation for this time of day; so it seemed that the ultra-violet rays had at last displayed their powers in an unquestionable manner. But after the upward turn in the diurnal pressure curve set in, about 2 p.m., the barometer rose at an unusual rate, and by sunset a strong, cold, southerly wind was blowing, thus showing that the transformations in the upper air of the forenoon were due to the advance portion of a pressure wedge overflowing the warm and relatively moist surface current. It may be added here that no rain fell anywhere near the place of observation for several weeks after this display (although March is still well within the rainy season of this region), nor have I, up to the present time, heard of such general and heavy rains over the earth during the latter part of the month as would commensurate with such unusual activity in the ultra-violet field of the sun.

Dr. Ramsauer may claim that the mere fact of condensation is sufficient proof of his theory, and this brings up another matter referred to in his first letter which I shall discuss briefly. He says:—"If we neglect the purely local formation of nuclei in large centres of industry, the ultra-violet . . . radiation of the sun is chiefly responsible," &c., implying that condensation can take place only on an infinitely small number of the solid impurities sustained in the air. There are probably not so many factory chimneys on the whole continent of South America as there are in London, yet within the past few days an area of several hundred thousand square miles in the central section of this continent was covered by a shallow fog caused by dust particles, raised by the high winds of a "dry cyclone," cooling by radiation into the calm air of a rapidly following high-pressure area. This is only a single instance of a phenomenon which is very common indeed during the fall and winter in all regions of the temperate zones, and it goes to show that clean dust particles raised by the winds from virgin soils are quite as effective as condensation nuclei as the particles of waste products which escape through the chimneys of manufacturing towns. If dust particles can act so efficiently as nuclei in the low-lying strata, why should they be denied this agency when they appear in the higher regions of the atmosphere? For their existence in those regions, even far out into interplanetary space, is impressively evidenced by the brilliancy of the twilight glow, the meteor tracks, and the zodiacal light.

L. G. SCHULTZ.

Oficina Meteorológica Argentina, Observatorio Magnético, Pilar, Córdoba, July 26.

Antiquity of Neolithic Man.

RECENT excavations in St. Helier, Jersey, have brought to light the following evidence bearing on the antiquity of Neolithic man:—

The soil beneath the town of St. Helier is, in descending order, composed as follows:—

(1) A deposit of blown sand and recent alluvium from 4 ft. to 6 ft. thick.

(2) A bed of brown sandy and clayey peat (with relics of Gallo-Roman times).

(3) A marine deposit, consisting of clay, shingle, and shell-gravel, from 2 ft. to 5 ft. thick.

(4) A bed of firm black peat and forest remains which ranges from 5 ft. to 14 ft. in thickness.

This peat and forest bed is traceable to the shore, where it forms the well-known "submerged forest," thence (as revealed by the dredge) across the channel that separates the island from the continent, and along the continental coast from Cape La Hague to Finisterre.

This no doubt is all one with the post-glacial submerged forests of the British Isles and north-western Europe in general, for all through the flora and fauna are the same, viz. oak, alder, birch, hazel, Juncus, and Equisetum, with hazel nuts in profusion. *Bos longifrons*, red deer, and wolf, even elytra of the little purplish-green beetle, *Geotropus vernalis*, are present in this layer beneath St. Helier, as they are from extreme north to south throughout the vast forest area.

This deposit, then, marks the period of the commencement of land elevation which followed the subsidence of glacial times, for it lies immediately upon unmistakable rubble-drift and blue marine clay.

Neolithic relics, in the way of stone implements and fragments of pottery, are very plentiful on the surface, and in the upper levels, of this forest bed, but, so far as I can ascertain, have never been recorded from the strata beneath.

In a series of excavations now in progress for the foundations of a building in St. Helier, the strata as above described have been cut through, and in the blue clay *beneath the forest bed* (which here is 8 ft. thick) were found Neolithic implements as follows:—(1) A squared block of diorite about 6 in. in width and in breadth, and about 2 in. thick, which has been used as an anvil, apparently for chipping flints. It is deeply scored on both sides. (2) A flat sandstone pebble about 3 in. in diameter, which has been used in the same way. (3) A flat pebble of dolerite about a foot in length, 4 in. wide at one end, and running to a point at the other.

This pebble has served three purposes, for it is worn and abraded on the broad and fairly sharp end, showing that it has been used as an axe; again, on the sharpest lateral edge, indicating use as an ordinary meat-chopper; finally, it is scored with many cuts on the flat surfaces, having apparently been used as an anvil for chipping flints. (4) Two good specimens of the very typical flat pebble implements of elongated triangular form, bevelled at the broad end—a crude form of implement which has persisted until the dolmen period, and occurs plentifully amongst the latest Neolithic relics.

Besides these there were numerous flint chippings, cores from which flakes had been struck, and some crude flint implements with no characteristic detail.

In the same stratum as these, and in a layer of yellow clay which lies beneath, flint implements of decided Chellian, Acheulian, and Mousterian types are frequent, but the relics above specified are very clearly and decidedly Neolithic.

As the portion of the forest bed at this spot must represent the vegetation that first fringed the land as it recovered from the depression of glacial times, and these relics lie beneath it, we cannot but conclude that the Neolithic races date from a period far more remote than has usually been assigned to them, and that they must, in fact, date back nearly into the last glacial period.

Question may arise as to the possibility of a disturbance of the area by floods or other agencies, and the possible mixing up of the relics, but the excavations have been closely watched and studied by myself and several fellow-members of the local Archæological Society, and if there is one point clearer than another it is that there has been no such disturbance. The tree stumps in the overlying forest bed are as they grew, with their roots passing into the underlying strata, and everything indicates quiescence. Nor could the objects have sunk through the peat, for of the abundant stones in the overlying deposits, none have even penetrated the surface; the material is too compact to admit of this.

These interesting relics now form part of the extensive and ever-growing collection in the museum of the local Archæological and Antiquarian Society, the Société Jersiaise.

It would be interesting to know if any of your numerous archæological readers have found evidences of Neolithic man at this geological horizon.

Jersey, August 28. J. SINEL.

The Structure of the Ciliary and Iris Muscles in Birds.

MAY I be allowed through your columns to direct the attention of physiologists and anatomists to certain special features in ocular accommodation, and in the movements of the iris in birds, and to a peculiarity of the ciliary muscle and sphincter of the pupil, which, so far as I have been able to ascertain, has not been previously described?

If the eye of any bird in which a light-coloured iris sharply contrasts with a black pupil be carefully watched, rapid changes in the size of the pupillary opening may be sometimes observed to take place during the few moments that the bird is fixedly looking at any object under the same intensity of illumination. Moreover, the character of these movements strongly suggests that they are under voluntary control.

The pupillary reaction to light is very rapid in birds; the recontraction following the transient dilation which accompanies the momentary closing and opening of the eyelids and nictitating membrane in the movement of blinking is so rapid that the contraction of the pupil seems to coincide with the re-opening of the eye, and not definitely to follow it as in man.

Atropine seems to have no effect in dilating, or Eserin in contracting, the pupil; neither does the former seem to affect accommodation in birds.

In connection with these facts it is also interesting to find that the ciliary muscle and the sphincter of the pupil in birds are both composed of striated fibres of the voluntary type, and not of plain unstriped muscle fibres as in man and other animals.

Thus, while in man with binocular vision the delicate movements of accommodation and the associated movements of the pupil are carried out by involuntary muscles, in birds, in which in many species vision is of the monocular type, the same movements are performed by voluntary muscles.

The extremely accurate and rapid movements of the beak in birds no doubt require a corresponding delicacy and rapidity of ocular accommodation at very short range.

Other interesting questions arise as to the representation of these intrinsic eye movements in the avian brain. The matter is also one of phylogenetic interest, and I hope to publish further histological details with photomicrographs of sections shortly. C. J. BOND.

Leicester, August 30.

The Attacks of Birds upon Butterflies.

MR. EVERSHED'S letter in NATURE of August 29 seems to me very suggestive, and it is to be hoped that his hypothesis may be tested by careful observation in many parts of the world. As regards the rarity with which these attacks have been witnessed in India by Mr. Evershed and many other naturalists, it is well to bear in mind the probability that the proportion of butterfly-eating birds differs in the different tropical regions. Indeed, it is difficult on any other hypothesis to understand why butterfly mimicry should be developed to such very different degrees in the three richest regions, being transcendent in the Neotropical, remarkable in the Ethiopian, but relatively poor in the Oriental region. Indirect evidence of the frequency of attacks in different areas might perhaps be obtained by a study of the relative amount of damage which could only have been inflicted by the beak of a bird. E. B. POULTON.

St. Helens, Isle of Wight, August 26.

A Flower-sanctuary.

IN reply to Sir Edward Fry's inquiry (NATURE, August 29, p. 661) as to the powers of county councils to protect particular flowers, I am now enabled, through the courtesy of the clerk to the Cornwall County Council, to send a copy of the by-law referred to; it is given below. It is obvious that the Somerset County Council must possess the same powers as the Cornwall County Council, and that a by-law on these lines would meet the requirements of the case, and I venture to hope that Sir Edward Fry will exert his influence in favour of the enactment of such a by-law.

FRANK H. PERRYCOSTE.

Higher Shute Cottage, Polperro, Cornwall, September 12.

County of Cornwall.—By-law for the Good Rule and Government of the Administrative County of Cornwall, made in pursuance of the Local Government Act, 1888, by the County Council of the said County, at a meeting held at Truro, on the 6th day of November, 1906, at which not less than two-thirds of the whole number of the Council were present:—

"No person shall (unless authorised by the owner or occupier, if any, or by law so to do) uproot or destroy any Ferns or other Wild Plants growing in any road, lane, roadside, waste, wayside bank or hedge, common, or other public place, in such a manner or in such quantities, as to damage or disfigure any such road, lane, roadside waste, wayside bank, or hedge, common or other public place. Provided that this by-law shall not apply to persons collecting specimens in small quantities for private or scientific use.

"Any person offending against this by-law shall be liable to a penalty not exceeding five pounds."

THE SUMMER OF 1912.

THE summer of 1912 has proved so thoroughly unsummerlike, and has been so marked a contrast to the abnormally fine and hot summer of 1911, that a few facts may be of interest. The period dealt with will be limited to the three months June, July, and August.

The drought experienced in April, followed by a general deficiency of rain in May, rendered the early summer rains in June agreeable rather than otherwise, but the wet weather soon became too persistent, and the frequent rains have been a special feature of the past summer. With the exception of a period of eight days, July 10 to 17, the weather throughout was unusually cold, and this was really the only dry period experienced over the country generally.

The following table gives the summary of temperature, rainfall, and duration of bright sunshine issued by the Meteorological Office for the several districts of the United Kingdom for the past summer (thirteen weeks ended August 31), and the corresponding results for the summer of last year have been added:—

District	Temperature: Accumulated number of day degrees above 42°		Rainfall: No. of days with rain		Rainfall: Total fall		Sunshine: Hours recorded

English Channel . .	1510	1929	65	27	14·21	5·49	510	861

The foregoing table shows that the highest temperature during the past summer occurred in the east and south-east of England and in the Channel Islands, and the temperature for the recent summer is largely in defect of that last year in all districts. In the Midland counties and in the south-west of England the day degrees above 42° are respectively 461 and 460 less than last year, which gives a deficiency of temperature of 5° for the whole period compared with 1911. The deficiency of temperature this summer compared with that of 1911 exceeds 4° in all the English districts except in the east of England, where it amounts to 3·9°.

The exceptionally heavy rains of August have greatly augmented the aggregate rainfall for the past summer over nearly the whole of Great Britain. At Darwen the fall for the month was 11·10 in. and at Norwich 10·50 in., the latter being more than four times the average; of the large total at Norwich 7·34 in. fell in the twenty-nine hours ending 9 a.m. August 27, and similar falls in the neighbourhood resulted in exceptionally severe floods. At Kew, the London reporting station of the Meteorological Office, the aggregate rainfall for August was 5·18 in., which is more than double the average, and it has only been exceeded once in August in the last fifty-seven years, 6·50 in. being measured in 1878; and there were only two days, the 1st and the 9th, absolutely without rain during the month.

The number of rainy days for the past summer is more in excess of the normal in the English districts than elsewhere, whilst the quantity of rain is largely in excess everywhere except in the north of Scotland, where it is seen from the table that the aggregate rainfall for the three months was less than in 1911.

The returns for the summer show that the heaviest rainfall occurred in the south-west of England, where the measurement was 16·74 in., which is 8·17 in. more than the average of the last twenty-five years. In the Channel Islands the excess was 7·45 in., and in the Midland counties 6·23 in. The rainfall for the closing week of the season amounted to more than seven times the average in the east of England.

The duration of bright sunshine was everywhere largely deficient, and the table shows that the amount in the several districts is only about one-half of that for the corresponding season in 1911.

The following results from the Greenwich observations exhibit in a very striking manner the exceptional character of the past summer, and the results for the summer of 1911 are also given to show the contrast:—

Period	Temperature: Mean max. or highest day			Temperature: Mean min. or lowest night			Rainfall: Days with rain		Rainfall: Total		Sunshine: No. of hours	
	1912	1911	Avge. 70 Years	1912	1911	Avge. 70 Years	1912	1911	1912	1911	1912	1911
	°	°		°	°	°			In.	In.		
June . .	70	71	71	50	50	50	18	12	2·34	2·11	219	224
July . .	75	81	74	55	55	53	11	3	1·25	0·26	164	335
August .	67	81	73	51	57	53	26	8	4·38	1·35	114	260
Summer .	71	78	73	52	54	52	55	23	7·97	3·72	497	819

It is seen that August is in every way the most exceptional of the three recent summer months. The mean of the day temperatures is 14° lower than in August, 1911, and the mean of the night temperatures is 6° lower. There were only five days without measurable rain, both the rainy days and the amount being more than three times as great as in 1911, whilst the duration of bright sunshine was less than one-half.

There were twelve days in the past summer with a shade temperature of 80° and above, whilst in the summer of 1911 there were thirty-seven such warm days, the average for the last seventy years being thirteen days. There were forty-five days this summer with the temperature 70° or above, and in the summer of 1911 there were seventy-three days with that temperature, the average for the past seventy years being fifty-nine days. The highest shade temperature in August this year was 73°, whilst in August last year it rose to 100°, the reading being a record for Greenwich.

The controlling factor of the weather over the British Isles during the past summer has been the unusual distribution of atmospheric pressure in our neighbourhood. During almost the whole of the summer a region of high barometer has been situated in the Atlantic to the south-west of our area, and a second region has been situated either over Iceland or Scandinavia. This has left a free passage over the British Isles for incoming disturbances from the Atlantic, and these have become imprisoned within our area, moving very sluggishly on their easterly track, and at times remaining practically stationary.

A feature of especial interest due to the unusual wind circulation set up by the abnormal atmospheric distribution was the exceptionally high temperatures which prevailed over Scandinavia during the first half of August, whilst in the British Isles and in other parts of western Europe the weather was peculiarly dull and cold. For the week ending August 12, the mean of the maxima or highest day readings at Haparanda was 80°, at Bodö 74°, and in London and at Jersey 63°; whilst at Lisbon the mean was only 76°, and at Nice 78°.

The temperature of the sea-surface in the North Atlantic and in proximity to our coasts has for some time past been much below the average.

Chas. Harding.

CHIRIQUIAN ANTIQUITIES.[1]

PROF. G. G. MacCURDY, of Yale University, has taken advantage of the fine collection of antiquities from Chiriqui under his charge to present to students a very valuable and interesting monograph, which is illustrated, in the usual lavish and artistic manner of our colleagues in the United States of America, by 384 figures in the text, 49 plates (five of which are coloured), and a map. The ancient cultured people of Chiriqui are apparently represented by the Guaymi, whose language shows affinity with that of the Chibcha of Colombia. The area now occupied by the republics of Colombia and Panama formed a linguistic and archæological barrier between the great civilisations of Mexico and Peru. In this culture zone the dominant factor is Chibchan; on the other hand, the ancient art of Chiriqui was influenced more by Mexico than by the south, but the Chiriquian culture was distinctively indigenous, and radiated into southern Costa Rica.

Attention is directed throughout the memoir to the general phylogenetic trend in the development of Chiriquian art as a whole. The elegant stone vessels carved in the form of a jaguar are traced back to an oval prototype with a hollow pedestal; with the exception of architecture, the stone art of Chiriqui compares favourably with that of Mexico or Peru. The especial interest of Chiriquian pottery was first emphasised by Prof. W. H. Holmes (Sixth Ann. Rep. Bur. Am. Ethnol., 1888), and Dr. MacCurdy has with slight modifications adopted his classification. The pottery, especially the unpainted ware, is the connecting link between the products of the stone worker and artificer in metal. The "prototype was presumably the calabash. Aside from this, the plant world had practically no influence on the elaboration of form and ornament." The unpainted ware includes the terra-cotta or biscuit group, or, as MacCurdy prefers to call it, the armadillo group, as its ornamentation is mainly based on the armadillo, and three smaller groups.

The painted ware consists of ten groups, of which the fish or tripod, lost colour, alligator, and polychrome groups are the most important (Fig. 1). As might be anticipated, the introduction of colour as a decorative factor often tended to minimise the importance of incised and plastic features; the armadillo and serpent are practically never executed in paint, while incised or plastic motives derived from the alligator are equally rare. Very characteristic of Chiriquian pottery is the presence of three hollow legs, provided with long slits and containing pellets, which serve as a rattle; most of these in the painted ware have a fish ornamentation. The lost colour process was confined to a single, rather large, group of ware; it consisted of tracing the design in wax, the application of a solid coat of black paint over the area to be decorated, and immersing the vessel in hot water, which melted the wax, the design part that was waxed thus showing up light. An analogous method is employed in Java for decorating sarongs.

In the alligator group the designs are always on a pale yellow slip; black and red are the delineating colours. As a matter of fact, it is the crocodile, and not the alligator, which is depicted. The modifications which occur in the form of the crocodile or of parts of it constitute a very pretty

Fig. 1.—Polychrome ware. Vase of eccentric form, the chief ornamental feature being the elaborate branching scroll filling each of the two shoulder panels; the engaged crocodile motives are easily distinguished.

example of the conventionalisation of designs. The highest technical excellence was achieved in the polychrome group; here a purple colour was introduced derived from a non-ferruginous metallic oxide, and not from the *Purpura patula*, which was used to dye cotton thread; it is also characterised by elegant scroll designs derived from crocodiles. The gold Chiriquian figurines are famous, and are here treated adequately for the first time. Squier (1859) says he "was informed by the late Governor of the Bank of England that several thousand pounds' worth were annually remitted from the Isthmus as bullion to that establishment," where they were melted down.

A. C. Haddon.

THE BRITISH ASSOCIATION AT DUNDEE.

ONE of the most successful meetings of the British Association in recent years, and the largest since the Cambridge meeting of 1904, when the total attendance was 2789, in comparison with about 2500 at Dundee, was brought to a close as we went to press last week. A distinguishing and pleasing characteristic of the meeting was the interest taken in scientific questions by the people of Dundee and the neighbourhood; and to this interest may perhaps be attributed the generous provision made privately for visitors.

In proposing a cordial vote of thanks to the Lord Provost, Magistrates, and Town Council of Dundee for this unbounded hospitality, at the closing meeting on September 11, the President, Prof. Schäfer, rightly remarked that though he had attended many meetings of the Association, he did not think that on any occasion had a more cordial welcome been extended than that enjoyed at Dundee. He could certainly say that the Association had never been entertained more royally or hospitably.

Lord Provost Urquhart, in acknowledging the vote of thanks, said that from the time the suggestion was first made by Prof. D'Arcy Thompson that it might be possible to have a visit from the British Association, the citizens had responded most enthusiastically. The providing of hospitality had been a problem owing to the limited hotel accommodation in the city, but the local committee had, he hoped, been able to solve it to the satisfaction of the visitors.

Sir William White, the President-elect, proposed thanks to the Council of University College, the governing bodies of the Chamber of Commerce, Technical College, and other institutions for their kindness in placing their buildings and resources at the disposal of the Association.

Principal Griffiths moved a vote of thanks to the Provost and Magistrates of the burghs of St. Andrews, Dunfermline, and Arbroath, and to all who had contributed by means of excursions, garden-parties, and in other ways to the entertainment of the members. Finally, Prof. Perry, the general treasurer, expressed the thanks of the Association to the local officers and executive for the admirable arrangements they had made, and remarked that it was the best engineered meeting he had attended in forty years.

At the meeting of the General Committee on September 11, the following resolutions submitted by the sections named were adopted:—

Mathematical and Physical Science.—(1) That it be recommended to the General Committee that the cordial thanks of the Association be forwarded to the *Falmouth* Committee for their valuable services since their appointment in 1901; and especially to their chairman, Sir William Preece, and the secretaries, Dr. R. T. Glazebook and Dr. W. N. Shaw.

That, having regard to the importance of the observations at Falmouth in the work of the previous survey and in other work in connection with terrestrial magnetism and meteorology, steps be taken to assist an appeal for a Treasury grant, in order that the observatory at Falmouth may be efficiently maintained.

(2) That it is desirable that a detailed magnetic survey of the British Isles, on the lines of that of Profs. Rucker and Thorpe for the epoch of 1891, should now be repeated, in order to answer the question as to the local variations of the terrestrial magnetic elements within twenty-five years.

That a representation to this effect be made to the Royal Society, the Admiralty, the Ordnance Survey, and the Meteorological Committee.

Zoology.—The British Association for the Advancement of Science deplores the rapid destruction of fauna and flora throughout the world, and regards it as an urgent duty that immediate steps be taken to secure the preservation of all kinds of animals and plants, irrespective of their economic or sporting value.

Anthropology.—That the copies of the fourth edition of "Notes and Queries in Anthropology," now on the point of publication through the committee appointed for the purpose of its preparation, be delivered as heretofore to the Royal Anthropological Institute for sale to its members and to the public, the proceeds to be reserved at the disposal of the Association towards the expenses of any future editions, and accounts of the sales to be submitted to the general treasurer of the Association on demand.

Papers to be printed *in extenso*:—Dr. J. V. Eyre, "Report on Solubility," part ii.; Sir John Macdonald, "The Road Problem."

A sum of 1036*l.* 18*s.* 8*d.* was appropriated for scientific purposes by the committee. Subjoined is a synopsis of the subjects for which the grants are made, and the names of chairmen of the committees:—

Mathematical and Physical Science.

Prof. H. H. Turner, seismological observations ...	£60 0 0	
Dr. W. N. Shaw, upper atmosphere	50 0 0	
Sir W. Ramsay, grant to the International Commission on Physical and Chemical Constants	40 0 0	
Prof. M. J. M. Hill, tabulation of Bessel functions ...	30 0 0	
		£180 0 0

Chemistry.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY P. CHALMERS MITCHELL, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

Zoological Gardens and the Preservation of Fauna.

IN thinking over possible subjects for this Presidential Address, I was strongly tempted to enter on a discussion of the logical methods and concepts that we employ in zoology. The temptation was specially strong to a Scot, speaking in Scotland, that he should devote the hour when the prestige of the presidential chair secured him attention, to putting his audience right on logic and metaphysics. But I reflected that zoology is doing very well, however its logic be wavering, and that as all lines subtend an equal angle at infinity, it would be of small moment if I were to postpone my remarks on metaphysics. And so I am to essay a more modest but a more urgent theme, and ask you to consider the danger that threatens the surviving land-fauna of this globe. A well-known example may serve to remind you how swift is the course of destruction. In 1867, when the British Association last met at Dundee, there were still millions of bison roaming over the prairies and forests of North America. In that year the building of the Union Pacific, the first great trans-continental railway, cut the herd in two. The southern division, consisting itself of several million individuals, was wiped out between 1871 and 1874, and the practical destruction of the northern herd was completed between 1880 and 1884. At present there are only two herds of wild bison in existence. In the Yellowstone Park only about twenty individuals remained in 1911, the greater part of the herd having been killed by poachers. A larger number, more than three hundred, still survive near the Great Slave Lake, and there are probably nearly two thousand in captivity, in various zoological gardens, private domains and State parks. It is only by the deliberate and conscious interference of man that the evil wrought by man has been arrested.

A second example that I may select is also taken from the continent of North America, but it is specially notable because it is sometimes urged, as in India, that migratory birds require no protection. Audubon relates that just a century ago passenger pigeons existed in countless millions, and that for four days at a time the sky was black with the stream of migration. The final extinction of this species has taken place since the last meeting of the Association in Dundee. In 1906 there were actually five single birds living, all of which had been bred in captivity, and I understand that these last survivors of a prolific species are now dead, although the birds ranged in countless numbers over a great continent.

It would be futile to discuss in detail the precise agencies by which the destruction of animal life is wrought, or the pretexts or excuses for them. The most potent factors are the perfection of the modern firearm and the enormous increase in its use by civilised and barbarous man. Sometimes the pretext is sport, sometimes wanton destructiveness rules. The extermination of beasts of prey, the clearing of soil for stock or crops, the securing of meat, the commercial pursuit of hides and horns and of furs and feathers, all play their part. Farmers and settlers on the outskirts of civilisation accuse the natives, and allege that the problem would be solved were no firearms allowed to any but themselves. Sportsmen accuse other sportsmen, whom they declare to be no real sportsmen, and every person whose object is not sport. The great museums, in the name of science, and the rich amateur collectors press forward to secure the last specimens of moribund species.

But even apart from such deliberate and conscious agencies, the near presence of man is inhospitable to wild life. As he spreads over the earth, animals wither before him, driven from their haunts, deprived of their food, perishing from new diseases. It is part of a general biological process. From time to time, in the past history of the world, a species, favoured by some happy kink of structure or fortunate accident of adaptability, has become dominant. It has increased greatly in numbers, outrunning its natal bounds, and has radiated in every possible direction, conquering woodland and prairies, the hills and the plains, transcending barriers that had seemed impassable, and perhaps itself breaking up into new local races and varieties. It must be long since such a triumphant progress was unattended by death and destruction. When the first terrestrial animals crept out of their marshes into the clean air of the dry land, they had only plants and the avenging pressure of physical forces to overcome. But when the Amphibians were beaten by the Reptiles, and when from amongst the Reptiles some insignificant species acquired the prodigious possibility of transformation to Mammals, and still more when amongst the Mammals Eutherian succeeded Marsupial, Carnivore the Creodont, and Man the Ape, it could have been only after a fatal contest that the newcomers triumphed. The struggle, we must suppose, was at first most acute between animals and their nearest inferior allies, as similarity of needs brings about the keenest competition, but it must afterwards have been extended against lower and lower occupants of the coveted territory.

The human race has for long been the dominant terrestrial species, and man has a wider capacity for adaptation to different environments, and an infinitely greater power of transcending geographical barriers than have been enjoyed by any other set of animals. For a considerable time many of the more primitive tribes, especially before the advent of firearms, had settled down into a kind of natural equilibrium with the local mammalian fauna, but these tribes have been first driven to a keener competition with the lower animals, and then, in most parts of the world, have themselves been forced almost or completely out of existence. The resourceful and aggressive higher races have now reached into the remotest parts of the earth and have become the exterminators. It must now be the work of the most intelligent and provident amongst us to arrest this course of destruction, and to preserve what remains.

In Europe, unfortunately, there is little left sufficiently large and important to excite the imagination. There is the European bison, which has been extinct in Western Europe for many centuries, whilst the last was killed in East Prussia in 1755. There remains a herd of about seven hundred in the forests of Lithuania, strictly protected by the Tsar, whilst there are truly wild animals, in considerable numbers, in the Caucasus, small captive herds on the private estates of the Tsar, the Duke of Pless and Count Potocki, and a few individuals in various zoological gardens. There is the beaver, formerly widespread in Europe, now one of the rarest of living mammals, and lingering in minute numbers in the Rhone, the Danube, in a few Russian rivers, and in protected areas in Scandinavia. The wolf and the bear have shrunk to the recesses of thick forests and the remotest mountains, gluttons to the most barren regions of the north. The chamois survives by favour of game-laws and the vast inaccessible areas to which it can retreat, but the mouflon of Corsica and Sardinia and the ibex in Spain are on the verge of extinction. Every little creature, from the otter, wild cat, and marten to the curious desman, is disappearing.

India contains the richest, the most varied, and, from many points of view, the most interesting part of the Asiatic fauna. Notwithstanding the teeming human population it has supported from time immemorial, the extent of its area, its dense forests and jungles, its magnificent series of river valleys, mountains, and hills have preserved until recent times a fauna rich in individuals and species. The most casual glance at the volumes by sportsmen and naturalists written forty or fifty years ago reveals the delight and wonder of travel in India so comparatively recently as the time when the Association last met in Dundee. Sir H. H. Johnston has borne witness that even in 1895 a journey "through almost any part of India was of absorbing interest to the naturalist." All is changed now, and there seems little doubt but that the devastation in the wonderful mammalian fauna has been wrought chiefly by British military officers and civilians, partly directly, and partly by their encouragement of the sporting instincts of the Mohammedan population and the native regiments, although the clearing of forests and the draining of marshlands have played an important contributory part. The tiger has no chance against the modern rifle. The one-horned rhinoceros has been nearly exterminated in Northern India and Assam. The magnificent gaur, one of the most splendid of living creatures, has been almost killed off throughout the limits of its range—southern Indian and the Malay Peninsula. Bears and wolves, wild dogs and leopards are persecuted remorselessly. Deer and antelope have been reduced to numbers that alarm even the most thoughtless sportsmen, and wild sheep and goats are being driven to the utmost limits of their range.

When I speak of the fauna of Africa, I am always being reminded of the huge and pathless areas of the Dark Continent, and assured that lions and leopards, elephants and giraffe still exist in countless numbers, nor do I forget the dim recesses of the tropical forests where creatures still lurk of which we have only the vaguest rumour. But we know that South Africa, less than fifty years ago, was a dream that surpassed the imagination of the most ardent hunter. And we know what it is now. It is traversed by railways, it has been rolled over by the devastations of war. The game that once covered the land in unnumbered millions is now either extinct, like the quagga and the black wildebeeste, or its scanty remnant lingers in a few reserves and on a few farms. The sportsman and the hunter have been driven to other parts of the continent, and I have no confidence in the future of the African fauna. The Mountains of the Moon are within range of a long vacation holiday. Civilisation is eating into the land from every side. All the great European countries are developing their African possessions. There are exploring expeditions, punitive expeditions, shooting and collecting expeditions. Railways are being pushed inland, water-routes opened up. The land is being patrolled and policed and taxed, and the wild animals are suffering. Let us go back for a moment to the Transvaal and consider what has happened since the Rand was opened, neglecting the reserves. Lions are nearly extinct. The hyæna has been trapped and shot and poisoned out of existence. The eland is extinct. The giraffe is extinct. The elephant is extinct. The rhinoceros is extinct. The buffalo is extinct. The bontebok, the red hartebeeste, the mountain zebra, the oribi, and the grysbok are so rare as to be practically extinct. And the same fate may at any time overtake the rest of Africa. The white man has learned to live in the tropics; he is mastering tropical diseases; he has need of the vegetable and mineral wealth that lie awaiting him, and although there is yet time to save the African fauna, it is in imminent peril.

When we turn to Australia, with its fauna of unique zoological interest, we come to a more advanced case of the same disease. In 1909 Mr. G. C. Shortridge, a very skilled collector, working for the British Museum, published in the Proceedings of the Zoological Society of London the results of an investigation he had carried out on the fauna of Western Australia south of the tropics, during the years 1904–7.

He gave a map showing the present and comparatively recent distribution for each of the species of Marsupials and Monotremes indigenous to that locality. West Australia as yet has been very much less affected by civilisation than Queensland, New South Wales, or Victoria, and yet in practically every case there was found evidence of an enormous recent restriction of the range of the species. Marsupials and Monotremes are, as you know, rather stupid animals, with small powers of adaptation to new conditions, and they are in the very gravest danger of complete extinction. In the island of Tasmania, the thylacine, or marsupial wolf, and the Tasmanian devil have unfortunately incurred the just hostility of the stock raiser and poultry farmer, and the date of their final extermination is approaching at a pace that must be reckoned by months rather than by years.

The development of the continent of North America has been one of the wonders of the history of the world, and we on this side of the Atlantic almost hold our breath as we try to realise the material wealth and splendour and the ardent intellectual and social progress that have turned the United States into an imperial nation. But we know what has happened to the American bison. We know the danger that threatens the pronghorn, one of the most isolated and interesting of living creatures, the Virginian deer, the mule-deer, and the bighorn sheep. Even in the wide recesses of Canada, the bighorn, the caribou, the elk, the wapiti, the white mountain goat, and the bears are being rapidly driven back by advancing civilisation. In South America less immediate danger seems to threaten the jaguar and maned wolf, the tapirs and ant-eaters and sloths, but the energy of the rejuvenated Latin races points to a huge encroachment of civilisation on wild nature at no distant date.

You will understand that I am giving examples and not a catalogue even of threatened terrestrial mammals. I have said nothing of the aquatic carnivores, nothing of birds, or of reptiles, or of batrachians and fishes. And to us who are zoologists, the vast destruction of invertebrate life, the sweeping out, as forests are cleared and the soil tilled, of innumerable species that are not even named or described is a real calamity. I do not wish to appeal to sentiment. Man is worth many sparrows; he is worth all the animal population of the globe, and if there were not room for both, the animals must go. I will pass no judgment on those who find the keenest pleasure of life in gratifying the primeval instinct of sport. I will admit that there is no better destiny for the lovely plumes of a rare bird than to enhance the beauty of a beautiful woman. I will accept the plea of those who prefer a well-established trinomial to a moribund species. But I do not admit the right of the present generation to careless indifference or to wanton destruction. Each generation is the guardian of the existing resources of the world; it has come into a great inheritance, but only as a trustee. We are learning to preserve the relics of early civilisations, and the rude remains of man's primitive arts and crafts. Every civilised nation spends great sums on painting and sculpture, on libraries and museums. Living animals are of older lineage, more perfect craftsmanship and greater beauty than any of the creations of man. And although we value the work of our forefathers, we do not doubt but that the generations yet unborn will produce their own artists and writers, who may equal or surpass the artists and writers of the past. But there is no resurrection or recovery of an extinct species, and it is not merely that here and there one species out of many is threatened, but that whole genera, families, and orders are in danger.

Now let me turn to what is being done and what has been done for the preservation of fauna. I must begin by saying, and this was one of the principal reasons for selecting the subject of my address, that we who are professional zoologists, systematists, anatomists, embryologists, and students of general biological problems, in this country at least, have not taken a sufficiently active part in the preservation of the realm of nature that provides the reason for our existence. The first and most practical step of world-wide importance was taken by a former president of the British Association, the late Lord Salisbury, one of the few in the long roll of English statesmen whose mind was attuned to science. In 1899 he arranged for a convention of the Great Powers interested in Africa to consider the preservation of what were curiously described as the "Wild Animals, Birds and Fish" of that continent. The convention, which did most important pioneer work, included amongst its members another president of this Association, Sir Ray Lankester, whom we hold in high honour in this section as the living zoologist who has taken the widest interest in every branch of zoology. But it was confined in its scope to creatures of economic or of sporting value. And from that time on the central authorities of the Great Powers and the local administrators, particularly in the case of tropical possessions, seem to have been influenced in the framing of their rules and regulations chiefly by the idea of preserving valuable game animals. Defining the number of each kind of game that can be killed, charging comparatively high sums for shooting-permits, and the establishment of temporary or permanent reserved tracts in which the game may recuperate, have been the principal methods selected. On these lines, narrow although they are, much valuable work has been done, and the parts of the world where unrestricted shooting is still possible are rapidly being limited. I may take the proposed new Game Act of our Indian Empire, which has recently been explained, and to a certain extent criticised, in the Proceedings of the Zoological Society of London, by Mr. E. P. Stebbing, an enlightened sportsman-naturalist, as an example of the efforts that are being made in this direction, and of their limitations.

The Act is to apply to all India, but much initiative is left to local governments as to the definition of the important words "game" and "large animal." The Act, however, declares what the words are to mean in the absence of such local definitions, and it is a fair assumption that local interpretations will not depart widely from the lead given by the central authority. Game is to include the following in their wild state:—Pigeons, sandgrouse, peafowl, junglefowl, pheasants, partridges, quail, spurfowl, florican and their congeners; geese, ducks and their congeners; woodcock and snipe. So much for birds. Mammals include hares and "large animals" defined as "all kinds of rhinoceros, buffalo, bison, oxen; all kinds of sheep, goats, antelopes and their congeners; all kinds of gazelle and deer."

The Act does not affect the pursuit, capture, or killing of game by non-commissioned officers or soldiers on whose behalf regulations have been made, or of any animal for which a reward may be claimed from Government, of any large animal in self-defence, or of any large animal by a cultivator or his servants, whose crops it is injuring. Nor does it affect anything done under licence for possessing arms and ammunition to protect crops, or for destroying dangerous animals, under the Indian Arms Act. Then follow prohibitory provisions, all of which refer to the killing or to the sale or possession of game or fish, and provisions as to licences for sportsmen, the sums to be paid for which are merely nominal, but which carry restrictions as to the number of head that may be killed. I need not enter upon detailed criticism as to the vagueness of this Act from the zoological point of view, or as to the very large loopholes which its provisions leave to civil and military sportsmen; these have been excellently set forth by Mr. Stebbing, who has full knowledge of the special conditions which exist in India. What I desire to point out is that it conceives of animals as game rather than as animals, and that it does not even contemplate the possibility of the protection of birds of prey and beasts of prey, and still less of the enormous number of species of animals that have no sporting or economic value.

Mr. Stebbing's article also gives a list of the very large number of reserved areas in India which are described as "Game Sanctuaries." His explanation of them is as follows:—"With a view to affording a certain protection to animals of this kind (the elephant, rhinoceros, ruminants, &c.), and of giving a rest to species which have been heavily thinned in a district by indiscriminate shooting in the past, or by anthrax, drought, &c., the idea of the Game Sanctuary was introduced into India (and into other parts of the world) and has been accepted in many parts of the country. The sanctuary consists of a block of country, either of forest or of grassland, &c., depending on the nature of the animal to which sanctuary is required to be given; the area has rough boundaries such as roads, fire lines, nullahs, &c., assigned to it, and no shooting of any kind is allowed in it, if it is a sanctuary pure and simple; or the shooting of carnivora may be permitted, or of these latter and of everything else save certain specified animals."

Mr. Stebbing goes on to say that sanctuaries may be formed in two ways. The area may be automatically closed and reopened for certain definite periods of years, or be closed until the head of game has become satisfactory, the shooting on the area being then regulated, and no further closing taking place, save for exceptional circumstances. The number of such sanctuary blocks, both in British India and in the Native States, will cause surprise and pleasure to most readers, and it cannot be doubted but that they will have a large effect on the preservation of wild life. The point, however, that I wish to make is that in the minds of those who have framed the Game Act, and of those who have caused the making of the sanctuaries—as indeed in the minds of their most competent critics—the dominant idea has been the husbanding of game animals, the securing for the future of sport for sportsmen. I do not forget that there is individual protection for certain animals; no elephant, except a rogue elephant, may be shot in India, and there are excellent regulations regarding birds with plumage of economic value. The fact remains that India, a country which still contains a considerable remnant of one of the richest faunas of the world, and which also is probably more efficiently under the autocratic control of a highly educated body of permanent officials, central and local, than any other country in the world, has no provision for the protection of its fauna simply as animals.

The conditions in Africa are very different from those in India. The land is portioned out amongst many Powers. The settled population is much less dense, and the hold of the white settler and the white ruler is much less complete. The possibility of effective control of native hunters and of European travellers and sportsmen is much smaller, and as there are fewer sources of revenue, the temptation to exploit the game for the immediate development of the struggling colonies is much greater. Still, the lesson of the extinction of the South African fauna is being taken to heart. I have had the opportunity of going through the regulations made for the shooting of wild animals in Africa by this country, by our autonomic colonies, by France, Germany, Italy, Portugal, and Belgium, and, with the limitation that they are directed almost solely towards the protection of animals that can be regarded as game, they afford great promise for the future. But this limitation is still stamped upon them, and even so enthusiastic a naturalist as Major Stevenson-Hamilton, the warden of the Transvaal Government Game Reserves, who has advocated the substitution of the camera for the rifle, appears to be of the opinion that the platform of the convention of 1900 is sufficient. It included the sparing of females and immature animals, the establishment of close seasons and game sanctuaries, the absolute protection of rare species, restrictions on the export for trading purposes of skins, horns, and tusks, and the prohibition of pits, snares, and game traps. Certainly the rulers of Africa are seeing to the establishment of game reserves. As for British Africa, there are two in Somaliland, two in the Sudan, two in Uganda, and two in British East Africa (with separate reserves for eland, rhinoceros, and hippopotamus), two in Nyasaland, three in the Transvaal, seven in Rhodesia, several in Natal and in Cape Colony, and at least four in Nigeria. These are now administered by competent officials, who, in addition, are usually the executive officers of the game laws outside the reserved territory. Here again, however, the preservation of game animals and of other animals of economic value, and of a few named species, is the fundamental idea. In 1909 I had the honour of being a member of a deputation to the Secretary of State for the Colonies, arranged by the Society for the Preservation of the Wild Fauna of the Empire, one of the most active and successful bodies engaged in arousing public opinion on the subject. Among the questions on which we were approaching Lord Crewe was that of changes in the locality of reserves. Sometimes it had happened that for the convenience of settlers or because of railway extension, or for some other reason, proposals were made to open or clear the whole or part of a reserve. When I suggested that the substitution of one piece of ground for another, even of equivalent area, might be satisfactory from the point of view of the preservation of large animals, but was not satisfactory from the zoological point of view, that in fact pieces of primeval land and primeval forest contained many small animals of different kinds which would be exterminated once and for all when the land was brought under cultivation, the point was obviously new not only to the Colonial Secretary, who very courteously noted it, but to my colleagues.

This brings me to the general conclusion to which I wish to direct your attention, and for which I hope to engage your sympathy. We may safely leave the preservation of game animals, or rare species if these are well known and interesting, and of animals of economic value, to the awakened responsibility and the practical sense of the governing powers, stimulated as these are by the enthusiasm of special societies. Game laws, reserves where game may recuperate, close seasons, occasional prohibition and the real supervision of licence-holders are all doing their work effectively. But there remains something else to do, something which I think should interest zoologists particularly, and on which we should lead opinion. There exist in all the great continents large tracts almost empty of resident population, which still contain vegetation almost undisturbed by the ravages of man, and which still harbour a multitude of small animals, and could afford space for the larger and better-known animals. These tracts have not yet been brought under cultivation, and are rarely traversed except by the sportsman, the explorer, and the prospector. On these there should be established, in all the characteristic faunistic areas, reservations which should not be merely temporary recuperating grounds for harassed game, but absolute sanctuaries. Under no condition should they be open to the sportsman. No gun should be fired, no animal slaughtered or captured save by the direct authority of the wardens of the sanctuaries, and for the direct advantage of the denizens of the sanctuaries, for the removal of noxious individuals, the controlling of species that were increasing beyond reason, the extirpation of diseased or unhealthy animals. The obvious examples are not the game reserves of the Old World, but the national parks of the New World and of Australasia. In the United States, for instance, there are now the Yellowstone National Park with more than two million acres, the Yosemite in California with nearly a million acres, the Grand Cañon Game Preserve with two million acres, the Mount Olympus National Monument in Washington with more than half a million acres, and the Superior Game and Forest Preserve with nearly a million acres, as well as a number of smaller reserves for special purposes, and a chain of coastal areas all round the shores for the preservation of birds. In Canada, in Alberta, there are the Rocky Mountains Park, the Yoho Park, Glacier Park, and Jasper Park, together extending to more than nine million acres, whilst in British Columbia there are smaller sanctuaries. These, so far as laws can make them, are inalienable and inviolable sanctuaries for wild animals. We ought to have similar sanctuaries in every country of the world, national parks secured for all time against all the changes and chances of the nations by international agreement. In the older and more settled countries the areas selected unfortunately must be determined by various considerations, of which faunistic value cannot be the most important. But certainly in Africa, and in large parts of Asia, it would still be possible that they should be selected in the first place for their faunistic value. The scheme for them should be drawn up by an international commission of experts in the geographical distribution of animals, and the winter and summer haunts of migratory birds should be taken into consideration. It is for zoologists to lead the way, by laying down what is required to preserve for all time the most representative and most complete series of surviving species without any reference to the extrinsic value of the animals. And it then will be the duty of the nations, jointly and severally, to arrange that the requirements laid down by the experts shall be complied with.

And now I come to the last side of my subject, that of zoological gardens, with which I have been specially connected in the last ten years. My friend M. Gustave Loisel, in his recently issued monumental "Histoire des Ménageries," has shown that in the oldest civilisations of which we have record, thousands of years before the Christian era, wild animals were kept in captivity. He is inclined to trace the origin of the custom to a kind of totemism. Amongst the ancient Egyptians, for instance, besides the bull and the serpent, baboons, hippopotami, cats, lions, wolves, ichneumons, shrews, wild goats, and wild sheep, and of lower animals, crocodiles, various fishes, and beetles were held sacred in different towns. These animals were protected, and even the involuntary killing of any of them was punished by the death of the slayer, but besides this general protection, the priests selected individuals which they recognised by infallible signs as being the divine animals, and tamed, guarded, and fed in the sacred buildings, whilst the revenues derived from certain tracts of land were set apart for their support. The Egyptians were also famous hunters, and kept and tamed various wild animals, including cheetahs, striped hyænas, leopards, and even lions, which they used in stalking their prey. The tame lions were sometimes clipped, as in ancient Assyria, and used both in the chase and in war. The rich Egyptians of Memphis had large parks in which they kept not only the domestic animals we now know, but troops of gazelles, antelopes, and cranes, which were certainly tame and were herded by keepers with wands. So also in China at least fifteen centuries before our era, wild animals were captured in the far north by the orders of the Emperor and were kept in the royal parks. A few centuries later the Emperor Wen-Wang established a zoological collection between Pekin and Nankin, his design being partly educational, as it was called the Park of Intelligence. In the valley of the Euphrates, centuries before the time of Moses, there were lists of sacred animals, and records of the keeping in captivity of apes, elephants, rhinoceroses, camels and dromedaries, gazelles and antelopes, and it may well be that the legend of the Garden of Eden is a memory of the royal menagerie of some ancient king. The Greeks, whose richest men had none of the wealth of the Egyptians or of the princes of the East, do not appear to have kept many wild animals, but the magnates of imperial Rome captured large numbers of leopards, lions, bears, elephants, antelopes, giraffes, camels, rhinoceroses and hippopotami, and ostriches and crocodiles, and kept them in captivity, partly for use in the arena, and partly as a display of the pomp and power of wealth. In later times royal persons and territorial nobles frequently kept menageries of wild animals, aviaries and aquaria, but all these have long since vanished.

Thus, although the taste for keeping wild animals in captivity dates from the remotest antiquity, all the modern collections are of comparatively recent origin, the oldest being the Imperial Menagerie of the palace of Schönbrunn, Vienna, which was founded about 1752, whilst some of the most important are only a few years old. These existing collections are of two kinds. A few are the private property of wealthy landowners, and their public importance is due partly to the opportunity they have afforded for experiments in acclimatisation on an extensive scale, and still more to the refuge they have given to the relics of decaying species. The European bison is one of the best-known cases of such preservation, but a still more extraordinary instance is that of Père David's deer, a curious and isolated type which was known only in captivity in the imperial parks of China. The last examples in China were killed in the Boxer war, and the species would be absolutely extinct but for the small herd maintained by the Duke of Bedford at Woburn Abbey. In 1909 this herd consisted of only twenty-eight individuals; it now numbers sixty-seven. The second and best-known types of collections of living animals are in the public zoological gardens and parks maintained by societies, private companies, States and municipalities. There are now more than a hundred of these in existence, of which twenty-eight are in the United States, twenty in the German Empire, five in England, one in Ireland, and none in Scotland. But perhaps I may be allowed to say how much I hope that the efforts of the Zoological Society of Scotland will be successful, and that before many months are over there will be a zoological park in the capital of Scotland. There is no reason of situation or of climate which can be urged against it. The smoke and fog of London are much more baleful to animals than the east winds of Edinburgh. The gardens of North Germany and the excellent institution at Copenhagen have to endure winters much more severe than those of lowland Scotland, whilst the arctic winter and tropical summer of New York form a peculiarly unfortunate combination, and none the less the Bronx Park at New York is one of the most delightful menageries in existence. The Zoological Society of Scotland will have the great advantage of beginning where other institutions have left off; it will be able to profit by the experience and avoid the mistakes of others. The Zoological Society of London would welcome the establishment of a menagerie in Scotland, for scientific and practical reasons. As I am speaking in Scotland, I may mention two of the practical reasons. The first is that in Great Britain we labour under a serious disadvantage as compared with Germany with regard to the importation of rare animals. When a dealer in the tropics has rare animals to dispose of, he must send them to the best market, for dealing in wild animals is a risky branch of commerce. If he send them to this country, there are very few possible buyers, and it often happens that he is unable to find a purchaser. If he send them to Germany, one or other of the twenty gardens is almost certain to absorb them, and, failing Germany, Belgium and Holland are near at hand. Were there twenty prosperous zoological gardens in Great Britain, they could be better stocked, at cheaper rates, than those we have now. The second practical reason is that it is a great advantage to menageries to have easy opportunities of lending and exchanging animals; for it often happens that as a result of successful breeding or of gifts on one hand, or of deaths on the other, a particular institution is overstocked with one species or deficient in another.

One of the ideas strongly in the minds of those who founded the earlier of modern zoological gardens was the introduction and acclimatisation of exotic animals that might have an economic value. It is curious how completely this idea has been abandoned and how infertile it has proved. The living world would seem to offer an almost unlimited range of creatures which might be turned to the profit of man and as domesticated animals supply some of his wants. And yet I do not know of any important addition to domesticated animals since the remotest antiquity. A few birds for the coverts, fancy water-fowl for ponds and lakes, and brightly plumaged birds for cages or for aviaries have been introduced, chiefly through zoological societies, but we must seek other reasons for their existence than these exiguous gains.

Menageries are useful in the first place as educational institutions, in the widest sense of the word. Every new generation should have an opportunity of seeing the wonder and variety of animated nature, and of learning something that they cannot acquire from books or pictures or lectures about the chief types of wild animals. For that reason zoological gardens should be associated in some form with elementary and secondary education. We in London admit the children from elementary schools on five mornings in the week at the nominal charge of a penny for each child, and in co-operation with the Educational Committee of the London County Council, we conduct courses of lectures and demonstrations for the teachers, who will afterwards bring their children to visit the gardens.

Menageries provide one of the best schools for students of art, for nowhere else than amongst living animals are to be found such strange fantasies of colour, such play of light on contour and surface, such intricate and beautiful harmonies of function and structure. To encourage art the London society allows students of recognised schools of drawing and painting, modelling and designing, to use the gardens at nominal rates.

Menageries provide a rich material for the anatomist, histologist, physiologist, parasitologist, and pathologist. It is surprising to note how many of the animals used by Lamarck and Cuvier, Johannes Müller and Wiedersheim, Owen and Huxley, were obtained from zoological gardens. At all the more important gardens increasing use is being made of the material for the older purposes of anatomical research and for the newer purposes of pathology and physiology.

There remains the fundamental reason for the existence of menageries, that they are collections of living animals, and therefore an essential material for the study of zoology. Systematic zoology, comparative anatomy, and even morphology, the latter the most fascinating of all the attempts of the human intellect to recreate nature within the categories of the human mind, have their reason and their justification in the existence of living animals under conditions in which we can observe them. And this leads me to a remark which ought to be a truism, but which, unfortunately, is still far from being a truism. The essential difference between a zoological museum and a menagerie is that in the latter the animals are alive. The former takes its value from its completeness, from the number of rare species of which it has examples, and from the extent to which its collections are properly classified and arranged. The value of a menagerie is not its zoological completeness, not the number of rare animals that at any moment it may contain, not even the extent to which it is duly labelled and systematically arranged, but the success with which it displays its inhabitants as living creatures under conditions in which they can exercise at least some of their vital activities.

The old ideal of a long series of dens or cages in which representatives of kindred species could mope opposite their labels is surely but slowly disappearing. It is a museum arrangement, and not an arrangement for living animals. The old ideal by which the energy and the funds of a menagerie were devoted in the first place to obtaining species "new to the collection" or "new to science" is surely but slowly disappearing. It is the instinct of a collector, the craving of a systematist, but is misplaced in those who have the charge of living animals. Certainly we like to have many species, to have rare species, and even to have new species represented in our menageries. But what we are learning to like most of all is to have the examples of the species we possess, whether these be new or old, housed in such a way that they can live long, and live happily, and live under conditions in which their natural habits, instincts, movements, and routine of life can be studied by the naturalist and enjoyed by the lover of animals.

Slowly the new conditions are creeping in, most slowly in the older institutions hampered by lack of space, cumbered with old and costly buildings, oppressed by the habits of long years and the traditions established by men who none the less are justly famous in the history of zoological science. Space, open air, scrupulous attention to hygiene and diet, the provision of some attempt at natural environment are receiving attention that they have never received before. You will see the signs of the change in Washington and New York, in London and Berlin, in Antwerp and Rotterdam, and in all the gardens of Germany. It was begun simultaneously, or at least independently, in many places and under the inspiration of many men. It is, I think, part of a general process in which civilised man is replacing the old hard curiosity about nature by an attempt at sympathetic comprehension. We no longer think of ourselves as alien from the rest of nature, using our lordship over it for our own advantage; we recognise ourselves as part of nature, and by acknowledging our kinship we are on the surest road to an intelligent mastery. But I must mention one name, that of Carl Hagenbeck, of Hamburg, to be held in high honour by all zoologists and naturalists, although he was not the pioneer, for the open-air treatment and rational display of wild animals in captivity were being begun in many parts of the world while the Thier-Park at Stellingen was still a suburban waste. He has brought a reckless enthusiasm, a vast practical knowledge, and a sympathetic imagination to bear on the treatment of living animals, and it would be equally ungenerous and foolish to fail to recognise the widespread and beneficent influence of his example.

However we improve the older menageries and however numerous and well-arranged the new menageries may be, they must always fall short of the conditions of nature, and here I find another reason for the making of zoological sanctuaries throughout the world. If these be devised for the preservation of animals, not merely for the recuperation of game, if they be kept sacred from gun or rifle, they will become the real zoological gardens of the future, in which our children and our children's children will have the opportunity of studying wild animals under natural conditions. I myself have so great a belief in the capacity of wild animals for learning to have confidence in man, or rather for losing the fear of him that they have been forced to acquire, that I think that man, innocent of the intent to kill, will be able to penetrate fearlessly into the sanctuaries, with camera and notebook and field-glass. In any event, all that the guardians of the future will have to do will be to reverse the conditions of our existing menageries and to provide secure enclosures for the visitors instead of for the animals.

I must end as I began this address, by pleading the urgency of the questions I have been submitting to you as an excuse for diverting your attention to a branch of zoology which is alien from the ordinary avocations of most zoologists, but which none the less is entitled to their fullest support. Again let me say to you that I do not wish to appeal to sentiment; I am of the old school, and, believing that animals are subject and inferior to man, I set no limits to human usufruct of the animal kingdom. But we are zoologists here, and zoology is the science of the living thing. We must use all avenues to knowledge of life, studying the range of form in systematic museums, form itself in laboratories, and the living animal in sanctuaries and menageries. And we must keep all avenues to knowledge open for our successors, as we cannot guess what questions they may have to put to nature.

SECTION E.

GEOGRAPHY.

From the Opening Address by Colonel Sir C. M. Watson, K.C.M.G., C.B., President of the Section.

Leaving the Sudan,[1] I would like to allude to a very important geographical undertaking which has made considerable progress during the past year. This is the production of the international map of the world on the scale of 1/1000000, a project which has been under the consideration of the leading geographers of the important countries for more than twenty years, since it was first proposed at the International Geographical Congress held at Berne in 1891. The question was discussed at succeeding geographical congresses, but did not take definite shape until the meeting held at Geneva in 1908, when a series of resolutions dealing with the subject were drawn up by a committee composed of distinguished men of many nations, which was appointed to formulate rules for the production of the maps, so as to ensure that they should be prepared upon a uniform system.

These resolutions were approved at a general meeting of the Geneva Congress, and were forwarded by the Swiss Government to the British Government for consideration, whereupon the latter issued invitations to the Governments of Austria-Hungary, France, Germany, Japan, Russia, Italy, Spain, and the United States of North America, asking them to nominate delegates to act as the members of an international committee to meet in London and debate the question. The committee assembled at the Foreign Office in November, 1909, and Colonel S. C. N. Grant, C.M.G., then Director-General of the British Ordnance Survey, was appointed president. The proceedings were opened by the Under-Secretary of State for Foreign Affairs, Sir Charles Hardinge, G.C.M.G., now Lord Hardinge, who, in his address, referred to the progress that had already been made with regard to the international map, and expressed the hope, on behalf of the British Government, that the great undertaking might be brought to a satisfactory conclusion.

The main business before the committee was to settle on the mode of execution of the map, especially as regards the size of the sheets, so as to ensure that adjacent sheets, published by different countries, should fit together; and also to settle upon the symbols, printing, and conventional signs to be used, in order that these should be uniform throughout. A series of resolutions, embodying the decisions arrived at concerning these various points, was approved and drawn up in English, French, and German, the first of these languages being taken as the authoritative text. As the map was to embrace the whole surface of the globe, the method of projection to be adopted was, of course, a very important consideration, and, after due deliberation, it was decided that a modified polyconic projection, with the meridians shown as straight lines, and with each sheet plotted independently on its central meridian, would prove the most satisfactory.

The surface of the sphere was divided into zones, each containing four degrees of latitude, commencing at the equator, and extending to 88° North and 88° South latitude. There were thus twenty-four zones on each side of the equator, and these were distinguished by the letters A to V north, and A to V south. This fixed the height of each sheet. For the width of the sheets, the surface of the sphere was divided into sixty segments, each containing six degrees of longitude, and numbered consecutively from one to sixty, commencing at longitude 180°. This arrangement made each sheet contain six degrees of longitude by four degrees of latitude; but, as the width of the sheets diminished as they approached the poles, it was decided that, beyond 60° North, or 60° South, two or more sheets could be combined. Each sheet could thus be given a clear identification number defining its position on the surface of the globe, without it being necessary to mention the country included in it, or the latitude and longitude. For example, the sheet containing the central part of England is called North, N 30.

In order to ensure that the execution of all the maps should be identical, a scheme of lettering and of conventional topographical signs was drawn up and attached to the resolutions; and it was decided that a scale of kilometres should be shown on each sheet, and also a scale of the national measure of length of the country concerned. As regards the representa-

[1] The main part of the address dealt with the geography of the Sudan and some important points in its history.

tions of altitude it was arranged that contours should be shown at vertical intervals of a hundred metres, or at smaller intervals in the case of very flat, and larger in the case of steep ground, the height being measured from mean sea-level, as determined in the case of each country; while the levels of the surface of the country were to be indicated by a scale of colour tints, the colours being green from 0 to 300 metres, brown from 300 to 2500 metres, and purple above 2500 metres. In the same manner the depths of the ocean and of large lakes were to be indicated by varying tints of blue, so as to show intervals of 100 metres. In order to ensure uniformity in the scale of colours to be used, a copy of it, as approved by the committee, was included in the plate of topographical symbols.

The whole scheme was thoroughly well worked out, and great credit is due to the members of the international committee for the manner in which they carried out their difficult task. Since the meeting of the committee in 1909 the preparation of the sheets, in accordance with the principles decided upon, has been taken in hand in several countries, and a number of these have been issued, which give a good idea of what this great map, the largest ever contemplated, will be like. These sheets deserve to be carefully studied, and will doubtless be the subject of considerable criticism, as there are several points which seem worthy of examination.

In the first place, it is for consideration whether it would not have been better if the colour scheme for representing differences of altitude had been omitted, as it is doubtful whether the advantage of the result gained is commensurate with the increased cost of printing the colours. And one naturally asks for what purpose is the map intended. Is it for the use of skilled geographers, of whom there are a comparatively small number in each country, or is it for the instruction of ordinary people? If it is for the latter, it is to be feared that the colour scheme will give rise to erroneous impressions. Compare, for example, sheet North, M 31, of France, with sheet South, H 34, of part of South Africa. In the former, as the greater part of the country shown is less than 300 metres above the sea, the general colour of the sheet is green, while in the latter, as nearly the whole of the country included has an altitude of more than 300 metres, the map is for the most part brown. This to the less educated man will probably convey the idea that, while France is a fertile country, South Africa is a desert. The fact, too, that the darker tint of green represents the lower level and the lighter the higher, while, in the case of the brown, the lighter represents the lower and the darker the higher, and, in the case of the purple, the relative strength of the tints is again reversed, is rather confusing.

There is another point as regards the colour scheme which might be noticed, that is, that it is not the same on different sheets. For example, the scale of tints adopted in sheet North, O 30 (Scotland), North, M 31 (France), and North, K 35 (Turkey), do not correspond. In the Scotch map the brown colour commences at an altitude of 200 metres, in the French at 300 metres, and in the Turkish at 400 metres. There may be some reason for this, but it appears not to be in accord with the resolutions of the committee. Another reason for omitting the colour scheme for altitudes is that it might be better to keep colour work for other purposes, such as indicating political divisions, as there can be little doubt that so good a map as this, when completed, will be largely used for many purposes. It might be better that on a map of this small scale only the horizontal features, such as coast lines, river courses, railways, roads, and the position of towns should be shown, while to represent height graphically tends to obscure the former.

Another criticism I would venture to make is that the resolutions of the committee appear to have been drawn up on the supposition that the whole world has been accurately surveyed, and no attempt seems to have been made to distinguish between those regions of which the maps are based on triangulation, such as England and parts of Europe, and the countries of which complete surveys have not yet been made. As the construction of the map proceeds and sheets are prepared of parts of the world our knowledge of which is imperfect, this want will become more pressing, but it is noticeable even with regard to the sheets already published. It is one of the evils of cartography that where anything is shown on a carefully engraved map it comes to be regarded as true, and, if it afterwards turns out to be erroneous, it is not easy to get it altered.

The scale of the map, 1/1000000, appears to have been wisely chosen, as it is sufficiently large to give an adequate amount of detail, while, at the same time, the sheets will not be unduly numerous. Of course, for an international map a cadastral scale was essential, although for national maps a scale based upon the national system of measures is more convenient, as, for example, in the United Kingdom, where the scale of one inch and six inches to the mile are better than scales of 1/50000 and 1/10000 would have been. They are more suited for the majority of individuals, and an ordinary foot-rule can be used for measuring distances, instead of having to take them off with a pair of dividers from the printed scale on the map.

Looked at from the general point of view, there can be no doubt that the international map is a most important and valuable undertaking. It is satisfactory that such a leading part in the matter has been taken by the British officers of the Royal Engineers and by the Royal Geographical Society.

In speaking of this map, I have referred to the advisability, if not the necessity, of distinguishing between what is accurately and what is inaccurately known, and this brings me to another matter of considerable interest, the preparation of maps based upon the observations and information collected by explorers in unknown or little known countries. To these explorers, some of whom have not been trained in geographical science, a large amount of detail shown upon modern maps is due, and it is only a small proportion of the land surface of the globe that has, up to the present, been surveyed in a scientific manner.

It is therefore of the greatest importance that the best value possible should be obtained from the work done by explorers, and this in the past has not always been sufficiently attended to, though during the last few years it is better understood. The people who stop at home in comfortable ease do not sufficiently realise the difficulties under which the conscientious traveller works and gathers together information about the country he passes through. Formerly, he generally had to work out his own observations and compile his own maps, but now conditions in this respect have greatly improved, and when he brings home his observations, notes, and sketches he can hand them over to some body, such as the Royal Geographical Society, by whom they will be put in shape in a better manner than he could do it for himself. One has heard of an explorer in a little-known country sitting up all night after a hard day's work, working out his astronomical observations, and trying to put his rough surveys into shape. He would have done better to have gone to sleep and prepared himself by a good rest for the next day's journey. In fact, it would be better if an explorer never looked at the figures of an observation after he had recorded them, or read over the notes of his past work, confining himself to recording what he has actually seen day by day as accurately as circumstances permitted, and carefully distinguishing what he really saw from what he thought he had seen, or what he had heard.

It would be easy to adduce instances of the errors which have arisen from the neglect of such precautions. Perhaps one of the best known is that I have already alluded to, when James Bruce, a careful explorer, because he had made up his mind that the Blue Nile was the real Nile, passed the White Nile without taking the trouble to examine it, and recorded it as being a comparatively insignificant river. Then there was the case of Sir Samuel Baker, who, having reached the shores of the Albert Nyanza with great difficulty, depended too much on what he was told by the natives, and showed it on his map as extending many miles to the south of the equator. But great responsibility rests also upon those who have the task of compiling a map from the notes of an explorer, and the greatest care has to be taken to show only what is really known, and not what is uncertain. Geographers, whether in the field or in the drawing office, should always hold up before themselves a standard of accuracy higher than it is always easy to live up to.

Geography under its more ancient name of geometry is, of course, the mother of all sciences, although at the present time geometry has got a more narrow meaning, and is perhaps regarded by some as independent of geography, although really only a branch of it. The study of the earth upon which they lived was, to the ancient nations, the most important of all studies, and it is interesting to trace how astronomy, mathematics, geology, and ethnology are all so interspersed with geography that it is difficut to separate them. It is satisfactory to note how from the very first the British Association has always recognised the great importance of geography, since the first meeting of the Association at Oxford in 1832, when Sir Roderick Murchison, so well known to fame, acted as president of the Geographical and Geological Section. These two sciences remained united in the same section until the meeting at Edinburgh in 1850, when Sir R. Murchison was again the president. But, at the next meeting at Ipswich in 1851, they were separated, and while geology remained as the subject of Section C, geography, on account of its great importance, was made the subject of Section E, and the science of ethnology was united with it. Sir R. Murchison was the first president of the new Geographical Section, and was afterwards president no fewer than six times of Section E, showing the great importance attached by him to the study of the science of geography. May I express the hope that the presidents of the section will endeavour in future to follow, however humbly, in the footsteps of that leader of science.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. ARCHIBALD BARR, D.Sc., PRESIDENT OF THE SECTION.

ONE of the great engineers of the past, Leonardo da Vinci, prefaced a collection of observations on various themes, including the mechanical arts, with the remark:—"Seeing that I cannot choose any subject of great utility or pleasure, because my predecessors have already taken as their own all useful and necessary themes, I will do like one who, because of his poverty, is the last to arrive at the fair, and not being able otherwise to provide himself, chooses all the things that others have already looked over and not taken, but refused as being of little value. With these despised and rejected wares—the leavings of many buyers—I will load my modest pack, and therewith take my course." These words describe, with some approach to exactitude, the position in which I find myself, and may form a fitting introduction to an address that will be discursive rather than systematic, and perhaps more critical than constructive.

It may be less true to-day than it was four hundred years ago to say that all important matters concerning the existing state of the mechanical arts have been dealt with in spoken or written addresses. Each year there might be found sufficient subject-matter for a general survey of the ground that has been covered or a sketch of what lies before us. But each important advance is nowadays recorded as soon as it is made, and I do not feel that I have any special call to assume the *rôle* of the historian, nor can I claim any right to don the mantle of the prophet.

A president of this section who is not disposed to deal with the general aspects of the progress being made in the department of science allotted to us can usually find a large enough subject for his address within the limits of that part of our wide field with which his own work has been more particularly identified, and it might be expected that I would devote my address to a discussion of the conclusions at which I have arrived during thirty-six years of practice and experience in the teaching of mechanical science. But so much has been said of late on the training of engineers, and so many divergent and even irreconcilable opinions have been expressed regarding the lines such training should follow, that I feel sure I shall be relieving the apprehensions of some of my audience if I begin by stating that I do not propose to inflict upon you a discourse on that threadbare theme. There are limits to the endurance even of those who practise a profession well calculated to inculcate the virtues of patience and forbearance.

When we have as president of the section one who has broken new paths in the exploration of the territory assigned to us, or to whose labours the fruitfulness of some corner of the domain may be chiefly attributed, we would scarcely be disposed to tolerate the omission from his address of an account of his own special work, in investigation or in practice, and the developments to which it is leading. But while, no doubt, every worker is the chief authority on something or other, the plot he cultivates may be so restricted in area, and its products may bulk so little in the general harvest, as to form no suitable topic to engage the attention of his fellow-workers on such an occasion as this.

When an engineer leaves practice in the great, and takes to the devising and production of what are usually referred to specifically as "scientific instruments" (though all machines and mechanical appliances may properly be classed as such), his colleagues in the profession may be disposed to look upon the change as a degeneration of species. Naturally I am not disposed to accept such a verdict. Remembering the careers of those who did most in the founding of the various branches of present-day practice, I am quite prepared to accept as applicable another phase borrowed from the language of the biologist, and to let it be called a "reversion to a more primitive type." But instead of dealing with the narrow branch of applied science with which my own practice is chiefly connected, I prefer to utilise the short time at my disposal to make some observations upon a larger and more general theme. The thesis which I propose to uphold may not fall very obviously within the scope of the original aims of the British Association, but it has, at least, an intimate bearing on the work of those who are concerned with the applications of mechanical science.

Tredgold's oft-quoted definition of engineering as "the art of directing the great sources of power in nature for the use and convenience of man" may well be taken, and often has been taken, as a text upon which to hang a discourse on the importance of the profession to which many of us belong, the leading part it has played in the process of civilisation, and the dependence of the world to-day on its activities. But the words suggest failures as well as achievements, and responsibilities no less than privileges. The definition suggests that the engineer not only fails in his vocation if he does not accomplish something for the use and convenience of man, but further, that he acts contrary to the spirit of his profession if he directs the sources of power in nature to the unuse[1] or inconvenience of man; and surely we must understand by "man" not the engineer's immediate client but mankind in general. The works of the engineer are to be used by some people; they have to be endured by all.

Taking the highest view of our calling—and surely we do not hold that ours is in any sense a sordid or selfish vocation—the engineer fails in the fulfilment of his duty in so far as his works are detrimental to the health or destructive to the property of the community, or in so far as they are unnecessarily offensive to any of the senses of those who are compelled to live with them. There has been too great a neglect of such considerations. The medical practitioner is held to be negligent of his duty if he acts solely in the immediate interests of his patient, and does not take due precaution to guard against the spread of disease or the offence of the community by the exhibition of unsightly forms. We should take as high a view of our responsibilities.

In his presidential address to the Association last year, Sir Wm. Ramsay said that the question for the engineer has come to be not "can it be done?" but "will it pay to do it?" The answer to this question, in respect to any particular proposal, depends on the width of view we take in answering two preliminary questions: whose interests are we to consider? and, what do we mean by paying? Of course, there are limits that must be set in answering each of these; my present contention is that these limits are usually much too narrowly drawn. A road surveyor may save a few pence or shillings to his county council by leaving a piece of newly metalled road unrolled—because the clock strikes the hour for retiring—and may thereby cause expense, amounting to pounds, it may be to hundreds of pounds, through damage to motor-cars or the laming of horses (not to speak of loss of life or limb), to the users of the road, who are, after all, the clientèle he is there to serve. Does it pay? The authorities of a city will spend large sums on the adornment of the streets with stately and ornate buildings, and on the purchase of works of art—and rightly so, though comparatively few of the citizens can appreciate or even give themselves the chance of appreciating them—while they will tolerate or even be directly responsible for the running on these same streets of quite unnecessarily ugly and noisy tramcars, and congratulate themselves on the drawing of a paltry income from the display of hideous advertisements that are constantly before the eyes of the whole community. Does it pay thus to separate æsthetic from utilitarian demands and interests?

It is too much to assume that engineers could meet all the reasonable demands of their immediate clients without producing, at least temporarily, secondary effects that may be of inconvenience to some members of the community. Bacon, indeed, said that "The introduction of new Inventions seemeth to be the very chief of all human actions. Inventions make all men happy without either Injury or Damage to any one single Person." But Bacon was a philosopher, and dealt with ideals rather than with hard facts, and in his times inventors had not yet begun to dominate all the elements of our physical environment. Had he lived to-day beside one of our country roads he might have had something to say, in another key, regarding motor-cars and dust; or had his lot been cast in the proximity of a great centre of industry he might have modified his conviction of the universality of the benefits conferred by the inventor. He might even have been disposed to agree with a literary man of to-day who is reported as asserting that "The universal and blatant intrusion of Science into our lives has resulted in a total disappearance of repose." Isolated and unqualified statements such as those I have quoted are like proverbs—you can always find two that are directly opposed. The truth lies about midway between these extremes, or rather there are aspects of the facts in regard to which one is an approach to the truth, and aspects in which the other has some justification. Our aim should be to make Bacon's dictum have more of truth and Mr. Stephen Coleridge's assertion have less foundation in fact. And the outlook seems to me to be a very hopeful one, though to be able to take an altogether favourable view of the tendencies of the present time, one must be an optimist of the true order—"One who can scent the harvest while the snow is on the ground."

When we examine into the immediate causes of the injuries and inconveniences that result from our activities we find that they are due in all, or almost all, cases to failures rather than to successes. The more completely the engineer achieves the primary end of his work the less is the damage or injury that can be laid to his charge. If it can be shown that this is a very general law, as I think it can be, we may look forward to the elimination, as a direct result of progress in the mechanical arts, of the nuisances and inconveniences for which, in some measure at least, we must accept responsibility. And not only so, but the converse will be equally true—the more we keep in view the removal or avoidance of anything that can cause offence, the more rapidly we shall advance in the attainment of the primary ends at which we aim. Consider, by way of example, the nuisance to which I have referred, and of which we hear so much—the raising of dust by motor-cars. I shall not discuss the debated question as to how far the motor-car produces dust, or only distributes it, nor shall I deal in detail with the possible remedies. We hope to have a paper on the subject at this meeting from one of our leading authorities. For my present purpose it suffices to point out that it is no part of the function of a road surface to fritter itself down into dust under traffic of any kind. The ideal road would be one that would not wear at all, and the nearer we approach this ideal of a permanent road surface, the less will be the inconvenience caused, not only to those responsible for the upkeep of the road, but to the general public. And conversely, the more attention we give to the devising of a dustless road the more rapid will be our advance towards the provision of one best suited for all the purposes which a road is intended to serve. We had dusty roads

1 We have no word to denote very clearly the negative of *use*, as the term here applied: *unuse* may serve for the present.

before the motor-car came into being, but the demand that is being forced upon the engineer to eliminate this nuisance is leading to an improvement of our roads for all users. The inventors of the automobile will yet merit the thanks even of those who, bemoaning the blatant intrusion of science into our lives, may discard the railway train and the motor-car and take to the stage-coach of their grandfathers with a view to the recovery of some of the lost repose.

Again, the combustion of fuel does little harm to anyone; it is the imperfection of the combustion that is the main cause, almost the sole cause, of injury to health, to property, and to the amenity of populous centres. Of course, one knows that smokeless combustion is not necessarily, nor always, the most economical, but that is only because we have not yet learned how to use fuel in anything like a perfect manner. But all the tendencies at the present time are towards improvement, and the more attention we pay to the elimination of the smoke nuisance the more rapid will be our progress in the economical use of one of the most valuable of our inheritances. It is therefore clearly the duty of every engineer who has to do with power or heat production—for the credit of his profession and even in the interests of his immediate clients—to consider the use and convenience of all who can be affected by the work for which he is responsible. The time is not far distant when the direct burning of bituminous coal in open grates will be looked upon as not only a source of serious harm but as a culpably wasteful practice. Great progress has been made in processes for the partial distillation of coal by which a free-burning and quite smokeless fuel is prepared and valuable by-products (so-called) are conserved. If all engineers concerned with the design and application of plants in which coal is used had a due sense of their responsibilities to the community, progress would have been, and would to-day be, much more rapid; and economies would be effected that would, in themselves, amply justify the application of more scientific methods of utilising the constituents of a very complex material, which we are too apt to look upon as merely a convenient source of heat—plentiful enough and cheap enough, as yet, to be used in a most wasteful manner. It will not be to the credit of our profession if it should require restrictive legislation not only to prevent a gross interference with the health and comfort of the community and the amenities of our centres of industry or of population, but to effect economies in the utilisation of the chief of the sources of power which it is our function to direct to the best advantage of all concerned.

In other directions also we see that progress towards economy is leading to a reduction, and possibly to the entire elimination, of all the nuisances associated with the older methods of power and heat production. The great improvements that have recently been made in producer plants and gas engines have rendered out of date, as regards economy, at least the smaller sizes of steam plants which are so fruitful a source of injury and inconvenience to the community; and we now have engines of the Diesel, and the so-called semi-Diesel, types that can utilise natural oils, and oils obtained in the distillation or partial distillation of coal, not only with an efficiency hitherto unattained in heat-engines, but "without injury or damage to any one single person"—except possibly the maker of inferior[2] plants.

Present indications point to the coming of a time, in the near future, when the power and heat required for industrial and domestic purposes will be distributed electrically, in a perfectly inoffensive manner, from large central stations; and even at these stations there will be no pollution of the atmosphere that could give the most sensitive of critics any just grounds of complaint against the intrusion of science into our lives. In his presidential address to the Institution of Electrical Engineers in November, 1910, Mr. Ferranti dealt in a most masterly way with this, which is undoubtedly the greatest of the many schemes at present before the engineering profession. That address reads like a chapter from a romance of Utopia, but unlike most of the forecasts that have been presented to us of ideal conditions in a world of the future, the system which Mr. Ferranti sketches out, and advocates with so much knowledge and convincing argument, does not depend for its reasonableness on the postulation of a perfected humanity. It would not only provide vastly improved conditions of life for the community as a whole, but it would satisfy the more selfish aims of the users of power and the makers of machinery, by increasing the economy of production and stimulating the demand for mechanical appliances. No doubt there may be some who will hold that to commend any worthy scheme, to those who might carry it out, by an appeal to their selfish interests is an altogether immoral kind of argument. I do not think so. Advancement of the race through benefits to the individual is, at least, not inconsistent with nature's method of securing progress. However much we may desire to develop a purely altruistic spirit in men of all classes, we must meantime make the best of human nature as it is, and recognise that the rapidity of our progress toward better conditions of life will be in proportion to the advantages that each advance can promise to those who would be immediately concerned in its realisation.

It is just a hundred years since passengers were first carried on the Clyde in a mechanically-propelled ship, and to-day—when they are not too completely obscured by smoke—we can see the successors of the *Comet* plying on that river with power plants of greatly superior overall efficiency but showing little advance in regard to the combustion of the fuel. Had the emission of smoke from river craft been prohibited years ago, there is little doubt that engineers would have let few days pass without arriving at some solution of the problem of inoffensive power production, and the demand for economy would have looked after itself. How much better it would be were engineers to take the wider view of their duties and responsibilities to which I have referred, and realise that they are acting contrary to the true spirit of their profession when they produce appliances that pollute the atmosphere for miles around to the hurt and inconvenience of those whose "use" they are intended to serve. But this year a ship has left the Clyde that we hope may be the forerunner of a new race which will attain a higher efficiency than any of the direct descendants of the *Comet*, and that will ply their trade without inconvenience to man or beast, who can claim some right to be permitted to enjoy an unpolluted atmosphere and the measure of sunshine which nature—sparingly enough in those regions—intended to provide.

But there are injuries which we may inflict upon the community other than those to health and physical comfort. Everyone, even the least cultured, has some sense of the beautiful and the comely, and is affected by the aspects of his environment more than he himself can realise. The engineer, then, whose works needlessly offend even the most fastidious taste is acting contrary to the spirit of his profession, at its best.

[2] My typist in transcribing a rather illegible draft of this passage substituted for the adjective I have here used the less restrained, but perhaps equally appropriate one, "infernal," but I noticed this in time to amend the emendation. I had no intention to speak so candidly of any of the works of members of my own profession.

There has been far too great a disregard of æsthetic considerations in the everyday work of the engineer—we usually take a too exclusively utilitarian view of our calling. We should not be prepared to accept, as referring to the arts we practise at their best, the distinction drawn by a philosophical writer between "the *mechanical* arts which can be efficiently exercised by mere trained habit, rote, or calculation," and "the fine arts which have to be exercised by a higher order of powers."[3] And I think it can be shown that a greater regard for artistic merit in our designs would not necessarily lead to extravagance, but, in many cases, would conduce to economy and efficiency. It is at least true—and much less than the whole truth—that greater artistic merit than is commonly found in our works could be attained with no sacrifice of structural fitness, or of suitability for the purposes they are designed to serve.

There was a time when engineers made desperate attempts to secure artistic effects by the embellishment (?) of their productions with features which they believed to be ornamental. Fortunately the standard of taste has risen above and beyond this practice in the case of most members of our profession and most of our clients. We are all familiar with illustrations of philosophical instruments, and other mechanical contrivances, of the early times, that vied in lavishness of adornment—though not in artistic merit—with those wonderful astronomical appliances that were carried—as trophies of war!—from Pekin to Sans Souci. Many of us can remember a time when the practice had not altogether disappeared, even in the design of steam engines, lathes, and other products of the mechanical engineer's workshop. I well remember in my apprenticeship days the building of a beam engine that was a triumph of ingenuity in the misapplication of decorative features. In place of the mildly ornamented pillars and entablature of Watt's design, there was provided, for the support of the journals of the beam, a pair of A frames constructed in the form of elaborately moulded Gothic arches flanked by lesser arches on each side, while the beam itself, and many other parts, were plentifully provided with even less appropriate embellishments borrowed from the art of the stonemason. It is some consolation to remember that the clients for whom the engine was built were not of this country, and that the design itself was not a product of the workshop that was favoured with the contract to produce this amazing piece of cast-iron architecture. We have all seen wrought-iron bridges the inattractive features of which were concealed by cast-iron masks—in the form of panelling, or of sham pillars and arches with no visible means of support—that not only have no connection with the structural scheme, but suggest types of construction that could not, by any possibility, meet the requirements. Structures of this kind remind one of the pudding which the White Knight (with good reason when we remember the characteristics of his genius) considered the cleverest of his many inventions. It began, he explained, with blotting-paper, and when Alice ventured to express the opinion that that would not be very nice, he assured her that though it might not be very nice *alone* she had no idea what a difference it made mixing it with other things—such as gunpowder and sealing-wax.

There are, and must always be, wide differences of opinion regarding what is good or bad in matters of taste, but we may go so far in generalisation as to say that we can admire the association of elements we *know* to be incongruous only in compositions that are intended to be humorous. "All human excellence has its basis in reason and propriety; and the mind, to be interested to any efficient purpose, must neither be distracted nor confused."[4] But to be able to judge of the propriety or reasonableness of any composition we must have some knowledge of the essential qualities and relationships of its component parts, and excellence cannot depend upon an appeal to ignorance. We can quite imagine that the White Knight's pudding would appeal as an admirable and most ingenious concoction to one who lacked a knowledge of the dietetic value of blotting-paper and was willing to take for granted the excellence of gunpowder as a spice and of sealing-wax as a flavouring. No artist would be bold enough to include a polar bear or a walrus in the composition of a picture of the African desert, nor be prepared to consider as a legitimate exercise of the artistic imagination the depicting an Arab and his camel wending their weary way across the Arctic snows. He would recognise the incongruity, and might even realise that it is only a lack of imagination or of true inventive power that could lead anyone to resort to such measures for the securing of a desired colour scheme. These are lengths to which even artists will not go in the arrangement of elements in a composition. But an artist *will* secure a colour scheme at which he aims by the introduction into his landscape of a rainbow in an impossible position, or of impossible form or dimensions, or with colours arranged according to his own fancy, though in this there is a much more essential unreasonableness. A polar bear might be transported to the desert, and an Arab might conceivably find his way to the regions of snow and ice, but a rainbow cannot wander from the place assigned to it by nature, nor can it have other than the ordained form or dimensions or sequence of colours. No artist would paint a figure holding a candle and make the light fall on the side of the face remote from the source, but he will, and usually does, paint the moon illuminated on the side remote from the sun. Why? Simply because he has not before his mind the essential absurdity of the scheme, if indeed he knows why the moon shines. Artists who deal with nature in any of its aspects may be commended to "mark, learn, and inwardly digest" Whistler's definition of their calling: "Nature contains the elements in colour and form of all pictures . . . but the artist is born to pick and choose, and group with science, these elements, that the result may be beautiful." Whether or not we are to understand that Whistler intended to include an accurate knowledge of physical facts and phenomena in what he calls *science*, he cannot have meant anything less than *sense*.

So in regard to the arts of construction, we may say that mechanical science provides the elements of all structures, and the craftsman—be he called engineer or architect—is born to pick and choose, and group with science, these elements, that the result may be useful—and not devoid of grace.

The only valid excuse for such departures from the fit and rational in painting or in structural design as those which I have instanced is ignorance on the part of the designer of the nature of the elements he employs, or a lack of skill to devise a possible or reasonable arrangement of details that will secure the general effect he desires.

It may almost savour of sacrilege to quote, in this connection, from the writings of that "Wild, wilful, fancy's child" the story of whose eight short years of life and literary work Dr. John Brown has given in his charming "Pet Marjorie"—a record of perhaps the shortest human life that has formed the subject of a biography. But the lines are too pertinent to my purpose to be withheld, and the frankness of the

[3] Enc. Brit., eleventh edition, article "Art."

[4] Mr. Duppa's "Life of Michelangelo."

confessions they contain, of a childlike limitation of artistic power, may be commended to those who practise either the fine arts or the arts of construction, and feel compelled to "trust to their imagination for their facts," or to resort to the association of incompatible details for lack of knowledge, or of ability to attain their ends by more reasonable means.

Marjorie writes of the death of James II.:—

"He was killed by a common splinter,
Quite in the middle of the Winter;
Perhaps it was not at that time,
But I could find no other rhyme?

"Quite in the middle of the winter" describes August 3, 1460 A.D., with no wider licence than we find assumed in the works of more experienced, if less candid, artists and craftsmen. Again in her sonnet to a monkey—written, we must remember, when she was six or seven years of age—she acknowledges the compelling power of an artistic aim:—

"His nose's cast is of the Roman:
He is a very pretty woman.
I could not get a rhyme for Roman
So was obliged to call him woman.

It may seem that I have wandered widely from my text: those who found discourses on texts usually do! But there is, or ought to be, a closer connection than is usually recognised between the work of the engineer and that of those to whom we usually restrict the title of artist. There was no great gulf fixed between the fine arts and the utilitarian arts in earlier times. Some at least of those to whom we owe the greatest advances in the fine arts were eminent also in the arts of construction. We may claim such men as Michelangelo, Raphael, and Leonardo da Vinci as masters in the arts of construction as well as in those with which their names are usually associated. The separation of the beautiful and the useful is quite a modern vice. But much that I have ventured to say in the digression—if such it be—is applicable, with little or no alteration of terms, to the work of our own profession. The architect or engineer who, for the sake of effect, fills the space between the flanges of a beam or girder with slabs of stone, or cast-iron pillars and arches, that could not fulfil the function of a web, exhibits just the same lack of skill as Pet Marjorie owns up to—shall I say?—like a *man*. Such practices have no "basis in reason and propriety," and the employment of such "decorative features" is certainly not a "grouping of elements with science." It is said that "The highest art is to conceal art"; the lowest in matters pertaining to our profession is to conceal ill-devised construction with false and senseless masks. But what I have said has, I think, a sufficiently obvious bearing on the mechanical arts—I need not further point the moral.

There is an old maxim to the effect that "the designer should ornament his construction and not construct his ornament." This is an admirable rule so far as it goes, but it should be subordinated to a higher rule, that he should ornament his structure only if he lacks the skill to make it beautiful in itself. A structure of any kind that is intended to serve a useful end should have the beauty of appropriateness for the purpose it is to serve. It should tell the truth, and nothing but the truth, and if its character be such that it can be permitted to tell the whole truth, so much the better. It should be beautiful in the sense in which we commonly use the term with respect to a machine—we call a mechanical device beautiful only if it strikes us as accomplishing the end for which it is designed in the simplest and most direct way. Our works—like the highest creations in nature—should be beautiful and not beautified. "Beautified" should be considered a vile phrase when applied to a work of construction, no less than when used to characterise a fair Ophelia. Artists accept the human form, at its best, as the highest embodiment of grace and beauty, but there is not a curve in the figure that is not the contour of some structural detail that is there for a definite purpose. The practice of resorting to extraneous adornments to minimise crudities of structural scheme had its rise—if I mistake not—in the comparatively recent times when culture and taste were at their lowest. It is specially characteristic not only of earlier times, but of the earlier stages of the design of any particular product. It has already disappeared in some cases, and will continue to disappear from the practice of the arts of construction as skill and taste develop. I have already alluded to the abandonment of ornament in the design of machines, and I think there can be no one, with any sense of the fit and pleasing, who does not approve this change in practice. The stage coach and horses of former times were lavishly decorated—the carriage of to-day is more graceful and pleasing in virtue of the simple elegance of its lines. In the best domestic architecture of to-day we see the same tendency to trust for effect, more and more, to an artistic grouping of the lines and masses of essential parts and the gradual abandonment of purely decorative features, without and within. There was a time when the hulls and riggings and sails of ships were lavishly ornamented; now even the figurehead—the last remnant of barbaric taste—has disappeared; and do we not find in a full-rigged ship of to-day (or yesterday, perhaps one should say) a grace and dignity that no extraneous embellishments would enhance? From the racing yacht the designer has been forced, by the demand for efficiency, to cast off every weight and the adornments that so beset the craft of earlier times, with the result that there is left only a beautifully modelled hull, plain masts, and broad sweeps of canvas, and we can scarcely imagine any more beautiful or graceful product of the constructive arts. These examples will serve to illustrate the contention that the attainment of the highest efficiency brings with it the greatest artistic merit. But in the development of the yacht of to-day, through many stages, the designer has been forced, from time to time, to strive to combine grace with efficiency. Selection on the part of clients must have eliminated ungraceful forms when more beautiful ones could be found, and therefore the advance has been rapid. I think I may appeal to this illustration to support the further contention that advance in efficiency may be helped and not hindered by keeping in view an æsthetic as well as a utilitarian aim. Further illustrations will occur to anyone who has studied the development of design of structures or machines.

It is a matter of constant remark, and with justice, that steel bridges, as a class, are much less pleasing to the eye than those of stone. The reasons for the contrast in artistic merit are not far to seek. The building of stone bridges is an ancient art, and survival of the fittest, and selection—even with little creative skill on the part of the designers—would have led to the development of types having, of necessity, at least the elegance of fitness. But further, this art has come down through the times to which I have referred when artistic and utilitarian aims had not yet been divorced, in the practice of the crafts; and further still, the practice of building in stone has been in the hands of architects as well as of engineers, and architects are expected to be artists, and are trained as such. On the other hand, construction in steel is a very modern art, and it has been in the hands of engineers who usually neglect, if they do not despise, the study of the fine arts. But why have architects, with their artistic training, not succeeded in producing structures in steel as admirably as those they design in stone? Partly, no doubt, because they are hampered by tradition. They have not yet fully realised the difference in spirit that must characterise fit designs in the newer and the older materials. No one can be an artist in any material the possibilities and limitations of which he has not fully mastered. Again—if a common engineer may venture the criticism—the architect, as a rule, has not sufficiently mastered the *science* of construction, and has been too much addicted to taking the easy course of adopting a decorated treatment instead of striving to secure elegance of structural scheme as such; and decoration, at least on anything like traditional lines, is wholly incompatible with the best possibilities of steel as a structural material. Progress is being made in the art of designing efficient and graceful structures in metal, but the best results can only be attained by a designer who has a thorough scientific and technical knowledge of the properties of steel and the processes of its manipulation on the one hand, and cultured artistic sense and capacity on the other. These should not be considered as appropriate equipments for separate professions.

There are many, however, who have a rooted conviction that structures in steel can never be so beautiful as those in stone. This I believe to be altogether wrong. It arises partly from the crudity of design that characterises most of the steel structures that have yet been erected, and partly from preconceived notions as to what is fitting in proportions and massiveness. We can quite imagine that a native of the Congo region whose notions of the proportions suitable and comely for a quadruped were founded on his familiarity with the hippopotamus would, at first sight, consider the racehorse sadly lacking in substance and solidity; but, in time, he might come to recognise some measure of gracefulness in a creature that has been developed to meet requirements that hitherto he had not fully considered.

Mr. Wells has said in his "Modern Utopia," "the world still does not dream of the things that will be done with thought and steel when the engineer is sufficiently educated to be an artist, and the artistic intelligence has been quickened to the accomplishment of an engineer." But we need not postpone until the advent of a complete Utopia, the full realisation of our duty to practise our profession, as far as in us lies, with due regard for the material interests and the æsthetic susceptibilities of all who can be affected by the works for which we are responsible.

NOTES.

A PUBLIC meeting will be held at the Mansion House on Wednesday, October 23, in support of the memorial to Lord Lister.

THE superintendent of the Meteorological Office Observatory at Eskdalemuir, near Langholm, Dumfries, reports that the seismographs at the observatory recorded a large earthquake at 11.30 p.m. on September 13. The centre of the disturbance is indicated at latitude 40·4° N., longitude 27° E., a point situated at the south coast of the Sea of Marmora.

WE learn from *The Lancet* that the Riberi prize of the University of Turin, amounting to 20,000 lire (about 800*l*.), will be awarded after the close of the year 1916 for the work which is adjudged to have most advanced the science of medicine. Such work, if published, must have been printed after 1911. Or it may be sent in before the end of 1916, in print or typoscript—the English language is admissible. Further information may be obtained from Prof. Dr. Oliva, Turin.

A SPECIAL number of the *Atti della R. Accademia dei Lincei*, containing the report of the proceedings at the anniversary meeting last June, announces a gift of 4000*l*. from Dr. Gino Modigliani towards the publication of the works of Leonardo da Vinci, and a legacy to the academy of 2000*l*., as well as of many of her personal effects, from the estate of the late Signora Celli Dutuit. Prizes given by the King of Italy have been awarded to Prof. Ernesto Manasse for mineralogy and geology, and to Prof. Giuseppe Chiovenda for jurisprudence and political science. The Minister of Public Instruction also gives four prizes, each of which has this year been divided, the recipients being Profs. G. Ercolini and A. Amerio for physics, Profs. A. Quartaroli and R. Salvadori for chemistry, and Profs. Enrico Carrara, Donadoni Eugenio, Levi Ezio, and Ribezzo Francesco for the two philology prizes. A prize founded by Santoro is awarded to Prof. Costantino Gorini for his discoveries in the bacteriology of cheese, while another most useful prize, founded by the late Alfonso Sella for assistant lecturers in the department of physics, is awarded to Dr. Paolo Rossi, of the University of Naples.

WE announced with regret last week the death on September 4, at forty-two years of age, of Dr. Stanley Dunkerley, formerly professor of engineering in the University of Manchester. Dr. Dunkerley was educated at the Burnley Grammar School and Manchester University, where he graduated in 1900 with honours in mathematics, and took, a year later, the degree in engineering. After two years on the construction work of the Manchester Ship Canal, he obtained the Bishop Berkeley fellowship, and returned to the University to carry out researches in the Whitworth Engineering Laboratory under the direction of the late Prof. Osborne Reynolds. Dr. Dunkerley held appointments as assistant-lecturer in engineering at Liverpool University and at Cambridge. In 1897 he was appointed professor of applied mechanics at the Royal Naval College, resigning in 1905 to succeed Prof. Osborne Reynolds at the Manchester University. He had only held this post three years when ill health compelled him to resign. Dr. Dunkerley was strongest on the mathematical side of engineering. His most important contributions to engineering science are the paper on the whirling and vibration of shafts published in the Transactions of the Royal Society, and an investigation of the straining actions in crank shafts, which appeared in the transactions of the Institute of Naval Architects. He was the author of text-books on mechanism and hydraulics. In 1905 his University conferred on him the doctor's degree in science, and in the same year he was elected a member of the Institution of Civil Engineers.

THROUGHOUT the wide circle of mining engineers the announcement of the death of Mr. J. A. Chalmers at Bournemouth, on September 9, will be deeply regretted. Born in 1864, son of the Rev. Dr. Chalmers, an esteemed missionary in China, Mr. Chalmers in 1889 took his diploma as an Associate of the Royal School of Mines, and left the same year to take up professional duties in the Transvaal. There he afterwards became an assistant engineer to the Consolidated Goldfields of South Africa, under J. H. Hammond. Apart from the important work which came to him in this connection upon the Rand, Mr. Chalmers, with Dr. F. H. Hatch, accompanied Mr. Hammond when, in 1894, this engineer made an important mining reconnaissance into Rhodesia, a land which had not at that time long been under British influence. Later, in the year 1895, he collaborated with Dr. Hatch in the preparation of "The Gold Mines of the Rand," the first important work on the Witwatersrand Goldfields. Mr. Chalmers was thus by his own good work forced to the front, and during the next ten years important commissions took him for their fulfilment to all parts of the world. Then it was found that a disease, all unsuspected, had taken a hold on him that attention and skill could do nothing to loosen. Slowly but surely Mr. Chalmers sank, Davos put off the day, Bloemfontein the hour, but six weeks after his return to this country death came, at the early age of forty-eight. During all this time the many friends which his modesty had made for him failed not in frequent inquiry, and now that he has gone all mining engineers, even the most self-assertive, will cherish the memory of this man of quiet quality.

The new Allegheny Observatory, situate in Riverview Park, Pittsburg, was dedicated on the afternoon of Wednesday, August 28, in the presence of the members of the Astronomical and Astrophysical Society of America and of many of the Pittsburg friends of the institution. The principal instruments of the new observatory are a 13-in. visual refractor, a 30-in. reflector (a memorial to the late James Edward Keeler), and a 30-in. photographic refractor (a memorial to William Thaw and his son, William Thaw, jun.). The last of these telescopes is not quite completed, as the objective remains to be supplied. Addresses were given by Dr. John A. Brashear, chairman of the observatory committee; by Dr. Samuel Black McCormick, Chancellor of the University of Pittsburg, of which the observatory forms the astronomical department; by Dr. Frank Schlesinger, director of the Allegheny Observatory; and by Prof. E. C. Pickering, director of the Harvard College Observatory. Mrs. William Reed Thompson, the daughter of William Thaw and the sister of William Thaw, jun., closed the ceremony with the unveiling of the memorial tablet on the Thaw telescope.

The objections which were indicated some time ago in *Engineering* to the style of monoplane which is dependent on the rotary type of engine have been illustrated by the death of four army officers in one week, and give occasion for a strong article in our contemporary for September 13. The French Deperdussin monoplane, in which Captain Hamilton and Lieutenant Stuart lost their lives, broke in the air; as this machine won the 2000*l*. prize in the War Office competition it is not unreasonable to suppose that it represents the most advanced stage of monoplane construction. Its failure shows that however much care may be exercised in the choice of a monoplane of the ordinary type, it cannot be absolutely trusted to last for a month without breaking in mid-air. The cause of the failure of the Bristol monoplane, in which Lieutenants Hotchkiss and Bettington were killed, was not brought to light at the inquest. The Deperdussin failure, it seems to be generally agreed, was caused by some part of the revolving engine failing and wrecking the aëroplane. A real endeavour should be made to secure a supply of engines of other than the revolving type. Where this type has to be used some provision should be made for safety in case of parts breaking. This might be done by placing a strong shield between the engine and any parts it might otherwise damage.

At the French Army manœuvres some portable apparatus for wireless telegraphy on aëroplanes, designed by M. Rouzet, is being officially tested under war conditions. M. Rouzet's apparatus, which was described recently by the Paris correspondent of *The Morning Post*, embodies the novelty—so far as aëroplane work is concerned—of using a rotating spark-gap. This consists of a fixed and a movable disc each carrying a number of metal points between which the sparks pass while the movable disc is rotated rapidly. The disc, and also a small alternator, are driven by the aëroplane motor, and the current, which is generated at a pressure of 110 volts, is raised to 30,000 volts by a transformer, and led to a condenser and to the gaps. By setting the disc properly with respect to the dynamo windings and poles, the sparks can be made to occur when the condenser is just fully charged. The advantages of this mode of operation are, of course, very well known as regards larger units, but it seems that rotating spark-gaps have not been used before in French aëroplane work. The oscillations produced by the discharge of the condenser through the spark-gap are transferred to the antenna by means of a high-frequency auto-transformer of the Oudin pattern. The antenna consists of an aluminium wire 100 ft. long, and can be rolled up or unrolled by the operator by aid of a small winch, while provision is made whereby the pilot can cut the antenna adrift in case of necessity. Instead of the earth connection employed in a land or ship station, a wire network is, as usual, spread along the wings of the aëroplane, and thus the antenna and its "electrical counterpoise" constitute a self-contained Hertzian oscillator. The power of the dynamo is 200 watts, and the distance already worked over is between fifty and sixty miles.

A lecture on non-operative methods as applied to cancer was delivered by Prof. V. Czerny, of Heidelberg, on September 16, before the Association of German Naturalists and Physicians at Münster, in Westphalia. From a report in *The Morning Post*, we learn that Prof. Czerny confessed at once that a specific cure for cancer had not yet been discovered, and perhaps never would be found. Every year, he said, we hear of new discoverers who promise more or less infallible results, but close examination of their specifics shows their worthlessness. Within the last year or two chemical therapeutics had received a fresh impulse of scientific value owing to the results of experiments on animals, and it was now tolerably certain that blood treatment must take the place of the former treatment of stomach and intestines. Turning to ray therapeutics, Prof. Czerny admitted its efficacy after the knife in removing injuries, but was not inclined to attach very great importance to electricity applied as rays. In his opinion the more remedies we are confronted with the more difficult it is to find one's way to a proper treatment. This, he said, should be the work of the numerous institutes springing up in various civilised lands the express object of which is the study of this terrible scourge. On the whole, says the correspondent of *The Morning Post*, the address was couched in rather pessimistic tones, and the lecturer did not seem to share the hopeful views which have been lately expressed regarding the chemical, as opposed to the operative, treatment of the disease.

IN *The Popular Science Monthly* for August Prof. Richard Pearce gives an interesting historical survey of research in medicine, and Dr. Heinemann discusses cold-storage problems. The latter states that with careful treatment there are no appreciable differences in chemical composition between fresh meat and meat kept frozen for a period of two years.

IN the Farmers' Bulletin, No. 487 (U.S. Department of Agriculture), by Dr. Langworthy and Caroline Hunt, cheese and its economical uses in diet are considered. A number of recipes for the preparation of cheese dishes is given, and it is stated that cheese does not differ materially in its digestibility from meat, and, weight for weight, contains rather more protein and 50 per cent. more fat than cooked beef, and hence is a valuable food.

WE have received the August and September numbers of *The Child*, a monthly journal devoted to child welfare. Each contains a number of articles of general and special interest to those who have to deal with children—parents, educationists, doctors, and health visitors—notably one by Dr. Mary Scharlieb on adolescent girls from the point of view of the physician, in which the characteristics and management of adolescent girls are critically considered.

DETAILS are given of an improved respiration calorimeter, and the results of experiments with it by the U.S. Department of Agriculture (Exp. Station Record, vol. xxiv., No. 7, and Year-book for 1910). The influence of mental activity on metabolism was one of the subjects investigated, and in half the cases at least sustained mental effort had no positive influence upon the transformations of matter and energy within the body. The gaseous exchange and energy metabolism during the ripening of picked fruit, the germination of seeds, and the incubation of eggs are other subjects under investigation.

IN the August *Fortnightly Review*, Mr. Adolphe Smith discusses the present menace of cholera. He points out how cholera has been more or less prevalent on the Continent in various districts during the last three or four years, and directs attention to the danger that exists of the introduction of the disease into this country, particularly by way of some of the smaller ports, where sanitary administration is still very inadequate. He pleads for the establishment of a Ministry of Public Health, and for the burden of port sanitary administration to be placed on the country as a whole, and not on the local authority. Finally, he maintains that despite improvements in water supply, sewage disposal, and general sanitary conditions, poverty is the most potent of all those grim allies that join together to render devastating epidemics possible!

A RECENT number of the Annals of Tropical Medicine and Parasitology (vol. vi., No. 2) contains the results of investigations by H. B. Fantham and Annie Porter upon the destructive bee disease commonly known as "Isle of Wight Disease," together with a detailed description of the parasite and its life-history. The parasite, *Nosema apis*, belongs to the order Microsporidia, and is a close ally of *N. bombycis*, the parasite of silkworms, which causes the disease only too well-known as "pebrine," the subject of memorable researches by Pasteur. The method of infection was found to be contaminative; hereditary infection through the egg, as in *N. bombycis*, though by no means improbable, has not yet been proved to occur. The only certain means of destroying the resistant spores of the parasite and eradicating the infection is by fire. It is to be regretted that the authors should have thought it necessary to complicate the bibliography of Protozoa, already sufficiently vast, by setting forth their important results in three distinct and separate memoirs, which, as they are printed successively in the same journal, might easily have been included under one title.

MR. LUDWIG GLAUERT describes, in the first volume of the Records of the Western Australian Museum and Art Gallery (Perth, 1912, p. 47), an important series of remains of extinct marsupials from Balladonia. Eight of the species have not been recorded previously from Western Australia. The author supports Owen's view that Thylacoleo, the "marsupial lion," was carnivorous, and illustrates the worn enamel of its incisors.

To the July issue of *The Agricultural Journal of India* Mr. T. B. Fletcher, entomologist to the Madras Government, communicates an article, illustrated by a coloured plate, on termites or white ants. At the commencement reference is made to the modern view that these insects are not Neuroptera, but are more probably related to cockroaches and other Orthoptera, termites and cockroaches having many structural peculiarities in common. Then follows a full account of termite social economy.

A SHORT time ago the editor of *Popular Mechanics* (U.S.A.) conceived the idea of taking the votes of a number of scientific men on what inventions they considered to be the "seven wonders of the modern world," and for this purpose a list of numerous inventions was circulated, from which seven had to be selected. The result is published in the August number, and the seven inventions which received the highest number of votes are as follows:—Wireless, telephone, aëroplane, radium, antiseptics and antitoxins, spectrum analysis, X-ray.

WE learn from the daily Press that considerable anxiety is felt in France regarding the frequent deaths that have recently occurred through eating poisonous fungi. Three precautionary measures are suggested. One is to avoid gathering mushrooms having a persistent volva at the base of the stem; another is to boil every mushroom in water with a little salt; and a third is to have some animal charcoal at hand to be swallowed when a case of poisoning occurs. It is stated in the notices that no species is poisonous in which the volva is absent. It would be, however, wrong to regard all such species as esculent, for several well-known kinds having this characteristic certainly produce temporary, if not fatal, poisoning, at least unless subjected to prolonged boiling.

Two useful lists of South African plants have recently been published. Mr. J. Burtt-Davy and Mrs. Reno Pott-Leendertz (Annals of the Transvaal Museum, vol. iii.) have compiled a "first check-list" of the flowering plants and ferns of the Transvaal and Swaziland, enumerating about 3300 species. Mr. F. Eyles (*South African Journal of Science*, vol. viii.) gives a preliminary list of the plants of southern Rhodesia, comprising about 1700 flowering plants and ferns.

A NEW and curious species of "ground bean" (*Kerstingiella geocarpa*, Harms) from tropical West Africa is described and figured in the Kew Bulletin, No. 5, 1912. When the flowers are fully developed they are close to the ground, and after fertilisation the hitherto short stalk of the ovary lengthens into a long "carpopodium," which turns down and drives the young pod into the ground, where it matures. The same number contains a description and fine plate of a remarkable new spurge (*Euphorbia multiceps*, Berger) received at Kew from South Africa; it resembles a green pineapple with a number of spikes protruding irregularly from it, the stout fleshy axis being densely covered with short coral-like horizontal branches—the spikes are barren inflorescences, but no flowers have been seen. There is also a useful compilation of the various timbers and trees to which the terms tulipwood and tulip tree have been applied, just as other names (gum, rosewood, cedar, pine, mahogany, &c.) are indiscriminately applied to diverse timbers and trees.

MR. CECIL H. HOOPER has contributed to *Irish Gardening* for June and July an account of some interesting experiments on the pollination of hardy fruits, made by himself, Mr. F. Chittenden, and others. These experiments were made in order to ascertain whether fruits can set and mature without the aid of bees, whether mature fruit can be obtained by pollination with the pollen of the same variety or the same flower, and whether better fruits result from pollination with pollen of another variety. It was found that gooseberries and currants, raspberries and loganberries, though freely self-fertile, set better fruit when visited by bees; that strawberries are apparently to some extent wind-pollinated, though this needs confirmation. As is well known, more or less complete self-sterility is common among the many varieties of cherry, plum, apple, and pear; in the majority of cases pollen from another variety is essential for fruit formation. Details are given of numerous interesting results obtained by covering otherwise untouched flowers with muslin bags, by brushing with pollen from the flower's own anthers or from those of other plants of the same variety, and by pollination with pollen from other varieties. In connection with the interplanting of different varieties in orchards, lists are given according to the times of flowering. The author estimates that about 80 per cent. of the pollination of hardy fruits is done by the hive bee, about 15 per cent. by the various humble bees, and the remainder by miscellaneous insects.

THE meteorological year-book for Bremen, 1911, one of the regular German series, contains two important summaries in addition to the observations for the year in question:—(1) A discussion of the daily maximum and minimum temperatures for 1890–1910 (twenty-one years) by Mr. J. Siedenburg; and (2) monthly tables of the climate of Bremen for 1876–1910 (thirty-five years). This long series gives an absolute maximum temperature of 93·9° in May and an absolute minimum of −13·0° in December, but a reading of −17·1° is quoted as having occurred on January 23, 1823. The heat and drought of 1911 lasted from July 4 to September 27 (twelve weeks). Prof. Grosse ascribes the abnormal conditions principally to the shifting of the Azores pressure maximum to the north-east, and possibly to some extent to the approximate occurrence of the minimum sunspot period.

IN the *Atti dei Lincei*, xxi. (2), 2, Prof. Augusto Righi describes experiments on the convection of ions produced by magnetic or magneto-kathodic rays. According to the author's hypothesis these rays cause some of the electrons to unite with positive ions, the combination behaving like a double star or the system formed by a planet and its satellite. Once formed, they are carried by magnetic action from regions of greater to regions of lesser magnetic force, where the elements again frequently become dissociated. To dectect the presence of these ions, Prof. Righi makes use of a small cylinder of paper suspended by a fibre in the magnetic field generated by a second induction coil. According to theory the ions, by their impact on the cylinder, should cause the latter to rotate in the same direction as the magnetising current of the coil, and this was observed to be the case.

CERTAIN formulæ relating to the pressure of fluids on oblique planes have been recently quoted as "Avanzini's law." Col. de Villamil has made several inquiries as to where these laws were published, and having failed to obtain the information from others, has taken the matter up himself, and publishes an abstract of Avanzini's work in *The Aëronautical Journal* for July. The work in question was published in the *Memorie dell' Istituto nazionale italiano* at Bologna early last century, and deals with experiments on the relations between the velocity of a plate in still water, the angle of attack, the position of the centre of pressure, the density of the fluid, the length and breadth of the plate. The paper is illustrated by copies of the original diagrams, and contains experimental data. There are, however, several errors which require correction in the formulæ.

THE annual report of the results of sight tests in the Mercantile Marine, for the year ending on December 31, 1911, just published as a Parliamentary paper (Cd. 6370), shows a slight increase in the percentage of failures, both in form and in colour vision, over the returns of the preceding year. 7309 candidates were examined, with 117 failures in form vision, none of whom were re-examined, and with 192 failures in the first examinations for colour vision, of whom 56 passed on re-examination. This gives a percentage of 1·89 failures in colour vision, as against 1·51 in 1910, and is the largest proportion yet recorded. The methods of testing employed were the same as in 1910, the recommendations of the Departmental Committee appointed in that year not having yet been acted upon. Those recommendations included the substitution of a dark brown test skein for the deep red at present in use, and the employment of a special lantern, designed by the committee, for all candidates. Preparations are being made to carry these alterations into effect at the earliest possible time, and they seem calculated to meet all reasonable objections to the tests hitherto employed. An article on the report of the committee appeared in NATURE of July 4 (vol. lxxxix., p. 453).

VOL. v. of the Journal of the Municipal School of Technology, Manchester, a record of investigations published by the staff and students during 1911, extends to nearly 300 pages. Like its predecessors, it shows the unique position as a centre of research in applied science occupied by the Manchester School amongst the technical schools of this country. Three of the nineteen papers reprinted deal with pure science, and of them that by Prof. Gee and Mr. Adamson, describing a neat and simple "dioptriemeter" for measuring the focal lengths of lenses by the deviation produced, may be specially mentioned. Of the technical papers, the most important are that on electricity meters, by Messrs. Ratcliff and Moore, read before the Institution of Electrical Engineers, that on the electrical theory of dyeing, by Mr. W. Harrison, who finds in the theory explanations of many facts previously not interpreted, and that on boiler economics by the use of high gas speeds, by Prof. Nicholson, who shows how boilers may be reduced in size about 30 per cent. without any diminution in their steam production. The journal is printed in the printing crafts department of the school, and its execution does credit to that department.

UNDER the title of "Geostatic Funiculars," Prof. A. F. Jorini, writing in the *Rendiconti del R. Istituto lombardo*, xlv., 13, gives a solution of the problem presented by a cylindrical tunnel subjected to earth pressure, the surface of the superincumbent earth being horizontal.

PROF. C. MATAIX's papers on aëroplane stability in the *Revista de la Sociedad matemática española* conclude with the July number. The author succeeds in satisfying the conditions for longitudinal but not lateral stability. The latter failure is due to the character of the systems of surfaces assumed in the investigation. If the author had studied a system furnished with two vertical auxiliary surfaces or fins, he would have had no difficulty in satisfying the necessary conditions, and it is to be hoped that readers of the paper will not accept the conclusion that *all* systems of planes are laterally unstable.

IN a paper read recently by Mr. Edwin O. Sachs, at the New York International Congress on the testing of materials, the author directs attention to the very small amount of scientific testing of reinforced concrete which has been carried out in Britain. Our public institutions have been very remiss, for there is practically nothing to place beside the elaborate researches carried out by engineering professors in the public laboratories of the United States, Germany, and France. The author thinks that it is almost hopeless to expect our Government or our engineering colleges to pay now any attention to the matter, so that we can only look for a continuance of the efforts of private bodies, such as the professional societies intimately concerned.

OUR ASTRONOMICAL COLUMN.

GALE'S COMET, 1912*a*.—The comet discovered by Mr. Gale on September 8 is apparently becoming brighter and travelling northwards. A second telegram from Kiel states that it was observed at Santiago on September 11, when its position at 7h. 49·2m. (Santiago M.T.) was:—

R.A. = 13h. 54m. 2·4s., decl. = 33° 10′ 50″ S.

Comparing this with the position at the time of discovery, we see that the comet moved about 4° 15′ to the east and 3° 20′ northwards in a little more than two and a half days. In a telegram announcing the discovery, Reuter's Agency gave the magnitude as 6; the Santiago observer reports it as 5, so that there is a possibility of the comet becoming a more or less conspicuous object in our evening sky. When discovered, the comet was about half-way between θ and ι Centauri, and is apparently travelling towards the neighbourhood of α Libræ; this region now sets at about 7 p.m.

In the *Astronomische Nachrichten* (No. 4601) Herr Prager describes the object seen at Santiago as round, diameter 2′, magnitude between 3 and 6, nucleus, no tail.

THE TOTAL SOLAR ECLIPSE OF OCTOBER 10.—From *The Observatory*, No. 452, we learn that the eclipse party from Greenwich, consisting of Messrs. Eddington and Davidson, with Mr. J. J. Atkinson as a volunteer, left for Brazil on August 30. They expect to make their observations from Christina, some 150 miles inland from Rio de Janeiro, and the programme includes the direct photography of the corona, the photography of the ultra-violet spectra of the corona and chromosphere, and an attempt to secure monochromatic photographs of the corona in the light of the corona line (λ5303). The observing station is some 3000 feet above sea-level.

THE PERSEID SHOWER OF METEORS.—His watches for meteors on August 10 and 11 having disclosed but very meagre displays, Mr. Denning is led to believe that something must have intervened to bring about a very marked decline in the splendour of this noted shower. In a table, appearing in No. 452 of *The Observatory*, he shows how very few Perseids are now seen as compared with a decade ago. In 1901, during two watches of $6\frac{3}{4}$ hours in all, he saw 104 Perseids, in 1907 (6 hours) he saw 101, and in 1909 (4 hours) 79. Last year only three Perseids were seen in $2\frac{1}{2}$ hours, while this year only fourteen rewarded his two watches of $2\frac{1}{4}$ and $1\frac{1}{2}$ hours respectively. The conditions were not good, but, when compared with the 252 Perseids seen in 4 hours in 1874, and 285 in 5 hours in 1877, it would appear that something more than poor observing conditions must be held accountable for the poverty of recent displays.

THE SOLAR CONSTANT AND CLIMATIC CHANGES.—In a third paper on climate and crops, published in the Bulletin of the American Geographical Society for August, Mr. Henryk Arctowski compares the temperature records made at Arequipa during the period 1900–10 with the Washington values for the solar constant, and finds evidence of agreement between them; he also shows that Arequipa is not exceptional. His results indicate that a departure of 1° F. in the monthly mean observed at Arequipa is due to a departure, of about 0·015, of the solar constant from its normal value. If this be true, a comparatively small, but permanent, lowering of the constant would account for such climatical conditions as existed during the Pleistocene Ice age. Mr. Arctowski also finds that the oscillations of temperature found in his data correspond to those of atmospheric pressure to which Lockyer assigned a mean period of 3·8 years.

THE LEEDS ASTRONOMICAL SOCIETY.—The Journal and Transactions (No. 19) of this society for 1911 contains reports of a number of papers read before the society. Among others, there is an interesting discussion of the mutual eclipses of the satellites of Jupiter, by Mr. Whitmell, a paper dealing with suitable observations for amateur astronomers, by Mr. Ellison Hawks, and a discussion of the structure and sidereal significance of nebulæ by the Rev. Ivo Gregg. The membership now totals seventy-five, and the average attendance at meetings is fourteen.

THE PERIOD AND ORBIT OF α PERSEI.—From measures of a number of radial-velocity spectrograms, secured at the Potsdam Observatory between 1900 and 1908, Dr. A. Hnatek has derived an orbit for the spectroscopic binary α Persei, which he publishes in No. 4599 of the *Astronomische Nachrichten*. The variability of the velocity of this star, although small, now appears to be established, and Dr. Hnatek's results indicate a very short period of 4·0938 days. The radial-velocity of the system is −3·43 km., the eccentricity of the orbit 0·47, and the length of the semi-major axis of the projected orbit 46,000 km.

NEW RULES FOR LIFE-SAVING APPLIANCES IN BRITISH SHIPS.

MR. BUXTON has lost no time in considering and giving effect to the recommendations made by Lord Mersey and his colleagues, as well as the report of the Advisory Committee. The character of these recommendations and of that report has been described fully in previous issues (see NATURE, August 8 and 29); it will suffice, therefore, briefly to indicate the most important points in the Parliamentary Paper (Cd. 6402) issued a few days ago, in which the new rules made by the Board of Trade are contained. Those rules will not have statutory effect until they have lain on the table of the House of Commons for forty days, and it is not proposed that they shall come into effect until January 1, 1913. It is practically certain that when Parliament reassembles the rules will be criticised, and it is possible that they may be amended in some respects as the result of that criticism.

Although the rules previously issued have been accepted without serious challenge, the circumstances of the present revision and the drastic nature of some of the new regulations may cause a departure from precedent. Mr. Buxton has recognised the special conditions of the revision of the rules, and has wisely prefaced them by an explanatory memorandum which is both comprehensive and clearly expressed. His memorandum gives the history of the steps which have been taken by the President of the Board of Trade to deduce all possible lessons from the loss of the *Titanic* in order to secure greater safety in future for life and property at sea.

It is also, in effect, an attempt to justify the rules themselves in those features wherein the report of the Advisory Committee has been departed from. That report has been dealt with somewhat harshly by critics, who are disposed to think that shipowners serving on the committee have been unduly influenced by consideration of their class-interests. There is no real foundation for such an opinion, and Mr. Buxton marks his dissent therefrom by stating that, although he has been unable to adopt the conclusions of the committee on some material points, its report has been of very great value, and that he desires to express a high appreciation of the time "and pains expended by the members of the committee and of its various subcommittees on the important questions referred to them." Nothing but prejudice could lead to the conclusion that the shipowners and shipbuilders, who have given gratuitous and unstinting service on these inquiries, would have allowed personal considerations to weigh with them. On the contrary, it is clear that no classes of the community can have a greater interest in securing safety at sea, and certainly no other persons have done so much during the last twenty-five years to increase that safety.

The main point of difference between the Advisory Committee and the new official rules is to be found in the provision that foreign-going passenger and emigrant ships are in future to have sufficient *lifeboat* accommodation for all on board; whereas the committee recommended that lifeboats should be supplemented by rafts, collapsible boats, &c. It is intended further to consider the extent, if any, to which life-rafts may be used when the report of the Davits and Boats Committee—which is about to commence its labours—has been received. Collapsible boats are not to be included in future estimates of life-saving accommodation, although they may be continued in use in existing vessels for a certain period—not specified. On this point there will be debate, and there is reason for difference of opinion. Whatever the final decision may be, it should be noted that there is now universal agreement that in all cases, even in the best subdivided foreign-going ships, *every soul on board shall have a chance of keeping afloat* in boats, rafts, or other appliances, in case a ship founders through collision, grounding, or other accident. For ships in the home trade less stringent provisions are insisted upon in respect of life-saving accommodation, and this course is reasonable having regard to the restricted range of their employment and the greater chance of external help in case of accident.

What remains to be demonstrated—and the task will not be an easy one—is whether the large number of lifeboats now thought to be essential can possibly be so carried as to be loaded and got into the water safely within a reasonable time after an accident has taken place—say within half an hour or an hour. Judging by the *Titanic*—in which case all the circumstances were most favourable to the loading and lowering of boats—radical changes will be required in the installation of lifeboats and in the means of lowering them, if this essential condition is to be fulfilled. All that need be added is that whatever may be the number of lifeboats carried, and however efficient may be the details of the arrangements for lowering these boats, it is obviously of primary importance to secure efficient watertight subdivision in passenger ships, so as to minimise the risk of foundering and to lengthen out the time which ships will remain afloat in cases of accidents so serious as to involve their final sinkage. On this matter another committee is still at work, and no action can be taken by the Board of Trade until its report has been presented.

ATMOSPHERIC PRESSURE AND TEMPERATURE.

IN *Aus dem Archiv der deutschen Seewarte*, 1911, No. 4, W. Brockmöller discusses the geographical distribution of the monthly range of oscillation of the barometer. So far as the southern hemisphere is concerned, the question was thoroughly investigated by Dr. W. J. S. Lockyer in a recent publication of the Solar Physics Committee, but Herr Brockmöller's treatment of the subject covers a wider area, and is based on a different definition of the "range." He takes as the measure of this the mean value of the difference between the highest and lowest barometer readings for each month, and deals with a selection of stations, about 300 in all. After correcting the values for the periodic semi-diurnal variation, and for height above sea-level in the case of a few high-level stations, he plots the values for winter (December–February), and for summer (June–August), and obtains two very interesting charts, showing the isobarometric lines, or lines of equal range. For the northern hemisphere he obtains also normals for different latitudes, and draws the isanomalies, or lines of equal departure from normal. The range is least, 3 or 4 mm., in the equatorial region, and greatest near the arctic circle, apparently diminishing again towards the pole. The outstanding features are the maxima, in both seasons, near Iceland and the Aleutian Islands, the regions of the "permanent cyclones." The maxima are naturally much less intense in summer than in winter. Perhaps even more remarkable is the large value of the anomaly on the east coast of North America, where it is greater than at any other place. The effect is possibly due to the proximity of the division between the Labrador current and the warmer water of the North Atlantic, but it is deserving of further investigation.

In the same journal, No. 5, Prof. Köppen and Dr. Wendt discuss the vertical distribution of temperature over Hamburg between the earth's surface and a height of 3000 m. The records obtained in nearly 1200 ascents of kites and balloons during the years 1904–9 have been analysed very thoroughly, and a new departure has been made in the special treatment of so-called inversions of temperature-gradient. The authors find that such inversions occur in 69 out of every 100 ascents, the temperature remaining constant or increasing with altitude. Inversions are most frequent in autumn and winter, and in December they are found in nearly every ascent. At all seasons they occur most frequently with southerly winds. Inversions in which the increase of temperature exceeds 3° C. are almost invariably accompanied by a decrease in the relative humidity except for those which occur in the layer between the earth's surface and a height of 500 m. At all seasons the sky is more frequently cloudy than clear on the occasions when inversions are recorded, but in spring and autumn the number of cases of clear sky is large. The clouds were found usually to have their lower surfaces below 500 m., *except in those cases in which inversions occurred below* 500 *m.* Another section of the paper deals with the dependence of temperature-gradient on wind direction. Near the surface the gradient is greatest with N. winds, above 500 m. with W. winds, and above 1000 m. with S.W. winds. As the wind usually veers with increasing height, it seems probable that the actual direction of the current for maximum gradient in the layer considered will be northerly at all heights.

PLANKTON INVESTIGATIONS.

IN the *Bulletin Trimestriel*, 1911, the second part of the "Résumé des Observations" continues the summary of the plankton investigations carried out under the international programme in the north-east Atlantic and north-west European waters during the years 1902–8. The subjects here dealt with are the Copepoda, Tunicata, Ostracoda, Chætognatha, Amphipoda, Rotatoria, and Ceratium. With the vast amount of material collected in course of the investigations external records are incorporated in a discussion of the seasonal occurrence and distribution of the species considered, and the hydrographic conditions associated in each case with such. The annual and seasonal distribution and intensity of many of the more important species are shown in a number of separate charts. From an economic point of view, attention is directed to the importance of many of the Copepoda and Amphipoda as constituting in a large measure the food supply of Clupeoids, Gadidæ, the mackerel, and other marketable fishes.

As bearing directly on questions of physical oceanography, Salpa and Doliolum among the Tunicata afford important examples of warm-water species drifted as annual visitors to our coasts by the agency of the Gulf Stream. Similarly, several species of Ceratium show a distribution largely increased by immigration through the Faroe-Shetland Channel into the North and Norwegian Seas and beyond. Some of the latter species have a second sphere of distribution in the West Atlantic, from Florida to Newfoundland, and the author of this section, who has traced some of them sparingly at wide intervals across the Atlantic to the American coast, is of opinion that the two spheres of distribution are indeed in communication by virtue of the east-going oceanic movement. Conversely, among the brackish-water Rotatoria, species find their extension during the summer months from the Gulfs of Finland and Bothnia over the Baltic and outwards, mainly dependent on the periodic surface outflow of low-salinity water in this region. For the further elucidation of these complex problems, more exact information is required concerning some of the more critical species, and the need is felt, in particular, for a greater extension of the area of investigations to the westward and south-westward of Ireland.

THE PLACE OF MATHEMATICS IN ENGINEERING PRACTICE.[1]

THE foundations of modern engineering have been laid on mathematics and physical science; the practice of engineering is now governed by scientific methods applied to the analysis of experience and the results of experimental research. Engineering has been defined as "the art of directing the great sources of power in nature for the use and convenience of man." An adequate acquaintance with the laws of nature, and obedience to those laws, are essential to the full utilisation of these sources of power. It is now universally recognised that the educated engineer must possess a good knowledge of the sciences which bear upon his professional duties, in combination with thorough practical training and experience in actual engineering work. Neither side of his education can be neglected without hampering him seriously, especially when he has to go beyond precedent and face new problems. Of these sciences, the mathematical is undoubtedly of the greatest importance to engineers. The range and character of mathematical knowledge which can be considered adequate are gradually being agreed upon as experience is enlarged; and present ideas are embodied in the courses of study prescribed in the calendars of schools of engineering. Absolute identity in the course of study and the standards laid down for degrees in engineering has not been attained, but the approach thereto has already been considerable, and the movement will undoubtedly continue in the same direction.

The preponderance of opinion amongst engineers now favours the teaching to students of engineering of science generally, and of mathematics in particular, being undertaken by recognised authorities in the several branches, and on lines which shall ensure greater breadth of view and fuller capability for dealing with new problems arising in their professional work than can be secured by means of special courses of instruction arranged for students of engineering as a class apart. Whatever branch of engineering a man may select for his individual practice, he must need a fundamental knowledge of mathematics, and in some branches, in order to do his work well, he will require to add considerably to the mathematical knowledge which is sufficient for a degree.

As time passes the mathematician and the practising engineer have come to understand one another better, and to be mutually helpful. While engineers as a class cannot claim to have made many important or original contributions to mathematical science, some men trained as engineers have done notable work of a mathematical character. The names of Rankine, William Froude, and John Hopkinson among British engineers also hold an honoured place in mathematics. Mathematicians of eminence have spent their lives in the tuition of engineers, and in that way have greatly influenced the practice of engineering; but while they have necessarily become familiar with the problems of engineering as a consequence of their connection therewith, they have not accomplished much actual engineering work, and none of it has been of first importance. Speaking broadly, there is an abiding distinction between mathematicians and engineers. Mathematicians regard engineering chiefly from the scientific point of view, and are primarily concerned with the bearing of mathematics on engineering practice, the construction of theories, and the framing of useful rules. Engineers, even when well equipped with mathematical knowledge, are primarily devoted to the design and construction of efficient and durable works, their main object being to secure the best possible association of efficiency and economy, and so to achieve practical and commercial success. There is evidently room for both classes, and their collaboration in modern times has produced wonderful results.

The proper use of mathematics in engineering practice is now generally agreed to include the following steps: first comes the development of a mathematical theory based on assumptions which are thought to embody and to represent conditions disclosed by past practice and observation. Frequently these theoretical investigations give rise to valuable suggestions for further observation or experimental investigations. Mathematical analysis must be applied to the results of observation and experiment; and, as a result, amendments or extensions are made of the original mathematical theory. Useful rules are also devised, in many instances, which serve for guidance in the future practice of engineers. Formerly it was thought by men of science that purely mathematical investigation and reasoning would do all that was required for the guidance of engineering practice; now it is admitted that such investigations will not suffice, and that the chief services which can be rendered to engineering by mathematicians will consist in the suggestion of the best directions and methods for experimental research, the conduct of observations on the behaviour of existing works, the establishment of general principles based on analysis of experience, and the framing of practical rules embodying scientific principles.

The contrast between present and past methods can be illustrated by comparing investigations made during the eighteenth century into the behaviour of ships amongst waves by Daniel Bernoulli, who won the prize offered by the Royal French Academy of Science in 1757, and work done by William Froude a century later in connection with the same subjects. Bernoulli was the greater mathematician, but had only a small knowledge of the sea and of ships. His memoir was a mathematical treatise; his practical rules, although deduced from mathematical investigations which were themselves correct, depended upon certain fundamental assumptions which did not correctly represent either the phenomena of wave-motion or the causes producing and limiting the rolling oscillations of ships. Bernoulli realised and dwelt upon the need for further experiment and observation and showed remarkable insight into what was needed; but the fact remains that he neither made such experiments himself nor was able to induce others to make them. As a consequence, his practical rules for the guidance of naval architects were incorrect and would have produced mischievous results if they had been applied in practice.

William Froude was a trained engineer who had a good knowledge of mathematics and a mathematical mind. His acquaintance with the sea and ships was considerable, his skill as an experimentalist was remarkable, and he was fortunate enough to secure the support of the Admiralty through the Constructive Department. He thus obtained the services of the officers of the Royal Navy in making a long series of accurate and detailed observations of the characteristic features of ocean waves as well as the rolling of ships amongst waves or in still water. In this way, starting with the formulation of a mathematical theory of wave-motion, and of a theory for unresisted rolling in still water and amongst waves, Froude added corrections based on experimental research, and succeeded eventually in devising methods by means of which naval architects can make close approximations to the probable behaviour of ships of new design when exposed to the action of waves,

[1] Lecture delivered at Cambridge before the Fifth International Congress of Mathematicians by Sir William H. White, K.C.B., F.R.S.

either forming a regular series or constituting an irregular sea. In these approximations allowance can be made for the effect of water-resistance to the rolling motion—a most important factor in the problem which could not be dealt with until experimental research had been made, and results had been subjected to mathematical analysis. In addition, Froude laid down certain practical rules for the guidance of naval architects, and the application of these rules has been shown by long experience to favour the steadiness—that is to say, the comparative freedom from rolling—of ships designed in accordance with these rules. In short, a problem which had proved too difficult when attacked by Daniel Bernoulli in purely mathematical fashion was practically solved a century later by Froude, who employed a combination of mathematical treatment and experimental research.

Another example of the contrast between earlier and present methods is to be found in the treatment of the resistance offered by water to the onward motion of ships. From an early date mathematicians have been attracted to this subject, and many attempts were made to frame mathematical theories. When steam-propulsion for ships was introduced, the matter became of great practical importance, because it was necessary to make estimates for the engine-power required to drive a ship at the desired speed. In making such estimates it was necessary to approximate to the value of the water-resistance at that speed, although the required engine-power was also influenced by the efficiency of the propelling apparatus and propellers. In addition, it was obvious that the water-resistance to the motion of a ship when she was driven by her propellers at a given speed would be in excess of the resistance experienced if she were towed at the same speed, and there was no exact knowledge in regard to that increment of resistance. The earlier mathematical theories of resistance proved to be of little or no service, and they were based on erroneous and incomplete assumptions. Rankine devised a "stream-line" theory which was superior to its predecessors, but it also for a time had no effect on the practice of naval architects. William Froude, adopting this stream-line theory, dealt separately with frictional resistance, and devised a "law of comparison" at corresponding speeds, by which from the "residual resistance" of models—exclusive of friction—it became possible to estimate the corresponding residual resistance for ships of similar forms. At first he stood alone in advocating these views, but subsequent experience during forty years has demonstrated their soundness.

Experimental tanks for testing models of ships, such as Froude introduced, are now established in all maritime countries, and the results obtained therein are of enormous value to the designing of steamships. In regard to the selection of the forms of ships, naval architects are now able to proceed with practical certainty; but in connection with the design of screw propellers, even after model experiments have been made with alternative forms of screws, there is still great uncertainty, and dependence upon the results obtained on "progressive" speed trials of ships is still of the greatest service. As yet the "law of comparison" between model screws and full-sized screws has not been determined accurately. The condition of the water in which screws act, as influenced by the advance of a ship and her frictional wake, the phenomena attending the passage of the water through a screw, and the impression thereon of sternward motion from which results the thrust of the propeller, the effect upon that thrust of variations in the forms and areas of the blades of screw propellers, and the causes of "cavitation," all form subjects demanding further investigation. In these cases the only hope of finding solutions lies in the association of experimental research with mathematical analysis. There have been very many mathematical theories of the action of screw propellers, but none of these has provided the means for dealing practically with the problems of propeller design, and there is no hope that any purely mathematical investigation ever will do so, because the conditions which should be included in the fundamental equations are complex and to a great extent undetermined.

In connection with other branches of engineering, model-experiments have also proved effective. Examples are to be found in connection with the estimates for wind-pressure on complicated engineering structures, such as girder or cantilever bridges. Experimental methods are also being applied with great advantage to the study of aeronautics and the problems of flight.

The association of the mathematical analysis of past experience with designs for new engineering works of all kinds is both necessary and fruitful of benefits. A striking example of this procedure is to be found in connection with the structural arrangements of ships of unprecedented size, which have to be propelled at high speeds through the roughest seas, to carry heavy loads, to be exposed to great and rapid changes in the distribution of weight and buoyancy, and to be subjected simultaneously to rolling, pitching, and heavy motion, as well as to blows of the sea. In such a case purely mathematical investigation would be useless; the scientific interpretation of past experience and the comparison of results of calculations based on reasonable hypotheses for ships which have seen service with similar results of calculations for ships of new design are the only means which can furnish guidance.

In the past the association of mathematicians and engineers has done much towards securing remarkable advances in engineering practice; and in future it may be anticipated that still greater results will be attained now that the true place of mathematicians in that practice is better understood and utilised.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A great cause of anxiety to those who are responsible for evening continuation schools and classes lies in the spasmodic attendances and lack of continuity of the casual student. The prospectus of the Municipal Technical Institute, Belfast, shows that the authorities in that city deal with this source of trouble courageously. Students must submit to an entrance examination, and must follow a course of study, and "any student who does not wish to conform to the regulation as to attending a definite course of study or passing the entrance examination can obtain exemption on making application at the office and paying *treble* the fee for the class it is desired to join." Side by side with these restrictions there is every opportunity and incentive to the serious student to equip himself thoroughly for his business.

The London County Council announces that the evening classes held in Polytechnics, technical institutes, schools of art, commercial centres, and evening schools will shortly be reopened. The programme which the Council has prepared includes classes to meet all kinds of needs. The enrolment of students began on Monday, September 16, and a leaflet giving full particulars as to where the classes are held, and as to fees (which it may be stated are very low), can be obtained at any of the Council's schools and of the Education Officer, Education Offices, Victoria Embankment. It is hoped that the efforts of the Council to improve the education of the young people of London by means of these valuable classes will result in a large influx of new and earnest students in the session now at hand.

THE 90th session of the Birkbeck College will commence on Wednesday, September 25. The opening address will be given in the theatre at 7.30 p.m., by Sir Sidney Lee. The class-rooms, &c., will afterwards be open for inspection, and there will be an exhibition in the Art School. The college is conducted in relation with the University of London; classes are held both in the day and evening; twenty-nine members of the staff are recognised teachers of the University. There is a very complete curriculum for chemistry, physics, mathematics, botany, zoology, and geology. The laboratories are well equipped with modern apparatus and appliances, and research work is encouraged in all the science departments. According to the calendar more than 118 students passed some examination of the University during the last session: forty-nine took degrees in arts or science, twenty-two with honours, and several students gained distinction at other universities.

THE new session of the Battersea Polytechnic opened on Tuesday, September 17, and the calendar gives full details of all the numerous courses and classes held at the Polytechnic. In the Day Technical College full-time courses are arranged in mechanical, civil, electrical and motor engineering, architecture and building, chemical engineering, and art, the courses covering a period of three years, at the end of which time students passing the necessary examinations are awarded the Polytechnic diploma. There are also full university and diploma courses in mathematics, physics, chemistry, botany, &c. Concurrently with the diploma courses, students can prepare for and take the degree courses in science and engineering of the University of London. In the electrical engineering department, a new course in electric lighting and illumination will be held during the second term of the session. The greatest development to be recorded this year is in the department of natural science, *i.e.* including the subjects of hygiene, physiology, geology, and bacteriology. The recent donation of 6000*l.* made by the Worshipful Company of Drapers has enabled the governing body to erect a four-storey building for the housing of the above sections of work, and thus airy and well-lighted laboratories and lecture-rooms of the latest design, and fitted with the most modern equipment, are now available for this most important work.

AN influentially signed appeal has reached us for support to a scheme for providing a systematic course of combined military and industrial training for lads from the age of fourteen years upwards. The object of the British Boys' Training Corps, on behalf of which the appeal is made, is the moral, physical, and industrial advancement of the cadets enrolled in it, to train them in the duties of citizenship, and to fit them for a life of industry. Military organisation and exercise will be used as a means for developing their *moral* and physique, and promoting among them habits of discipline, application, adaptability, and resourcefulness, which are indispensable to proficiency in the workshop or the factory. The corps will, in effect, be a military and industrial boarding-school, and is designed to train and instruct a boy for a period of three or four years continuously from the time he leaves the elementary school. Alike upon social, economic, and industrial grounds the scheme is commended to the public. The annual loss to the nation of promising material presents a grave problem. Far too many boys on leaving school are engaged in "blind-alley" occupations; when they have outgrown these, they find themselves adrift without either the skill or the knowledge to qualify them for permanent employment; they swell the ranks of casual labour, and the prison or the workhouse is the ultimate destiny of an increasing number of them. To mitigate these evils in some measure at least is the aim of the corps. It is estimated that the cost of establishing and maintaining the corps at first will be 15,000*l.* No appeal for funds has hitherto been made, but two members of the council have generously promised to guarantee 1000*l.* and 500*l.* respectively towards the expenses on condition that the total amount guaranteed or subscribed is not less than 15,000*l.*, and various unsolicited donations, including an anonymous one of 50*l.*, have already been placed to the credit of the corps at the Bank of England. Guarantees, donations, or subscriptions may be sent to the account of the corps at the Bank of England (Western Branch), Burlington Gardens, W.; to Colonel Pollock, Wingfield, Godalming; or to the hon. secretary, Mr. J. C. Medd, 37 Russell Square, W.C., from whom particulars of the scheme can be obtained.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 2.—M. P. Appell in the chair.—A. **Lacroix**: The origin of the transparent quartz of Madagascar. The hyaline quartz of Madagascar is of complex origin, but there are only two classes of deposits furnishing the mineral in large quantities and of sufficient transparency for industrial purposes. One of these is in lodes of the Ampangabé type, in which the quartz is without crystalline form; the other is of hydrothermal origin, and here the quartz forms well-defined crystals.—A. **Riccò**: Filaments, *alignements*, and solar prominences. The author confirms the view that there is a relation between the prominences and the filaments and *alignements*.—Jean **Danysz** and William **Duane**: The electrical charges carried by the α and β rays. From the experiments described the electrical charge carried by the α rays of one Curie of emanation in equilibrium with radium A, B, C is deduced as 90·8 electrostatic units per second, or nearly three times the charge found by Rutherford for radium C alone in equilibrium with one Curie of emanation. From this constant are deduced the volume of one Curie of emanation (0·595 mm.^{3} at 15° C.), and the volume of helium given off by one gram of radium in equilibrium with its emanation and radium A, B, and C (157 mm.^{3}), both in good agreement with the experimental values. Victor **Henri** and René **Wurmser**: Study of the law of photochemical absorption for reactions produced by the ultra-violet rays. There is a striking parallelism between the absorption curve of acetone in the ultra-violet and the chemical activity of the different rays. This reaction affords an example where the extreme ultra-violet rays are less active chemically than ultra-violet rays of greater wave-length.—Claude **Verne**: *Solanum maglia* and *tuberosum*, and the results of experiments on cultural bud mutations undertaken on these wild species of potato.—H. **Busquet**: The comparative cardiac action of the physiological extract of digitalis and other digitalis preparations.—Romuald **Minkiewicz**: *Ciliata chromatophora*, a new order of Infusoria with unusual morphology and reproduction.—C. **Maltézos**: Contribution to the phenomena of lightning.

September 9.—M. P. Appell in the chair.—A. **Müntz**: The evaporation of the soil and of plants as a factor in causing the persistence of wet and cold weather.—Daniel **Berthelot** and Henry **Gaudechon**: The action of the ultra-violet rays upon gaseous hydrocarbons. Remarks on a recent note by Marc Landau.—Em. **Bourquelot** and M. **Bridel**: A new synthesis of the glucoside of an alcohol with the aid of emulsin. β-Benzylglucoside.—Ch. **Jolin**: The specific histological characters of the "luminous cells" of *Pyrosoma giganteum* and of *Cyclosalpa pinnata*.

NEW SOUTH WALES.

Linnean Society, July 31.—Mr. W. W. Froggatt, president, in the chair.—Rev. W. W. **Watts**: The ferns of Lord Howe Island. During a two months' stay, last year, Mr. Watts collected specimens of the unique fern-flora of the island. The paper indicated the species to be found on the northern hills, in the central area, and at the southern end of the island, where Mts. Lidgbird and Gower rise to a height of 2500 and 2800 ft. respectively. The plateau on the top of Mt. Gower is the home of a number of beautiful species to be found nowhere else.—R. J. **Tillyard**: Some new and rare Australian Agrionidæ (Neuroptera: Odonata). In this paper, a considerable number of new Australian species are described, and new genera are proposed for the reception of these and other species.—H. J. **Carter**: Descriptions of some new species of Coleoptera.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2239, Vol. 90] THURSDAY, SEPTEMBER 26, 1912 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,

SOUTH KENSINGTON, LONDON, S.W.,

INCLUDING

ROYAL COLLEGE OF SCIENCE,
ROYAL SCHOOL OF MINES,
CITY AND GUILDS (ENGINEERING) COLLEGE.

Special Courses of Advanced Lectures, as follows, will begin during October next:

Subjects.	*Conducted by*
Spectroscopy	Assistant-Professor A. FOWLER, A.R.C.S., F.R.A.S., F.R.S.
Economic Geology:	
A. Mining Geology ...	Prof. W. W. WATTS, LL.D., Sc.D., M.Sc., F.R.S., F.G.S., and Assistant-Professor C. G. CULLIS, D.Sc., F.G.S.
B. Engineering Geology	HERBERT LAPWORTH, D.Sc., M.Inst.C.E., F.G.S., and Professor W. W. WATTS.
C. Geology of Petroleum	A. WADE, A.R.C.S., D.Sc., F.G.S.

Particulars of these and other Courses to follow free on application to the SECRETARY.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,

SOUTH KENSINGTON, LONDON, S.W.,

INCLUDING

ROYAL COLLEGE OF SCIENCE,
ROYAL SCHOOL OF MINES, and
CITY AND GUILDS (ENGINEERING) COLLEGE.

A Special Course of Lectures, with practical work, on

PLANT BIO-CHEMISTRY,

itable for advanced students in Botany and Plant Physiology, will be given by

Mr. S. G. PAINE, F.I.C.,

commencing on October 9 next.

Particulars of these and other Courses to follow free on application to the SECRETARY.

SESSION OPENS 30th SEPTEMBER, 1912.

EAST LONDON COLLEGE.

(UNIVERSITY OF LONDON.)

Classics	F. R. EARP, M.A.
English	H. BELLOC, M.A.

Electrical Engineering	J. T. MORRIS, M.I.E.E.

* University Professors.

Fees ten guineas per annum. Valuable Entrance Scholarships awarded y Drapers' Company.

Special facilities for Post-Graduate and Research Students. Particulars of courses of study, &c., on application to the REGISTRAR, or to

J. L. S. HATTON, M.A., Principal, at the College.

ENGINEERING AND TECHNICAL OPTICS.

NORTHAMPTON POLYTECHNIC INSTITUTE,

CLERKENWELL, LONDON, E.C.

MECHANICAL AND ELECTRICAL ENGINEERING AND ELECTRO-CHEMISTRY.

Full Day Courses in the Theory and Practice of the above Subjects will commence on Monday, September 30, 1912. The courses in Mechanical Engineering include specialisation in Automobile and Aëronautical Engineering, and those in Electrical Engineering include specialisation in Radio-Telegraphy. ENTRANCE EXAMINATION on Wednesday and Thursday, September 25 and 26. These courses include periods spent in Commercial Workshops, and extend over four years. They also prepare for the degree of B.Sc. in Engineering at the University of London. Fees, £15 or £11 per annum.

THREE ENTRANCE SCHOLARSHIPS of the value of £52 each will be offered for competition at the Entrance Examination in September next.

TECHNICAL OPTICS.

Full and Part Time Day Courses in all branches of this important department of Applied Science given in specially equipped laboratories and lecture rooms.

Full particulars as to fees, dates, &c., and all information respecting the work of the Institute can be obtained at the Institute or on application to

R. MULLINEUX WALMSLEY, D.Sc., Principal.

BIRKBECK COLLEGE,

BREAMS BUILDINGS, CHANCERY LANE, E.C.

Principal: G. Armitage-Smith, M.A., D.Lit.

COURSES OF STUDY (Day and Evening) for the Degrees of the UNIVERSITY OF LONDON in the

FACULTIES OF SCIENCE & ARTS

(PASS AND HONOURS)

under RECOGNISED TEACHERS of the University.

SCIENCE.—Chemistry, Physics, Mathematics (Pure and Applied), Botany, Zoology, Geology and Mineralogy.

ARTS.—Latin, Greek, English, French, German, Italian, History, Geography, Logic, Economics, Mathematics (Pure and Applied).

Evening Courses for the Degrees in Economics and Law.

SESSIONAL FEES { *Day*: Science, **£17 10s.**; Arts, **£10 10s.** *Evening*: Science, Arts, or Economics, **£5 5s.**

POST-GRADUATE AND RESEARCH WORK.

Particulars on application to the Secretary.

South-Western Polytechnic Institute,

MANRESA ROAD, CHELSEA, S.W.

Evening Courses of Lectures with practical work:—

BIOLOGICAL CHEMISTRY.

HUGH MacLEAN, M.D., Ch.B., M.Sc.

HUMAN PHYSIOLOGY & HISTOLOGY.

E. L. KENNAWAY, M.D., M.A.

SYSTEMATIC BOTANY.

S. E. CHANDLER, D.Sc., A.R.C.S., F.L.S.

Further particulars on application to the SECRETARY.

SIDNEY SKINNER, M.A., Principal.

CITY OF LONDON COLLEGE.

ACTING IN CONJUNCTION WITH THE LONDON CHAMBER OF COMMERCE.

WHITE ST., and ROPEMAKER ST., MOORFIELDS, E.C.

(Near Moorgate and Liverpool Street Stations).

PRINCIPAL: SIDNEY HUMPHRIES, B.A., LL.B. (Cantab.)

Michaelmas term begins Monday, September 30th.

EVENING CLASSES in SCIENCE. Well-equipped **LABORATORIES** for Practical Work in **CHEMISTRY, BOTANY, GEOLOGY.**

Special Courses for Conjoint Board, Pharmaceutical and other examinations. Classes are also held in all Commercial Subjects, in Languages, and Literature. Art Studio. All Classes are open to both sexes.

DAY SCHOOL OF COMMERCE. Preparation for a COMMERCIAL or BUSINESS career.

Prospectuses, and all other information, gratis on application.

DAVID SAVAGE, *Secretary.*

BOROUGH POLYTECHNIC INSTITUTE,

BOROUGH ROAD, LONDON, S.E.

CHEMISTRY DEPARTMENT.

Under the direction of C. DORÉE, M.A., D.Sc.

The Classes—Elementary, Advanced and Honours, Inorganic and Organic Chemistry—commence September 23, 1912.

The following Special Evening Courses in Applied Chemistry have also been arranged:—

THE CHEMISTRY AND TECHNOLOGY OF THE ESSENTIAL OILS.

Lectures and Practical Work, Wednesday, 7.30. C. T. BENNETT, B.Sc., F.I.C.

THE CHEMISTRY AND MANUFACTURE OF FOODSTUFFS.

Lectures, Monday, 7.30. E. HINKS, B.Sc., F.I.C., and T. MACARA, F.I.C.

ELECTROCHEMISTRY. Wednesday and Friday, 7.30.

THE ANALYSIS AND VALUATION OF LAUNDRY TRADE MATERIALS.

A Practical Course, Monday and Friday, 7.30. C. DORÉE, M.A., D.Sc.

For full particulars apply to the Principal, C. T. MILLIS.

THURSDAY, SEPTEMBER 26, 1912.

SCIENTIFIC PEDAGOGY.

(1) *Rationalist English Educators.* By Dr. G. E. Hodgson. Pp. 254. (London: S.P.C.K.; New York: E. S. Gorham, 1912.) Price 3*s.* 6*d.*

(2) *The Montessori Method: Scientific Pedagogy as Applied to Child Education in "The Children's Houses."* With additions and revisions by the author. By Maria Montessori. Translated from the Italian by Anne E. George. Pp. xliii + 377. (London: W. Heinemann, 1912.) Price 7*s.* 6*d.* net.

(3) *The Evolution of Educational Theory.* By Prof. John Adams. Pp. ix + 410. (London: Macmillan and Co., Ltd., 1912.) Price 10*s.* net. (The Schools of Philosophy.)

(1) PROBABLY Miss Hodgson is by temperament incapable of entering sympathetically into the point of view of those of whom she writes in this volume—Locke, the Edgeworths, and John Stuart Mill. In any case she should show a more adequate acquaintance with the Edgeworths when she writes about them. In the first line of her essay she misquotes the title of the only book of theirs she refers to, and continues so to misquote it throughout her text. A competent reader will soon discover that she has missed the message of the book in her superficial *résumé* of its contents. It is therefore scarcely necessary to examine her criticisms. The treatment of Locke is the most satisfactory performance of the three.

(2) Mdme. Montessori's work for young children in the slum districts of Rome had received widespread recognition before the translation of her chief pedagogical writing appeared. The ground had in other ways been well prepared, and now we are threatened with a regular invasion of Montessori machinery. This is not said to belittle what has been accomplished in the "Children's Houses" in Rome. The idea of a central nursery for children from three to seven in the great tenement blocks was admirable in itself, and it was made still more so by associating the parents with its management and by appointing *directrices* who should live on the spot amongst those whom they were trying to serve. As a great social experiment, there is much to learn from Mdme. Montessori's success, whether it is the little school societies themselves which we regard, or the whole social setting of the establishments which she set up.

From the point of view of scientific pedagogy, the book and the experiment are interesting because of the sources of Mdme. Montessori's inspiration. Primarily a medical woman, the author made a special study of psychiatry, and took up the education of mentally deficient children. This brought her into touch with the pioneer works of Séguin and Itard, and led her to take courses in experimental psychology. For two years she was the working director of the State orthophrenic school. Her experience and her reading had led to the collection of a great quantity of didactic *matériel,* but, as she found at Bicêtre and elsewhere, admirable *matériel* is of little use, even when used in ways that are technically accurate, unless the spirit of its inventor is present.

The idea of these "tenement nurseries" and of applying the apparatus designed for the mechanical exercise of defective neural apparatus to the education and training of young but normal children occurred to her. The volume before us is a simple and fascinating account of what has been accomplished on these lines. Obviously much more than the transference of the apparatus was involved. It had to be adapted to children in whom the power of self-direction and self-education was present. But the principle of "training the senses," &c., was preserved. It is an interesting reversal of the ordinary tendency which is to apply modified infant school methods to the defective schools, and another instance of the way in which the scientific study of the abnormal may react upon the treatment of the normal. Whether or not Dr. Montessori's methods will lead to a reversion to formal training—none the less soulless because it is derived from modern psychology—is perhaps debateable. That there is some danger of this nobody who knows the schools will be likely to deny.

(3) It is quite impossible to do justice to Prof. Adams's latest contribution to the literature of education within the limits laid down. It is the first volume of a series which is to appear under the general editorship of Sir Henry Jones—"The Schools of Philosophy." The task assigned to Prof. Adams was a supremely difficult one, and we know nobody who could have attempted it with greater chances of success. He had no predecessors in the field upon whose work he might have improved, as he necessarily abandoned the usual methods of presentation employed by historians of educational thought. Instead of a strictly chronological treatment he has given us a broad view of the development of educational concepts—of their interaction, of the recognition of their mutual implications, and of their relation to social and scientific advance. Thus many of the dangers implicit in the study of the history of education are avoided—there is no mistaking the external shell of teaching devices for the spirit and substance of the thought behind them.

It need scarcely be said that Prof. Adams's method occasionally upsets the conventional sense of proportion. Some of the things that we had supposed really mattered are treated with indifference; a new sense of values is introduced. Whether these will bear closer examination remains to be seen, but in any case we may warmly congratulate the author on the successful completion of an arduous undertaking.

J. A. G.

ATOMIC DYNAMICS.

Prinzipien der Atomdynamik. By Prof. J. Stark. I. Teil: "Die elektrischen Quanten." Pp. x + 124. (Leipzig: S. Hirzel, 1910.) Price 3.20 marks. II. Teil: "Die elementare Strahlung." Pp. xv + 286. (Leipzig: S. Hirzel, 1911.) Price 7.80 marks.

IN this work Prof. Stark gives a systematic account of the experimental facts which throw light on the constitution of the atom, and develops a theory of the structure of the atom, mainly on the basis of optical phenomena. The work is divided into three parts. Part i. is intended as an introduction, and deals with our knowledge of the nature and properties of electrons, and of the energy and structure of the electromagnetic field. Little space is devoted to the description of the methods by which the experimental results were obtained, and more prominence is given to the discussion of the validity of the experiments and their value in elucidating the internal structure of the atom.

In chapter iii. the constitution of the atom on Stark's theory is described. It is assumed that electrons and positively charged entities (archions) which are endowed with mass form the constituent parts of an atom. On account of magnetic forces, the archions form a definite configuration in the atom, and cannot be separated without causing its disruption. On the other hand, the electrons which are attached to the archions can be separated without causing the atom to decay. This atomic system, which is more fully developed in part ii., is capable of explaining and systematising many of the experimental facts.

The second part is mainly concerned with electromagnetic radiation. After a discussion of the theoretical principles of radiation, the grouping of spectrum lines into series and the relations existing between the frequencies of the lines are considered. A detailed discussion of line and band spectra and similar phenomena exhibited by Röntgen rays is also given. The archion theory is then worked out more fully, and hypotheses are put forward to account for the origin of spectra. The band spectra are ascribed to the vibrations of the electrons which are attached to the archions, while the archion itself, after losing the electron attached to it, is the elementary oscillator responsible for the line spectrum. The continuous spectrum is ascribed to the vibrations of the free electrons. These by frequent collisions suffer irregular accelerations, and thus give rise to a continuous succession of frequencies. A full and interesting account of the bearing of the author's theory on such problems as the Doppler effect in canal rays, the Zeeman effect, fluorescence, and allied phenomena is given. Also the results obtained with Röntgen and γ-rays are considered in relation to the theory.

The third part, which has not yet appeared, is, according to a statement in the preface, mainly intended for the chemist. It will deal with the structure of the electromagnetic field on the surface of chemical atoms, and with the forces which hold the atoms together in chemical combinations.

A work of this nature, which aims at a discussion of the principles of atomic dynamics, must to a large extent be of a speculative character. In this connection, however, it is important to remember that the work always distinguishes very clearly between experimental facts and speculative theory. Also, the reader who does not agree with the speculations put forward in the work will find in it a very useful record of all researches which contribute to the elucidation of the internal structure of the atom. Perhaps one misses a fuller discussion of radioactive phenomena, which are intimately connected with the problems discussed in this work. Stark's book, which deals with such a fascinating subject in an interesting manner, will prove very useful as a guide to further research.

H. G.

MODERN ROAD CONSTRUCTION.

Modern Road Construction: a Practical Treatise for the Use of Engineers, Students, Members of Local Authorities, &c. By Francis Wood. Pp. xi + 137; illustrated. (London: Charles Griffin and Co., Ltd., 1912.) Price 4*s.* 6*d.* net.

THE conditions relating to the maintenance of roads during the last few years have undergone so much alteration, owing to the introduction of motor vehicles, that the publication of a practical treatise on the subject is fully justified.

The book now under notice cannot fail to be of great service to those having charge of urban roads. The author, who has the supervision of the roads in the Borough of Fulham, appears to have devoted a great deal of attention to observing and recording the wear and tear of different kinds of material used; and in obtaining statistics as to their cost and endurance. The book gives, in a concise, and not too technical a form, the leading characteristics and details of modern road construction, and the results of the traffic to which these roads are subject. The relative merits of macadam, granite sets, asphalt, and wood paving are fully dealt with.

The author considers that macadam on a good foundation, for horse-drawn vehicles, is the best, and the condition of these roads is greatly improved, both as to cleanliness and endurance, when the surface is sprayed with tar; that creosoted soft wood, such as red pine or yellow deal, gives more satisfactory results for urban traffic as regards wear than the harder woods, such as oak or jarrah; that wood paving has the advantage of being silent and not slippery; and that for motor traffic asphalt paving is the best. The relative endurance, and the time the surface will last without replacing, is given as two years for macadam laid on a good foundation; for soft creosoted wood paving laid on concrete, fifteen years; and for rock asphalt on concrete, twenty years.

Statistics are given showing the great advantage that is derived from the use of tar for spraying macadam roads, both in the prevention of dust and by increasing the length of the life of such roads, which the author calculates at 33 per cent. It is also shown that the use of motor vehicles reduces considerably the amount of refuse that has to be removed from the surface of the roads.

The book contains eleven chapters dealing with a general introduction on modern road construction; macadam roads; wear of roads; effect of traffic; tarring macadam roads; methods of using tar and bitumen; rollers and rolling; paving; cost of maintenance of roads; with appendices giving a specification for road-making; wood paving; tarring; and copies of the Road Board specification for pitch.

HISTORICAL GEODESY.

Grandeur et Figure de la Terre. By J. B. J. Delambre. Ouvrage augmenté de notes, de cartes, et publié par les soins de G. Bigourdan. Pp. viii+402. (Paris: Gauthier-Villars, 1912.) Price 15 francs.

"LES conquêtes passent, et ces opérations restent," was the compliment with which Napoleon accepted from Delambre a copy of his "Base du Système métrique décimal." The publication of this work of the great French geodesist offers a good reason why the second half of the above remark was as true as the first. The manuscript which Delambre left unpublished at his death gave an interesting historical account of the pioneer work of the eighteenth century in investigating the size and shape of the earth, and it also reveals the value of his own share in that work. Names well known outside the world of astronomy appear in the book: Colbert gave the first order for a measure of an arc along the meridian of Paris; Robespierre signed a document expelling Lavoisier, Laplace, Coulomb, and Delambre, with others, from the Commission des Poids et Mesures. Many other French names also occur in the book to remind the world how much geodesy owed in its earliest stages to the Académie des Sciences.

The direct effect on contemporary scientific work of such a tremendous upheaval as the French Revolution is well shown in Delambre's account of the delays caused by his repeated arrests at the hands of ignorant provincials. One is tempted to wonder whether, if the metric system had been established at a time when more friendly relations existed between France and England, this country would also have adopted it. M. de Talleyrand's invitation to the British Parliament to appoint a commission of Fellows of the Royal Society to cooperate with members of l'Académie des Sciences in fixing natural and invariable units of weight and length, is still of more than academic interest.

Enough has been said of the historical side of this book. It must now be added that Delambre's accounts of the surveys of arcs in the different parts of the world are marked by very close study of all available sources of information. Where possible, the original manuscripts were studied, and by very acute criticism the faults of much of the earlier work and some of the later work were elucidated. Several investigators, notably J. Cassini, come in for pretty severe treatment; Delambre's critical remarks may still be most useful to warn the young observer as to faults to be avoided. The accounts of the journeys of some of the surveying parties are very interesting, in particular the journal of the Abbé Outhier on the Lapland survey of 1736. Curiously interesting, too, it is to see new items of knowledge gradually entering in as factors in elucidating the problem under discussion. Thus the first emergence of spherical trigonometry and the modification of results owing to the discovery of nutation, come upon the present-day reader with a curious sense of shock.

A debt of gratitude is owing to M. Bigourdan for his work in editing the manuscript. We note only one misprint; Groombridge is spelt wrongly on p. 314. The successful way in which the editing has been done may be taken as a sign of the pleasure that M. Bigourdan has felt in carrying through the undertaking.

OUR BOOKSHELF.

Norse Tales. By Edward Thomas. Pp. 159. (Oxford: The Clarendon Press, 1912.) Price 2s.

This book is a successful attempt to popularise the romance and poetry of ancient Norse literature. Though he has not quite attained the dignity and charm of style which render Sir G. Dasent's "Story of Burnt Njal" and the "Popular Tales" from the collection of Asbjorsen classics in our folk-lore literature, this presentment by Mr. Thomas offers little ground for criticism.

The collection falls into two parts:—first, stories of the gods, a rearrangement of the Prose or Younger Edda, compiled by Snorri Sturleson in the thirteenth century; secondly, an adaptation of the excellent collection of early poetry made by Gudbrand Vigfuson and F. York Powell, under the title of "Corpus Poeticum Boreale." Mr. Thomas, perhaps wisely, does not discuss at length the many problems of the Eddas. All that is certain is that the poems were collected in Iceland, that some bear internal evidence of being older than others, and that they assumed their present shape long after the time of their composition. The land in which they were originally written is still uncertain. The editors of the "Corpus Poeticum Boreale" suggest that some may have their origin in these islands, or may have been re-edited here "at a time when the Irish Church, with her fervent faith, her weird and wild imaginings, and curious half-Eastern legends, was impressing the poetic mind on one side, while the rich and splendid court of Eadgar or Canute would stimulate it on the other."

The introduction by Mr. Thomas is excellent, so far as it goes. But as the book seems to be intended for school use, it might with advantage have been extended, and a bolder attempt might have been made to prepare the student for the assimilation of much that is unfamiliar. We must, however, be thankful for what he has given us: "The Making of the Worlds, of Gods, and of Giants"; the twisting of Loki in the cave which causes earthquakes; the tale of Balder and Loki, where a note might have been added to direct the reader to Prof. Frazer's explanation of the myth; Thor, Helgi, and Sigurd—a splendid feast of poetry and romance.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Further Researches into Induced Cell Reproduction and Cancer.

The reviewer of Mr. H. C. Ross's book, "Further Researches into Induced Cell Reproduction and Cancer," vol. ii. (Nature, August 15, page 601), appears to me to have been very unfortunate in saying that "The accuracy of the observations now described depends upon the accuracy of those described before, and they in turn depend upon the accuracy of an equation in which degrees of temperature, minutes of time, and cubic centimetres of solutions are added together." The accuracy of Mr. Ross's observations does not depend in any way upon the equation referred to, which is simply a formula for making a certain jelly. The reviewer would imply that the equation itself is unscientific because degrees of temperature, minutes of time and cubic centimetres of solutions are added together, and that therefore the author does not possess even an elementary knowledge of the subject. The reviewer, however, is himself obviously ignorant of the fact that such an addition is quite scientific and allowable. It is not degrees of temperature and minutes of time which are added together, but the numbers of units of these entities concerned. He might as well criticise any chemical formula, such as H_2O, because such would imply that the hydrogen is multiplied by the oxygen. As a matter of fact, Mr. H. C. Ross's equation was given on my advice, because it is the most suitable way of representing the various factors concerned in the proper concoction of the jelly. The equation represents the differential coefficient of a function of many independent variables, which is the sum of the partial differential coefficients obtained from each variable.

The other remarks of the reviewer show the same want of accuracy. Mr. Ross has proved that human leucocytes can be forced to divide in large numbers by certain agencies, as described by me in Nature of December 14, 1911, No. 2198, p. 231, and it seems to me absurd to maintain that the facts found by him "necessitate the abandonment of every generally accepted belief with regard to mitosis." If the mode of division of human blood leucocytes had been previously determined with certainty, your reviewer's remarks might have been justified; but this is not the case. If Mr. Ross's observations cannot be reconciled with previous hypotheses (which I do not admit), so much the worse for the hypotheses. At all events the leucocytes actually do divide exactly as he has described.

During the last two and a half years Mr. Ross has been subjected to many criticisms of this nature—which criticisms remind me very strongly of the story of Galileo and his critics regarding the satellites of Jupiter. So far as I remember, it is said that the critics denied the possibility of Jupiter having satellites, but at the same time refused to look at them through Galileo's telescope. I think that if some of Mr. Ross's critics would spend as much time over his specimens as I have done they would not be so free with their *a priori* objections.

Ronald Ross.

Johnston Tropical Laboratory, University of Liverpool, August 31.

A Flower-sanctuary.

I beg to thank Mr. Perrycoste for his letter in Nature of September 19. The county of Somerset has for some time had a by-law similar to that of the county of Cornwall; but you will observe that the by-law does not justify the protection of any particular plant, and that the special flora of Cheddar might easily disappear without any violation of its provisions. It only applies to the uprooting or destruction of plants "in such a manner and in such quantities as to damage or disfigure any road," &c., and it is further limited by the proviso which enables persons to collect specimens in small quantities for private and scientific use. I fear that the cases in which a prosecution under such a by-law would succeed are very few, and certainly the by-law falls far short of the realisation of the wish to protect a rare flora.

Edw. Fry.

Fairland, near Bristol, September 21.

William Higgins and the Imponderable Elements.

It is interesting to compare the semi-prophetic speculations of Oersted as so ably stated by Prof. Silvanus Thompson in NATURE of August 29 with a theory put forward by William Higgins in a book published at Dublin in 1814. This work, entitled "Experiments and Observations on the Atomic Theory and Electrical Phenomena," was primarily intended to prove that Dalton's theory had been anticipated by the author in 1789,[1] but some thirty pages in the early part of the book are devoted to a statement of his views on the "imponderable elements."

The following extracts may serve to give some idea of the nature of his surmises:—

"The ultimate particles of ponderable matter are exceedingly minute, but those of imponderable elements, such as caloric, electricity, and light, are so beyond calculation. The utmost stretch of the human mind can no more estimate the size of those particles than it can measure space and duration. However, their divisibility is limited" (p. 24).

"Every ultimate particle of a metal is surrounded with a small although dense atmosphere of caloric, together with a small portion of the electric or some other subtile fluid . . . when two atoms unite, the compound becomes surrounded with one common atmosphere of caloric and rejects a third atom of either of its constituents" (p. 13 *et seq.*).

"When two ultimate particles unite chemically their individuality is destroyed, and they form one solid atom whose capacity is less than its constituents in a detached or simple state, hence it is that caloric is liberated by chemical union. These atoms however retain a sufficient quantity of caloric to furnish them with atmospheres" (p. 20).

"The ultimate particles of different kinds of matter, whether in a solid or gaseous state, do not retain the same quantity of caloric in their respective atmospheres. This probably is occasioned by their different forces of attraction to it. Those particles which attract caloric with most force are surrounded with more of it, in a less space than those particles that attract it with a smaller force" (p. 19).

"Solids also contain a prodigious quantity of caloric, as may be shewn by deflagrating together nitre, brimstone, and crude antimony, reduced to powder, and intimately mixed" (p. 25).

"Caloric and the electric fluid are antagonistic elements, whereas light and caloric seem to be kind and almost constant associates. The light of the sun, and that produced by artificial means, are accompanied by caloric" (p. 40).

Good conductors are those part of the caloric of which is capable of being readily replaced by the electric fluid. "Dry oxides are non-conductors, as their calorific atmospheres are small and strongly attached to their atoms" (p. 43).

The electric spark inflames gunpowder or alcohol owing to "caloric which is disengaged from these substances or from the air in contact with them." Wires are fused by a battery because of "a rapid dislodgement of the specific heat of the metals by the electric matter," and since a wire remains heated during the passage of a current the electric fluid "must also possess the power of urging on, during its passage, through the battery and conductors, a sufficiency of caloric to supply the waste occasioned by the ignition" (p. 26 *et seq.*).

In similar fashion he "explains" the luminosity of meteors, why the electric spark causes combustion between oxygen and hydrogen, and why earthquakes and volcanic eruptions are accompanied by thunder and lightning. The production of heat in Rumford's experiment he admits presents a difficulty, and suggests that it might be due to the displacement of some of the specific heat by electricity, which, it was well known, could be produced by friction. He precedes this by saying that "Heat evolved by friction, however unaccountable and mysterious it may appear, is not sufficient to invalidate the doctrine of the materiality of caloric, being only a solitary fact opposed to thousands that tend to establish its existence as an elementary substance" (p. 37).

He concludes this part of his work with a touch of the true Baconian philosophy:—"The theory, or rather the hypothesis, which I have advanced, on electrical phenomena . . . according to my knowledge is quite new." "So fully convinced am I, at present, of the truth of this doctrine that no vague or superficial objections will be able to stagger my creed; at the same time, I am ready to submit to convincing facts and arguments, for truth should be the sole object of every writer on philosophical subjects" (p. 45 *et seq.*).

It will be seen that his speculations, though crude, and, of course, erroneous in the light of modern theory, are none the less characterised by considerable lucidity in expression and no little ingenuity in application. In this connection we may well remember the words of Liebig: "All our views have been developed from errors." From the flashing embers of fallacy springs the Phœnix of Truth.

[1] See Meldrum, *Chem. News*, 1910, for a discussion of his claims on this point.

Glaciation and Striation.

PROF. COLE (NATURE, September 12, p. 37) would scarcely maintain the assumption that the stones seen in Boulder Clay were in the "englacial" distribution of the materials in closer juxtaposition than we find them in the deposit itself. The tendency of the larger stones to gravitate towards the bottom of the moving and shearing ice-mass through liquefaction and regelation is well illustrated in the Harlow "till." But Prof. Cole seems to forget that a "conglomerate with an ice-cement" would give us a glacial gravel or a "schotter" on the melting of the ice, and not a Boulder Clay. The efficiency as a graving-tool of a grain of quartz or of some harder mineral when caught between the contact-surfaces of two fragments of rock undergoing differential movement can scarcely be doubted.

As to the pre-Boulder Clay age of the "Ipswich man," the evidence of which I have examined on the spot, the attention of Mr. J. R. Moir (*ibid.*, p. 38) and others may be fairly directed to the new light thrown upon the question by the *Thorley* section.

With reference to scratches on flints, I venture to ask Sir Ray Lankester whether in plate 17 of his monograph (Phil. Trans. R.S., Series B, vol. ccii., pp. 203 ff.) he has not overlooked (1) the fact that the striations shown in Fig. 1 are on the original cortex of the flint-nodule, and therefore not necessarily connected with glaciation, and (2) the probability that the markings shown in Fig. 2 (enlarged in Figs. 3, 4, 5) are the etched-out skeletons of some spongoid fossil, by humus acids acting differentially as a solvent on the various modifications of the silica found often in the same flint-nodule? Of such differential solvent action I have a large collection of examples, in some cases showing corrosion to the extent of the complete obliteration of the lithological character of the flint as such.

Bishop's Stortford, September 17.

BIRD-MIGRATION.[1]

THIS book has been long expected, and it is certainly one worth waiting for. The author remarks "that no country in the world is more favourably situated than our own for witnessing the movements of migratory birds; that there is none in which the many phases of the phenomenon are of a more varied nature; and none in which the subject has received greater attention." To which we venture to add that no one has made so much use of these opportunities as Mr. Eagle Clarke has done, and that no contribution to the subject compares in importance with the work which is summarised in the book before us. It is, indeed, a striking fact that although the book deals almost wholly with the author's own work, it has a completeness and scope far superior to that of any other book on migration. It represents the spare-time industry of a quarter of a century, a remarkable persistence of observation under difficult conditions on lighthouses, lightships, and lone islands of the sea, a resolute courage in facing and accomplishing the dreary task of analysing the immense masses of data provided by the British Association Committee, and a remarkable restraint in dealing with a fascinating subject which has repeatedly proved itself fatally provocative of romantic treatment. It is scarcely necessary to say that the author has given us from time to time instalments of his results, but here we have a revised and unified presentation of the whole—an achievement calling for the warmest congratulation.

[W. E.

FIG. 1.—Fair Isle: a rift in the western cliffs. From "Studies in Bird Migration."

The plan of the book is simple. After a pleasant chapter on antiquated views (such as the "hibernation" theory, which lasted from Aristotle to Gilbert White and longer) and another—tantalisingly short—on some modern views, the author plunges *in medias res.* He classifies our migratory birds—summer visitors, partial migrants, winter visitors, and birds of passage—gives a summary of the movements of these several groups under their seasons, and indicates in a general way—the only possible way as yet—whence they come to us and whither they go from us. The next chapter, on "The Geographical Aspects of British Bird-Migration," is a masterly account of a very complicated subject, with rather more insistence on definite routes than we have been accustomed to from recent writers. Perhaps a more critical attitude might have been adopted towards the earlier work of Palmen and others.

The next three chapters, which are devoted to "Round the Year among British Migratory Birds," bring out very clearly the contrasts between the spring, autumn and winter movements, and there are two valuable appendices giving the dates of the arrivals and departures of the various species. The last general chapter deals with the vexed

[1] "Studies in Bird Migration." By William Eagle Clarke. Vol. i., pp. xvi+323. Vol. ii., pp. vii+346+25 plates. (London: Gurney and Jackson; Edinburgh: Oliver and Boyd, 1912.) Price 18s. net. 2 vols.

question of "Weather Influences," and is an admirable instance of careful scientific discussion. So much nonsense has been written on this subject that an authoritative statement is doubly welcome; and not only has Mr. Eagle Clarke had the vast data of the British Association Committee to draw upon, but he has secured the valuable cooperation of Dr. W. N. Shaw, Director of the Meteorological Office.

To those who glibly theorise on insufficient data with regard to migrants' supposed preference for "tail-winds," "beam-winds," and such like, we commend what is said on page 173: "The *direction* of the wind has in itself nothing to do with the results described. The winds and the performance, or non-performance, of the migratory movements are the effects of a common cause namely, the particular type of weather prevailing at the time, which may be favourable or unfavourable for the flight of birds to or from our islands." Furthermore we learn that similar conditions—including wind directions—are favourable for a movement both in spring and in autumn, although the direction of the movement is, of course, exactly the opposite at one season to what it is at the other. Thus "south-easterly weather" (a large continental anticyclone to the east of our shores but extending to them, and south-easterly winds in the British area) favours migration across the North Sea in either direction (according to the season), but is unfavourable to intermigration between Britain and Iceland.

The remainder of the book may be divided into two parts. Chapters ix.–xvi. deal in detail with the migrations of eight typical birds—swallow, fieldfare, white-wagtail, song-thrush, skylark, lapwing, starling, and rook. Much of this valuable work is already well known to those who have followed the author's separate papers, but the whole has been thoroughly revised. The second volume and one chapter of the first deal with the author's observations at typical stations round the British coasts the Eddystone Lighthouse (shown on a "bird-night" in a fine frontispiece by Marian Eagle Clarke), the Kentish Knock Lightship, Fair Isle ("the British Heligoland"), St. Kilda, the Flannan Isles, Sule Skerry (west of Orkney), Ushant (where the author was treated as a spy!), and Alderney. An account is given of the movements observed at each station, and what is known in regard to each species of bird is tersely summarised.

It must be clearly understood that this admirable piece of work is not intended as a treatise on bird-migration, summing up all that has been done by various methods in different parts of the world; it is an account of the author's personal observations and inductions. This explains what we cannot help regretting the deliberate condensation and reserve of the second chapter, which is intended as a general introduction for the non-expert, as the majority of zoologists, for instance, must in this connection be called. But even for such as these—the most appreciative of all readers after ornithologists proper—the terseness is surely overdone. Let us illustrate. In the few lines devoted to migration in the southern hemisphere, an important point has surely been obscured in ignoring the great difference between migration in the two hemispheres, that while *many* northern summer birds go far south of the equator to "winter" in the southern summer, only a few petrels and others from the south perform a reverse journey of corresponding extent. Similarly some mention of alternative views on the origin of the migratory habit might well have been given. Again, Mr. Clarke quotes with apparent approval Mr. Chapman's opinion that the recent experimental proof of the homing power of the noddy and sooty terns dispels "the so-called mystery" of how migrants find their way, placing it on a par with "any other instinctive functional activity." But this is an obvious *non sequitur*. Nor does it help matters to describe the special sense of direction (in which Mr. Clarke firmly believes) in Prof. Newton's phrase as "inherited but unconscious experience." An interest-

Fig. 2.—Flannan Islands: Eilean Mor from the east. From "Studies in Bird Migration."

ing point in this chapter is the author's suggestion that night travelling is an adaptation to the necessity that most birds have of devoting the daytime to the seach for food.

The book is lucidly and carefully written and the author occasionally slackens his rein and reveals his power as a stylist, the description of a "bird-night" at Eddystone being perhaps the finest example. There are several good photographs of various stations, notably those of Fair Isle by Mr. W. Norrie, but the chief illustrations are maps and weather-charts—all conspicuous for clearness and simplicity. We have already referred to the admirable first frontispiece. The book is dedicated to the Duchess of Bedford, herself an ardent ornithologist, who has given the author valued assistance.

THE QUESTION OF THE BIPLANE VERSUS *THE MONOPLANE.*

The recent order of the War Office suspending the use of monoplane flying machines for military purposes has led to the renewal, in the daily Press, of a discussion of the old riddle, "Which is the better, the monoplane or the biplane?" When Blériot crossed the Channel, the daily papers rang with the praises of the monoplane; now everyone favours the biplane, and there is a danger lest the monoplane may be condemned for faults not necessarily attributable to the mere fact that it is a monoplane.

The military authorities have wisely called in the assistance of the National Physical Laboratory in seeking an explanation of why so many of the recent accidents have occurred with monoplane machines. Even if the work placed in the hands of the Teddington department does not extend beyond overhauling and testing the machines used in the Army, the physicists ought to have sufficient scope for arriving at many important conclusions regarding essential features of aeroplane construction. For the purposes of an inquiry of the type proposed, it appears desirable that the same tests should be applied to biplanes as to monoplanes; but the value of the work will be greatly enhanced if the investigation is conducted on general lines, and not confined to the mere testing of the Army machines. It is easy enough to say that when a stay has broken it should be replaced by a stronger one, and to draw up a report which would suffice to enable any defects in existing machines to be patched up, but it is essential for real progress that the Laboratory authorities should have a free hand to assist in the evolution of a more perfect type of flying machine than either the existing monoplane or biplane.

It must not be forgotten that the terms monoplane and biplane usually imply something more than the mere difference between a "single-decker" and "double-decker" (to quote the German equivalents). The former usually has the propeller in front, the latter behind. Thus an inquiry necessarily turns on at least two points, namely, the relative advantages of the single- and double-decker, and whether the propeller is better placed in front or behind. Further subjects suggested are the gyrostatic effect of the propellers, the relative merits of rotary and oscillating engines, and so forth.

In regard to the first point, it must be remembered that even Lilienthal experimented successfully with the double-decked type; that Chanute, after trying not only "single-" and "double-decked" gliders, but also "multiple-winged machines," finally decided on the glider with two superposed surfaces as the best on which to experiment; that his experiments were continued by the Wrights, and led to their first realisation of artificial flight. One advantage of the two-surfaced arrangement is that, with an equivalent area, the wings can be made of lesser span, and thus the bending moments they have to sustain are proportionately reduced; moreover, these bending moments are much better sustained by the framework, which naturally takes the form of a latticed girder. Of course, from this point of view a triplane would even be better than a biplane, but the gain would be less important.

There would be no difficulty in constructing a "two-decker" with a propeller in front, and, from the point of view of the physicist, the position of the propeller depends largely on whether it is better for the propeller to receive the wash from the planes or for the planes to receive the wash from the propeller. One advantage of the latter plan has not, perhaps, received the attention that it deserves. It must not be forgotten that the action of the propeller sets up a rotation in the "wash" behind it, and, as Sir G. Greenhill has pointed out, so far from being negligible, the amount of this rotation is directly related to the horse-power and rate of revolution of the engine. In fact, the propeller exerts on the air a constant torque, which tends to produce angular momentum, and is equal in amount to the torque of the engine. If, then, the main planes are placed in the wash of the propeller, the rotating air on striking them will produce a difference of pressure on the two sides tending to counteract the corresponding torque on the aeroplane, and the machine will not heel over sideways to the same extent that it would if a single propeller were placed behind. For the purposes of the War Office, the propeller in front is disadvantageous, as it interferes with scouting or shooting from an aeroplane. On the other hand, we have the recommendation of a well-known engineer that the engine should be in front of the aviator, so that the latter shall not be crushed underneath the former in case of an accident.

Apart from these essential differences between monoplane and biplane, great importance attaches to an investigation into the gyrostatic couples caused by both rotary engines and propellers. At present, apart from setting up strains in the framework, which require the latter to be adequately stayed, these cause a mixing-up of the longitudinal and lateral motions of the machine which must necessarily greatly increase the danger of accidents when the machine is being navigated in gusts of wind. It is important that more attention should be given to the question of balancing, not only of the actual propeller torque by the use of two propellers, but also of the gyrostatic couples due to both the propeller and the rotary engine. Why do not the makers try an engine rotating about a horizontal axis perpendicular to the line of flight, driving a pair of propellers rotating in opposite directions by means of bevelled cogs? The arrangement would be perfectly symmetrical, and the gyrostatic couple of the engine *might* be used to assist in lateral steering.

Another disadvantageous feature of many monoplanes, though not an essential feature of them, is that the wings are usually of considerable breadth, and, of course, are cambered. The result is that when such a machine pitches, effects may occur the nature of which will remain entirely unknown until some experimental knowledge has been obtained regarding air pressures on rotating planes. To assume that these effects are negligible, or even that they may not be the cause of accidents, is, in the circumstances, scarcely justifiable.

It will be interesting to see whether any questions of stability are considered in connection with the present inquiry. The tendency which has existed up to the present time of shelving the problem of inherent stability, and attempting to attribute accidents to other causes, is, after all, very natural. If stability could be ignored altogether, the problem of aviation would be greatly simplified, and much laborious work, both theoretical and experimental, would be saved. Those of us who have spent much time in studying the theory of stability would have been glad to give our attention to other subjects instead, had we believed that a final solution of the problem of flight was possible which should make aviation independent of stability considerations. At the present time, no experimental information exists regarding inherent stability, and a comparison of theory with practice is urgently needed. Under theoretically assumed conditions, stability, both longitudinal and lateral, is greatly affected by variations in the inclination of the flight path to the horizon, and this is a point on which experimental tests would be of particular interest. The fact that so many accidents have occurred the causes of which are unknown shows that aviators have not yet been altogether successful in their attempts to dispense with theories of, and experiments on, stability. The accounts of many accidents are strangely suggestive of what would happen under theoretical conditions if an aeroplane should be flying at an inclination to the horizon consistent with inherent instability.

As regards the monoplane and biplane, these limits are probably very different in existing machines of the two types, but there is no essential difference between the "single-" and "double-decker" in regard to stability. Many monoplanes are of the Antoinette type, and can be made laterally stable by making the tail of sufficient length; many existing biplanes do not possess sufficient auxiliary surfaces for lateral stability, though this defect is probably remedied when the planes are bent up; on the other hand, the auxiliary planes in them are as a rule more favourable to longitudinal stability. These are, however, details of construction which do not depend on whether the machine is a monoplane or biplane. It is probable that most existing aeroplanes satisfy the condition that lateral, like longitudinal, *instability* increases when rising in the air.

It is necessary to repudiate any suggestion that a so-called "theory" of stability (which is really an experimental study of the results of certain assumed hypotheses, the apparatus for which are the methods of mathematical analysis) should be applied to actual aeroplanes without first being subjected to a second experimental test performed with the actual aeroplanes or models of them. But would not even this course be better than continuing to use aeroplanes about the stability of which nothing is known? And admitting that most flights have to be performed in gusty winds, is this any reason for being satisfied with a flying machine which would not fly straight in still air? Some people appear to think so. But is it not probable that the problem of stability presented by an actual aeroplane is more complex and not less complex than that presented by a system of narrow planes moving at small angles through a resisting medium? If this be so, the complexities of the simpler problem may afford some clue to those existing in the more difficult and at present unsolved problem.

It is hoped that no suggestions made in the present article will be regarded as authoritative statements except so far as they may be confirmed by experiments conducted with the aid of mathematical or physical apparatus. If any conclusions are to be drawn from these remarks, they should be to the effect that it is far less important to try to decide whether a biplane is better than a monoplane than to investigate the relative merits of flying machines on a perfectly broad basis. It is, therefore, to be hoped that the staff of the National Physical Laboratory will not only be given a very free hand in the investigations that are placed in their hands, but that they will produce a powerful and thorough report, and—if a small criticism is permissible—give a little more attention to formulating broad general principles, and confine themselves a little less exclusively to the tabulation of minute experimental details than they have done on some previous occasions

G. H. B.

THE INTERNATIONAL METEOROLOGICAL COMMITTEE.

Weather Telegraphy and Maritime Meteorology.

MEETINGS were held in London during the week ending on Friday, September 20, of two Commissions constituted by the International Meteorological Committee to deal with questions concerning international weather telegraphy on the one hand, and with those concerning maritime meteorology and storm warnings on the other. The Commissions were first provisionally appointed at the meeting of the International Committee held in Paris in 1907; they held meetings in London in June, 1909, and upon their report to the meeting of the International Committee held at Berlin in 1910, it was decided to recommend to the meteorological institutes of Europe to substitute a reading of the "barometric tendency" (the change of pressure in the three hours preceding the morning observation) for the reading of the wet-bulb thermometer in the international code. A scheme of storm signals for daylight, using two cones, was also recommended as an international system.

In the telegraphic reports of the morning of May 1, 1911, the change of code recommended was introduced simultaneously by all the countries of Europe, and the "barometric tendency" has now become an important feature of the daily weather message. The recommendation as to storm warnings was hampered by the fact that no agreement could be reached as to the signals that were to take the place of the cones at night.

Having regard to the various incidental questions which remained unsettled, the International Committee at Berlin decided that the two Commissions, which had consisted of only few persons, should be enlarged and become permanent. All the members of the International Committee had therefore been invited to join these Commissions, and also to nominate other persons interested in weather telegraphy and maritime meteorology respectively.

In accordance with the tradition of the International Meteorological Organisation, the administrative work of a commission rests entirely with its president; both the Commissions mentioned are under the presidency of the Director of the Meteorological Office, London, who is also president of the International Meteorological Committee, by which they were appointed. Meetings of the Commissioners were accordingly arranged to be held in London on Tuesday, Wednesday, Thursday, and Friday of the third week in September.

The Board of Education kindly lent the committee-room of the Science Museum for the meetings. The members present were:—For the Commission for weather telegraphy, General Rykatcheff, Director of the Meteorological Service of Russia; Geheimrat Hellmann, Director of the Prussian Meteorological Service, secretary of the International Committee; Prof. Grossmann, representing the Deutsche Seewarte; Prof. Palazzo, Director of the Meteorological and Geodynamic Institute of Rome; M. Angot, Director of the Central Meteorological Bureau of France; Prof. Mohn, Director of the Meteorological Service of Norway; Prof. Van Everdingen, Director of the Meteorological Service of the Netherlands; Captain Ryder, Director of the Meteorological Service of Denmark; Mr. R. G. K. Lempfert, Superintendent of the forecast division of the Meteorological Office. For the Commission for Maritime Meteorology and Storm Warnings there were, in addition, Comandatore Santi, Director of the Hydrographic Bureau of the Royal Italian Marine at Genoa; Dr. van der Stok, Superintendent of Marine Meteorology at de Bilt; and Commander Hepworth, Superintendent of the Marine Division of the Meteorological Office. His Highness the Raj Rana of Jhalawar, and Señor Duarte, chef de service of the Brazilian Meteorological Service, now being reorganised, were invited to attend the meetings of the Commissions.

The representatives of Japan, Dr. Nakamura and Dr. Okada, were prevented from coming by the death of the Emperor. Letters of regret were also received from Prof. Willis Moore, of the United States Weather Bureau; Mr. H. A. Hunt, Commonwealth meteorologist of Australia; Rev. L. Froc, of Zikawei Observatory; Mr. T. F. Claxton, of Hong Kong Observatory; and others.

As regards weather-telegraphy, the questions for discussion grouped themselves into four subjects, which may be mentioned in turn:—

(1) The first was the revision of the international code, incidental to the substitution last year of the "barometric tendency" for the reading to the wet bulb.

After a long discussion agreement was reached whereby two consecutive figure-places can be obtained in the morning groups by using only two figures for the barometric tendency, and also for the air temperature. It is suggested that for ordinary stations one of these places be assigned to the characteristic of the barometric variation in the past three hours, and the other to the direction of motion of the upper clouds; but, in order to encourage the preparation of a daily map of the circulation of the upper air over Europe, it is proposed that for those few international stations where observations of the direction and apparent velocity of clouds can be obtained, the two figures shall be assigned to those elements. For a figure-place incidentally available in the evening groups, the "characteristic of the weather in the past twenty-four hours" is suggested. Figure codes for the four new meteorological "elements" here mentioned were drawn up.

(2) Secondly, the question of the extension and proper organisation of the evening telegraphic weather service was brought forward by the Seewarte, and General Rykatcheff brought before the meeting a project of the Russian service for synchronous observations twice a day over the whole of the Russian Empire, covering 150° of longitude, in cooperation with the service of middle and western Europe.

A schedule of the present hours of observation in all parts of the globe was put forward; and in order to assist these projects it was agreed to recommend 7 a.m., 1 p.m., and 6 p.m. (G.M.T.) as "international hours" for the region between the longitude 30° W. and 30° E., and 6 a.m., 12 noon, and 6 p.m., G.M.T. (8h., 2h., 8h. of St. Petersburg time), as international hours between the longitudes 30° E. and 180° E.

(3) The form of the Iceland telegrams was the third general subject of consideration; and, with reference to that, the Director of the Danish service undertook to give effect as far as possible to any modification that was generally acceptable and that might be regarded as permanent. The opinion of the institutes upon the question will therefore be invited.

(4) The last subject of discussion, mooted by Prof. Willis Moore as a sequel to the deliberations of the recent conference on radiotelegraphy in London, was the notification, to certain centres, of observations at Greenwich noon by all vessels at sea carrying radio-telegraphic apparatus, and the issue of forecasts from the centres to the vessels. The suggestion of organising the distribution of reports by radio-telegraphy on an international plan was welcomed. Some doubt was expressed as to Greenwich noon being the most suitable international hour for the observations, as it would not fit in well with the European system, and some provision for the more general distribution of the information was mentioned as desirable. As the scheme implied legislative action by the various countries, it was decided as a first step to invite the opinions of the various institutes upon the scheme.

The Commission for Maritime Meteorology and Storm Warnings was chiefly concerned with the question of the signals to be used at night to replace the day signals already agreed upon.

Copies of a third edition of the provisional summary of the maritime weather signals at present in use in the various countries of the globe had been prepared for distribution at the meeting.

The various schemes, either at present in operation or advocated on various grounds, group themselves into (1) schemes of three lanterns in the vertical, (2) two lanterns in the vertical, and (3) one lantern only. The scheme of three lanterns was proposed by the Bureau Central Météorologique of France on behalf of the French Ministry of Marine, on the ground that a combination of two lanterns might be confused with signals already adopted in the "regulations for avoiding collisions at sea" or with harbour lights. The Board of Trade approved of these proposals, and undertook to use its good offices to get the harbour lights at two ports where confusion might arise so arranged as to obviate that difficulty. On the other hand, a scheme of two lanterns for gales in the four quadrants, with three lanterns for a hurricane, originally proposed by the Commission in 1909, and objected to first by the Seewarte, and subsequently by others, on account of the liability to confusion, had been tried by the Seewarte on the German coast, and no confusion had arisen; whereas the alternative scheme of three lanterns was pronounced unmanageable, and the hurricane signal was accordingly replaced by one red lamp for an "atmospheric disturbance."

Prof. Willis Moore, to whose initiative the work of the Commission is due, also expressed the opinion that a scheme of three lanterns is unmanageable, and therefore modified the original proposal by proposing two red lamps for a hurricane (instead of one white between two red) and one white lamp for a gale in the north-west quadrant. One red lamp is at present used in some countries to replace any day signal.

In these circumstances it was evident that there was no general agreement in favour of a single scheme of signals, and it was therefore necessary to place the recommendations for the present on the lower plane of agreeing that any combination of lamps forming a storm signal shall have the same significance in whatever country it is used.

The propositions to be submitted to the various institutes will therefore be that, in countries which use three lanterns in the vertical for storm warnings at night, the lanterns shall not be less than two metres apart, and shall be arranged according to the approved scheme of three lanterns; that in countries which use two lanterns, the lanterns shall be not less than two metres apart, generally four metres or fifteen feet, and shall be arranged in accordance with the original proposal of the Commission, with one red lamp to signify an atmospherical disturbance without indication of the direction of the winds instead of three lamps to signify a hurricane; that in countries which use only one lamp for night signals, one red lamp shall replace any of the day signals.

It was agreed to take the opinion of the institutes on a proposal to indicate at a signal-station by a green flag or a green lamp, or otherwise, the information that no warning can be hoisted on account of telegraphic communication being interrupted or for some other cause, as is now done at Thorshavn.

It was also agreed to take the opinion of the institutes upon the desirability of adopting a scheme of international "non-local signals" indicating the position of an atmospheric disturbance, on the lines of the code used at Zikawei and elsewhere on the China coast. Another scheme of day and night signals for a similar purpose, using three cones or three lanterns to indicate the position of a tropical revolving storm, was submitted by Commander Hepworth, and will be circulated also for comments with the report.

Finally the Commission agreed, on the motion of Dr. van der Stok, to recommend the collection of extracts of data from the meteorological logs of ships of all nations for certain ocean squares on the trade routes, with a view to their publication as a contribution to the meteorology of the globe.

The proceedings of the week commenced with a reception by Mrs. Shaw at 10 Moreton Gardens on Monday, September 16. Tuesday, Wednesday, and Friday morning and afternoon, and Thursday morning, were occupied with meetings. Thursday afternoon was set free to enable the reports of proceedings to be prepared in the Meteorological Office. Instead of meeting, the delegates visited Kew Observatory by motor, and took tea in Kew Gardens. In the evening they dined together on the invitation of Dr. Shaw, the President of the International Committee, who was honoured by the presence of the Raj Rana of Jhalawar, and was supported by Sir Norman Lockyer, Sir Charles Watson, Sir George Gibb, the Deputy-Master of Trinity House, the President of the Royal Meteorological Society, Captain Loring, R.N., Captain Sueter, R.N., Captain Clarke, Captain Thomson, C.B., Captain Lyons, R.E., Captain Henrici, R.E., and other representatives of various public offices.

The Raj Rana entertained the members of the Commission at dinner at Bailey's Hotel on Friday, September 20. Some of the delegates remaining in England were entertained for the week-end by Mr. and Mrs. Cave at Ditcham Park, Petersfield.

The reports of the proceedings at the meetings, which were read and signed at the final meetings on Friday, September 20, will now be printed and circulated to the various meteorological institutes for comments. These will be taken into consideration at the next meeting of the International Meteorological Committee, which, it is hoped, may be held in Rome in the week after Easter Week in the year 1913. The meeting will have to consider not only the reports of the Commissions which have already met, but also the important question of the application of meteorology to agriculture, which has been raised by a letter addressed to the president of the International Meteorological Committee by the president of the International Institute for Agriculture, which has its seat at Rome.

Besides the Commissions, the proceedings of which have been referred to here, it may be noted that the Commission for Radiation, under the presidency of Prof. J. Maurer, of Zürich, met in Switzerland in the first week of September; and, earlier in the year—May 27 to June 1—a largely attended meeting of the Commission for Scientific Aëronautics was held at Vienna, under the presidency of Prof. Hergesell. The Commission passed a number of resolutions, one of which, in favour of the establishment of a network of stations for daily observations with pilot balloons, has already been communicated to various Governments through diplomatic channels.

Perhaps the most noteworthy of the resolutions were those passed on the initiative of Prof. Bjerknes, formerly of Christiana, and now of Leipzig, proposing that the results of upper air observations shall be arranged according to definite steps of pressure instead of steps of height; that the heights shall be given in "dynamic" meters—that is, a step corresponding to a certain difference of gravity potential, not of geometrical height; and, thirdly, that pressures shall be recorded in millibars (C.G.S. units) instead of millimetres or inches. These important steps in the direction of arranging the material obtained from the investigation of the upper air in a form suitable for dynamical calculation are to come into effect with January, 1913, but the resolution as to pressure units is to be subject to the approval of the International Meteorological Committee. The forthcoming meeting proposed for Rome is therefore likely to be one of great importance.

SCIENTIFIC COLLECTIONS OF THE GERMAN CENTRAL AFRICA EXPEDITION OF 1907–1908.[1]

IN 1902 the Duke Adolf Friedrich visited East Africa. In 1904 he returned there and explored the region immediately to the south-east of Lake Victoria Nyanza. In 1907 he started again, this time at the head of a well-equipped scientific expedition charged with the special task of examining the volcanic regions west of the Victoria Nyanza and north of Tanganyika. The general results of this 1907–8 expedition have already been published, both in German and in English, the English version having been brought out by Cassell and Co. in 1910. The Duke, after leading his expedition through the countries of Karagwe, Ruanda (including the Kivu district), and the Virunga volcanoes, travelled past Lake Edward Nyanza to the Semliki, the Albert Nyanza, the gold-mines of Kilo, and then westwards through the Ituri Forest and down the Aruwimi to the main Congo, and so back to Germany by the Atlantic Ocean.

The volume before us is the third issued as the result of a careful examination of the immense collections made by this scientific expedition. The two previous volumes have dealt with the topography, geology, and meteorology, and with botany. Vol. iii. gives us, first, a remarkably interesting dissertation on the earth-worms or Oligochæta; on the Serphidæ, Cynipidæ, Chalcididæ, Evaniidæ, and Stephanidæ of hymenopterous insects; on the decapod crustaceans (the land-crabs, shrimps, prawns, &c.) of equatorial Africa; on the bees, the Cladocera, the molluscs (especially land-snails), the bivalves, the burrowing Hymenoptera, and wasps; the birds of the Central African lake region; the ants; the Braconidæ and beetles; the copepods of the East African lake region; the cockroaches and butterflies of Ruwenzori and the Congo Forest. The separate articles have evidently been inserted in the order in which they were written, and have thus been cited here. It would have been more convenient to the zoologist, however, if they had been arranged systematically, so that one passed on, for example, from bees and wasps to ants, or from one group of crustaceans to another, without some intervening description of a totally different group of animals.

Probably the most valuable part of the present compilation will be that on the earth-worms and the birds. Earth-worms—it has long been realised, even by those who do not specialise in any way in that study—are amongst the most interesting and certain means of estimating the relationship between the existing distribution of land and water on the earth's surface and that of past times. The article on the Oligochæta collected by the Adolf-Friedrich Scientific Expedition is accompanied by a well-written summary of the

[1] "Wissenschaftliche Ergebnisse der Deutschen Zentral-Afrika-Expedition, 1907–8," unter Führung Adolf Friedrichs, Herzogs zu Mecklenburg. Band iii., Zoologie i., herausgegeben von Dr. H. Schubotz. Pp. xxiii+560+plates xi–xiv. (Leipzig: Klinkhart and Biermann, 1912.) Price 24 marks.

distribution peculiarities of the earth-worms of Africa and adjoining regions, showing, amongst other things, the intimate faunistic relationships (involving, of course, continuous land surface at one time) between Spain, Syria, and Persia, and again between Sardinia, Sicily, and Tunis; between all equatorial or tropical Africa (Senegambia to Abyssinia and Moçambique), and—it might be added in a lesser degree—Guiana and Brazil; and the very separate and peculiar character, from an earth-worm point of view, of Madagascar and the southern extremity of Africa, both of which constitute very distinct regions in the character of their earth-worms. So far as our knowledge yet extends, the most interesting and richly endowed earth-worm region in Africa is round about Ruwenzori, between the west coast of Victoria Nyanza and the north coast of Tanganyika.

In the article on birds, the survey of all well-known collections is somewhat incomplete, very little reference being made to the reports on the collections made by the writer of this review in Uganda and on Ruwenzori. (In his general summary of the results of the expedition, the Duke Adolf Friedrich attributes the discovery of the Okapi, not to the writer of this review, but to Lieutenant Eriksson; the true facts of the case have been so well stated in M. Jules Fraipont's monograph on the Okapi that it is not necessary to repeat them here.) Several mistakes are made in the spelling of names of non-German authorities and certain place-names. This article, however, like some which have recently appeared in the *Ibis*, emphasises the remarkable beauty and strangeness in coloration of the Central African shrikes (Malaconotus) and the tree hoopoes (Scoptelus). The most striking species of Scoptelus has been named after the Duke Adolf Friedrich.

H. H. Johnston.

NOTES.

Sir W. T. Thiselton-Dyer, K.C.M.G., F.R.S., has been elected an honorary fellow of the Royal Society of South Africa.

A memorial to Lord Lister is to be established at University College Hospital, where Lister was a student. A special committee has been formed under the presidency of the Duke of Bedford, president of the hospital, with Sir John Tweedy, consulting ophthalmic surgeon, as hon. treasurer of the fund. The exact nature of the tribute will be largely decided by the amount of the subscriptions received, but it has been suggested that either a bust or a tablet should be placed in both the hospital and the college. It is understood that the memorial will be local in character, and only those who have been in some way connected with University College or the hospital are being asked to subscribe.

A new case has just been arranged in the Geological Department of the British Museum (Natural History) to illustrate the characteristic coral of each of the successive layers or zones in the Carboniferous Limestone of the Avon Gorge, Bristol, as determined by Dr. Arthur Vaughan. The actual fossils and photographs of the cliff-sections are explained by accompanying diagrams, prepared by Mr. W. D. Lang. It appears that the successive faunas, including the corals, are not directly derived from each other on the spot, but represent a series of migrations. Dr. Vaughan has presented to the museum the whole of the collection of corals on which his well-known researches were based, and this gift has been supplemented by another from Dr. Albert Wilmore, illustrating similar researches undertaken by him in the Carboniferous Limestone of Yorkshire.

The Geological Department of the British Museum (Natural History) has also recently received a valuable gift of Wealden fossils from the Revs. P. Teilhard and F. Pelletier, S.J., who made the collection during a four years' residence near Hastings. A large proportion of the specimens are small teeth from bone-beds which had previously been very little examined, and among them is the unique mammalian tooth described under the name of *Dipriodon valdensis* by Dr. Smith Woodward in 1911. There are numerous teeth of the dwarf crocodile Theriosuchus, which has hitherto been known only from the Purbeck Beds. The series of plant-remains is also important and will shortly be described by Prof. A. C. Seward in a communication to the Geological Society.

Mr. William H. Hogg having been appointed an inspector under the Board of Agriculture for Scotland, the post of resident manager of the Royal Agricultural Society's Experimental Farm at Woburn has become vacant. Applications for the appointment are to be made to the secretary of the society, at 16 Bedford Square, London, W.C., not later than Saturday, November 2.

Prof. Karl Pearson has recently addressed two lectures to the medical profession. One, entitled "Eugenics and Public Health," was delivered at the York Congress of the Royal Sanitary Institute, and the other, "Darwinism, Medical Progress and Eugenics," before the West London Medico-Chirurgical Society as the "Cavendish Lecture." In both the importance of statistical training is insisted on in dealing with the data collected in the Public Health service, and also in deciding the method for their collection. Instances are given of the kind of errors which may be or have been made and can only be avoided by the application of the requisite knowledge and experience. The matter is one of urgent public importance, as social legislation of a kind that is difficult to repeal may be based on conclusions such as Prof. Pearson here criticises in his usual clear and forcible style.

A volume entitled "Problems in Eugenics" (London: The Eugenics Education Society, 1912, pp. 490) contains the majority of the papers read before the recent International Congress in Eugenics, together with translations into English of those which were written in other languages. Such contributions as were sent in too late for inclusion in this volume are to be published in a supplement, which will contain also reports of the discussions and of the speeches delivered at the inaugural banquet. As might be expected, a very wide range of subjects is covered. On one page we read of the inheritance of fecundity in fowls and on another of proposed temperance legislation in Norway. The comparative merits of hectine and salvarsan are set forth by one author, while another discusses the elements which go to make up a successful demagogue. History, anthropology, and experimental psychology have all been drawn on, yet nothing has been included which is not to some extent or in some manner relevant.

During this season's excavations of the Maumbury Rings, Dorchester, the removal of much material from the terrace thrown up during the Civil Wars (1642-43) has disclosed remains of the Roman period, including Samian and other ware of that age, with a brass coin of Constantine. Search was made for indications of tiers of seats, but without result. It must, however, be remarked that according to Valerius Maximus the Senate forbade the erection of such conveniences for public use, although Ovid records that it was Romulus who first arranged seats of turf for the spectators.

The Bureau of American Ethnology announces a forecast of the results of a tour conducted in Argentine territory by Dr. Hrdlicka with the object of studying the remains of early man in that region. In order to ensure the verification of the necessary geological data, he was accompanied by Mr. Bailey Willis, of the U.S. Geological Survey. Unfortunately, the results of this investigation are not in harmony with claims previously made by the discoverers of certain "finds" in South America. The conclusion now reached is unfavourable to the hypothesis of the great antiquity of man in this region, more especially as to the existence of very early predecessors of the Indian in South America; nor does it sustain the theories of the evolution of man in general, or even that of an American race alone, in the southern continent. The facts collected attest only the existence of the already differentiated and relatively modern American Indian. It is not, of course, denied that early man may have existed in South America, but the position taken is that this hypothesis cannot be accepted without much additional scientific evidence. The importance of this announcement in connection with the theories advanced by Prof. Elliot Smith at the recent meeting of the British Association is sufficiently obvious.

In a paper published in the *Archives of the Roentgen Ray*, Dr. Hall-Edwards directs attention to diffusion figures—figures obtained by dropping different coloured dyes in definite amount and regular order on absorbent paper. Very beautiful coloured geometrical figures may thus be produced, four of which are reproduced in a coloured plate, and Dr. Hall-Edwards anticipates that their study may throw some light on the production of patterns in nature.

A technical engineering journal is a somewhat curious place in which to describe new species of mosquitoes, and yet this has been done by Dr. M. N. Tovar in the June issue of the *Revista Tecnica del Ministerio de Obras Publicas*, published at Caracas, Venezuela, in the course of an article on the biting gnats and flies of the Monagas estate, Maturin, such new species being respectively named *Psorophora blanchardi* and *Sabethoides rangeli*. In a second illustrated article in the same issue Dr. L. Alvarado describes certain prehistoric objects from Venezuela.

The fiftieth number of "Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India" contains a preliminary report by Captain W. S. Patton upon his investigations into the etiology of Oriental sore in Cambay. The author concludes that the house-flies (Musca spp.) play no part whatever in the transmission of the disease in Cambay. Although he has failed up to the present to transmit the parasite by the bed-bug, he has "no doubt whatever that the bug *Cimex rotundatus* is the only insect transmitter of the disease' in Cambay, on the ground that the parasite only passes into its flagellate stage in the bug below a certain temperature, and that "this observation exactly coinsides with the geographical distribution of the disease in India." The problem of the transmission of this disease is therefore still without its final solution.

The importation of tuberculosis in frozen meat forms the subject of a short note by Prof. Guido Bordoni-Uffreduzi in the *Rendiconti del R. Istituto lombardo*, xlv., 12. According to this writer something like a scare has occurred in Italy, and exaggerated statements have been circulated to the effect that 90 per cent. of the cattle in the Argentine Republic, whence the beef is obtained, are tuberculous. Prof. Uffreduzi, on the other hand, finds the Argentine cattle to be far less affected by tuberculosis than those bred in Italy; further, he refers to the circumstances (1) that the bacillus occurs rarely in the muscular parts and that only in animals obviously unfit for food; (2) that cooking destroys the bacillus; (3) that adults are not very liable to infection from tuberculosis introduced in the form of food. Hence it is concluded that the danger is more imaginary than real, and is not based on circumstantial evidence.

The need of legislative protection for the Californian so-called valley quail (*Lophortyx californica*) forms the subject of an article by Mr. H. C. Bryant in the July number of *The Condor*. In some districts these birds show a great diminution in number, although in certain areas there is an increase. The provision of sufficient food and proper covert is stated to be necessary.

The Egyptian Gazette of August 1 contains a list of twenty-four species of Sudani mammals and ten of birds living examples of which have been recently received at the Government Zoological Gardens at Giza. The most interesting of these is a white-eared kob antelope (*Cobus leucotis*), from the swamps of the White Nile, believed to be the first example of its kind that has ever left the Sudan alive.

A new species of the minute annelids of the genus Achæta—so called from the absence of bristles—from Armagh is described by the Rev. H. Friend in the

September number of *The Irish Naturalist* as *A. spermatophora*. A second addition to the British fauna is recorded by Mr. N. H. Joy in *The Entomologist's Monthly Magazine* of the same date in the shape of *Orthochaetes insignis*, a beetle common in Brittany.

THE American Camp Fire Club has issued a circular letter setting forth the part played by that body in regard to legislation for the protection of the Pribilow fur-seals. It is claimed that both the recent international fur-seal treaty and the Bill establishing a five-year close season for the fur-seals are the result of action taken by the club. Be this as it may, the enactment of such a close can scarcely fail to be a source of satisfaction in this country. During the Russian occupation of the Pribilows the number of fur-seals was at one time reduced to 31,000, but when the United States came into possession of the islands, after a ten-years' close season, it had increased to nearly five millions. At the present time it is believed that the seal herd does not comprise more than 125,000 head, but it is confidently expected that at the end of the five-years' close season the number will have risen to more than a million.

THE greater part of *Naturen* for July and August is occupied by an illustrated article by Mr. K. E. Schreiner on "the oldest men," in which skulls of the Neanderthal, Spy, and other early races are figured, as well as the lower jaw of *Homo heidelbergensis*, and the skull, teeth, and femur of *Pithecanthropus*, are figured. Genealogical diagrams illustrating different views which have been expressed as to the relationship of the genus last mentioned to the Neanderthal and modern man are of interest. In one case Pithecanthropus is regarded as the direct ancestor of *Homo sapiens*, with *H. neandertaliensis* as the intermediate link; in a second Pithecanthropus and the Neanderthal race are regarded as separate lateral offshoots of the stem which gave rise to the modern races, while in a third Pithecanthropus occupies the same collateral position, but is supposed to have given rise to Neanderthal man, who is accordingly only a distinct cousin of the existing races of mankind.

UNDER the title "An American Lepidostrobus," Prof. J. M. Coulter and Dr. W. J. G. Land have described (*Botanical Gazette*, vol. 51) the first hitherto discovered American coal-measure cone showing the internal structure. Until now American palaeozoic fructifications and seeds have been known only as impressions or casts, in striking contrast to the richness of the coal-measures in Britain and France in petrified remains showing beautifully preserved structure, though the mesozoic formations have yielded a rich harvest of material to American palaeo-botanists such as is unequalled in any other country.

The well-known work of Prof. H. de Vries on the evening primrose, *Oenothera Lamarckiana*, and the various forms (mutants and hybrids) derived from it has been followed up by various cytologists in the hope of elucidating the origin and nature of these forms with reference to the nuclear phenomena. Miss Anne M. Lutz has published an extensive paper (*Biologisches Centralblatt*, 1912, No. 7) based upon the counting of the chromosomes in the dividing nuclei of various Œnotheras, especially in the forms called "triploid mutants"—in which the somatic cells have thrice instead of twice the number of chromosomes normally found in the male and female germ-cells from which the plant arose. The results obtained by Gates, Davis, Geerts, and the writer herself are discussed at length, and considerable ingenuity is shown in the explanation of the various numbers of chromosomes observed in different Œnotheras—a list is given of more than forty possible combinations and permutations in the chromosome numbers in the germ-cells, and the writer claims to have demonstrated "the harmonious relationship existing between practically all of the observed phenomena thus far reported for the germ and somatic cells of *Oenothera*."

PROF. H. E. ARMSTRONG's lecture to the Royal Horticultural Society on "The Stimulation of Plant Growth" is printed in the current number (vol. 38, part 1) of the Society's journal. It is primarily concerned with the action of volatile activating bodies or hormones, which can pass through the membranes of plant cells and stimulate enzymes to set up chemical changes in the cell contents. In the growth of an ordinary green plant two periods may be distinguished —that in which assimilation occurs under the influence of light, and that in which growth takes place at the expense of the materials thus produced. The latter is apparently the period during which stimulation is necessary, that in which enzymes are brought into action as simplifying agents and the products of their action enter into circulation and are carried to the places where they can be used as building materials in promoting growth; probably during this period the membranes become more or less permeable to substances which do not pass them during the period of assimilation. It is pointed out that manures probably act largely as hormones; that ammonia is the most active "natural" stimulant, and that a substance (ammonia, for instance) which is a valuable hormone when used in proportions not exceeding a certain low maximum at once becomes toxic when this maximum is exceeded.

IN the Quarterly Journal of the Geological Society of London for 1912, vol. lxviii., part 2 (price 5*s*.), the president, Prof. W. W. Watts, F.R.S., reviews the important subject of the coal supply of Britain. He urges forcibly that an exploration by boring of concealed coal areas might well be undertaken by the State. The "Summary of Progress of the Geological Survey of Great Britain for 1911" (1912, price 1*s*.) shows how the Coal Measures of the Denbighshire district are being examined, and coal again attracts attention in Staffordshire, Warwickshire, and Scotland (pp. 22, 23, and 46). A second edition has been issued of the Survey's memoir on the country around Cardiff (1912, price 2*s*.), with especial reference to the growth of information as to mines. The memoir on the country around Ollerton, by G. W. Lamplugh and others (price 2*s*.), accompanies sheet

113 of the map (price 1*s.* 6*d.*). Both in the memoir and in the section on the map, the position of the concealed coalfield under Sherwood Forest is well emphasised. Perhaps in anticipation of the comprehensive publication that we expect from the International Geological Congress of 1913, Mr. E. F. Pittman has prepared a handy volume on "The Coal Resources of New South Wales" (Geol. Surv., N.S.W., 1912, price 1*s.*).

THE series of papers on the development of the theories of mathematical logic and the principles of mathematics, by Mr. P. E. B. Jourdain, appearing in *The Quarterly Journal of Pure and Applied Mathematics*, forms a useful contribution to mathematical literature. The sections dealing with Leibniz and Boole appeared some time ago, and we have now received the part (*Quarterly Journal*, No. 171, 1912) dealing with the work of Hugh McColl (1837–1909), Gottlob Frege (born 1848), and Giuseppe Peano. All these sections have been revised, both by the respective authors with whose work they deal and by Mr. Bertrand Russell.

A PAPER contributed to the *Atti dei Lincei*, xxi. (2), 1, by Prof. S. Salaghi bears the title "On the vulgarisation and application of mathematical physics in medicine." It constitutes a plea for the application of hydrodynamical principles to the study of the circulation of the blood, the formulæ for the purpose being the ordinary equations of hydraulics applicable to the motion of liquids in tubes, a subject which the author claims to have introduced into Italy for the first time, but which is now being investigated by Dr. Morandi under the name hæmodynamics.

A SMALL pamphlet on "Rubies," written by Mr. Noel Heaton, has been issued by the Burma Ruby Mines, Ltd. In the course of a few concise paragraphs, Mr. Heaton explains how the natural ruby may be distinguished from other red gem-stones, and especially from the reconstructed and synthetic rubies. The difference in structure between the natural and the artificially prepared stones is clearly brought out by some admirable illustrations. The pamphlet will be found invaluable by jewellers and dealers in precious stones, to whom of late years the identification of rubies has been a troublesome problem. The salient items of the pamphlet are also reprinted in the form of a chart, which may be framed and hung in a convenient position on a wall.

THE Journal of the Institution of Electrical Engineers for July contains a description of a portable instrument for the detection of combustible gases and vapours in air, devised by Messrs. A. Philip and L. J. Steele. It depends on the possibility of causing the gas or vapour to combine with the oxygen of the air by bringing the mixture into contact with a platinum spiral raised to the necessary temperature by the passage of an electric current through it. The combustion thus brought about produces heat which raises the temperature of the platinum spiral still further. The electric current passes through a second spiral identical with the first, but protected from contact with the mixture of gases. By combining the two spirals in any of the well-known ways, the difference of their electrical resistances may be made to indicate the presence of the combustion. In the instrument described, the spirals are in series with the coils of a differential relay, and the redistribution of current which results from the heating of one spiral actuates the relay and a red lamp lights up.

IN the Chemical Society's Journal Prof. Pope and Mr. C. S. Gibson give an account of their successful resolution of *sec*-bitylamine, $C_2H_5.CH(NH_6).CH_3$, a simple substance which had resisted earlier attempts to separate it into two optically-active isomerides. Although the base behaves normally, and its hydrochloride is highly dispersive, a series of sulphonic derivatives were found to produce practically constant rotations in the yellow and green regions of the spectrum. This absence of rotatory dispersion is very exceptional, though some parallel is found in substances such as ethyl tartrate, which show a maximum of specific rotatory power in the yellow or green region of the spectrum.

THE current issue of *Science Progress* contains a second article by Dr. Charles Walker on theories and problems of cancer, and a long article by Dr. F. G. Hopkins on Dr. Pavy and diabetes. Prof. Love contributes an article on tides and the rigidity of the earth, and Mr. J. N. Worthington gives a critical review of the possibilities and limitations of observations of the planet Mars, to be followed in a later article by an account of what these observations have revealed. Chemists will welcome an extremely lucid exposition, by Mr. F. W. Aston, of Sir J. J. Thomson's new method of chemical analysis, which precedes a second article by Mr. D. L. Chapman on conditions of chemical change. Dr. Desch contributes an illustrated article on the structure of metals, Mr. C. T. Gimingham discusses variations in pastures, with special reference to the "fatting" and "non-fatting" pastures of the Romney Marshes, and the "teart" lands of Somersetshire, and Mr. Allan Ferguson gives an historical account of the genesis of logarithms.

THE latest addition to the handy little subject lists issued by the Patent Office, London, W.C., is the subject list of works on horology in the library of the office. The list comprises works on the determination and division of time, dialling, clocks, watches, and other timekeepers.

OUR ASTRONOMICAL COLUMN.

COMET 1912*a* (GALE).—From observations made on September 8, 11, and 15, Dr. Ebell has calculated a set of elements and an ephemeris for comet 1912*a*. The time of perihelion is given as October 4·7088 (Berlin M.T.), and the following is an extract from the ephemeris given in the Kiel Centralstelle Circular, No. 135:—

Ephemeris 12h. (Berlin M.T.)

	R.A.	Decl. S.		R.A.	Decl. S.
	h. m.	° ′		h. m.	° ′
Sept. 27	15 7·3	11 14·8	Sept. 30	15 16·3	7 19·3
,, 28	15 10·5	9 55·2	Oct. 1	15 19·0	6 3·0
,, 29	15 13·4	8 36·7	,, 2	15 21·6	4 48·0

The calculated magnitude for the whole of this period is 5·0, and as the comet sets at about 7 p.m. it is only possible, in these latitudes, to see it low down in the south-west, immediately after sunset. But as the southern declination is decreasing the conditions will become more favourable; also as the comet nears the sun it may brighten intrinsically. Consequently, at the beginning of October, it may become visible about an hour after sunset at an altitude of about 10° above the south-western horizon.

REPORTED METEORIC FALL IN FRANCE.—According to a message transmitted by Reuter's Agency a large and brilliant meteorite fell at two o'clock on Friday morning (September 20), in the department of the Aube, Central France. The report states that the meteorite exploded with such great violence as to shake the neighbouring houses and to cause the residents to believe that an earthquake was occurring.

THE GALACTIC DISTRIBUTION OF CERTAIN STELLAR TYPES.—In a paper appearing in No. 4600 of the *Astronomische Nachrichten*, Dr. Hertzsprung publishes some interesting results concerning the distribution of certain special types of celestial objects in relation to the galaxy.

The seven types considered are shown in the following table, together with the coordinates of the pole of the plane in which each type principally gathers :—

Type	No. of objects	Coordinates, for 1900, of the pole of the favoured plane: Galactic Long.	Galactic Lat.	α	δ
Helium stars Oe_5–B_9	1402	179·2°	+83·0°	182·1	+27·0°
Eclipsing variables...	150	234·0	+87·3	188·2	+25·8
c and *ac* stars	98	243·9	+88·1	189·1	+26·3
Type V., Oa o–Oe o	87	300·0	+88·7	190·7	+26·9
Gaseous nebulæ ...	130	4·2	+87·6	192·7	+28·1
Type IV., N	228	352·6	+86·2	194·2	+27·4
δ Cephei variables ...	60	348·9	+84·6	195·9	+26·8

The data providing these results were taken from vol. lvi. of the Harvard Annals, and Pickering's value, $\alpha=190°$, $\delta=+28°$ (1900), for the position of the galactic pole was used. As will be seen from the results, the type V. stars chiefly lie in a plane nearly coincident with that of the galaxy, while the mean pole for the six other types is practically the same. It should be remarked that the helium stars and those of the fifth type show a tendency to cluster in various galactic longitudes. Thus 72 per cent. of the helium stars lie within 90° of galactic longitude 248°, and 69 per cent. of the fifth type stars lie within 90° of long. 305°, the two positions 248° and 305° being, respectively, the places of greatest density.

RADIO-ACTIVE ELEMENTS IN CELESTIAL BODIES.—Having secured excellent spectrograms of the chromosphere during the Spanish eclipse of 1905, Dr. S. A. Mitchell has compared his (unpublished) wave-lengths with those of Exner and Haschek's radium spectrum, and finds himself unable to confirm Prof. Dyson's suggestion that radium may be present in the chromosphere. As previously noted in these columns, the chromospheric spectrum is probably adequately explained by the presence of other elements. Dr. Mitchell finds no sufficient evidence for the presence of radium emanation and uranium in the chromosphere, and deduces that we must wait for better photographs with greater dispersion than those of Nova Geminorum (2) obtained by Dr. Giebeler before seriously contemplating the presence of these radio-active substances in novæ (*Astronomische Nachrichten*, No. 4600).

THE PHYSICAL CHEMISTRY OF THE LOAF.

THE question of strength in wheaten flour has of late years repeatedly engaged the attention of chemists. Recent researches, more particularly those of Prof. T. B. Wood, have established that strength, or, in other words, the capacity of the flour to give a bold, well-risen loaf, depends in the main on the influence of the electrolytes naturally present on the gluten. The difficulties of the problem have hitherto prevented a more quantitative study of the electrolytes present in flour, but a recent paper from the Carlsberg Laboratory, Copenhagen, by Jessen-Hansen, perhaps marks a first step in this direction. Use is made by him of Sörensen's methods of determining small amounts of acidity, either colorimetrically or by determinations of electrical conductivity, to study the degree of acidity, or, as it is usually termed, the "hydrogen ion concentration" of a number of doughs made in the usual way.

In particular, the effect of the addition of different quantities of acid to the dough was examined, and the acidity compared with the result obtained on baking. The conclusion is drawn that there is a certain optimum concentration of hydrogen ions, in presence of which the best results are obtained on baking; this concentration is rather higher than that of dough prepared from natural flour and distilled water. It differs only slightly according to the quality of the flour, being somewhat higher for the superior grades and rather lower for the lower kinds; it also differs slightly in flour milled from different parts of the berry, being highest for the so-called patents. The optimum concentration corresponds approximately to a hydrogen ion concentration of 10^{-5} normal, pure distilled water being about 10^{-7} normal. It will be obvious that doughs made in this country with the hard alkaline service water must diverge a good deal from this concentration.

Dr. Jessen-Hansen seeks to explain the effect of the various flour improvers which have been brought forward during the last year or so, as due to their increasing the hydrogen ion concentration and not to any subtle working of the improver, as the patentee would sometimes have us believe. Nothing is said, however, to indicate in what way the optimum acidity may be supposed to condition the subtle changes in the gluten which produce a good loaf. It is perhaps significant that the acidity also corresponds to the optimum acidity for protein coagulation.

E. F. A.

AGRICULTURE IN INDIA.[1]

IN his report on the condition of agriculture in India, Mr. Coventry is able to state that the progress recorded in earlier reports has been well maintained, and the beneficent and productive character of the Department's undertakings made much more apparent. Sustained efforts are being made in the cotton tracts to improve the quality and increase the quantity of the staple. In Madras, the improvements have taken two lines—the separation and selection of the best indigenous variety and the introduction of the exotic Cambodia. Similar improvements are also noted in the Central Provinces and Bombay. The well-known work of Mr. and Mrs. Howard on the improvement of Indian wheats is being carried on, and has entered a new phase by the establishment of seed farms where the new varieties can be grown on the large scale for distribution

[1] Report on the Progress of Agriculture in India. (Calcutta, 1912.)
Memoirs of the Department of Agriculture in India. (Pusa.)
The Agricultural Journal of India. (Pusa.)

to the growers. The sugar industry, however, is in a critical condition, the native product failing to compete with sugar from the West, but it is hoped that the industry can be remodelled on scientific lines.

Turning to the memoirs published recently from Pusa, Mr. and Mrs. Howard have succeeded in crossing rust-resistant wheat from northern Europe with some of the native wheats. It was not possible to do this at Pusa, on account of the impossibility of getting the rust-resisting parents to flower in time for crossing to be done and for the resulting grain to ripen before the hot weather set in. The difficulty was overcome by sending the Indian parents to Cambridge for spring sowing, and by carrying out the actual hybridisation work in England. In this way crosses were made between various Indian types and American club and other rust-resistant wheats that promise to be very useful.

In the chemical department Mr. Annett has begun an important study of the date-palm sugar industry, which has hitherto been entirely worked by native methods, involving considerable losses. There can be no doubt of the value of this kind of work; success in putting native industries on a sound foundation would be an achievement of which any department might be proud. The saltpetre industry has already been investigated by Dr. Leather, and we may hope for further good results. Dr. Leather also reports further work on the water requirements of crops.

The Entomological Department has proceeded on its usual lines. Progress has been made with inquiries into the life-histories and habits of injurious insects, amongst the more important being the rhinoceros beetle, the surface and painted grasshoppers, potato bug, lucerne Hypera, small cabbage caterpillar, termites, &c. Steady progress has been made in the preparation and issue of coloured plates illustrative of insect pests of crops, and these have been distributed to various institutions. Useful work has also been done on sericulture.

The Bacteriological Department is now in full work, and may be expected shortly to turn out useful results; whilst the mycologist, the agriculturist, and the cotton specialist are all able to report good work done.

THE BRITISH ASSOCIATION AT DUNDEE. SECTION F.

ECONOMIC SCIENCE AND STATISTICS.

FROM THE OPENING ADDRESS BY SIR HENRY H. CUNYNGHAME, K.C.B., PRESIDENT OF THE SECTION.

HAVING endeavoured to the best of my ability to protest against the idea that economics is not a science, but a mere collection of copybook aphorisms that may be used at random like quack medicines, I should like, with your leave, to endeavour to establish its claim to come among the exact sciences by the surest test that can be applied—namely its capability of being demonstrated by means of geometry and mathematics.

Everyone in this room is no doubt acquainted with the machine known as a barograph or registering barometer. It is constructed as follows: A vertical cylinder covered with white paper revolves once in a week. A light arm is hinged on to a series of hollow elastic circular chambers, from which the air has been pumped out. As the pressure of the atmosphere varies, the air chambers dilate and contract, carrying the arm with them. The arm carries a pen which marks with a dot on the paper the height of the barometer at any time. As the paper moves the dot is drawn out into a line, which gives a continuous record of barometric variations. This diagram is a picture of one of the records.

Now, a little consideration will show what a useful diagram we have here. If we were to attempt to give the information contained in it in words we should have to say something like this. On Monday at 0 a.m. the barometer stood at 28·8 in.; during the morning of Monday it rose until about 2 p.m., when it remained stationary for three hours. It again steadily rose in the evening, until at midnight it stood at 29·9 in. (Fig. 1). On Tuesday it still continued to rise until midday, when it again experienced a fall, &c. Or, if the same results were put into arithmetical form, we should have quite a column of figures.

But this diagram shows us the height of the barometer at any time, and all its fluctuations. Its

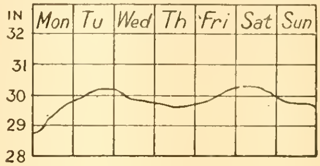

FIG. 1.

life-history for the week and the law of its variations are obvious at a glance, in a way which no words could convey to us. So great are the advantages of this method that barographs are printed in many of the newspapers.

But the use of such curves is not confined to the registration of atmospheric pressure or temperature. They may be used for all purposes. Thus, for example, we might have a curve indicating the variation in successive years of the number of marriages per head of the population.

Line 1 (Fig. 2) shows the proportion of marriages to population from 1870 to 1910. The advantages of this synoptic view are obvious. But they become more obvious still when we add other curves. For instance, line 4 shows the price of wheat in various

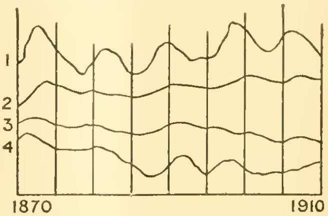

FIG. 2.

years, line 3 the price of coal, line 2 the average of money wages, and line 1 the number of marriages per head of the population. A simple inspection shows that these curves rise and fall sympathetically, and proves beyond doubt that the facts they represent are causally connected.

How eloquently this diagram represents on a space that in a printed book may be three inches square, a series of relations which would take three or four pages to describe even imperfectly in words. And would any description in words enable us to follow the changes like this diagram? The diagram, in fact, plays the part that maps play in geography, and when duly appreciated becomes as valuable as maps of countries.

We may use similar diagrams in the exposition of economic facts. It was, however, reserved for Cournot to show that the use of curves might go further still. Not only might they be used to display statistical facts, but they might also be used to solve problems. I will endeavour to illustrate this very ingenious and interesting development.

It is a well-known fact that in certain departments of industry the cost of making an article increases in proportion to the number produced. The growth of corn is a familiar example of this principle. The principle depends on two facts: (1) that corn can be grown in some places with a less expenditure of capital and labour than in others; and (2) that the quantity of the more favourable land is limited. Whence it follows that growers will first have recourse to the most fertile land; afterwards to that which is

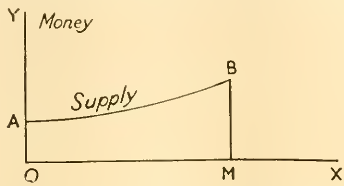

FIG. 3.

less fertile. If we were acquainted exactly with the economics of corn-growing we could represent this state of things in any country at any given time by a curve like a barograph.

Along the line OX (Fig. 3), instead of the progressive days of the week, we should mark off successive quantities of corn, and the vertical height of the curve above any given quality would represent the price per quarter of production of that part which was produced at greatest expense. Thus, the cost of production of the first and most easily grown quarter would be, say 18*s.*, of the next 18*s.* 1*d.*, and so on. And it would be evident that the total cost of the whole of the wheat grown would be obtained by adding all these prices together, that is to say, by the area of the curve OMBA; for an area is but the sum

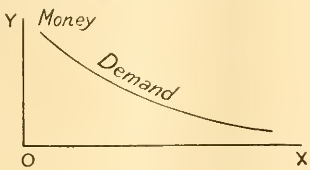

FIG. 4.

of all its constituent parallel lines, just as the total of a bill for goods is an addition of all its items.

Let us now dismiss this corn-growing graph from our minds and turn to another side of the question. Let us consider the various prices which consumers would give for various quantities of corn if they could get these and no more. I do not mean the market prices of the quantities, but what might be called the famine prices, which they would give rather than not have the corn. If we draw a corn-consumers' graph it will obviously be a descending curve, for the more they can get the less they will value successive portions. In fact, if the supply of corn were unlimited the surplus would be used first to feed animals, then to consume as fuel, then as manure, and at last have to be destroyed as a nuisance.

The curve would be of the form shown in Fig. 4.

The contemplation of these curves of corn will no doubt suggest the question whether if we had them we could tell what the market price would be. For it seems obvious that if we know all the conditions, both of demand and supply, we ought to be able to foretell the market price. This is the case and can be easily done. All that is necessary is to superpose the curves, as is done in Fig. 5.

We then see at once that PM must represent the market price of corn per quarter at a given epoch, and OM the quantity produced in a standard time. For if more than OM were grown it could only be sold at a loss; if less the growing of corn would produce an abnormal profit, which would soon cause an expansion, so as to bring the quantity grown and sold up to the maximum that could be profitably produced.

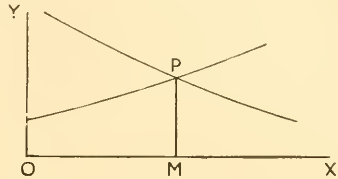

FIG. 5.

These diagrams have therefore done more than present a state of facts; they have solved a problem, just as could be done by a pair of algebraic equations.

Moreover, other illustrations can be derived from Fig. 5. By drawing the series of lines shown in Fig. 6 meanings can be given to various parts of the diagram. The area NPMO represents the total price paid for the corn; the area APMO represents the total cost of growing; the area APN, which is the difference between them, represents the surplus profit obtained from the use of the better lands, or, in other words, rent; the area BPMO represents the total enjoyment the consumer derives from the corn, expressed in terms of money; and since NPMO is the

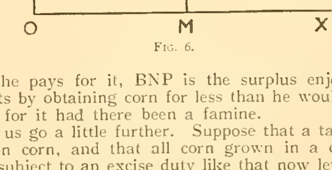

FIG. 6.

price he pays for it, BNP is the surplus enjoyment he gets by obtaining corn for less than he would have given for it had there been a famine.

Let us go a little further. Suppose that a tax were laid on corn, and that all corn grown in a country were subject to an excise duty like that now levied on the manufacture of spirits. Suppose the duty were 5*s.* a quarter, and to simplify the problem suppose no corn came in from the outside. Then the curve APS (Fig. 7) would be pushed upwards all along its length by 5*s.*, and assume a position A'P'S'. And notice that the price would rise, not by 5*s.*, but by some amount rather less than 5*s.* For M'P' – MP must always be less than the upward movement of the curve APS. Again, the rent would be decreased, for the area

N'P'A' is less than NPA. The amount grown would decrease from OM to OM'. The proceeds of the tax would be OM times five shillings, and the consumers' surplus of enjoyment would have considerably diminished. This is all obvious enough if you look at the curves. But I want to ask whether, without a curve, you could have got all that so quickly by logical cogitation? I agree it could have been done by hard thought, but what a help the diagram has been in thinking it out. It is like drawing a genealogical tree when you are thinking out some complex problems of family relationship. A simple inspection of the figure also shows that an *ad valorem* tax on rent would not increase price or diminish production.

Again, what is a monopoly? A monopoly is simply

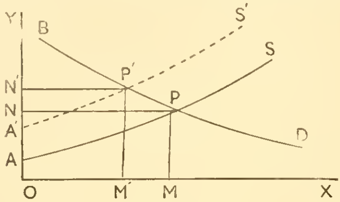

FIG. 7.

a power of stopping production at a point short of that which it would reach under conditions of free production, sale, and distribution. You can stop production by means of statutes regulating quantities produced, or by combinations to limit production, or to limit the supply of labour produced, or by statutes regulating the employment of capital, or by statutes fixing minima of wages, or in various other ways. If you exercise the power, then the state of things shown in Fig. 8 comes into play. The quantity produced is reduced to OM'. The price rises from PM to P'M', the surplus producers' profit (including rent) rises from ANP to AQP'N'. So that profits, interest, and wages increase, but the consumers' surplus enjoyment goes down from NPB to N'P'B. The limitation of output plays a far larger part in the regulation of prices than is commonly supposed. Those who are engaged in the manipulation of the meat trade, and the bread trade, and the petroleum industry, the supply of machinery or other articles, do not usually advertise the means they have taken to limit supply, nor do trade unions publicly descant upon the means they adopt to limit the labour of adults or apprentices. It is no part of our business here to discuss the necessity or the legitimate limits of such limitations. All that I am here to do is to show how useful diagrams are in explaining their effects.

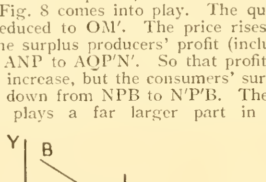

FIG. 8.

The monopoly controller seeks, of course, to make the area AQP'N' a maximum, arranging his price just in the way a milliner would do who had to cut the biggest square she could out of a remnant of material. How much reduction of output and increase of price will the market bear? is the question that all monopolists present to themselves.

I could go on with these curves through a great variety of questions. They become especially interesting where applied to show the effects of tariffs upon export and import trade, but I must forbear.

My principal object has not been to introduce to the notice of the audience a subject already known to many of them, but rather to use it as an illustration of the truth that national economics is subject to laws —laws which, though complicated, are as exact and unfailing as the laws of physics, chemistry, or engineering, and which, if neglected by political engineers, will as certainly bring the State to ruin as the miscalculation of a mechanical engineer in designing a boiler, or of a civil engineer in designing a bridge. Whence, then, instead of consigning economics to Saturn, let us study it, not in a metaphysical or Aristotelian manner, using question-begging epithets, or, on the other hand, in the manner of some moderns, as, for example, Ruskin, by replacing reason by sentiment; but let us approach it in the spirit of positive science.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY PROF. G. ELLIOT SMITH, M.A., M.D., CH.M., F.R.S., PRESIDENT OF THE SECTION.[1]

The Evolution of Man.

AT the outset it is fitting that I should express our sense of the loss this section has sustained in the death of Mr. Andrew Lang. Meeting as we do so near to his home at St. Andrews, it was hoped at one time that his versatile scholarship and literary skill would have been available to add lustre to our deliberations. But early last winter we learned with deep regret that the state of his health would not permit him to accept the presidency of the section. In associating ourselves with those who are deploring the loss literature and history have sustained, we realise that our science also is the poorer to-day through the death of one of its most brilliant expositors.

The Scope of Evolution.

In a recent address Lord Morley referred to "evolution" as "the most overworked word in all the language of the day"; nevertheless, he was constrained to admit that, even when discussing such a theme as history and modern politics, "we cannot do without it." But to us in this section, concerned as we are with the problems of man's nature and the gradual emergence of human structure, customs, and institutions, the facts of evolution form the very fabric the threads of which we are endeavouring to disentangle; and in such studies ideas of evolution find more obvious expression than most of us can detect in modern politics. In such circumstances we are peculiarly liable to the risk of "overworking" not only the word evolution, but also the application of the idea of evolution to the material of our investigations.

My predecessor in the office of president of this section last year uttered a protest against the tendency, to which British anthropologists of the present generation seem to be peculiarly prone, to read evolutionary ideas into many events in man's history and the spread of his knowledge and culture in which careful in-

[1] This report represents the address as it was delivered at the meeting; it is a somewhat condensed and rearranged form of that appearing in the Association's Reports.

vestigation can detect no indubitable trace of any such influences having been at work.

I need offer no apology for repeating and emphasising some of the points brought forward in Dr. Rivers's deeply instructive address; for his lucid and convincing account of the circumstances that had compelled him to change his attitude toward the main problems of the history of human society in Melanesia first brought home to me the fact, which I had not clearly realised until then, that in my own experience, working in a very different domain of anthropology on the opposite side of the world, I had passed through phases precisely analogous to those described so graphically by Dr. Rivers. He told us that in his first attempts to trace out "the evolution of custom and institution" he started from the assumption that "where similarities are found in different parts of the world they are due to independent origin and development, which in turn is ascribed to the fundamental similarity of the workings of the human mind all over the world, so that, given similar conditions, similar customs and institutions will come into existence and develop on the same lines." But as he became more familiar with the materials of his research he found that such an attitude would not admit of an adequate explanation of the facts, and he was forced to confess that he "had ignored considerations arising from racial mixture and the blending of cultures."

I recall these statements to your recollection now, not merely for the purpose of emphasising the far-reaching significance of an address which is certain to be looked back upon as one of the most distinctive and influential utterances from this presidential chair, nor yet with the object of telling you how, in the course of my investigations upon the history of the people in the Nile Valley,[2] I also started out to search for evidences of evolution, but gradually came to realise that the facts of racial admixture and the blending of cultures were far more obtrusive and significant. My intention is rather to investigate the domain of anthropology in which unequivocal evolutionary factors have played a definite rôle; I refer to the study of man's genealogy, and the forces that determined the precise line of development his ancestors pursued and ultimately fashioned man himself.

I suppose it is inevitable in these days that one trained in biological ways of thought should approach the problems of anthropology with the idea of independent development as his guiding principle; but the conviction must be reached sooner or later, by everyone who conscientiously, and with an open mind, seeks to answer most of the questions relating to man's history and achievements—certainly the chapters in that history which come within the scope of the last sixty centuries—that evolution yields a surprisingly small contribution to the solution of the difficulties which present themselves. Most of the factors that call for investigation concerning the history of man and his works are unquestionably the direct effects of migrations and the intermingling of races and cultures.

But I would not have you misunderstand my meaning. Nothing could be further from my intention than to question the reality of evolution, as understood by Charles Darwin, and the tremendous influence it is still exerting upon mankind. In respect of certain perils man may, perhaps, have protected himself from "the general operation of that process of natural selection and survival of the fittest which, up to his appearance, had been the law of the living world" (Sir Ray Lankester); but it has been demonstrated quite definitely that man, in virtue of these very heightened powers, which, to some observers, seem to have secured him an immunity from what Sir Ray Lankester calls "nature's inexorable discipline of death," is constantly exposing himself to new conditions that favour the operations of natural selection, as well as other forms of "selection" which his increased powers of intelligent choice and his subjection to the influences of fashion expose him.

It is not, however, with such contentious matters as the precise mode of operation of evolution at the present day that I propose to deal; nor yet with the discussion of when and how the races of mankind became specialised and differentiated the one from the other. It is the much older story of the origin of man himself and the first glimmerings of human characteristics amidst even the remotest of his ancestors to which I invite you to give some consideration to-day.

In a recently published book[3] the statement is made that "the uncertainties as to man's pedigree and antiquity are still great, and it is undeniably difficult to discover the factors in his emergence and ascent." There is undoubtedly the widest divergence of opinion as to the precise pedigree; nevertheless, there seems to me to be ample evidence now available to justify us sketching the genealogy of man and confidently drawing up his pedigree as far back as Eocene times —a matter of a million years or so—with at least as much certainty of detail and completeness as in the case of any other recent mammal; and if all the factors in his emergence are not yet known, there is one unquestionable, tangible factor that we can seize hold of and examine—the steady and uniform development of the brain along a well-defined course throughout the primates right up to man—which must give us the fundamental reason for "man's emergence and ascent," whatever other factors may contribute toward that consummation.

What I propose to attempt is to put into serial order those vertebrates which we have reason to believe are the nearest relatives to man's ancestors now available for examination, and to determine what outstanding changes in the structure of the cerebral hemispheres have taken place at each upward step that may help to explain the gradual acquirement of the distinctively human mental faculties, which, by immeasurably increasing the power of adaptation to varying circumstances and modifying the process of sexual selection, have made man what he is at present.

The links in the chain of our ancestry supplied by palæontology are few, and of doubtful value, if considered apart from the illumination of comparative anatomy.

Psychologists have formulated certain definite phases through which the evolution of intelligence must have passed in the process of gradual building-up of the structure of the mind. The brain in a sense is the incarnation of this mental structure; and it seemed to me that it would be instructive, and perhaps useful, to employ the facts of the evolution of the brain as the cement to unite into one comprehensive story the accumulations of knowledge concerning the essential facts of man's pedigree, and the factors that have contributed to his emergence, which have been gathered by workers in such diverse departments of knowledge as zoology and comparative anatomy, geology and palæontology, and physiology and psychology.

For it was the evolution of the brain and the ability to profit by experience, which such perfecting of the cerebral mechanism made possible, that led to the emergence of mammals, as I attempted to demonstrate in opening the discussion on the origin of mammals at the Portsmouth meeting last year[4]; and from

[2] "The Ancient Egyptians," Harpers, 1911.

[3] J. A. Thomson and P. Geddes, "Evolution," 1912, p. 102.

[4] Discussion on the "Origin of Mammals" at the meetings of Section D (Brit. Assoc. Reports, 1911, p. 424).

the mammalia, by a continuation of this process of building-up the cerebral cortex, or, if you prefer it, the structure of the mind, was eventually formed that living creature which has attained the most extensive powers of profiting by individual experience.

The study of the brain and mind, therefore, should have been the first care of the investigator of human origins. Charles Darwin, with his usual perspicuity, fully realised this; but since his time the rôle of intelligence and its instruments has been almost wholly ignored in these discussions; or when invoked at all wholly irrelevant aspects of the problems have been considered.

There can be no doubt that this neglect of the evidence which the comparative anatomy of the brain supplies is in large measure due to the discredit cast upon this branch of knowledge by the singularly futile pretensions of some of the foremost anatomists who opposed Darwin's views in the discussions which took place at the meetings of the British Association and elsewhere more than forty years ago.

Many of you no doubt are familiar with Charles Kingsley's delightful ridicule of these learned discussions in the pages of "Water Babies." The controversy excited by Sir Richard Owen's contention that the great distinctive feature of the human brain was the possession of a structure that used to be called the hippocampus minor was not unjustly the mark of his scathing satire.

"The professor had even got up at the British Association and declared that apes had hippopotamus majors in their brains, just as men have. Which was a shocking thing to say; for, if it were so, what would become of the faith, hope, and charity of immortal millions? You may think that there are other more important differences between you and an ape, such as being able to speak, and make machines, and know right from wrong, and say your prayers, and other little matters of that kind; but that is only a child's fancy, my dear. Nothing is to be depended upon but the great hippopotamus test. If you have a hippopotamus major in your brain you are no ape, though you had four hands, no feet, and were more apeish than the apes of all aperies. Always remember that the one true, certain, final, and all-important difference between you and an ape is that you have a hippopotamus major in your brain and it has none. If a hippopotamus was discovered in an ape's brain, why, it would not be one, you know, but something else."

The measure of the futility of the contention thus held up to scorn can be more justly realised now; for some years ago I discovered that the feature referred to in Kingsley's burlesque phrase, "hippopotamus major," which Owen claimed to be distinctive of the human brain, and Huxley maintained was present also in apes, is quite a primitive characteristic, and the common property of the mammalia in general.

This illustration of the nature of the discussions which distracted attention from the real problems, although the most notorious one, is unfortunately characteristic of the state of affairs that prevailed when prejudice blinded men's eyes to the obvious facts that were calling so urgently for calm investigation.

Man's Pedigree.

No one who is familiar with the anatomy of man and the apes can refuse to admit that no hypothesis other than that of close kinship affords a reasonable or credible explanation of the extraordinarily exact identity of structure that obtains in most parts of the bodies of man and the gorilla. To deny the validity of this evidence of near kinship is tantamount to a confession of the utter uselessness of the facts of comparative anatomy as indications of genetic relationships, and a reversion to the obscurantism of the dark ages of biology. But if anyone still harbours an honest doubt in the face of this overwhelming testimony from mere structure, the reactions of the blood will confirm the teaching of anatomy; and the susceptibility of the anthropoid apes to the infection of human diseases, from which other apes and mammals in general are immune, should complete and clinch the proof for all who are willing to be convinced.

Nor can anyone who, with an open mind, applies similar tests to the gibbon refuse to admit that it is a true, if very primitive, anthropoid ape, nearly related to the common ancestor of man, the gorilla, and the chimpanzee. Moreover, its structure reveals indubitable evidence of its derivation from some primitive Old World or catarrhine monkey akin to the ancestor of the langur, the sacred monkey of India. It is equally certain that the catarrhine apes were derived from some primitive platyrrhine ape, the other, less modified, descendants of which we recognise in the South American monkeys of the present day; and that the common ancestor of all these primates was a lemuroid nearly akin to the curious litle spectral tarsier, which still haunts the forests of Borneo, Java, and the neighbouring islands, and awakens in the minds of the peoples of those lands a superstitious dread—a sort of instinctive horror at the sight of the ghost-like representative of their first primate ancestor.

This much of man's pedigree will, I think, be admitted by the great majority of zoologists who are familiar with the facts; but I believe we can push the line of ancestry still further back, beyond the most primitive primate into Haeckel's suborder Menotyphla, which most zoologists regard as constituting two families of insectivora. I need not stop to give the evidence for this opinion, for most of the data and arguments in support of it have recently been summarised most excellently by Dr. W. K. Gregory.[5]

This group includes the Oriental tree-shrews and the African jumping-shrews. The latter (Macroscelididæ), living in the original South African home of the mammalia, present extraordinarily primitive features linking them by close bonds of affinity to the marsupials. The tree-shrews (Tupaiidæ), however, which range from India to Java, while presenting very definite evidence of kinship to their humble African cousins, also display in the structure of their bodies positive evidence of relationship to the stem of the aristocratic primate phylum.

Quite apart from the striking similarities produced by identical habits and habitats, there are many structural identities in the tree-shrews and lemuroids, not directly associated with such habits, which can be interpreted only as evidences of affinity.

The Neopallium and its Relation to the Ability of Learning by Experience.

Having now sketched the broad lines of man's pedigree right back to the most primitive mammals, let us next consider what were the outstanding factors that determined the course of his ancestors' progressive evolution.

The class mammalia, to which man belongs, is distinguished in structure from all other vertebrates mainly by the size and high development of the brain, and, as regards the behaviour of its members, by the fact that they are able, in immeasurably greater degree than all other animals, not excluding even birds, to profit by individual experience. The behaviour of most, or perhaps it would be more correct to say all, animals, however complex and nicely adapted to their

5 "The Orders of Mammals," Bull. Amer. Mus. Nat. Hist., vol. xxvii., 1910, p. 321.

circumstances it may seem, is essentially instinctive; and the main problem we have to solve, in attempting to explain the emergence of the distinctive attributes of the creature which in greater measure than any other has succeeded in subordinating its instincts to reason, is the means by which it has become possible for the effects of individual experience to be brought to bear upon conduct.

The ability to learn by experience necessarily implies the development, somewhere in the brain, of a something which can act not only as a receptive organ for impressions of the senses and a means for securing that their influence will find expression in modifying behaviour, but also serve in a sense as a recording apparatus for storing such impressions, so that they may be revived in memory at some future time in association with other impressions received simultaneously, the state of consciousness they evoked, and the response they called forth.

Such an organ of associative memory is actually found in the brain of mammals. It is the cortical area to which eleven years ago I applied the term "neopallium."[6] Into it pathways lead from all the sense organs; and each of its territories, which receives a definite kind of impression, visual, acoustic, tactile, or any other, is linked by the most intimate bonds with all the others. In spite of the disapproval of the psychologists, we can indeed regard this neopallium as fulfilling all the conditions of the *sensorium commune*, which Aristotle and many generations of philosophers have sought for twenty centuries; for it is unquestionably a "unitary organ the physical processes of which might be regarded as corresponding to the unity of consciousness" (Wm. MacDougall).

Nothing that happens in this area in the course of its enormous expansion and differentiation in the higher mammals materially affects this fundamental purpose of the neopallium, which continues to remain a unifying organ that acts as a whole, though each part is favourably placed to receive and transmit to the rest its special quota to the sum-total of what we may call the materials of conscious life.

The consciousness which resides, so to speak, in this neopallium, and is fed by the continual stream of sensory impressions pouring into it and awakening memories of past sensations, can express itself directly in the behaviour of the animal through the intermediation of a part of the neopallium itself, the so-called motor area, which is not only kept in intimate relation with the muscles, tendons, and skin by sensory impressions, but controls the voluntary responses of the muscles of the opposite side of the body.

The Differentiation of Mammals and the Effects of Specialisation.

The possession of this higher type of brain enormously widened the scope for the conscious and intelligent adaptation of the animal to varying surroundings; and in the exercise of this newly acquired ability to learn from individual experience, and so appreciate the possibilities of fresh sources of food supply and new modes of life, the way was opened for an infinite series of adaptations to varying environments, entailing structural modifications in which the enhanced plasticity of the new type of animal found expression.

Nature tried innumerable experiments with the new type of brain almost as soon as the humble Therapsid-like mammal felt the impetus of its new-found power of adaptation. In turn, the Prototherian and Metatherian types of brain were tried before the more adaptable scheme of the Eutherian brain was evolved.

[6] "The Natural Subdivision of the Cerebral Hemisphere," *Journ. Anat. and Phys.*, vol. xxxv., 1901, p. 431; Arris and Gale Lectures on the Evolution of the Brain, *Lancet*, January 15, 1910, p. 153.

The new breed of intelligent creatures rapidly spread from their South African home throughout the whole world, and exploited every mode of livelihood. The power of adaptation to the particular kind of life each group chose to pursue soon came to be expressed in a bewildering variety of specialisations in structure, some for living on the earth or burrowing in it, others for living in trees or even for flight; others, again, for an aquatic existence. Some mammals became fleet of foot, and developed limbs specially adapted to enhance their powers of rapid movement. They attained an early pre-eminence, and were able to grow to large dimensions in the slow-moving world at the dawn of the age of mammals. Others developed limbs specially adapted for swift attack and habits of stealth, successfully to prey upon their defenceless relatives.

Most of these groups attained the immediate success that often follows upon early specialisation; but they also paid the inevitable penalty. They became definitely committed to one particular kind of life; and in so doing they had sacrificed their primitive simplicity and plasticity of structure, and in great measure their adaptability to new conditions. The retention of primitive characters, which so many writers upon biological subjects, and especially upon anthropology, assume to be a sign of degradation, is not really an indication of lowliness. We should rather look upon high specialisation of limbs and the narrowing of the manner of living to one particular groove as confessions of weakness, the renunciation of the wider life for one that is sharply circumscribed.

The stock from which man eventually emerged played a very humble rôle for long ages after many other mammalian orders had waxed great and strong. But the race is not always to the swift, and the lowly group of mammals which took advantage of its insignificance to develop its powers evenly and very gradually, without sacrificing in narrow specialisation any of its possibilities of future achievement, eventually gave birth to the dominant and most intelligent of all living creatures.

The tree-shrews are small squirrel-like animals which feed on "insects and fruit, which they usually seek in trees, but also occasionally on the ground. When feeding they often sit on their haunches, holding the food, after the manner of squirrels, in their forepaws."[7] They are of "lively disposition and great agility."[8] These vivacious, large-brained little insectivores, linked by manifold bonds of relationship to some of the lowliest and most primitive mammals, present in the structure of their skull, teeth, and limbs undoubted evidence of a kinship, remote though none the less sure, with their compatriots the Malaysian lemurs; and it is singularly fortunate for us in this inquiry that side by side there should have been preserved from the remote Eocene times, and possibly earlier still, these insectivores, which had almost become primates, and a little primitive lemuroid, the spectral tarsier, which had only just assumed the characters of the primate stock, when nature fixed their types and preserved them throughout the ages, with relatively slight change, for us to study at the present day.

Thus we are able to investigate the influence of an arboreal mode of life in stimulating the progressive development of a primitive mammal, and to appreciate precisely what changes were necessary to convert the lively, agile Ptilocercus-like ancestor of the primates into a real primate.

In the forerunners of the mammalia the cerebral hemisphere was predominantly olfactory in function; and even when the true mammal emerged, and all the

[7] Flower and Lydekker, "Mammals, Living and Extinct," 1891, p. 618.
[8] W. K. Gregory, *op. cit.*, p. 260, and pp. 279, 28 .

other senses received due representation in the neopallium, the animal's behaviour was still influenced to a much greater extent by smell impressions than by those of the other senses.

This was due not only to the fact that the sense of smell had already installed its instruments in, and taken firm possession of, the cerebral hemisphere long before the advent in this dominant part of the brain of any adequate representation of the other senses, but also, and chiefly, because to a small land-grubbing animal the guidance of smell impressions, whether in the search for food or as a means of recognition of friends or enemies, was much more serviceable than all the other senses. Thus the small creature's mental life was lived essentially in an atmosphere of odours, and every object in the outside world was judged primarily and predominantly by its smell; the senses of touch, vision, and hearing were merely auxiliary to the compelling influence of smell.

Once such a creature left the solid earth and took to an arboreal life all this was changed, for away from the ground the guidance of the olfactory sense lost much of its usefulness. Life amidst the branches of trees limits the usefulness of olfactory organs, but it is favourable to the high development of vision, touch, and hearing. Moreover, it demands an agility and quickness of movement that necessitates an efficient motor cortex to control and co-ordinate such actions as an arboreal mode of life demands (and secures, by the survival only of those so fitted), and also a well-developed muscular sensibility to enable such acts to be carried out with precision and quickness. In the struggle for existence, therefore, all arboreal mammals, such as the tree-shrews, suffer a marked diminution of their olfactory apparatus, and develop a considerable neopallium, in which relatively large areas are given up to visual, tactile, acoustic, kinæsthetic, and motor functions, as well as to the purpose of providing a mechanism for mutually blending in consciousness the effects of the impressions pouring in through the avenues of these senses.

Thus a more equable balance of the representation of the senses is brought about in the large brain of the arboreal animal; and its mode of life encourages and makes indispensable the acquisition of agility. Moreover, these modifications do not interfere with the primitive characters of limb and body. These small arboreal creatures were thus free to develop their brains and maintain all the plasticity of a generalised structure, which eventually enabled them to go far in the process of adaptation to almost any circumstances that presented themselves.

Amongst the members of this group, as in all the other mammalian phyla, the potency of the forces of natural selection was immensely enhanced by the fact that the inquisitiveness of an animal which can learn by experience, *i.e.*, is endowed with intelligence, was leading these plastic insectivores into all kinds of situations which were favourable for the operation of selection. Various members of the group became specialised in different ways. Of such specialised strains the one of chief interest to us is that in which the sense of vision became especially sharpened.

The Origin of Primates.

Towards the close of the Cretaceous period some small arboreal shrew-like creature took another step in advance, which was fraught with the most far-reaching consequences; for it marked the birth of the primates and the definite branching off from the other mammals of the line of man's ancestry.

A noteworthy further reduction in the size of the olfactory parts of the brain, such as is seen in that of Tarsius,[9] quite emancipated the creature from the dominating influence of olfactory impressions, the sway of which was already shaken, but not quite overcome, when its tupaioid ancestor took to an arboreal life. This change was associated with an enormous development of the visual cortex in the neopallium, which not only increased in extent so as far to exceed that of Tupaia, but also became more highly specialised in structure. Thus, in the primitive primate, vision entirely usurped the controlling place once occupied by smell; but the significance of this change is not to be measured merely as the substitution of one sense for another. The visual area of cortex, unlike the olfactory, is part of the neopallium, and when its importance thus became enhanced the whole of the neopallium felt the influence of the changed conditions. The sense of touch also shared in the effects, for tactile impressions and the related kinæsthetic sensibility, the importance of which to an agile tree-living animal is obvious, assist vision in the conscious appreciation of the nature and the various properties of the things seen, and in learning to perform agile actions which are guided by vision.

An arboreal life also added to the importance of the sense of hearing; and the cortical representation of this sense exhibits a noteworthy increase in the primates, the significance of which it would be difficult to exaggerate in the later stages, when the simian are giving place to the distinctively human characteristics.

The high specialisation of the sense of sight awakened in the creature the curiosity to examine the objects around it with closer minuteness, and supplied guidance to the hands in executing more precise and more skilled movements than the tree-shrew attempts. Such habits not only tended to develop the motor cortex itself, trained the tactile and kinæsthetic senses, and linked up their cortical areas in bonds of more intimate associations with the visual cortex, but they stimulated the process of specialisation within or alongside the motor cortex of a mechanism for regulating the action of that cortex itself—an organ of attention which co-ordinated the activities of the whole neopallium so as the more efficiently to regulate the various centres controlling the muscles of the whole body. In this way not only is the guidance of all the senses secured, but the way is opened for all the muscles of the body to act harmoniously so as to permit the concentration of their action for the performance at one moment of some delicate and finely adjusted movement.

In some such way as this there was evolved from the motor area itself, in the form of an outgrowth placed at first immediately in front of it, a formation, which attains much larger dimensions and a more pronounced specialisation of structure in the primates than in any other order; it is the germ of that great prefrontal area of the human brain which is said to be "concerned with attention and the general orderly co-ordination of psychic processes,"[10] and as such is, in far greater measure than any other part of the brain, deserving of being regarded as the seat of the higher mental faculties and the crowning glory and distinction of the human fabric.

[By means of lantern slides representing Dr. Scharff's convincing elucidation of the modifications of the land connections during Tertiary times, a demonstration was given of the wanderings of the primates, which the facts of palæontology and comparative anatomy demand; the object being to direct attention to the fact

9 "On the Morphology of the Brain in the Mammalia, with Special Reference to that of the Lemurs, Recent and Extinct," Trans. Linn. Soc. Lond., second series; *Zoology*, vol. viii., Part 10, February, 1903.

10 J. S. Bolton "The Functions of the Frontal Lobes," *Brain*, 1903.

that at each stage in the migrations of man's ancestors, menotyphlous, prosimian, platyrrhine, catarrhine and anthropoid, the unprogressive members remained somewhere in the neighbourhood of the home of their immediate ancestors, and that those which wandered into new surroundings had to struggle for their footing, and as the result of this striving attained a higher rank.

Other slides were shown to demonstrate the fact that in this series of primates there was a steady development of the brain—expansion and differentiation of the visual, tactile and auditory centres, and development of the meeting territory between them; a marked growth and specialisation of the motor centres, and the power of skilled movements, especially of the hands and fingers; and a regular expansion of the prefrontal area—along the lines marked out once for all when the first primate was formed from some menotyphlous progenitor.]

Thus the outstanding feature in the gradual evolution of the primate brain is a steady growth and differentiation of precisely those cortical areas which took on an enhanced importance in the earliest primates.

So far in this address I have been delving into the extremely remote, rather than the nearer, ancestry of man, because I believe the germs of his intellectual preeminence were sown at the very dawn of the Tertiary period, when the first anaptomorphid began to rely upon vision rather than smell as its guiding sense. In all the succeeding ages since that remote time the fuller cultivation of the means of profiting by experience, which the tarsioid had adopted, led to the steady upward progression of the primates. From time to time many individuals, finding themselves amidst surroundings which were thoroughly congenial and called for no effort, lagged behind; and in Tarsius and the lemurs, the New World monkeys, the Old World monkeys, and the anthropoids, not to mention the extinct forms, we find preserved a series of these laggards which have turned aside from the highway which led to man's estate.

The primates at first were a small and humble folk, who led a quite unobtrusive and safe life in the branches of trees, taking small part in the fierce competition for size and supremacy that was being waged upon the earth beneath them by their carnivorous, ungulate, and other brethren. But all the time they were cultivating that equable development of all their senses and limbs, and that special development of the more intellectually useful faculties of the mind which, in the long run, were to make them the progenitors of the dominant mammal—the mammal which was to obtain the supremacy over all others, while still retaining much of the primitive structure of limb that his competitors had sacrificed. It is important, then, to keep in mind that the retention of primitive characters is often to be looked upon as a token that their possessor has not been compelled to turn aside from the straight path and adopt protective specialisations, but has been able to preserve some of his primitiveness and the plasticity associated with it, precisely because he has not succumbed or fallen away in the struggle for supremacy. It is the wider triumph of the individual who specialises late, after benefiting by the many-sided experience of early life, over him who in youth becomes tied to one narrow calling.

In many respects man retains more of the primitive characteristics, for example, in his hands, than his nearest simian relatives; and in the supreme race of mankind many traits, such as abundance of hair, persist to suggest pithecoid affinities, which have been lost by the more specialised negro and other races. Those anthropologists who use the retention of primitive features in the Nordic European as an argument to exalt the negro to equality with him are neglecting the clear teaching of comparative anatomy, that the persistence of primitive traits is often a sign of strength rather than of weakness. This factor runs through the history of the whole animal kingdom.[11] Man is the ultimate product of that line of ancestry which was never compelled to turn aside and adopt protective specialisation either of structure or mode of life, which would be fatal to its plasticity and power of further development.

Having now examined the nature of the factors that have made a primate from an insectivore and have transformed a tarsioid prosimian into an ape, let us turn next to consider how man himself was fashioned.

The Origin of Man.

It is the last stage in the evolution of man that has always excited chief interest and has been the subject of much speculation, as the addresses of my predecessors in this presidency bear ample witness.

These discussions usually resolve themselves into the consideration of such questions as whether it was the growth of the brain, the acquisition of the power of speech, or the assumption of the erect attitude that came first and made the ape into a human being. The case for the erect attitude was ably put before the Association in the address delivered to this section by Dr. Munro in 1893. He argued that the liberation of the hands and the cultivation of their skill lay at the root of man's mental supremacy.

If the erect attitude is to explain all, why did not the gibbon become a man in Miocene times? The whole of my argument has aimed at demonstrating that the steady growth and specialisation of the brain has been the fundamental factor in leading man's ancestors step by step right upward from the lowly insectivore status, nay, further, through every earlier phase in the evolution of mammals—for man's brain represents the consummation of pr c!s-ly those factors which throughout the vertebrata have brought their possessors to the crest of the wave of progress. But such advances as the assumption of the erect attitude are brought about simply because the brain has made skilled movements of the hands possible and of definite use in the struggle for existence: yet once such a stage has been attained the very act of liberating the hands for the performance of more delicate movements opens the way for a further advance in brain development to make the most of the more favourable conditions and the greater potentialities of the hands.

It is a fact beyond dispute that the divergent specialisation of the human limbs, one pair for progression, and the other for prehension and the more delicately adjusted skilled action, has played a large part in preparing the way for the emergence of the distinctively human characteristics; but it would be a fatal mistake unduly to magnify the influence of these developments. The most primitive living primate, the spectral tarsier, frequently assumes the erect attitude, and uses its hands for prehension rather than progression in many of its acts, and many other lemurs, such as the Indrisinæ of Madagascar, can and do walk erect.

In the remote Oligocene, a catarrhine ape, nearly akin to the ancestors of the Indian sacred monkey, Semnopithecus, became definitely specialised in structure in adaptation for the assumption of the erect attitude; and this type of early anthropoid has persisted with relatively slight modifications in the gibbon of the present day. But if the earliest gibbons were already able to walk upright, how is it, one might ask, that they did not begin to use their hands, thus freed from the work of progression on the earth, for skilled work, and at once before men? The

[11] "The Brain in the Edentata," Trans. Linn. Soc., 1899.

obvious reason is that the brain had not yet attained a sufficiently high stage of development to provide a sufficient amount of useful skilled work, apart from the tree-climbing, for these competent hands to do.

The ape is tied down absolutely to his experience, and has only a very limited ability to anticipate the results even of relatively simple actions, because so large a proportion of his neopallium is under the dominating influence of the senses.

Without a fuller appreciation of the consequences of its actions than the gibbon is capable of, the animal is not competent to make the fullest use of the skill it undoubtedly possesses. What is implied in acquiring this fuller appreciation of the meaning of events taking place around the animal? The state of consciousness awakened by a simple sensory stimulation is not merely an appreciation of the physical properties of the object that supplies the stimulus: the object simply serves to bring to consciousness the results of experience of similar or contrasted stimulations in the past, as well as the feelings aroused by or associated with them, and the acts such feelings excited. This mental enrichment of a mere sensation so that it acquires a very precise and complex meaning is possible only because the individual has this extensive experience to fall back upon; and the faculty of acquiring such experience implies the possession of large neopallial areas for recording, so to speak, these sensation-factors and the feelings associated with them. The "meaning" which each creature can attach to a sensory impression presumably depends, not on its experience only, but more especially upon the neopallial provision in its brain for recording the fruits of such experience.

Judged by this standard, the human brain bears ample witness, in the expansion of the great temporo-parietal area, which so obviously has been evolved from the regions into which visual, auditory, and tactile impulses are poured, to the perfection of the physical counterpart of the enrichment of mental structure, which is the fundamental characteristic of the human mind.

The second factor that came into operation in the evolution of the human brain is merely the culmination of a process which has been steadily advancing throughout the primates: I refer to the high state of perfection of the cortical regulation of skilled movements, many of which are acquired by each individual in response to a compelling instinct that forces every normal human being to work out his own salvation by perpetually striving to acquire such manual dexterity.

This brings us to the consideration of the nature of the factors that have led to the wide differentiation of man from the gorilla. Why is it that these two primates, structurally so similar and derived simultaneously from common parents, should have become separated by such an enormous chasm, so far as their mental abilities are concerned?

There can be no doubt that this process of differentiation is of the same nature as those which led one branch of the Eocene tarsioids to become monkeys while the other remained prosimiæ; advanced one group of primitive monkeys to the catarrhine status, while the rest remained platyrrhine; and converted one division of the Old World apes into anthropoids, while the others retained their old status. Put into this form as an obvious truism, the conclusion is suggested that the changes which have taken place in the brain to convert an ape into man are of the same nature as, and may be looked upon merely as a continuation of, those processes of evolution which we have been examining in the lowlier members of the primate series. It was not the adoption of the erect attitude or the invention of articulate language that made man from an ape, but the gradual perfecting of the brain and the slow upbuilding of the mental structure, of which erectness of carriage and speech are some of the incidental manifestations.

The ability to perform skilled movements is conducive to a marked enrichment of the mind's structure and the high development of the neopallium, which is the material expression of that enrichment. There are several reasons why this should be so. The mere process of learning to execute any act of skill necessarily involves the cultivation, not only of the muscles which produce the movement, and the cortical area which excites the actions of these muscles, but in even greater measure the sensory mechanisms in the neopallium which are receiving impressions from the skin, the muscles, and the eyes, to control the movements at the moment, and incidentally are educating these cortical areas, stimulating their growth, and enriching the mental structure with new elements of experience. Out of the experience gained in constantly performing acts of skill, the knowledge of cause and effect is eventually acquired. Thus the high specialisation of the motor area, which made complicated actions possible, and the great expansion of the temporo-parietal area, which enabled the ape-man to realise the "meaning" of events occurring around it, reacted one upon the other, so that the creature came to understand that a particular act would entail certain consequences. In other words, it gradually acquired the faculty of shaping its conduct in anticipation of results.

Long ages ago, possibly in the Miocene, the ancestors common to man, the gorilla, and the chimpanzee became separated into groups, and the different conditions to which they became exposed after they parted company were in the main responsible for the contrasts in their fate. In one group the distinctively primate process of growth and specialisation of the brain, which had been going on in their ancestors for many thousands, even millions, of years, reached a stage when the more venturesome members of the group, stimulated perhaps by some local failure of the customary food, or maybe led forth by a curiosity bred of their growing realisation of the possibilities of the unknown world beyond the trees which hitherto had been their home, were impelled to issue forth from their forests, and seek new sources of food and new surroundings on hill and plain, wherever they could obtain the sustenance they needed. The other group, perhaps because they happened to be more favourably situated or attuned to their surroundings, living in a land of plenty which encouraged indolence in habit and stagnation of effort and growth, were free from this glorious unrest, and remained apes, continuing to lead very much the same kind of life (as gorillas and chimpanzees) as their ancestors had been living since the Miocene or even earlier times. That both of these unenterprising relatives of man happen to live in the forests of tropical Africa has always seemed to me to be a strong argument in favour of Darwin's view that Africa was the original home of the first creatures definitely committed to the human career; for while man was evolved amidst the strife with adverse conditions, the ancestors of the gorilla and chimpanzee gave up the struggle for mental supremacy simply because they were satisfied with their circumstances; and it is more likely than not that they did not change their habitat.

The erect attitude, infinitely more ancient than man himself, is not the real cause of man's emergence from the simian stage; but it is one of the factors made use of by the expanding brain as a prop still further to extend its growing dominion, and by fixing and establishing in a more decided way this erectness it liberated the hand to become the chief instrument of man's further progress.

In learning to execute movements of a degree of delicacy and precision to which no ape could ever attain, and the primitive ape-man could only attempt once his arm was completely emancipated from the necessity of being an instrument of progression, that cortical area which seemed to serve for the phenomena of attention became enhanced in importance. Hence the prefrontal region, where the activities of the cortex as a whole are, as it were, focussed and regulated, began to grow until eventually it became the most distinctive characteristic of the human brain, gradually filling out the front of the cranium and producing the distinctively human forehead. In the diminutive prefrontal area of Pithecanthropus,[12] and to a less marked degree, Neanderthal man,[13] we see illustrations of lower human types, bearing the impress of their lowly state in receding foreheads and great brow ridges. However large the brain may be in *Homo primigenius,* his small prefrontal region, if we accept Boule and Anthony's statements, is sufficient evidence of his lowly state of intelligence and reason for his failure in the competition with the rest of mankind.

The growth in intelligence and in the powers of discrimination no doubt led to a definite cultivation of the æsthetic sense, which, operating through sexual selection, brought about a gradual refinement of the features, added grace to the general build of the body, and demolished the greater part of its hairy covering. It also led to an intensification of the sexual distinctions, especially by developing in the female localised deposits of fatty tissue, not found in the apes, which produced profound alterations in the general form of the body.

Right-handedness.

To one who considers what precisely it means to fix the attention and attempt the performance of some delicately adjusted and precise action it must be evident that one hand only can be usefully employed in executing the consciously skilled part in any given movement. The other hand, like the rest of the muscles of the whole body, can be only auxiliary to it, assisting, under the influence of attention, either passively or actively, in steadying the body or helping the dominant hand. Moreover, it is clear that if one hand is constantly employed for doing the more skilled work, it will learn to perform it more precisely and more successfully than either would if both were trained, in spite of what ambidextral enthusiasts may say. Hence it happened that when nature was fashioning man the forces of natural selection made one hand more apt to perform skilled movements than the other. Why precisely it was the right hand that was chosen in the majority of mankind we do not know, though scores of anatomists and others are ready with explanations. But probably some slight mechanical advantage in the circumstances of the limb, or perhaps even some factor affecting the motor area of the left side of the brain that controls its movements, may have inclined the balance in favour of the right arm; and the forces of heredity have continued to perpetuate a tendency long ago imprinted in man's structure when first he became human.

The fact that a certain proportion of mankind is left-handed, and that such a tendency is transmitted to some only of the descendants of a left-handed person, might perhaps suggest that one half of mankind was originally left-handed and the other right-handed, and that the former condition was recessive in the Mendelian sense, or that some infinitesimal advantage may have accrued to the right-handed part of the original community, which in time of stress spared them in preference to left-handed individuals; but the whole problem of why right-handedness should be much more common than left-handedness is still quite obscure. The superiority of one hand is as old as mankind, and is one of the factors incidental to the evolution of man.

It is easily comprehensible why one hand should become more expert than the other, as I have attempted to show; and the fact remains that it is the right hand, controlled by the left cerebral hemisphere, which is specially favoured in this respect. This heightened educability of the (left) motor centre (for the right hand) has an important influence upon the adjoining areas of the left motor cortex. When the ape-man attained a sufficient degree of intelligence to wish to communicate with his fellows other than by mere instinctive emotional cries and grimaces, such as all social groups of animals employ, the more cunning right hand would naturally play an important part in such gestures and signs; and, although the muscles of both sides of the face would be called into action in such movements of the features as were intended to convey information to another (and not merely to express the personal feelings of the individual), such bilateral movements would certainly be controlled by the left side of the brain, because it was already more highly educated.

The Origin of Speech.

[This argument was elaborated to explain the origin of speech. The increasing ability to perform actions demanding skill and delicacy received a great impetus when the hands were liberated for the exclusive cultivation of such skill: this perfection of cerebral control over muscular actions made it possible for the ape-man to learn to imitate the sounds around him, for the act of learning is a training not only of the motor centres and the muscles concerned, but also of the attention, and the benefits that accrued from educating the hands added to the power of controlling other muscles, such as those concerned with articulate speech.

The usefulness of such power of imitating sounds could be fully realised in primitive man, not only because he had developed the parts of the brain which made the acquisition of such skill possible, but also because he had acquired, in virtue of the development of other cortical areas, the ability to realise the significance and learn the meaning of the sounds heard.]

I do not propose to discuss the tremendous impetus that the invention of speech must have given to human progress and intellectual development, in enabling the knowledge acquired by each individual to become the property of the community and be handed on to future generations, as well as by supplying in words the very symbols and the indispensable elements of the higher mental processes.

We are apt to forget the immensity of the heritage that has come down to us from former generations of man, until we begin dimly to realise that for the vast majority of mankind almost the sum-total of their mental activities consists of imitation or acquiring and using the common stock of beliefs. For this accumulation of knowledge and its transmission to our generation we are almost wholly indebted to the use of speech. In our forgetfulness of these facts

[12] Eug. Dubois, "Remarks upon the Brain-cast of Pithecanthropus," Proc. Fourth Internat. Cong. Zool., August, 1898, published Camb., 1899, p. 81.

[13] Boule and Anthony, "L'encéphale de l'homme fossile de la Chapelle-aux-Saints," *L'Anthropologie*, tome xxii., No. 2, 1911, p. 50.

we marvel at the apparent dulness of early man in being content to use the most roughly chipped flints for many thousands of years before he learned to polish them, and eventually to employ materials better suited for the manufacture of implements and weapons. But when we consider how slowly and laboriously primitive man acquired new ideas, and how such ideas—even those which seem childishly simple and obvious to us—were treasured as priceless possessions and handed on from tribe to tribe, it becomes increasingly difficult to believe in the possibility of the independent evolution of similar customs and inventions of any degree of complexity.

The hypothesis of the "fundamental similarity of the working of the human mind" is no more potent to explain the identity of customs in widely different parts of the world, the distribution of megalithic monuments, or the first appearance of metals in America, than it is to destroy our belief that one man, and one only, originally conceived the idea of the mechanical use to which steam could be applied, or that the electric battery was not independently evolved in each of the countries where it is now in use.

In these discursive remarks I have attempted to deal with old problems in the light of newly acquired evidence; to emphasise the undoubted fact that the evolution of the primates and the emergence of the distinctively human type of intelligence are to be explained primarily by a steady growth and specialisation of certain parts of the brain; that such a development could have occurred only in the mammalia, because they are the only plastic class of animals with a true organ of intelligence; that an arboreal mode of life started man's ancestors on the way to pre-eminence, for it gave them the agility, and the specialisation of the higher parts of the brain incidental to such a life gave them the seeing eye, and in course of time also the understanding ear; and that all the rest followed in the train of this high development of vision working on a brain which controlled ever-increasingly agile limbs.

If, in pursuing these objects, I may have seemed to wander far from the beaten paths of anthropology, as it is usually understood in this section, and perhaps encroached upon the domains of the Zoological Section, my aim has been to demonstrate that the solution of these problems of human origins, which have frequently engaged the attention of the Anthropological Section, is not to be sought merely in comparisons of man and the anthropoid apes. Man has emerged not by the sudden intrusion of some new element into the ape's physical structure or the fabric of his mind, but by the culmination of those processes which have been operating in the same way in a long line of ancestors ever since the beginning of the Tertiary period.

If I have made this general conception clear to you, however clumsily I have marshalled the evidence and with whatever crudities of psychological statement it may be marred, I shall feel that this address has served some useful purpose.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

AMONG the honorary degrees to be conferred by the University of Leeds on October 3, in connection with the visit of the Iron and Steel Institute, are:—LL.D. on the president of the institute, Mr. Arthur Cooper, and degrees of D.Sc. on Sir Robert Hadfield, past-president, Mr. J. E. Stead, and M. Adolph Greiner, vice-presidents, and the president of the Society of German Ironmasters.

AMONG the public lectures to be delivered in connection with the opening of the new session at University College, London, we notice the following:—*Faculty of Arts.*—October 3, amulets, Prof. Flinders Petrie; October 4, the philosophy of Shadworth Hodgson, Prof. G. Dawes Hicks; October 5, general phonetics, D. Jones; October 9, introduction to comparative psychology, Carveth Read. *Faculty of Science.*—October 4, Joseph Dalton Hooker, Prof. F. W. Oliver. *Faculty of Engineering.*—October 9, the sources of energy available to man, Prof. J. A. Fleming.

IN connection with the Faculty of Engineering of the East London College, one of the constituent colleges of the University of London, a special course of lectures on the management of public electric supply undertakings has been arranged. The lectures will be given by Mr. A. Hugh Seabrook, and will commence on Monday evening, October 14. It is hoped by this means to arouse the interest of electrical engineers and others in the practical working of modern electrical undertakings. The principal of the college will be pleased to provide particulars of the fees for these lectures, and also of other special courses in connection with the engineering faculty of the college.

IT is unusual to find astronomy and meteorology among the subjects of courses of lectures arranged by a local education committee. We are glad to see that the Manchester Education Committee is an exception to the rule, and that such lectures are being given at the Municipal School of Technology. Mr. W. C. Jenkins is delivering a course of twenty-six lectures on descriptive astronomy in the Godlee Observatory, of which he is curator, dealing with the descriptive and popular aspect of astronomy; a course of twelve lectures on elementary meteorology, supplementary to those on descriptive astronomy, demonstrations to be given at the Meteorological Station, established in the garden adjacent to the Municipal Secondary School; and a course of twenty-six lectures on astronomical observations and the use of the Nautical Almanack for students familiar with the elements of astronomy.

THE Newcastle Section, the Society of Chemical Industry, and the Armstrong College are this winter arranging courses of evening lectures on special chapters in applied chemistry, which, it is anticipated, will prove specially interesting to those chemists and engineers already engaged in the industries. To inaugurate the scheme a special fund is being raised, which has already received liberal support from the principal manufacturers in the district. Two courses of five lectures each have been arranged for this winter, for which the committee has secured the services of well-known specialists. The first course is one on coal-gas manufacture and the carbonisation of coal, by Dr. Harold G. Colman, of London, and the second on metallography, by Dr. Desch, of Glasgow University. The first course will commence on October 16, and continue at fortnightly intervals; the second course is to commence on January 28, 1913.

THE East Ham Technical College begins its seventh session this month. Being situated in a district largely devoted to chemical industries, it endeavours to provide instruction suitable to the locality. The chemical department, which has been reconstructed during the vacation, comprises two lecture rooms, an inorganic laboratory, with bench accommodation for sixty-four students, an organic laboratory of similar dimensions, specially arranged for technological work, two smaller organic laboratories, and a research laboratory. A metallurgical subdepartment has been recently equipped. Practical and theoretical courses in pure chemistry extend over five years, and a college certificate is granted; there are also complete courses in gas engineering, gas supply and distribution, coal-tar distillation, chemical engineering, soap manufacture, painters' oils, colours and varnishes, oils, fats and waxes, metallurgy, and sugar manufacture, all of which are largely attended by students who are engaged either in the laboratories or on the plant in the respective industries.

MORE accommodation has for some time been urgently needed in the departments of bacteriology and public health of King's College (University of London). This has now been provided, with the sanction and approval of the University, by the removal of these departments with their staffs to 62 Chandos Street, Strand, W.C. (Charing Cross Medical School Buildings), where an excellent suite of laboratories is at present vacant owing to the transference of the Charing Cross Medical School's preliminary and intermediate medical studies to King's College. The laboratories at Chandos Street are being altered and refitted, and the accommodation there provided will comprise a large class laboratory, research laboratory, professors' laboratory, and lecturer's laboratory for each department, bacteriology and public health respectively; a photomicrographic laboratory, preparation and animal rooms; a large theatre, office, and library for the joint use of the two departments. There will be the regular courses of instruction in bacteriology, clinical pathology, and photomicrography, and for the diploma of public health. Research and investigation work for public bodies and others will also be carried on as before. The new laboratories will be opened on or about October 1. The laboratories vacated at King's College by this removal will be utilised for increasing the accommodation for the preliminary and intermediate medical studies.

THE volume of announcements of the Northampton Polytechnic Institute, London, E.C., for the session 1912–13 shows that the equipment of the institute has been steadily extended since last year, but there is no large item like a new generating station to report on this occasion. In the mechanical engineering department the equipment for experimental work in aëronautics has been considerably augmented and a new steam power plant has been laid down, which will enable students to experiment on the efficiency of steam plant from the coal and water to the brake of the engine with measuring appliances at every stage. In the evening classes in the electrical engineering department the heavy electrical engineering work now so well known is being continued. An important departure has been made in radio-telegraphy by the extension of the single course previously given to additional courses. The courses and classes in telegraphy and telephony have been remodelled to suit the changed conditions in the public services. In the mechanical engineering department the courses in aëronautical engineering have been further developed, especially on the experimental side. The new equipment referred to above will form a prominent feature of the laboratory instruction. The extensive work of this department in automobile and other branches of engineering is being continued. In technical optics and in technical chemistry the courses have been brought quite up-to-date, but there is no development that calls for special remark. The half-time trade courses in technical chemistry and in horology inaugurated last session are being further developed. In these classes the students, all of whom are engaged in commercial workshops, are in attendance from 9 a.m. to 1 p.m., and spend the afternoons in their employers' workshops. The experiment appears to meet the needs of the particular trades mentioned, and if it continues to be as successful as in the past year it will probably be extended to other trades.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 16. M. A. Grandidier in the chair.—H. **Deslandres**: The relations of the prominences with the filaments and *alignements* of the upper layers of the solar atmosphere. Further details on the character of the *alignements* and the filaments (long dark flocculi, absorption markings of Hale and Evershed). The *alignements* are subdivided into two classes, those with dark and with bright lines. The properties of the latter are consistent with the assumption of a circulation current of the upper atmosphere.—A. **Lacroix**: The mineralogical constitution of the volcanoes of the Island of Reunion. The essential characteristic of the mineralogy of Reunion is the production in the same volcano, and at the expense of the same magma, of well-characterised types of subalkaline and alkaline rocks. These have hitherto been regarded as necessarily of independent origin.—Fred **Vlès**: Remarks on the form of the sun and moon.—Paul **Gaubert**: The influence of the velocity of attack of calcite by acids on the form of the corrosion figures of this mineral. An account of experiments with calcite and dolomite when attacked with dilute solutions of hydrochloric, acetic, formic and nitric acids.—Walter T. **Swingle**: The slow artificial ripening of the Deglet-nour date. The Algerian date was introduced into the United States (Arizona and California) in 1900, but the fruit did not ripen properly on the tree. It has been proved that the dates may be ripened in twenty-four hours by incubation at a temperature of 43° to 49° C. It has now been found that in presence of moisture the fruit can be slowly ripened at the ordinary temperature.—M. **Foëx** and P. **Berthault**: A disease of maize in Cochin China. The disease, the effects of which are described in detail, is due to a fungus of the genus Dothiorella.—E. C. **Teodoresco**: The influence of temperature on nuclease. Nuclease from the plants studied only completely lost its diastatic properties after having been heated to about 90° C. The maximum diastatic action is at about 34° C.—Alphonse **Berget**: An arrangement of apparatus designed for the relative measurement of the acceleration of gravity.—De Montessus de **Ballore**: Earthquakes and sunspots.

CAPE TOWN.

Royal Society of South Africa, August 21.—Dr. J. K. E. Halm in the chair.—A. G. **Howard**: The blizzard of June 9–12, 1902. In continuation of the paper by Mr. Stewart, read in November, 1904, before the South African Association for the Advancement of Science, the writer of the present paper brings to notice a series of synoptic charts of the weather conditions from June 8 to 13, 1902, inclusive.—J. **Hewitt** and J. H. **Power**: A list of South African Lacertilia, Ophidia, and Batrachia in the McGregor Museum, Kimberley, with field notes on various species. The paper is offered primarily as a contribution to our knowledge of the fauna of the Kimberley district. The present-day fauna of that neighbourhood is shown to be composite, a new element having been introduced along with timber from Bechuanaland. The faunistic lists are accompanied with field notes, and in the case of some of the Batrachia the authors have been able to give a short account of the larval metamorphosis.—Dr. **Dreyer**: The salivary and mouth glands of the Nudibranchiata. W. T. **Saxton**: The leaf-spots of *Richardia albo-maculata*, Hook. The author describes the structure and development of the white streaks characteristic of the leaves of two species of Richardia, and discusses their origin.—Dr. R. **Marloth**: Some new or little known South African succulents.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2240, VOL. 90] THURSDAY, OCTOBER 3, 1912 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

THURSDAY, OCTOBER 3, 1912.

THE SPECIFIC TREATMENT OF TUBERCULOSIS.

The Treatment of Tuberculosis by means of the Immune Substances (I.K.) Therapy. An introduction to Carl Spengler's work on Immunity and Tuberculosis. By Walter H. Fearis. With a Foreword by Dr. Carl Spengler. Pp. xx + 206. (London: John Murray, 1912.) Price 6*s.* net.

THOSE who turn to this book for an account of Spengler's work and records will, we are afraid, be sorely disappointed. The opinions of an enthusiastic admirer of Dr. Carl Spengler, his school, and its work are here in abundance, but any detailed description of much that is peculiar to Spengler's method is wanting.

We are told, however, that in man tuberculous infection is a symbiotic infection, and that with rare exceptions two antagonistic types of tubercle bacilli are found:—(1) *Typus humanus brevis*, Koch; (2) *humano-longus*, Spengler, this latter differing from the *Typus bovinus* only in that it branches more and forms pigment, that it is less acid-fast, is more sensitive to the action of distilled water, is more highly pathogenic to cattle, rabbits, guinea-pigs, and adult human beings, and that there are differences between the two as regards certain optical properties. It is interesting to note that Spengler believes that although the two types, *bovinus* and *humano-longus*, are morphologically identical, their pathogenic action is markedly different; still, he rejects experiments on animals as being of little or no value in helping to distinguish between the different types.

It is insisted that the toxins of the true bovine bacillus are antagonistic to those formed by Koch's *Bacillus brevis* and the converse, and also that whilst the toxins of the true bovine bacillus act as vaccins towards man, those of Koch's *Bacillus brevis*, with rare exceptions, act as toxins towards man. Whatever may ultimately be accepted as to this and other points, the arguments as here put forward are scarcely convincing. Much of the latter part of the book is devoted to an attempt to prove that Dr. Carl Spengler was chiefly responsible for the development of Koch's tuberculin treatment, and that, following this up, he has devised a method for the production of an immunity in which are combined both active and passive elements.

This method depends on the production of certain immune substances or antibodies in the sheep or rabbit, whence, apparently, they can be transferred to the human subject, these immune bodies sometimes being used along with tuberculin, but, in certain cases, alone. Bacteriological methods of examining sputum, &c., of determining the amount of antitoxic substance in the "I.K.," special methods of inoculation, dry, subcutaneous, intramuscular, and the like, are described, and a series of directions for treatment are given, the most important of which (noted after long descriptions of systematic treatment) appears to be—watch the condition of the patient, and then inject just as may be thought fit. A rapid precipitation method used in determining the approximate immunity value of a sample of blood is mentioned, and figures bearing on these values are given, but nowhere is anything said about the method itself.

From this, and from other features of the book, one cannot help feeling that the work before us is the outcome of observations and discussion amongst a set of enthusiastic workers at a subject concerning which the author, at least, is content to accept everything that is put before him, whether he understands it fully or not. This somewhat serious statement is made after due consideration, though it may be that the author is so full of the methods here suggested that he is unaware of the ignorance of many of us "outsiders" of what, in the circle in which he moves, is common knowledge. Nowhere is this more marked than in connection with the reports of different physicians who are recorded as giving evidence for and against "I.K." treatment. There may be a very great field for this treatment, and this book may stimulate those interested to a further study of Carl Spengler's methods, but in it are collected such a mixture of elementary details and imperfect accounts of very difficult and complicated questions that it will certainly fail in its main object, *i.e.*, to be "of real practical value to the physicians who may desire to administer this treatment."

In an introductory note Dr. Carl Spengler writes: "Obgleich mir das vorliegende Buch nur in seiner Disposition bekannt ist. . . ." This is well for Dr. Spengler if he be a fairly modest man, but whether it is equally good for the book is another matter, and we suggest that in the larger work that is promised by the author an attempt should be made to cut out a number of the "Carl" Spenglers, "I.K.'s," and the almost endless repetitions by which the pages of this book will appear, to most readers, to be disfigured. Indeed, many will be so irritated by this constant repetition and reiteration that there will be great risk of any real merit in the work being overlooked.

Finally, in giving explanations, statistics, and comparative results, the author appears to be under the impression that if he makes a statement sufficiently frequently it must ultimately be accepted by any reasonable individual. May we make the suggestion that when the larger work appears it should contain more accurate accounts of the really fundamental differences between Spengler's work and that of his contemporaries, that full descriptions of all special methods be given, and that, in order to make room for many things that are here taken for granted, much irrelevant matter and repetition should be omitted?

SCIENCE OF TANNING.

The Puering, Bating, and Drenching of Skins. By J. T. Wood. Pp. xv+300. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1912.) Price 12*s*. 6*d*. net.

THE author in his preface claims that this volume is merely a collection of notes he has made during the past twenty years on the practical and scientific aspect of the puering, bating, and drenching of skins. "Puering" and "bating" are two processes commonly used in the manufacture of light and fancy leather from various skins. They consist of steeping the skins prior to tanning in a fermenting solution of excrement—in the case of "puering," dog excrement is used; in "bating," hen or pigeon manure. Subsequent to either of these processes the skins are "drenched," in which process they are placed in a fermenting solution of bran, which, by reason of its acid nature, swells the skins prior to tanning. The original of the words puering and bating is French *puer*, to stink; *bête*, animal. The aim of scientific technologists is to substitute these two disgusting processes by cleaner materials which can be scientifically controlled. Puering and bating of skins reduce them in thickness, take out the lime and grease, and make them soft and velvety. Mr. Wood has put together his notes upon these subjects in such a way as to make this volume indispensable both to leather trades chemists and to those who wish specially to study the subject. It is, in short, a text-book bringing together in handy form all that has been done and all that is known of this, one of the most complicated processes in connection with leather manufacture.

In the first chapter the author gives an outline of the practical processes of puering and bating. This chapter deals more with the practical side, although scientific data are given in the form of analyses and analytical results connected with practical trials. The author describes also the use of Sand's electrometric apparatus for the controlling of puer and bate liquors.

In subsequent chapters the author deals with the physics and chemistry of bating. These chapters are probably beyond the ken of the average leather manufacturer, as the author deals with the measurement of the hydrogen-ion concentration, the conductivity of puer liquors, and also describes a new apparatus for measuring the degree of falling, illustrating the work of the instrument by curves.

Chapter iv. deals with the bacteriology of the bate, and here the author excels and gives a fund of information which will be most valuable to all branches of the leather industry. The author gives microphotographs of many of the active bacteria of the puer and bate, some of which have been isolated and named by himself.

The remaining chapters contain a number of Mr. Wood's original papers which have been contributed to various learned societies from time to time. A further chapter deals with artificial bates which from time to time have been suggested, some of which are being used with satisfactory results. Lastly, Mr. Wood has collected in convenient form a *résumé* of all the patents and the bibliography of the subject.

A special portion of the book deals with drenching, one of the subsequent processes to puering or bating, and one which must be treated quite apart. Various analyses and bacteriological investigations are fully described.

The book is one which all interested in the scientific side of the leather trade must possess. To the practical leather manufacturer the book may be a disappointment, as the author does not deal with the old practical difficulties.

Mr. Wood describes his book in the concluding chapter as follows:—

"Limited in extent, imperfect in execution, and in parts only suggestive in character, this little book may perhaps serve as a foundation on which students of the science of tanning may raise the superstructure of their own experience and eventually perfect the processes touched upon, so that the use of such filthy materials may be entirely avoided."

This is another example of Mr. Wood's modesty. The book goes further than he claims. It is indeed refreshing to find someone brave enough to publish the results of his years of study of this, one of the least understood and most complicated processes connected with the manufacture of leather.

Needless to add, the printing, illustrations, and the general get-up of the book leave nothing to be desired.

J. G. P.

THREE BOOKS ON AGRICULTURE.

(1) *Fertilisers and Crops; or, The Science and Practice of Plant-Feeding.* By Dr. L. L. Van Slyke. Pp. xiv+734. (New York: Orange Junn Company; London: Kegan Paul and Co., Ltd., 1912.) Price 2.50 dollars.

(2) *Farm Dairying.* By Laura Rose. Pp. 303. (London: T. Werner Laurie, n.d.) Price 6*s.* net.

(3) *Fungoid Diseases of Agricultural Plants.* By Prof. Jakob Eriksson. Translated from the Swedish by Anna Molander. Pp. xv+208. (London: Baillière, Tindall and Cox, 1912.) Price 7*s.* 6*d.* net.

(1) THE system of soil depletion as practised in the United States of America and in our colonies is beginning to receive serious consideration from the agricultural economist. The continuous growth of grain crops and the failure to make any adequate returns of plant food to the soil soon lead not only to a lack of food reserve, but also to the loss of those organic compounds which are of such importance in the production of crops in dry regions. This in itself is deplorable enough, but even where manure is to be had much of its fertilising value is wasted. Dr. van Slyke puts forward the interesting computation that the annual loss caused by the careless treatment of the manure produced by the different farm animals in the States is equivalent in value to an annual wheat crop in that country, or to 700,000,000 dollars.

With a view to minimise this and similar losses caused by haphazard use of artificial manures, this book has been written, and is designed to meet the requirements of farmers and classes in agricultural colleges and high schools. The treatment is such as to lay a foundation in the general principles relating to soil fertility and plant nutrition, and to stimulate a desire on the part of the reader to know more about the subjects discussed. In this way it would serve as an introduction to special treatises on agricultural chemistry, soil physics, plant physiology, soil bacteriology, &c.

The four parts of the book each contain a number of chapters under the heading of factors of soil fertility, sources and composition of materials used as fertilisers, factors in the selection of fertilising materials, and the practical use of fertilisers in the growing of individual crops. The last part is distinctly valuable from the grower's point of view.

The book is copiously illustrated and is to be warmly recommended for anyone interested in the production of farm and garden crops.

(2) The second publication would appear to be intended for a large and general class of readers, viz., the members of farm households. The subject matter is divided into fifty-two chapters, and deals in a brief manner with many questions, not perhaps vital, but incidental to success and comfort in farming. The book contains advice on the general arrangements of farm buildings, the care and feeding of the cow, butter- and cheese-making, milk-testing, and the treatment of the common diseases of cattle. In perusing this book one cannot help feeling that much of the space occupied by minor issues might well have been devoted, with much advantage, to a more detailed treatment of farm operations; for instance, the mixing of limewash is given as much prominence as the discussion of feeding rations. The book is well illustrated and might possibly conduce to a better understanding of farm and dairy work.

(3) Prof. Eriksson's work will be welcomed by agriculturists and horticulturists as a valuable contribution to our literature on the subject. It is intended, primarily, as a practical guide for planters and to enable them to recognise, prevent and battle with diseases often occurring in practice. Bacterial and fungal diseases of common farm and garden crops are admirably described and preventive and remedial measures are treated in detail. A special chapter deals with unexplored diseases, whilst a useful appendix of diseases, arranged according to the host plant, is included.

TOPOGRAPHY AND GEOGRAPHY.

(1) *The Land of Goshen and the Exodus.* By Sir Hanbury Brown, K.C.M.G. Second edition. Pp. 92+2 maps. (London: Edward Stanford, 1912.) Price 3*s.* net.

(2) *Rambles in the Pyrenees and the Adjacent Districts, Gascony, Pays de Foix and Roussillon.* By F. Hamilton Jackson. Pp. xii+419. (London: John Murray, 1912.) Price 21*s.* net.

(3) *The Oxford Country.* Its Attractions and Associations described by several authors. Collected and arranged by R. T. Günther. Pp. xvi+319. (London: John Murray, 1912.) Price 7*s.* 6*d.* net.

(4) *Man and his Conquest of Nature.* By Dr. M. I. Newbigin. Pp. viii+183. (London: A. and C. Black, 1912.) Price 2*s.* (Black's School Geography Series.)

(1) SIR HANBURY BROWN takes the opportunity of this second edition of his study of the journey of the Israelites from Egypt to deal with some of the criticisms met with by the first edition. The subject is one which has received attention from a number of writers in

various aspects, such as the direction of the exact route followed, and the explanation of the various events which preceded and accompanied the journey, and bear on their face in the original narrative an appearance of the supernatural; for some of these natural explanations are afforded, as in the case of the passage over the Red Sea, without imposing any strain upon the received text. The short volume carries the journey as far as Elim, and the discussion is illustrated with two maps, which are noteworthy as indicating the author's view of the further northward extension of the Arabian Gulf at the time of the Exodus.

(2) Mr. Hamilton Jackson has produced a beautiful volume on a fascinating region. He deals with the Pyrenean lands from a general descriptive point of view, but his main interest, which is that of architecture, obtains the greatest share of attention, not only in his text, but more especially in the fine illustrations which come both from his own pen and from photographs by Mr. J. C. Ashton, which are excellent, and excellently reproduced. The French Pyrenean country is one of which travellers from this country know less than it deserves. Some of its monuments of antiquity, such as the city of Carcasonne and the church of St. Bertrand de Comminges, are unsurpassed in interest elsewhere in Europe, and of these and many others the author supplies full descriptions.

(3) It was a happy idea to bring together a collection, by various authors, of articles which have appeared from time to time in *The Oxford Magazine* and elsewhere, on the country neighbouring to Oxford, its geology, natural history, archæology, and the like. The territory, within a radius (let us say) of twenty miles of Oxford, is one which includes a remarkable variety of types of English rural scenery, such as the fresh charm of the Thames above Oxford and its more mature beauties below, the bolder scenery of the hills south of White Horse Vale, or the curious fen-like expanse of Otmoor. This country succeeds in exerting its charm over a good proportion of the sons of Oxford, among whom many well-known names appear as authors in this volume. Among writers who discuss scientific studies of one sort or another may be mentioned Prof. Poulton, Prof. Warde Fowler, Dr. Aplin, and Mr. Claridge Druce; while no less notable are the names of those who deal with other aspects of the country. The volume has been excellently arranged by Mr. R. T. Günther, who contributes a chapter on the Rollright Stones.

(4) Dr. Newbigin has already in her "Modern Geography" shown herself to be a student of that subject along the lines indicated chiefly by the name of "human geography," an important department which is receiving continually growing attention as an educational topic. In the present volume she deals mainly with the economic aspect in this department, showing how certain regions are suited, whether well or ill, by their climatic and physical conditions, for the cultivation of plants of economic value; how the distribution of minerals affects human settlement, and also how the products of the sea have done so. She deals skilfully with the inter-relation of these considerations in their effect upon the density of settlement and upon conditions of life. The book is suited for teachers and more advanced students; it has none of the less attractive characteristics of the school-book.

OUR BOOKSHELF.

Ueber die Einwirkung von Wasser und Natronlauge auf Baumwollecellulose. By Dr. Ing. Michael Robinoff. Pp. ii+94. (Berlin: Gebrüder Borntraeger, 1912.) Price 3.60 marks.

THIS is an account of investigations of cotton cellulose in regard chiefly to constitutional modifications determined by treatment with water, and with alkaline solutions (NaOH) under widely varied conditions of action. The author's work further confirms the diagnostic value of the reactions of cellulose with cupric oxide (alkaline solution), viz., (*a*) the reaction of combination, or fixation of CuO; (*b*) reduction.

These have been brought into prominence by Prof. C. G. Schwalbe, and are adopted, together with a special terminology, by a number of workers in Germany. The quantitative results are expressed as coefficients in terms of Cu per cent. cellulose, but under descriptive terms, such as "Cellulosezahl," "Korrigierte Cellulosezahl," which are not happily selected.

The results recorded are of considerable empirical value, and the author keeps with evident intention to a strictly empirical interpretation, particularly pointing out the bearings of the constitutional modifications resulting from the action of water at temperatures 100° to 150° C., dilute solutions of sodium hydrate (1-5 per cent. NaOH) at similar temperatures, more concentrated solutions in the cold (mercerisation reactions), upon the various treatments of cellulose textiles incidental to "bleaching" and lustre-finishing.

By means of the careful systematic application of the reactions in question, he is enabled to establish constitutional modifications of cotton cellulose resulting from treatments of such feeble chemical intensity as (1) contact with highly dilute acids in the cold, and (2) the papermakers' beating processes, in the convincing form of self-consistent numbers. He is thus able to confirm the general statements in the leading text-books, that cellulose responds to all and any chemical treatment, however feeble, by constitutional changes, and, as a particular case, that the beating preparation of the fibrous celluloses is in effect a hydration process.

The Main Drainage of Towns. By F. Noel Taylor. Pp. xi+313; illustrated. London: Charles Griffin and Co., Ltd., 1912.) Price 12*s.* 6*d.* net.

DESPITE the fact that this book is entitled "Main Drainage of Towns," the author has attempted the almost impossible task of dealing, in the course of 295 pages, not only with matters strictly pertaining to main drainage work, but also with questions of house drainage, the theoretical side of sewage disposal, sewage disposal works, &c.

It is therefore scarcely surprising to find that the author has not been successful in his treatment of the whole of the above subjects, particularly as throughout the work there is unmistakable evidence of the lack of that careful revision of the text so essential to the production of a scientific work of value.

In justice to the author, it should be stated that he has collected a great deal of useful information in regard to main drainage work, together with a large number of plans, tables, &c., which must have entailed considerable labour. On the other hand, the value of the book is very seriously impaired by the careless way in which it is written, the errors in composition being in many cases so serious as to render the meaning of the text obscure.

Careful perusal of the chapters relating to the theory of sewage disposal, sewage disposal works, &c., clearly indicates that the author would have been well advised to have left this part of the subject alone, especially in view of the various excellent text-books already available on the subject of sewage purification.

The book contains sufficient material for the production of a useful work on the subject of main drainage providing the matter is carefully edited, but as published it certainly cannot be recommended. E. A.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Tribe of White Eskimos.

CONSIDERABLE interest has been aroused by the announcement made by M. Vilhjalmar Stefansson (see NATURE of August 22, p. 644), communicated to the Press through Reuter on September 10, that he had discovered a tribe—or, to be more accurate, thirteen tribes—of white Eskimos living in the neighbourhood of Coronation Gulf and Victoria Island. It is stated that ten of these tribes had never heard of white people—other than themselves. Consequently, it cannot be assumed that this fair complexion is derived from the intercourse, so frequent in recent times, between Eskimos and the men of whaling ships. The telegraphed account states that "M. Stefansson believes the white Eskimos are descendants of the colony which set out from Norway to Greenland some time after the discovery of that island. Ethnologically, the white Eskimos bear not a single trace of the Mongolian type, differing in the shape of the skull and general features, colour of eyes, and texture of hair, which in many cases is red. They spoke Eskimo, though the explorer thought he detected some Norse words. They probably numbered two thousand. Many of them had perfectly blue eyes and blonde eyebrows."

It is, of course, quite possible that a newspaper correspondent may have given a very free rendering of the statements made to him by M. Stefansson. But, in any case, it is important to bear in mind that a description of a race of fair-complexioned Eskimos, living on the shores of Davis Straits, was printed in Europe in 1658. This account occurs in De Poincy's "Histoire Naturelle & Morale des Iles Antilles de l'Amérique," which was published at Rotterdam in that year, and contains a chapter (xviii.) incorporating the narrative of Nicolas Tunes, captain of a Flushing vessel, just returned from Davis Straits at the time when De Poincy was occupied with a description of the narwhal—a subject which led him into a long digression on the hunters of the northern narwhal. De Poincy indicates the locality in question in the following terms, here translated from his somewhat archaic French:—"The captain, from whom we have received this narrative, having set out from Zealand at the end of the spring of 1656, with the intention of discovering some new source of trade in those northern lands, arrived at the end of June in Davis Straits, whence, having entered a river which begins at 64° 10′ N. lat., he sailed to the seventy-second degree, where the land about to be described is situated."

A very full description is given of the natives, but only the following sentences need be quoted here:—"As regards the inhabitants, our travellers report having seen two kinds, who live together on the most friendly terms. Of these, one kind is described as very tall, well-built, of rather fair complexion, and very swift of foot. The others are very much smaller, of an olive complexion, and tolerably well-proportioned, except that their legs are short and thick. The former kind delight in hunting, for which they are suited by their agility and natural disposition, whereas the latter occupy themselves in fishing. All of them have very white, compact teeth, black hair, animated eyes, and the features of the face so well made that they present no notable deformity. Moreover, they are all so vigorous and of such a strong constitution that several of them who have passed their hundredth year are still lively and robust."

In the small, olive-complexioned, short-legged people here described, there is no difficulty in recognising true Eskimos. Those of the tall, comparatively fair type may easily have been the descendants of the Norse colonists, intermingled, it may be, with Eskimos. It is believed by many—for example, by Dr. Nansen ("In Northern Mists," London, 1911, vol. ii., p. 103)—that the early Norsemen in Greenland were not exterminated by the Eskimos, but were gradually absorbed by them through successive intermarriages. Admitting this, it would seem that the fusion of the two races was still only partial in 1656. Tunes and his comrades speak of black hair as common to both types, but that need not mean much. If black hair was not common among tenth-century Norsemen, there would have been no distinction in Harald's designation of *haar-fager.*

However, the point is that an expedition of the year 1656 reported a tall, light-complexioned caste of natives living on the shores of Davis Straits at the same time as others of genuine Eskimo type. It is quite possible that the former, still retaining their individuality, may have migrated westward to Victoria Land. DAVID MACRITCHIE.

4 Archibald Place, Edinburgh, September 23.

Antiquity of Neolithic Man.

THE letter of Mr. J. Sinel, in NATURE of September 19, on the submerged forest bed in Jersey, deals with several questions of great interest in relation to the submerged forest on the south-western coast of Wales. I hope to publish shortly an account of this forest-bed (so far as it is seen in Pembrokeshire) and the deposits associated with it, but in the meantime I may state that I have found worked flints—flakes and cores—in two localities on the Pembrokeshire coast in positions which correspond with that of the stratum of blue clay below the forest-bed at St. Heliers. These flints were clearly worked by men who inhabited the woodland, now submerged, before the trees fell into decay and formed the peaty mass of trunks, branches, leaves, &c., overlying the true root-bed of the "submerged forest." One locality near Amroth, in Carmarthen Bay, yielded cores and flakes in abundance; the circumstances indicate the existence of a chipping-floor or implement-factory on this part of the submerged land-surface, which now, during spring tides, is covered by not less than 20 ft. of water. In the patch of submerged forest recently exposed at Freshwater West, in southern Pembrokeshire (see NATURE, March 28, 1912), a few small flint implements were also found.

Both at Amroth and Freshwater West the flints occurred below the peaty layer in a thin blue slime or clayey silt, which rests in turn upon clayey rubble largely composed of material derived from older superficial deposits. There is evidence that the forest trees in Pembrokeshire are rooted either in unquestionable glacial Boulder Clay or in a clayey drift allied to the glacial deposits. There appears, therefore, an interesting agreement in the character of the substratum of the submerged forest in Jersey and on the Pembrokeshire coast, and the agreement further extends to the composition of the peat. All the plants (with others) mentioned by Mr. Sinel occur in the peat near Amroth and the remains of beetles are fairly common.

A point of difference, which may be more apparent than real, between the two localities, is the occurrence, according to Mr. Sinel, of blue "marine" clay below the peat at St. Heliers. In Pembrokeshire the blue slime, whence the flints were obtained, has yielded no evidence of marine origin; it appears rather to resemble an old marsh silt which developed into swampy soil, but it is quite possibly only the estuarine fringe of a marine clay which is now wholly submerged. The deposits, it may be, would be similar if compared at corresponding levels.

The geological horizon of the worked flints of the Pembrokeshire submerged land-surface appears identical with that of the Neolithic implements from St. Heliers. One of the most important questions that arises is whether these implements are so distinctively Neolithic in character as to exclude the possibility that they may belong to an earlier period. Two implements from the Pembrokeshire submerged forest were submitted to Mr. Reginald Smith, of the British Museum, but they were not found sufficiently characteristic in form to be dated according to modern detailed classifications of implements.

The term "Neolithic" is frequently applied to any surface finds of implements which are unabraded and not obviously of the familiar heavy Palæolithic forms. But while on the one hand many so-called "Neolithic" implements belong to the later prehistoric ages of Bronze and Iron, on the other hand some surface sites yield implements closely resembling Late Palæolithic types. This is so, for instance, in South Pembrokeshire, where recently I have obtained from several chipping-floors on the high ground bordering the coast a number of small implements, amongst which Mr. Reginald Smith has recognised several scrapers, probably of Late Palæolithic (Aurignacian) types. But some of these early forms occur on sites which have yielded also typical Neolithic tools (with ground edges) and pottery, and, moreover, it is not yet possible to show that they are older than the submerged forest.

I join with Mr. Sinel in expressing the hope that other records of implements from the submerged forest may be obtained, but further I should like to suggest that it is of great importance that all finds should be compared with the series of implements in our national collections in order that their age may be definitely ascertained. A. L. LEACH.

Giltar, Shooter's Hill, London.

Human Jaw of Palæolithic Age from Kent's Cavern.

PROF. A. KEITH, in discussing the paper read at Dundee by Prof. Boyd Dawkins for Dr. Duckworth on the fragment of a jaw of Palæolithic age from Kent's Cavern, is reported by *The Times* to have said that "the whole thing was ridiculous and was not even scientific, for the specimen had not been shown in the position in which it had been found."

The specimen in question is in the museum of the Torquay Natural History Society. Its position has been defined in the late Mr. W. Pengelly's reports to the British Association, and more particularly in his Cavern Note-book and Diary, which are at present, with all his other records of Kent's Cavern, in the possession of his elder daughter, Mrs. Louis Maxwell.

By the kindness of Mrs. Maxwell, I have had the opportunity of examining the diary, and have also had a look at the specimen now in its place in the museum. The actual record of the fragment is as follows:—"Thursday, January 3 [1867]. To the Cavern. The objects found to-day were as below:—

"No. 1930. In granular stalagmite. 7th Parallel, including part of a Human Jaw, a Flint Flake, a well-rolled Flint pebble from which a chip had been broken."

In the British Association's Third Cavern Report, 1867, the further fact is stated, viz. that the object was found "'about 30 feet from the Northern Entrance to the Cavern and deeply imbedded in Granular Stalagmite 20 inches thick."

The position of the jaw in the cavern is thus ascertainable to a few feet, and its depth in the stalagmite to a few inches. But it tells its own tale. It is practically a specimen of the characteristic granular stalagmite, which seems to have been of Palæolithic age throughout. Pengelly mentions (Fifth Report) how cave bear, hyæna, and rhinoceros were met with not only in the granular stalagmitic floor, but quite at its upper surface (Trans. Devon Assoc., v., xvi., p. 250). Indeed, Pengelly records the occurrence of a tooth of rhinoceros found in another part of the cavern (No. 4090, found May 27, 1869), "which was not only in quite the upper part of the stalagmite, but instead of being completely covered, projected above its surface" (Trans Devon Assoc., vol. xvi., p. 207).

Having known Kent's Cavern long before the British Association exploration, and having been instructed therein by Mr. Pengelly for cave research elsewhere, I trust you will permit me to bear this testimony to the accuracy and detail of Pengelly's Kent's Cavern records.

I may mention that in 1884 Pengelly collected the whole of the sixteen Kent's Cavern reports in a single paper to the Devonshire Association. Not only is this paper much more convenient for reference than the reports scattered over sixteen years of the British Association, but occasional notes review the early evidence. For instance, with reference to the jaw under discussion Pengelly adds the remark, "Nothing of the kind was subsequently met with in or under the Granular Stalagmite" (*loc. cit.*, p. 221).

A. R. Hunt.

Torquay, September 16.

Mr. Hunt is under a misapprehension regarding my criticism of Prof. Boyd Dawkins's communication at the Anthropological Section of the British Association at Dundee. In making the important announcement that the remains of Neanderthal man had been discovered in England, Prof. Dawkins exhibited merely a rough sketch of a fragment of a human jaw —not the actual specimen itself. So far as the sketch went it showed none of the usual Neanderthal characters. Further, he was unable to say from which stratum of the floor of Kent's Cavern the original specimen had been derived. My criticism of "ridiculous" and "unscientific" applies merely to the fact that the meeting was asked to accept the discovery of Neanderthal man in England on a specimen which was absent and of uncertain origin. From Mr. Hunt's communication it is clear that the exact origin of the specimen could have been ascertained. I firmly believe that the remains of Neanderthal man will be discovered in England—it may be that Dr. Duckworth is right regarding the specimen from Kent's Cavern—but the discovery cannot be accepted unless the evidence is produced.

A. Keith.

EXPERIMENTAL RESEARCHES ON VARIATIONS IN THE COLOURING OF LEPIDOPTERA.[1]

This is a very comprehensive treatise by Dr. Pictet, a former treatise by whom on a cognate subject was reviewed in Nature in 1905 (vol. lxxii., p. 632). It begins with a *résumé* of previous researches by various authors, classified under several heads, and proceeds to describe the author's own researches and the conclusions he draws from them. Many of the details are highly interesting, and his observations upon them are of much weight.

Lepidoptera, Dr. Pictet tells us, with few exceptions, vary in only two directions, melanism and albinism; the law laid down by Oberthur may be thus summed up: Any part of the wing of a butterfly can become separately darker or lighter than it is normally; in the former case, whatever its colour (except green) it can darken sufficiently to become brown, and even of so deep a brown as to have the appearance of blackness, leading in all the parts so darkened to melanism; in the latter case these same parts can become lighter, sufficiently to become tawny (*fauve*), yellow, and even of a yellow so pale as to appear white, leading, in like manner, to albinism.

The dark markings of the wing can spread or be displaced, or merge in neighbouring parts, or mask them more or less completely, or they can contract, become partly effaced, or even disappear, giving place to the light markings of the ground colour (*fond*). In other cases certain markings may become darker, and others lighter, or the general colour may become darker or lighter without altering the pattern. Opposite exciting causes, *e.g.* heat and cold, may produce the same result, this being caused, not by the special quality of the abnormal factor, but by the fact of the passing of the individual from a normal environment to that which does not suit it.

Among the exciting causes M. Pictet includes, but apparently with some doubt, electricity and mechanical vibration (*trépidation*)—the last, I believe, has been abandoned.

As regards the mechanism of variation, this has its principal seat in the scales, all of which, whether red, yellow, white, brown, or black, as well as the blue and violet ones, are striated on the surface so as to be capable of displaying the optical colours, and most of which are more or less filled with pigment in a granular form. The optical effect is related to the quantity of pigment in the scale, the intensity of the iridescence growing in inverse proportion to the pigment. In many cases the basal part of a scale is less filled with pigment than the distal part. Where the colours of the wing are light, the scales generally contain less pigment than where the colours are darker. There are, however, white pigment scales, as in the Pierids.

There are various ways in which melanism may be caused:—(1) The contained pigment may be greater in quantity; (2) it may be more strongly oxidised, which darkens it; (3) where there are both light and dark scales the latter may increase in number; (4) the scales may become so numerous as to overlap each other, and thus reinforce the darkness; (5) the scales may be enlarged, which increases the overlapping; (6) dark hairs may increase in number—like the scales, these are susceptible of change in their colouring matter; (7) one face of the wing may appear darker if, owing to the small quantity of pigment in its scales, the darker opposite face of the wing shows. Converse considerations apply to the causation of albinism; as regards (5), a very frequent cause, the scales may so diminish in size that instead of overlapping they scarcely touch, and leave empty spaces; they may diminish in size on both sides of the wing, which thus becomes transparent. (6) They may curl up at the sides, producing similar consequences to those numbered (4) and (5).

There is a very interesting chapter on cases where the optical and the pigmentary effects are combined. Green in the Pierids is not caused by green pigment, but by a mixture of yellow and black scales having *reflets bleus*; and in *V. io* the violet and green is caused by red and yellow scales mixed with white scales having *reflets bleus*.

The cause of variation may be generally stated thus. An individual which in the course of its ontogeny makes less pigment than its congeners, albinises; inversely, it melanises if it makes more pigment than is normal; the quantity of pigment

[1] "Recherches Expérimentales sur les Mécanismes du Mélanisme et l'Albinisme chez les Lépidoptères." By Dr. Arnold Pictet. Mémoires de la Société de Physique et d'Histoire naturelle de Genève, vol xxxvii. Pp. 111–278+5 plates. (Genève: George & Cie.; Paris: G. Fischbacher. 1912.)

is much more important than chemical modification of it.

The author states that his researches confirm in some measure a fact which seems general among animals, viz. that melanism is a sign of vigour and health; albinism, on the contrary, of the enfeebling of the organism. In melanism we have great abundance of pigment, increase in the size of scales and sometimes in their number, usually greater size, the females generally with voluminous abdomen, full of eggs: among Bombyces a great increase in pilosity. In albinism, on the other hand, we have the opposite state of things; the scales also frequently deformed, curled, and atrophied, the wings often failing to develop, the abdomen slender, with few eggs or none; in the Bombyces little pilosity.

The author refers to Standfuss's hypothesis that this enfeebling may begin in the larva, and to his own experiments supporting this. Caterpillars ill-nourished, having been supplied with leaves they could ill bite into, produced imagines struck with albinism, supporting the view that albinism is a sort of anæmia of the organism. These modifications increase in succeeding generations subjected to similar conditions, but at the end of four generations the caterpillars adjust themselves to the leaves they found difficult, and then recover their vigour, size, and habitual colour. There are certain characters which exposure to abnormal conditions does not seem able to modify, such characters as are common to a group or genus, for instance, the discoidal spot of *L. quercus*, and the discoidal V. of *Ocneria dispar*.

Dr. Pictet's valuable researches certainly cannot be considered to exhaust the subject of the cause of variation in the colouring of lepidoptera. In the case of seasonally dimorphic species, for example, experiments seem to have shown that the difference in colouring is dependent more on the differential life habit of the spring and summer emergences than on mere exposure to environment or change of environment. With many lepidoptera long duration in the pupal stage, such as is produced by a low temperature, usually causes darkness, but in *A. levana* cooling the summer pupa for many months results in an imago so much brighter than the nearly black imago which comes from a pupal life in a summer temperature of five or six days that it looks quite a different species.

F. MERRIFIELD.

THE SENSITIVENESS OF SELENIUM TO LIGHT OF DIFFERENT COLOURS.

SOME curious facts about the behaviour of the selenium cell are mentioned in a recent paper by A. H. Pfund.[1] The possibility of using these cells for ordinary photometric processes has often been discussed, but there are certain irregularities in their behaviour which set a limit to their usefulness.

One obvious difficulty lies in the fact that the rays of light to which the eye is most sensitive are not necessarily those which have the most effect on selenium. Pfund brings this out by reproducing—what has seldom been published before—a curve showing the distribution of sensitiveness of this material throughout the spectrum of a Nernst filament. The energy-maximum in this spectrum lies far out in the infra-red; the maximum luminosity to the eye (at moderate illuminations) is situated in the yellow-green. The maximum sensitiveness of selenium, however, is located in the red, and the shape of the curve is also distinctly different from the luminosity curve for the eye, so that inconsistent results would evidently be obtained if one tried to compare the light from various illuminants (having radically different energy-curves) by means of the selenium cell. But it may be mentioned that, according to a recent number of *The Illuminating Engineer*, such cells have a possible sphere for purely comparative measurements of one and the same illuminant; for example, they have been used for studying the fluctuations in daylight and the variation in illumination in the course of an eclipse.

Perhaps the most curious point brought out in these researches is the dependence of the maximum sensitiveness of the selenium cell on the intensity of the stimulus. With a very bright light the maximum is in the red, near $0{\cdot}7\,\mu$. But as the illumination is weakened, this maximum becomes less definite, and ultimately, in a feeble light, another maximum point, situated about $0{\cdot}57\,\mu$, appears. Ruhmer makes two kinds of selenium cells. The "hard" type is most sensitive to strong light, but relatively insensitive to feeble stimuli, and has its maximum in the red. The "soft" type, on the contrary, is most sensitive to weak light, and has its maximum in the green. This explains the discrepancies between earlier observers, some of whom found selenium to be most sensitive to yellow light, while others thought that red had most effect.

Now the interesting point to observe here is that this behaviour of the selenium cell is curiously similar to that of the eye. It is a well-authenticated fact, demonstrated many years ago by Sir Wm. Abney, that whereas at strong illuminations the maximum luminosity occurs near $0{\cdot}58\,\mu$ in the yellow, in weak light it shifts to the green, probably near $0{\cdot}51$–$0{\cdot}53\,\mu$. This is known as the Purkinje effect. In very feeble light the eye seems almost insensitive to red, while green and blues appear an uncanny light grey. Formerly this singular effect was ascribed to a struggle for predominance between the minute light-perceptive organs on the retina known as the "rods" and "cones." But, according to a later theory, this is not necessarily so, for the accentuation of the red end of the spectrum with increasing stimuli is characteristic of all photo-chemical processes.

At all events the similarity between the eye and the selenium cell in this respect is very suggestive. At first sight this complicated behaviour of selenium would seem unfavourable to

[1] *Phys. Review*, xxxiv., No. 5, May, 1912.

its extended use in photometry. But in a sense it appears fortunate, since it suggests that one might conceivably prepare selenium in such a way as to follow out almost exactly the behaviour of the eye as regards the perception of luminous energy.

NOTES.

THE typhoon which recently visited Japan, isolated Tokyo telegraphically from September 22 to 24, and carried widespread devastation, is said to have been the severest experienced in half a century. Accounts so far are meagre, but according to reports already received the loss of life and damage to property afloat and on shore are appalling. The storm appears to have been most violent in the middle of the south coast. Typhoons are revolving storms of tropical origin that may occur in Far Eastern seas—the North Pacific or the China Seas—during any month of the year. In Japan and its neighbourhood they are, as a rule, confined to the months of June to September inclusive, and are most frequent in September. In general, all tropical revolving storms follow a parabolic track. The typhoons that visit Japan in September usually originate in the Pacific south-eastward of Formosa, move N.W. by W., recurve when abreast of that island, and then take the direction of the Japan Sea. Algué divides the tracks of typhoons in the Far East into two classes—those of the Pacific, which do not cross the meridian of 124 E., and those of the China Sea. A typhoon is said to travel rapidly when its rate of motion exceeds twelve nautical miles an hour; if its rate of motion be less than six miles an hour it is said to travel slowly. The September typhoons come under the former category.

DURING the recent meeting at Geneva of the fourteenth International Congress of Prehistoric Anthropology and Archæology, an important piece of work was carried out by the Committee for the Unification of Anthropometric Measurements. The committee (or commission) included representatives of most of the European countries, as well as of the United States of America, and the number amounted to about thirty. Dr. Duckworth (of the Cambridge Anthropological Laboratory) was one of the three secretaries appointed to prepare a report of the proceedings. The secretaries made out a report, which was adopted at the final meeting of the commission, and was confirmed at the concluding meeting of the congress. The official report will be published in French, but it is intended to issue translations in English and in German simultaneously, if possible, with the official version. The illustrations are to be uniform in all three publications. Dr. Duckworth is at present engaged (for the third year in succession) upon excavations at Gibraltar, but he will be pleased to give further information as to the above-mentioned report after his return to England early this month. Communications should be addressed to the Anthropological Laboratory, New Museums, Cambridge.

A CONFERENCE of members of the Museums Association and of others interested in similar work will be held on the afternoon of Thursday, November 7, at the Manchester Museum, for the purpose of discussing subjects of common interest to those concerned in the work of museums, art galleries, and kindred institutions.

THE Huxley lecture will be delivered at Charing Cross Hospital Medical College on Thursday, October 31, by Prof. Simon Flexner, of the New York Rockefeller Institute, on "Recent Advances in Science in relation to Practical Medicine." On the same day the extensive new laboratories of public health and bacteriology, recently formed by the school and taken over by the University of London as the public health and bacteriological departments of King's College, will be formally opened and handed over to the University.

ON the suggestion of Mr. Mark Sykes, M.P., Sir Tatton Sykes has kindly sent for exhibition in the Hull Museum the objects of prehistoric date in his possession. These include the contents of the famous Duggleby Howe burial mound, which contained flint and bone weapons and implements of exceptional interest; a prehistoric jet necklace containing several hundred beads; a fine series of prehistoric implements in flint, sandstone, bronze, &c., and some earthenware vases taken from British burials on the Yorkshire Wolds.

THE extensive collection of east Yorkshire and north Lincolnshire diatoms, made by the late R. H. Philip, of Hull, also the specimens which have been figured and described in the well-known work by Mills and Philip, together with his microscope, a fine collection of microscopical slides (including several made by Robt. Harrison, a former Hull microscopist), and his scientific books, have been presented by Mrs. Philip and family to the Hull Museum. The collection of slides contains more than 3000 specimens, and among the books are such important works as "Diatomées Marines de France," by MM. H. et M. Peragallo; "A Treatise on the Diatomaceæ," by Van Heurck; "Diatomaceæ Germaniæ," by H. von Schonfeldt; "British Desmidiaceæ," by W. West, and numerous other volumes dealing with microscopy.

THE British Fire Prevention Committee opened its autumn session on September 25 with two important series of official fire tests, namely, (1) a series of twenty tests with ordinary celluloid kinematograph films *versus* a non-inflammable celluloid film; and (2) an extensive series of some twenty-five fire tests as to the possibility of extinguishing petrol fires, celluloid fires, and similar outbreaks by the application of chemical foam. Reports upon the tests, which were witnessed by representatives of about thirty Government departments and other institutions, will be published by the committee later.

THE next meeting of the Australasian Association for the Advancement of Science is to be held at Melbourne in the University, from January 7 to 14, 1913, under the presidency of Prof. T. W. E. David, C.M.G., F.R.S., Sydney. The presidents of the various sections are as follows:—A, Astronomy, Mathematics, and Physics, Prof. H. S. Carslaw, Sydney; B, Chemistry, Prof. C. Fawsitt, Sydney; C, Geology and Mineralogy, Mr. W. Howchin, Adelaide; D, Biology, Prof. H. B. Kirk, Wellington, N.Z.; E, Geography and History, Hon. Thos. M'Kenzie, Wellington, N.Z.; F, Ethnology and Anthropology, Dr. W. Ramsay-Smith, Adelaide; G1, Social and Statistical Science, Mr. R. M. Johnston, Hobart; G2, Agriculture, Mr. F. B. Guthrie, Department of Agriculture, N.S.W.; Subsection, Veterinary Science, Prof. Douglas Stewart, Sydney; H, Engineering and Architecture, Colonel W. L. Vernon, Sydney; I, Sanitary Science and Hygiene, Dr. T. H. A. Valintine, Wellington, N.Z.; J, Mental Science and Education, Sir J. Winthrop Hackett, K.C.M.G., Perth, W.A. In addition to the meetings of the sections, arrangements are in progress for evening lectures and entertainments, and for excursions to places of interest. Full particulars can be obtained from the permanent hon. secretary, Mr. J. H. Maiden, Botanic Gardens, Sydney. The hon. treasurer for the Melbourne meeting is Mr. G. H. Knibbs, C.M.G., Melbourne, and the general secretary Dr. T. S. Hall, University, Melbourne.

Dr. W. E. Garforth has recently presented to the University of Leeds and placed in the geological department a large case containing specimens which show the structures of numerous seams of coal from Yorkshire, Lancashire, Staffordshire, and Australia. The lower part of the case contains coal-balls, or bullions, which are found in the Halifax Hard Bed of Yorkshire and its equivalent, the Bullion Mine, in Lancashire. The coal-balls are simply masses of vegetable material which were impregnated with calcium carbonate while the tissues were still in a fresh condition, and so preserved during the subsequent changes which the surrounding vegetable matter underwent in the process of its conversion into coal. Many of the microscopic sections of these coal-balls are of an extraordinary size, measuring 8 in. by 6 in., and show the structure of the plants most beautifully. The centre of the case is occupied by a series of models illustrating the structure of Lepidostrolius, the "fruit" of Lepidodendron and its allies, showing the position of the megasporangia and microsporangia. Perhaps the most interesting sections are those from coal seams in which explosions have occurred, such as those from No. 3 Bank Pit, Atherton, near Bolton. These were prepared with the view of ascertaining whether any connection could be traced between the microscopic structure of the coal and the character of the coal dust, and were the first sections to be prepared for that purpose. The whole of the sections were made by the Lomax Palæobotanical Co., Bolton, and the case was exhibited at the Franco-British Exhibition.

In *L'Anthropologie* for June-July-August, MM. C. Maska, H. Obermaier, and H. Breuil describe a remarkable discovery of an ivory statuette of a mammoth found near the village of Prerau, not far from the battlefield of Austerlitz. This site has already supplied a vast number of remains of extinct animals and flint implements of the palæolithic period. The present figure measures 116 mm. in length and 96 mm. in breadth. It represents the animal with full details of head and trunk. It is referred to the Salutrian Age, and is thus much older than the carvings of the animal in the flat from La Madelaine, Combarelles, Font-le-Gaume, and Pindal in Spain, of which drawings for the purpose of comparison are supplied in the article. This is the finest representation hitherto found of this great beast which flourished for ages in the steppes and prairies of ancient Europe, and was hunted for food by its early races.

The *National Geographic Magazine* for July devotes one of its usual well-illustrated articles to an exploration of the little-known parts of Panama by Mr. H. Pitter. The Guaymies, one of the aboriginal tribes, who were formerly under the influence of Roman Catholic missionaries, have now reverted to their ancient customs and manner of life. Among the Suna-Cunis, while some of the men have visited the United States and Nova Scotia, and have thus acquired some degree of culture, primitive habits are perpetuated among the women, who have not as yet been allowed a glimpse of the outer world. The article, as a whole, gives an instructive picture of the gradual acquirement of a new phase of culture in its varied forms.

In the report of the Warrington Museum for the year ending June 30, the director and librarian records some progress in all departments, but no change in the programme, of that institution.

In an article on type-specimens, published in the August number of *The Victorian Naturalist* (vol. xxix., p. 59), Mr. F. Chapman proposes the new term "tectotype" for specimens, fragmentary or otherwise, selected to illustrate the external or internal microscopic characters of a species or genus. Such a specimen may be the section of a tooth, a flake of a shell, a slice of a foraminifer, or a preparation from a fossilised leaf.

Prof. W. L. McAtee commences a long article in the Proceedings of the Philadelphia Academy for June on the experimental method of testing the efficiency of warning and cryptic coloration in protecting animals from their enemies by the statement that the theories on this subject long preceded any knowledge of the food-preferences of insectivorous species sufficient to justify such speculations. At the conclusion he states that the behaviour of animals in captivity, as regards food, does not afford trustworthy indications of what they would do in the wild state when offered similar food, thereby showing that the results of such experiments do not indicate the parts the animals might play in natural selection. He therefore urges that the time expended in making such experiments might be better employed in collecting trustworthy data in regard to the food-habits of animals in the wild condition, as "the result would be truth, not imaginative inferences from abnormal behaviour."

It is a well-known fact that in certain aquatic hemipterous insects belonging to the genera Zaitha and Serphus, the females—in Europe, Japan, the West Indies, and America—are in the habit of attaching their eggs to the backs of their apparently unwilling partners, in such a manner as to form a complete coating. According to an article by Prof. J. F. Abbott in the September number of *The American Naturalist*, a somewhat analogous, although more remarkable, instance of abnormal "nursery arrangements" occurs in the case of a North American hemipterous insect (*Rhamphocorixa balanodis*) belonging to the family Corixidæ, which is related to the Notonectidæ, as represented by the well-known "water-boatman." In 1910 it was observed that many of the crayfish (*Cambarus immunis*) near Colombia, Mo., were more or less completely coated with the eggs of this insect, each egg being imbedded in a small cup fixed to the shell of the crayfish. Each crayfish carried hundreds of eggs, and as each female Rhamphocorixa lays comparatively few, several insects must have cooperated in investing the crayfish. It is suggested that the coating of eggs renders the crayfish less conspicuous than in its ordinary condition, just as crabs carrying colonies of algas, sponges, or sea-anemones probably profit in some manner by the investiture.

We have received from Dr. Friedrich König, of Krailling-Planegg, near Munich, a small pamphlet on the reconstruction of extinct vertebrate animals, with photographs of models which he has prepared in accordance with the principles he explains. He emphasises especially the important aid afforded by the new kinematograph films of wild animals in motion, and points out how much less hypothetical are restorations made with our present knowledge than those which were attempted some years ago. His pamphlet forms an interesting summary of the whole subject, its problems and difficulties, with full references to all the important literature. Among his own restorations that of Diplodocus is particularly striking, for he has tried to avoid the appearance of a sleek pachyderm by assuming the presence of a series of glands beneath the skin, which give the dorsal region of the body a segmented aspect.

In the September number of *The American Journal of Science* Prof. Roy L. Moodie publishes a detailed description of the remains of *Eobatrachus agilis* from the Upper Jurassic of Wyoming, U.S.A., and confirms the opinion of the late Prof. O. C. Marsh that they represent a true anourous amphibian. Prof. Moodie finds that the bones are closely similar to those of a modern toad, and he comments on the great interest of the discovery of so highly specialised an animal in rocks so ancient as those of the Jurassic period. He overlooks the fact, however, that a well-preserved skeleton of a frog, *Palaeobatrachus gaudryi*, is already known from the Upper Jurassic of northern Spain (L. M. Vidal, *Mem. Real Acad. Ciencias de Barcelona*, vol. iv., No. 18, 1902).

The Rev. M. Saderra Masó, the well-known student of the Philippine earthquakes, finds that most of the earthquakes in southern Luzon originate along three great fractures, two of which lie to the east and west of the island, and are roughly parallel to the coast-lines, while the third, and most important, traverses the Taal volcano (the seat of the disastrous eruption of 1911), and runs in a north-north-easterly direction, passing some miles to the east of Manila. The earthquakes which originate in the south-western part of this line are characterised by relatively long duration and rather slow undulations of large amplitude, while those which proceed from the north-eastern part of the fracture are more dangerous, owing to the rapidity of their vibrations. It is in the latter part of the fracture that the destructive earthquakes of Manila have for the most part originated.

All the available space in *Symons's Meteorological Magazine* for September is devoted by Dr. Mill to an account and preliminary map of the distribution of rain in East Anglia on August 26 and 27, which was altogether unprecedented for a cyclonic storm in that part of Great Britain. The relation of the track of the depression to the rain area was similar to that of the great Irish fall of August 24–26, 1905 ("British Rainfall," pp. [110]–[114]). On the morning of August 26 the Daily Weather Report issued by the Meteorological Office showed a depression off the North Foreland; by 6 p.m. it had moved northwards and deepened off the most easterly part of the Norfolk coast, and during the night turned to the right, across the North Sea. The storm seems to have been central close to Norwich, and the area of torrential rain lay in the north-east of Norfolk. The more important facts relating to the heavy rainfall are given in letters from several of Dr. Mill's staff of observers. Among these Mr. J. H. Willis, of Norwich, took the trouble to read his gauge twelve times between 4 a.m. of August 26 and 4 a.m. of August 27; he recorded 6·32 in. in the twelve hours to 4 p.m. of August 26, and a further inch exactly in the following twelve hours. Only 0·04 in. fell between 4 and 9 a.m. on August 27, making 7·36 in. in twenty-nine hours. Although the twenty-four hours in question do not count as a "rainfall day" (twenty-fours ending at 9 a.m.), and the amount does not compare with other falls, it has not been surpassed in the British Isles on more than two or three occasions. The remarkable amount of 8·09 in. was recorded at Brundall, five miles east of Norwich, for the two days. Dr. Mill computes that the county of Norfolk, with an area of 2044 square miles, had a general rainfall of probably 4·88 in., which would be equivalent to twice as much water as is contained in Windermere, the largest of the English lakes.

The Journal of the Franklin Institute for September contains an account of some experiments on the electrical precipitation of solid and liquid matter suspended in gases by Mr. W. W. Strong, of the department of industrial research of the University of Pittsburg. The suspended matter was obtained by blowing lime dust or the smoke produced by burning soft coal or the spray from a nozzle through which alcohol, ether, or toluol was forced, into the space between an earthed electrode and one connected to six different types of high-tension apparatus. The experiments show that the problem of precipitating smoke is identical with that of removing dust, and that the coronal discharge is much more effective than the brush discharge, especially with large velocities of the gas containing the suspended particles. With this type of discharge the size of the precipitating chamber may be materially reduced. The ionic currents due to secondary ionisation appear to play a more important part in the process than has been supposed.

In an interesting note in the *Gazzetta chimica italiana* (vol. xlii., ii., 85) by F. Calzolari, the relationship between solubility and electro-affinity is discussed with especial reference to the chlorates and perchlorates of the alkali-metals, potassium, rubidium, and cæsium. According to the electrochemical theory of Abegg and Bodländer, the solubility should diminish, in the case of these salts, as the atomic weight of the metal increases, so that the solubility of the rubidium salts should be intermediate between the solubilities of those of potassium and cæsium; actually, however, it was found that at 20° the solubility of the cæsium salts is intermediate between those of the potassium and rubidium compounds, whilst, owing to the crossing of the solubility curves at higher temperatures, the order of the arrangement is entirely different at different temperatures. The case is apparently similar with the nitrates. The solubility of these salts, which has been cited in favour of the theory of electro-affinity, is in reality not in accord with it.

The Biochemical Journal, vol. vi., part 3, contains an important paper by Messrs. E. S. Edie, W. H. Evans, B. Moore, G. C. E. Simpson, and A. Webster from the laboratories of biochemistry and tropical medicine of the University of Liverpool, on the question of the cause and curative treatment of beri-beri and polyneuritis. An alcoholic extract of ordinary yeast, after removal of the alcohol at a low temperature, is extremely active in curing the convulsions and lameness of birds suffering from polyneuritis. An organic base, to which the name *torulin* has been given, has been isolated from this extract; its nitrate has apparently the composition, $C_7H_{16}O_2N,HNO_3$, forms feathery crystals, and is not precipitated by basic lead acetate, although thrown down by phosphotungstic acid. The alcoholic yeast extract loses its activity on warming, and the active substance is apparently easily destroyed by heat. Experiments are in progress to ascertain whether birds can fully maintain their weight and activity on a diet of polished rice, which ordinarily produces neuritis, when taken in conjunction with small doses of torulin; or whether it will only prevent the onset of convulsions or nervous changes without being able to maintain full nutrition.

The Builder for September 27 gives some interesting particulars of ancient iron beams in India. At the Black Padoga of Orissa, Kanarak, there are some very large forged iron beams; the two largest members, as described by Mr. H. G. Graves, of Calcutta, are 35 ft. long by 8 in. square, and 25·5 ft. long by 11 in. square. The broken end of one of them indicates that the method of construction was by the welding up of billets. The age of the temple has been placed by some as early as the ninth, and by others as late as the thirteenth, century. Examination indicates that the small blooms were of 3 to 4 lb. in weight; in some places the blooms appear to have been welded together in strings to form short bars, which in turn were welded into place. No special care seems to have been taken to make the blooms break joint. The beams are nearly all of uniform size, and square in section from end to end. The designers do not appear to have understood the advantage of making the depth of the beam greater than the width. The beams could have been of but little structural value, although they constitute interesting examples of smiths' work.

Commenting on Sir W. H. White's address at the recent International Mathematical Congress, *Engineering* for September 27 states that it is not a little remarkable how little information mathematics is able to give us as to the strength of any engineering structure. In many cases, the service which mathematics renders is to furnish laws of comparison by which, without knowing the actual limits of the stresses, we can conclude that a structure which has successfully met certain conditions may be used as a basis for designing another similar structure, larger or smaller, to meet similar conditions. Perhaps the greatest service that mathematics can render to the engineer is in directing the course of a series of experiments and in analysing the results observed. There is unquestionably an immense mass of data uselessly pigeon-holed in the archives of manufacturing firms simply and solely because their technical staff are insufficiently equipped with mathematical knowledge to analyse these records effectively, and the art of the engineer and the profits of the manufacturer suffer in consequence.

Messrs. John Bartholomew and Co., of the Geographical Institute, Edinburgh, have published two additional sheets to their "half-inch to mile" map of Scotland. One sheet deals with Berwick and Haddington, the other with Inverness and Spey. The familiar greens and browns associated with this excellent series of reduced survey maps serve admirably to bring out the build of the country depicted, and the points of the compass arranged to show the magnetic variation, with the annual decrease of the variation indicated, is a commendable feature which will be of great assistance to tourists using the map with a compass. The price of the sheet on paper is 1*s*. 6*d*., and on cloth 2*s*.

Several additions have recently been made to the "Home University Library of Modern Knowlege" and to "The People's Books." Messrs. Williams and Norgate have added to the former series, among other volumes, the following books: "The Human Body," by Prof. Arthur Keith, "Electricity," by Prof. Gisbert Kapp, and "The Making of the Earth," by Prof. J. W. Gregory, F.R.S. To "The People's Books" Messrs. T. C. and E. C. Jack have added, with others, the following volumes: "The Evolution of Living Organisms," by Mr. E. S. Goodrich, F.R.S.; "Embryology," by Dr. Gerald Leighton; "Practical Astronomy," by Mr. Hector Macpherson, Jun.; and "Aviation," by Mr. S. F. Walker. It may be hoped that the recent rapid growth of scientific literature for the general reader is an indication of a fuller understanding of the important part which science must take in the work and development of modern States.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR OCTOBER :—

Oct. 3. 18h. 0m. Mercury in superior conjunction with the Sun.
4. 9h. 25m. Neptune in conjunction with the Moon (Neptune 5° 46′ S.).
9. 3h. 0m. Uranus stationary.
10. 2h. 0m. Sun eclipsed, invisible at Greenwich.
,, 11h. 36m. Mercury in conjunction with the Moon (Mercury 1° 35′ N.).
,, 17h. 10m. Mars in conjunction with the Moon (Mars 1° 44′ N.).
12. 4h. 6m. Venus in conjunction with the Moon (Venus 2° 52′ N.).
13. 16h. 51m. Mercury in conjunction with Mars (Mercury 0° 11′ S.).
14. 6h. 15m. Jupiter in conjunction with the Moon (Jupiter 5° 2′ N.).
17. 22h. 40m. Uranus in conjunction with the Moon (Uranus 4° 35′ N.).
19. 6h. 0m. Neptune at quadrature to the Sun.
22. 21h. 0m. Uranus at quadrature to the Sun.
27. 23h. 9m. Saturn in conjunction with the Moon (Saturn 6° 26′ S.).
31. 15h. 12m. Neptune in conjunction with the Moon (Neptune 5° 43′ S.).

GALE'S COMET 1912*a*.—Dr. Ebell's elements and an extended ephemeris for comet 1912*a* appear in No. 4602 of the *Astronomische Nachrichten*.

Ephemeris 12h. (M.T. Berlin).

1912	α (true) h. m.	δ (true) ° ′	log r	log Δ
Oct. 3	15 24·0	−3 34·3		
5	15 28·6	−1 10·7	9·8616	0·0301
7	15 32·7	+1 7·4		
9	15 36·5	+3 20·2	9·8653	0·0454
11	15 40·0	+5 27·5		
13	15 43·1	+7 29·6	9·8740	0·0600

The calculated magnitude remains about 5·0 until the middle of October, so that given a good clear horizon the comet should not be a difficult object for field glasses, or even the naked eye; during the current week it should be looked for almost due west. On October 5, at about 7.30 p.m., it will lie about halfway between β Libræ and α Serpentis, and will form the apex of an isosceles triangle, having the base, α Coronæ Arcturus, about two-thirds the length of the side. Its apparent path lies nearly along the line joining β Libræ to a point one-third the distance from α to ε Serpentis, a point which it will pass on October 11. As may be seen from the ephemeris, the comet's distance from the sun increases after October 5, and its distance from the earth is also increasing, so that it will not become any brighter; at perihelion passage, October 5, it will be some 67·5 million miles from the sun, and 99·4 million from the earth, while on October 13 these distances will be 69·5 and 106·7 million miles respectively. The orbit of this comet is peculiar by reason of its great inclination, 82°, to the ecliptic.

EPHEMERIS FOR TUTTLE'S COMET.—In No. 4602 of the *Astronomische Nachrichten*, M. N. Miličević gives an ephemeris for Tuttle's comet, based on the elements, uncorrected for perturbations, published in No. 3552 of the same journal. According to this ephemeris, the comet should now be high up in Ursa Major (October 6, α=8h. 36m., δ=+76° 19′), and should travel southwards to α=10h. 8m., δ=70° 24·7′ on October 31. Its calculated distances from the sun and earth on October 6 are 153 and 123 millions of miles respectively. Discovered by Méchain in 1790, this comet was rediscovered by Tuttle in 1858, and, having a period of about 13·7 years, was seen again in 1871, 1885, and May, 1899, so that it should pass perihelion some time early next year.

THE LATITUDE OF THE KHEDIVIAL OBSERVATORY AT HELWAN.—Some interesting facts concerning latitude determinations are brought to light in a paper published by Messrs. Wade and Knox Shaw in Bulletin No. 6 of the Khedivial Observatory, Helwan. The observations discussed were made (1) because observations made in September, 1908, gave a value for the latitude 3″ lower than that formerly accepted, and (2) because the observations at other geodetic stations suggested a night-to-night variation, possibly due to some atmospheric variation such as the shifting of the refractive zenith. They were also intended to show whether any abnormal variation of latitude took place from month to month.

The instruments and observations are fully discussed, Talcott's method having been employed, and the final value for the latitude of the geodetic pillar is given as 29° 25′ 31·82″ N. ±0·11″. The authors conclude that there is no very definite evidence for a night-to-night variation, but there seems to be a variation from month to month; thus August, 1911, shows the largest residual, +0·92″, from the mean value, although the probable error of the determination is small. August, 1910, also gave an abnormal value, and during the period July, 1910, to August, 1911, the mean latitude actually varied from 31·67 to 32·1″.

THE MANCHESTER ASTRONOMICAL SOCIETY.—The report of this society shows that a vigorous interest in astronomy is exhibited in the Manchester district, an interest which would be welcome in other centres. The membership for 1910–11 was 128, as compared with 98 in 1903–4, and the average attendance at the meetings was 72. Many interesting papers were read and discussed, the lecturers including Father Cortie and Mr. T. Thorp. On alternate Wednesdays the Godlee Observatory is open to members for practical work.

FORTHCOMING BOOKS OF SCIENCE.

AGRICULTURE.

A. and C. Black.—Ranching in the Canadian West, A. B. Stock. *Blackie and Son, Ltd.*—Woman's Place in Rural Economy, translated from the French of Paul de Vuyst. *C. METALLURGY.

C. Griffin and Co., Ltd.—The Mineralogy of the Rarer Metals: a Handbook for Prospectors, E. Cahen and W. O. Wootton; The Sampling and Assay of the Precious Metals: Comprising Gold, Silver and Platinum, in Ores, Bullion and Products, E. A. Smith, illustrated; The Microscopic Analysis of Metals in Theory and Practice, F. Osmond and J. E. Stead, F.R.S., with a chapter on the Metallography of the Deformation of Iron and Steel, and an Appendix on the Theory of the Iron-Carbon System, revised, corrected and re-written by L. P. Sidney.

TECHNOLOGY.

Edward Arnold.—Electroplating, W. R. Barclay and C. H. Hainsworth, illustrated. *Cassell and Co., Ltd.*—Cassell's Reinforced Concrete, edited by B. E. Jones, illustrated; Wireless Telegraphy: and How to Make the Apparatus, edited by the Editor of *Work*, illustrated; Motor-cars and Their Story, F. A. Talbot, illustrated. *Constable and Co., Ltd.*—Materials used in Sizing, W. F. A. Ermen; Seasonal Trades, A. Freeman; Mineral and Aerated Waters, C. A. Mitchell; Testing of Electrical Machinery J. H. Morecroft and F. W. Hehre; The Practical Mechanic's Handbook, F. E. Smith; Bells, Telephones, &c., J. B. Redfern and J. Savin; Toll Telephone Practice, J. B. Theiss and G. A. Joy. *C. Griffin and Co., Ltd.*—Briquetting: Coal, Shale, &c., Ores, Furnace Products, Metal Swarf, &c., G. Franke, translated and edited by F. Lantsberry, 2 vols., illustrated; A Handbook for Buyers and Sellers in the Cotton Trade, H. B. Heylin; Painters' Colours, Oils, and Varnishes, G. H. Hurst, revised by N. Heaton, new edition, illustrated. *Crosby Lockwood and Son.*—Stone Quarrying and the Preparation of Stone for the Market, A. Greenwell and Dr. J. V. Elsden; The Art of Modern Fretcutting, J. Makinson, illustrated. *Longmans and Co.*—Advanced Textile Design, W. Watson; Textile Design and Colour Elementary Weaves and Figured Fabrics, W. Watson. *George Routledge and Sons, Ltd.*—The Broadway Textbooks of Technology, edited by G. U. Yule and C. Hamilton, illustrated, Introductory Volume on Organisation and Teaching; Preliminary Technical Course, First Year; Building Construction, First Year; Geometry for Builders, First Year; Science for Builders, First Year; Machine Construction, First Year; Mechanics for Engineers, First Year; Practical Mathematics and Geometry, First Year; Mechanics for Textile Students, First Year; Safety Lamps and Testing for Mine Gases; Elementary Electrical Engineering, First Year; Telephotography, C. F. Lan-Davis, illustrated. *The University Tutorial Press, Ltd.*—Manual Training, A. H. Jenkins. *Whittaker and Co.*—The Baudôt Printing Telegraph System, H. W. Pendry, illustrated; Magneto and Electric Ignition, W. Hibbert, illustrated; Wireless Telegraphy and Telephony, W. J. White, illustrated; Practical Sheet and Plate Metal Work, E. A. Atkins.

MISCELLANEOUS.

Edward Arnold.—Questions of the Day in Philosophy and Psychology, Dr. H. L. Stewart. *A. and C. Black.*—Forged Egyptian Antiquities, T. G. Wakeling, illustrated. *Blackie and Son, Ltd.*—Safety in Coal Mines, Prof. D. Burns; Tillage, Trade, and Invention, G. T. Warner. *R. Friedländer und Sohn (Berlin).*—Jade, a Study of Chinese Archæology and Religion, B. Laufer, illustrated. *C. Griffin and Co., Ltd.*—The Official Year-Book of the Scientific and Learned Societies of Great Britain and Ireland, compiled from Official Sources, twenty-eighth annual issue. *Harper and Brothers.*—Rough Stone Monuments and their Builders, T. E. Peet. *Henry Holt and Co. (New York).*—Leading American Inventors, G. Iles, illustrated. *T. C. and E. C. Jack.* Psychology, Dr. H. J. Watt; The Meaning of Philosophy, Prof. A. E. Taylor; Kant's Philosophy, A. D. Lindsay. *Longmans and Co.*—The Aviation World Who's Who and Industrial Directory, third issue, 1912; Introduction to Experimental Education, Dr. R. R. Rusk. *Macmillan and Co., Ltd.*—Statistics, the late Sir Robert Giffen, edited by H. Higgs, C.B. *Methuen and Co., Ltd.*—The Ancient History of the Near East from the Earliest Period to the Persian Invasion of Greece, H. R. Hall, illustrated; Survivals and Tendencies: being Sundry Sociological Interpretations and Forecasts, V. V. Branford; The Malthusian Limit: a Theory of a Possible Static Condition for the Human Race, E. Isaacson. *Seeley, Service and Co., Ltd.*—Heroes of Science, C. R. Gibson, illustrated.

CLIMATOLOGICAL OBSERVATIONS.

A VALUABLE instalment has been added to the long series of meteorological observations taken at the Radcliffe Observatory, Oxford, by the publication of a volume containing the results for the five years 1906–1910. In its main features the volume is arranged on the same lines as before, the principal exceptions being the omission of (1) the readings of the underground platinum-resistance thermometers, which will be dealt with in a separate paper, and (2) the results obtained from the photographic recording instruments, but the records are continued at present. The tables exhibit very clearly the mean daily, monthly, and annual results for the various elements. The wind velocity is deduced with the old factor 3, but to reduce this to the new factor 2·2 it is only necessary to multiply the quantities by 0·733. From a special table prepared by Dr. Rambaut for the thirty years 1881–1910, the mean yearly horizontal motion of the air is 108,000 miles; it shows an apparent periodic annual variation, with an amplitude of about 3·8 miles an hour, the maximum occurring in March and the minimum in September.

The report recently issued by the Survey Department of Egypt upon the rains of the Nile basin and the flood of 1910 claims that the decade which has just passed ranks as the most important in the study of the Nile from the hydrographical and meteorological points of view. The investigations during that period are chiefly due to the instigation and personal efforts of Sir W. Garstin and to the discussion of his data by various men of science. Among the principal results of this work are:—(1) A proper appreciation of the enormous loss of water in marshy regions. (2) The regulating effect of the trough wherever a rapid tributary joins a more sluggish one. (3) A more precise knowledge of the relative parts played by the different tributaries. (4) The importance of the contribution returned to the river from underground sources. During 1910 there was a general or partial failure of rain in the first half of the year, but during the critical months, July to September, there was heavy rain in Abyssinia and round the Bahr el Jebel, and this condition persisted into the last quarter. The low stage preceding the flood was very satisfactory and water was plentiful. The flood started well in April, but was subject subsequently to several fluctuations; from November 1 the fall was rapid, but the river remained above its normal level.

In our "Notes" column of April 25 we made a brief reference to a report on the climate of Tripoli by Dr. Philip Eredia, based on direct observations between 1892 and 1911. He has now supplemented that useful paper by one on the diurnal range of temperature, based on readings of a self-recording thermometer since September, 1905 (*Rendiconti R. Accad. Lincei*, July, 1912). The tables contain, *inter alia*, ten-day and monthly means for every even hour (2h., 4h., &c.). These show that the highest mean values occur about 2h. p.m., and differ little from those at other hours near that time, except in the decades of the extreme months; the lowest readings generally occur near sunrise, as is usually the case. The mean daily extremes occur early in February (11·4° C.) and about the middle of August (26·5°), giving a mean range of 15° C., which differs little from that of the coastal towns of southern Italy. The peculiarities exhibited by the hourly means in the various months are well shown by thermo-isopleths.

We have received Nos. 7–9 of the *Finländische hydrographisch-biologische Untersuchungen* in the gulfs of Bothnia and Finland and the northern part of the Baltic Sea during the years 1900–1910. These very valuable observations and results, including sea-temperature at various depths, salinity, wind direction and force, and other data at lightships, lighthouses, and other fixed stations, as well as during expeditions to sea, have been discussed by Dr. Rolf Witting, director of the investigations, and translated into German by Mrs. Ellen Witting. The principal results are also shown graphically by a number of coloured plates. We note that the author is of opinion that more importance should be given to detailed observations at fixed stations in supplementing the observations made in the open sea than has hitherto been the case. The discussion covers too wide a range to allow of our entering into further details here, but we may mention that one of the chapters contains an interesting historical account of the development of our knowledge of the hydrography of the Baltic prior to the commencement of the international exploration of the ocean.

THE BRITISH ASSOCIATION AT DUNDEE.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY LEONARD HILL, M.B., F.R.S., PRESIDENT OF THE SECTION.

LAST year the distinguished president of this section raised us to the contemplation of the workings of the soul. I ask you to accompany me in the consideration of nothing higher than a stuffy room. Everyone thinks that he suffers in an ill-ventilated room owing to some change in the chemical quality of the air, be it want of oxygen, or excess of carbon dioxide, the addition of some exhaled organic poison, or the destruction of some subtle property by passage of the air over steam-coils, or other heating or conducting apparatus. We hear of "devitalised" or "dead" air, and of "tinned" or "potted" air of the battleship. The good effects of open-air treatment, sea and mountain air, are no less generally ascribed to the chemical purity of the air. In reality the health-giving properties are those of temperature, light, movement, and relative moisture of the surrounding atmosphere, and leaving on one side those gross chemical impurities which arise in mines and in some manufacturing processes, and the question of bacterial infection, the alterations in chemical composition of the air in buildings where people crowd together and suffer from the effects of ill-ventilation have nothing to do with the causation of these effects.

Satisfied with the maintenance of a specious standard of chemical purity, the public has acquiesced in the elevation of sky-scrapers and the sinking of cavernous places of business. Many have thus become cave-dwellers, confined for most of their waking and sleeping hours in windless places, artificially lit, monotonously warmed. The sun is cut off by the shadow of tall buildings and by smoke—the sun, the energiser of the world, the giver of all things which bring joy to the heart of man, the fitting object of worship of our forefathers.

The ventilating and heating engineer hitherto has followed a great illusion in thinking that the main objects to be attained in our dwellings and places of business are chemical purity of the air and a uniform draughtless summer temperature.

Life is the reaction of the living substance to the ceaseless play of the environment. Biotic energy arises from the transformation of those other forms of energy—heat, light, sound, &c.—which beat upon the transformer—the living substance (B. Moore). Thus, when all the avenues of sense are closed, the central nervous system is no longer aroused and consciousness lapses. The boy paralysed in almost all his avenues of sense fell asleep whenever his remaining eye was closed. The patient who lost one labyrinth by disease, and, to escape unendurable vertigo, had the other removed by operation, was quite unable to guide his movements or realise his position in the dark. Rising from bed one night, he collapsed on the floor and remained there helpless until succour arrived.

A sense organ is not stimulated unless there is a change of rate in the transference of energy; and this to be effectual must occur in most cases with considerable quickness. If a weak agent is to stimulate, its application must be abrupt (Sherrington). Thus the slow changes of barometric pressure on the body-surface originate no skin sensations, though such changes of pressure if applied suddenly, are much above the threshold value for touch. A touch excited by constant mechanical pressure of slight intensity fades quickly below the threshold of sensation. Thus the almost unbearable discomfort which a child feels on putting on for the first time a "natural" wool vest fades away, and is no longer noticed with continual wear. Thomas à Beckett soon must have become oblivious to his hair-shirt, and even to its harbingers. It is not the wind which God tempers to the shorn lamb, but the skin of the lamb to the wind. The inflow of sensations keeps us active and alive and all the organs working in their appointed functions. The cutaneous sensations are of the highest importance. The salt and sand of wind-driven sea air particularly act on the skin and through it brace the whole body. The changing play of wind, of light, cold, and warmth stimulate the activity and health of mind and body. Monotony of sedentary occupation and of an over-warm still atmosphere endured for long working hours destroys vigour and happiness and brings about the atrophy of disuse. We hear a great deal of the degeneration of the race brought about by city life, but observation shows us that a drayman, navvy, or policeman can live in London, or other big city, strong and vigorous, and no less so than in the country. The brain-worker, too, can keep himself perfectly fit if his hours of sedentary employment are not too long and he balances these by open-air exercise. The horses stabled, worked, and fed in London are as fine as any in the world; they do not live in windless rooms heated by radiators.

The hardy men of the north were evolved to stand the vagaries of climate—cold and warmth—a starved or full belly have been their changing lot. The full belly and the warm sun have expanded them in lazy comfort; the cold and the starvation have braced them to action. Modern civilisation has withdrawn many of us from the struggle with the rigours of nature: we seek for and mostly obtain the comfort of a full belly and expand all the time in the warm atmosphere afforded us by clothes, wind-protected dwellings, and artificial heat—particularly so in the winter, when the health of the business man deteriorates. Cold is not comfortable, neither is hunger; therefore we are led to ascribe many of our ills to exposure to cold, and seek to make ourselves strong by what is termed good living. I maintain that the bracing effect of cold is of supreme importance to health and happiness, that we become soft and flabby and less resistant to the attacks of infecting bacteria in the winter, not because of the cold, but because of our excessive precautions to preserve ourselves from cold; that the prime cause of "cold" or "chill" is not really exposure to cold, but to the overheated and confined air of rooms, factories, and meeting-places. Seven hundred and eleven survivors were saved from the *Titanic* after hours of exposure to cold. Many were insufficiently clad and others wet to the skin. Only one died after reaching the *Carpathia*, and he three hours after being picked up. Those who died perished from actual cooling of the body. Exposure to cold did not cause in the survivors the diseases commonly attributed to cold.

Conditions of city and factory life diminish the physical and nervous energy, and reduce many from the vigorous health and perfectness of bodily functions which a wild animal possesses to a more secure, but poorer and far less happy, form of existence. The ill-chosen diet, the monotony and sedentary nature of daily work, the windless uniformity of atmosphere, above all, the neglect of vigorous muscular exercise in the open air and exposure to the winds and light of heaven—all these, together with the difficulties in the way of living a normal sexual life, go to make the pale, undeveloped, neurotic, and joyless citizen. Nurture in unnatural surroundings, not nature's birth-mark, moulds the criminal and the wastrel. The environment of childhood and youth is at fault rather than the stock; the children who are taken away and trained to be sailors, those sent to agricultural pursuits in the Colonies, those who become soldiers, may develop a physique and bodily health and vigour in striking contrast to their brothers who become clerks, shop assistants, and compositors.

Too much stress cannot be put on the importance of muscular exercise in regard to health, beauty, and happiness. Each muscle fills with blood as it relaxes, and expels this blood on past the venous valves during contraction. Each muscle, together with the venous valves, forms a pump to the circulatory system. It is the function of the heart to deliver the blood to the capillaries, and the function of the muscles—visceral, respiratory, and skeletal—to bring it back to the heart. The circulation is contrived for a restless mobile animal; every vessel is arranged so that muscular movement furthers the flow of blood.

The pressure of the blood in the veins and arteries under the influence of gravity varies with every change of posture. The respiratory pump, too, has a profound influence on the circulation. Active exercise, such as is taken in a game of football, entails endless changes of posture, varying compressive actions—one with another struggling in the rough and tumble of the game—forcible contractions and relaxations of the muscles, and a vastly increased pulmonary ventilation; at the same time the heart's action is accelerated and augmented and the arterial supply controlled by the vasomotor system. The influence of gravity, which tends to cause the fluids of the body to sink into the lower parts, is counteracted; the liver is rhythmically squeezed like a sponge by the powerful respiratory movements, which not only pump the blood through the abdominal viscera but thoroughly massage these organs, and kneading these with the omentum clean the peritoneal cavity and prevent constipation. At the same time the surplus food metabolic products, such as sugar and fat, stored in the liver, are consumed in the production of energy, and the organs swept with a rapid stream of blood containing other products of muscular metabolism which are necessary to the interrelation of chemical action. The output of energy is increased very greatly; a resting man may expend two thousand calories per diem; one bicycling hard for most of the day expended eight thousand calories, of which only four thousand was covered by the food eaten.

Such figures show how fat is taken off from the body by exercise, for the other four thousand calories comes from the consumption of surplus food products stored in the tissues. While resting a man breathes some 7 litres of air, and uses 300 c.c. of oxygen per minute, against 140 litres and 3000 c.c. while doing very hard labour. The call of the muscles for oxygen through such waste products as lactic acid impels the formation of red corpuscles and hæmoglobin. The products of muscular metabolism in other ways not yet fully defined modify the metabolism of the whole body.

Exposure to cold, cold baths, and cold winds has a like effect, accelerating the heart and increasing the heat production, the activity of the muscles, the output of energy, the pulmonary ventilation, and intake of oxygen and food. In contrast with the soft pot-bellied, over-fed city man the hard, wiry fisherman trained to endurance has no superfluity of fat or tissue fluid. His blood volume has a high relative value in proportion to the mass of his body. His superficial veins are confined between a taut skin and muscles, hard as in a racehorse trained to perfection. Thus the adequacy of the cutaneous circulation and loss of heat by radiation rather than by sweating is assured. His fat is of a higher melting point, hardened by exposure to cold. In him less blood is derived to other parts, such as adipose tissue, skin, and viscera. He uses up the oxygen in the arterial blood more completely and with greater efficiency; for the output of each unit of energy his heart has to circulate much less blood (Kreogh); his blood is sent in full volume by the well-balanced activity of his vasomotor system to the moving parts. Owing to the perfect coordination of his muscles, trained to the work, and the efficient action of his skin and cutaneous circulation—the radiator of the body—he performs the work with far greater economy and less fatigue. The untrained man may obtain 12 per cent. of his energy output as work, against 30 per cent., or perhaps even 50 per cent., obtained by the trained athlete. Hence the failure and risk suffered by the city man who rushes straight from his office to climb the Alps. On the other hand, the energetic man of business or brain worker is kept by his work in a state of nervous tension. He considers alternative lines of action, but scarcely moves. He may be intensely excited, but the natural muscular response does not follow. His heart is accelerated and his blood pressure raised, but neither muscular movements and accompanying changes of posture, nor the respiratory pump materially aid the circulation. The activity of his brain demands a rapid flow of blood, and his heart has to do the circulatory work, as he sits still or stands at his desk, against the influence of gravity. Hence a high blood pressure is maintained for long periods at a time by vaso-constriction of the arteries in the lower parts of the body and increased action of the heart; hence, perhaps, arise those degenerative changes in the circulatory system which affect some men tireless in their mental activity. We know that the bench-worker, who stands on one leg for long hours a day, may suffer from degeneration and varicosity of the veins in that leg. Long-continued high arterial pressure, with systolic and diastolic pressures approximately the same, entails a stretched arterial wall, and this must impede the circulation in the vaso-vasorum, the flow of tissue lymph in, and nutrition of, the wall. Since his sedentary occupation reduces the metabolism and heat production of his body very greatly, the business man requires a warmer atmosphere to work in. If the atmosphere is too warm it reduces his metabolism and pulmonary ventilation still further; thus he works in a vicious circle. Exhausting work causes the consumption of certain active principles, for example, adrenin, and the reparation of those must be from the food. To acquire certain of the rarer principles expended in the manifestation of nervous energy more food may have to be eaten by the sedentary worker than can be digested and metabolised. His digestive organs lack the kneading and massage, the rapid circulation and oxidation of foodstuffs which is given by muscular exercise. Hence arise the digestive and metabolic ailments so common to brain workers.

Mr. Robert Milne informs me that of the thousands of children who have passed through Barnardo's Homes—there are 9000 in the homes at any one time—not one after entering the institution and passing under its regimen and the care of his father, Dr. Milne, has developed appendicitis. Daily exercise and play, adequate rest, a regular, simple diet have ensured their immunity from this infection. It pays to keep a horse healthy and efficient; it no less pays to keep men healthy. I recently investigated the case of clerks employed in a great place of business, whose working hours are from 9 to 6 on three days, and 7 to 9 on the other three days of each week, and working such overtime, they make 1*l.* to 2*l.* a week; these clerks worked in a confined space—forty or fifty of them in 8200 cubic feet, lit with thirty electric lamps, cramped for room, and overheated in warm summer days. It is not with the chemical purity of the air of such an office that fault is to be found, for fans and large openings ensured this sufficiently. These clerks suffered from their long hours of monotonous and sedentary occupation, and from the artificial light, and the windless, overwarm and moist atmosphere. Many a girl cashier has worked from 8 to 8.30, and on Saturdays from 8 to 10, and then has had to balance her books and leave perhaps after midnight on Sunday morning. Her office is away in the background—confined, windless, artificially lit. The Shops Act has given a little relief from these hours. What, I ask, is the use of the State spending a million a year on sanatoria and tuberculin dispensaries, when those very conditions of work continue which lesson the immunity and increase the infection of the workers?

The jute industry in this town of Dundee is carried out almost wholly by female and boy labour. "The average wages for women are below 12*s.* in eight processes, and above 12*s.*, but under 18*s.*, for the remaining five processes." The infant mortality has been more than 170 per 1000. The Social Union of Dundee reported in 1905 that of 885 children born to 240 working mothers no fewer than 520, or 59 per cent., died—and almost all of them were under five years of age. The life of these mothers was divided between the jute factory and the one-roomed tenement. Looking such conditions squarely in the face, I say it would be more humane for the State to legalise the exposure of every other new-born infant on the hillside rather than allow children to be slowly done to death. The conditions, as given in the report, contravene those rights of motherhood which the meanest wild animal can claim.

Isolation hospitals, sputum-pots, and anti-spitting regulations will not stamp out tuberculosis. Such means are like shutting the door of the stable when the horse has escaped. Flügge has shown that tubercle bacilli are spread by the droplets of saliva which are carried out as an invisible spray when we speak, sing, cough, sneeze. Sputum-pots cannot control this. The saliva of cases of phthisis may teem with the bacilli. The tuberculin reaction tests carried out by Hamburger and Monti in Vienna show that 94 per cent. of all children aged eleven to fourteen have been infected with tubercle. In most the infection is a mere temporary indisposition. I believe that the conditions of exhausting work, and amusement in confined and overheated atmospheres, together with ill-regulated feeding, determine largely whether the infection, which almost none can escape, become serious or not. Karl Pearson suggests that the death statistics afford no proof of the utility of sanatoria or tuberculin dispensaries, for during the very years in which such treatment has been in vogue, the fall in the mortality from tuberculosis has become less relatively to the fall in general mortality. He opines that the race is gradually becoming immune to tubercle, and hence the declination in the mortality curve is becoming flattened out—that nature is paramount as the determinant of tuberculosis, not nurture. From a statistical inquiry into the incidence of tuberculosis in husband and wife and parent and child, Pearson concludes that exposure to infection as in married couples is of little importance, while inborn immunity or diathesis is a chief determinant. Admitting the value of his critical inquiries and the importance of diathesis, I would point out that in the last few years the rush and excitement of modern city life has increased, together with the confinement of workers to sedentary occupations in artificially lit, warm, windless atmospheres. The same conditions pertain to places of amusement, eating-houses, tube railways, &c.

Central heating, gas-radiators, and other contrivances are now displacing the old open fire and chimney. This change greatly improves the economical consumption of coal and the light and cleanliness of the atmosphere. But in so far as it promotes monotonous, windless, warm atmospheres, it is wholly against the health and vigour of the nation. The open fire and wide chimney ensure ventilation, the indrawing of cold outside air, streaky air—restless currents at different temperatures, which strike the sensory nerves in the skin and prevent monotony and weariness of spirit. By the old open fires we were heated with radiant heat. The air in the rooms was drawn in cool and varied in temperature. The radiator and hot-air system give us a deadly uniformly heated air—the very conditions we find most unsupportable on a close summer's day.

In Labrador and Newfoundland, Dr. Wakefield tells me, the mortality of the fisherfolk from tuberculosis is very heavy. It is generally acknowledged to be four per 1000 of the population per annum, against 1·52 for England and Wales. Some of the Labrador doctors talk of seven and even eight per 1000 in certain districts. The general death-rate is a low one. The fishermen fish off shore, work for many hours a day in the fishing season, and live with their families on shore in one-roomed shanties. These shanties are built of wood, the crannies are "stogged" with moss, and the windows nailed up, so that ventilation is very imperfect. They are heated by stoves and kept at a very high temperature, *e.g.*, 80° F. Outside in the winter the temperature may be 30 degrees below freezing. The women stay inside the shanties almost all their time, and the tuberculosis rate is somewhat higher in them. The main food is white bread, tea stewed in the pot till black, fish occasionally, a little margarine and molasses. The fish is boiled and the water thrown away. Game has become scarce in recent years; old, dark-coloured flour spoken of with disfavour—has been replaced by white flour. In consequence of this diet beri-beri has become rife to a most serious extent, and the hospitals are full of cases. Martin Flack and I have found by our feeding experiments that rats, mice, and pigeons cannot be maintained on white bread and water, but can live on wholemeal, or on white bread in which we incorporate an extract of the sharps and bran in sufficient amount. Recent work has shown the vital importance of certain active principles present in the outer layers of wheat, rice, &c., and in milk, meat, &c., which are destroyed by heating to 120° C. A diet of white bread or polished rice and tinned food sterilised by heat is the cause of beri-beri. The metabolism is endangered by the artificial methods of treating foods now in vogue. As to the prevalency of tuberculosis in Labrador, we have to consider the intermarriage, the bad diet, the over-rigorous work of the fishermen, the overheating of, and infection in, the shanties. Dr. Wakefield has slept with four other travellers in a shanty with father, mother, and ten children. In some there is scarce room on the floor to lie down. The shanties are heated with a stove on which pots boil all the time; water runs down the windows. The patients are ignorant, and spit everywhere, on bed, floor, and walls. In the schools the heat and smell are most marked to one coming in from the outside air. In one school 50 cubic feet per child is the allowance of space. The children are eating all day long, and are kept in close hot confinement. They suffer very badly from decay of the teeth. Whole families are swept off with tuberculosis, and the child who leaves home early may escape, while the rest of a family dies.

Here, then, we have people living in the wildest and least populated of lands with the purest atmosphere suffering from all those ill-results which are found in the worst city slums—tuberculosis, beri-beri, and decayed teeth.

The bad diet probably impels the people to conserve their body heat and live in the over-warm, confined atmosphere, just as our pigeons fed on white bread sit, with their feathers out, huddled together to keep each other warm. The metabolism, circulation, respiration, and expansion of the lung are all reduced. The warm, moist atmosphere lessens the evaporation from the respiratory tract, and therefore the transudation of tissue lymph and activity of the ciliated epithelium. The unexpanded parts of the lung are not swept with blood. Everything favours a lodgment of the bacilli, and lessens the defences on which immunity depends. In the mouth, too, the immune properties of the saliva are neutralised by the continual presence of food, and the temperature of the mouth is kept at a high level, which favours bacterial growth. Lieutenant Siem informs me that recently in Northern Norway there has been the same notable increase in tuberculosis. The old cottage fireplaces with wide chimneys have been replaced with American stoves. In olden days most of the heat went up the chimney, and the people were warmed by radiant heat. Now the room is heated to a uniform moist heat. The Norwegians nail up the windows and never open them during the winter. At Lofoten, the great fishing centre, motor-boats have replaced the old open sailing and row boats. The cabin in the motor-boat is very confined, covered in with watertight deck, heated by the engine, crowded with six or eight workers. When in harbour the fishermen used to occupy ill-fitted shanties, through which the wind blew freely; now, to save rent, they sleep in the motor-boat cabins.

Here, again, we have massive infection, and the reduction of the defensive mechanisms by the influence of the warm, moist atmosphere.

The Norwegian fishermen feed on brown bread, boiled fish, salt mutton, margarine, and drink, when in money, beer and schnapps; there is no gross deficiency in diet, as in Labrador, and beri-beri does not attack them. They return home to their villages and longshore fishing when the season is over. The one new condition which is common to the two districts is confinement in stove-heated, windless atmospheres. In old days the men were crowded together, but in open boats or in draughty shanties, and had nothing but little cooking-stoves.

The conditions of great cities tend to confine the worker in the office all way, and to the heated atmosphere of club, cinema show, or music hall in the evening. The height of houses prevents the town dweller from being blown upon by the wind, and, missing the exhilarating stimulus of the cool, moving air, he repels the dull uniformity of existence by tobacco and by alcohol, or by indulgence in food, *e.g.*, sweets, which are everywhere to his hand, and by the nervous excitement of business and amusement. He works, he eats, and is amused in warm, windless atmospheres, and suffers from a feeble circulation, a shallow respiration, a disordered digestion, and a slow rate of metabolism.

Many of the employments of modern days are detestable in their long hours of confinement and monotony. Men go up and down in a lift all day, and girls in the bloom of youth are set down in tobacco stalls in underground stations, and their health and beauty there fade while even the blow-flies are free to bask in the sun. In factories the operatives feed machines, or reproduce the same small piece of an article day after day. There is no art, or change; no pleasure in contrivance and accomplishment. The miner, the fisherman, even the sewer-man, face difficulties, changing risks, and are developed as men of character and strength. Contrast the sailor with the steward on a steamer, the drayman outside with the clerk inside who checks the goods delivered at some city office, the butcher and the tailor, the seamstress and the market woman, and one sees the enormous difference which a confined occupation makes. Monotonous sedentary employment makes for unhappiness because the inherited functional needs of the human body are neglected, and education—when the outside field of interest is narrowed intensifies the sensitivity to the bodily conditions. The sensations arising within the body—proprioceptive sensations—come to have too large a share in consciousness in comparison with exteroceptive. In place of considering the lilies how they grow, or musing on the beauty and motions of the heavenly bodies, the sedentary worker in the smoke-befouled atmosphere, with the limited activity and horizon of an office and a disturbed digestion, tends to become confined to the inward consideration of his own viscera and their motions.

Many of the educated daughters of the well-to-do are no less confined at home; they are the flotsam and jetsam cast up from the tide in which all others struggle for existence—their lives are no less monotonous than the sweated sempstress or clerk. They become filled with "vapours" and some seek excitement not at the cannon's mouth but in breaking windows, playing with fire, and hunger strikes. The dull monotony of idle social functions, shopping and amusement no less than that of sedentary work and an asexual life, impels to a simulated struggle—a theatrical performance, the parts of which are studied from the historical romances of revolution. Each man, woman, and child in the world must find the wherewithal for living, food, raiment, warmth, and housing, or must die or get some other to find it for him. It seems to me as if the world is conducted as if ten men were on an island—a microcosm—and five sought for the necessaries of life, hunted for food, built shelters and fires, made clothes of skins, while the other five strung necklaces of shells, made loin-cloths of butterfly wings, gambled with knuckle-bones, drew comic pictures in the sand, or carved out of clay frightening demons, and so beguiled from the first five the larger share of their wealth. In this land of factories, while the many are confined to mean streets and wretched houses, possessing no sufficiency of baths and clean clothing, and are ill-fed, they work all day long, not to fashion for themselves better houses and clothing, but to make those unnecessaries such as "the fluff" of women's apparel, and a thousand trifles which relieve the monotony of the idle and bemuse their own minds.

The discovery of radium and its disintegration as a source of energy has enabled the physicist to extend Lord Kelvin's estimate of the world's age from some thirty to a thousand million years. Arthur Keith does not hesitate to give a million of these years to man's evolution. Karl Pearson speaks of hundreds of thousands of years. The form of the human skull, the brain capacity of man, his skill as evidenced by stone implements and cave drawings of animals in action, was the same tens of thousands of years ago as now. For ages primitive man lived as a wild animal in tropical climes, discovered how to make fire, clothe himself in skins, build shelters, and so enable himself to wander over the temperate and arctic zones. Finally, in the last few score of years, he has made houses draughtless with glass windows, fitted them with stoves and radiators, and every kind of device to protect himself from cold, while he occupies himself in the sedentary pursuits and amusements of a city life. How much better, to those who know the boundless horizon of life, to be a frontiersman and enjoy the struggle, with body hardened, perfectly fit, attuned to nature, than to be a cashier condemned to the occupation of a sunless, windless pay-box. The city child, however, nurtured and educated in confinement, knows not the largeness and wonders of Nature, is used to the streets with their ceaseless movement and romantic play of artificial light after dark, and does not need the commiseration of the country mouse any more than the beetle who lives in the dark and animated burrows of his heap. But while outdoor work disciplines the body of the countryman into health, the town man needs the conscious attention and acquired educated control of his life to give him any full measure of health and happiness.

Experimental evidence is strongly in favour of my argument that the chemical purity of the air is of no importance. Analyses show that the oxygen in the worst-ventilated school-room, chapel, or theatre is never lessened by more than 1 per cent. of an atmosphere; the ventilation through chink and cranny, chimney, door, and window, and the porous brick wall, suffices to prevent a greater diminution. So long as there is present a partial pressure of oxygen sufficient to change the hæmoglobin of the venous blood into oxyhæmoglobin there can arise no lack of oxygen.

At sea-level the pressure of oxygen in the pulmonary alveolar air is about 100 mm. Hg. Exposed to only half this pressure the hæmoglobin is more than 80 per cent. saturated with oxygen.

In noted health-resorts of the Swiss mountains the barometer stands at such a height that the concentration of oxygen is far less than in the more ventilated room. On the high plateau of the Andes there are great cities: Potosi with a hundred thousand inhabitants is at 4,105 metres, and the partial pressure of oxygen there is about 13 per cent. of an atmosphere in place of 71 per cent. at sea-level; railways and mines have been worked up to altitudes of 14,000 to 15,000 feet. At Potosi girls dance half the night, and toreadors display their skill in the ring. On the slopes of the Himalayas shepherds take their flocks to altitudes of 18,000 feet. No disturbance is felt by the inhabitants or those who reach these great altitudes slowly and by easy stages. The only disability to a normal man is diminished power for severe exertion, but a greater risk arises from want of oxygen to cases of heart disease, pneumonia, and in chloroform anæsthesia at these high altitudes. The newcomer who is carried by the railway in a few hours to the top of Pike's Peak or the Andes may suffer severely from mountain sickness, especially on exertion, and the cause of this is want of oxygen. Acclimatisation is brought about in a few days' time. The pulmonary ventilation increases, the bronchial tubes dilate, the circulation becomes more rapid. The increased pulmonary ventilation lowers the partial pressure of carbon dioxide in the blood and pulmonary air, and this contributes to the maintenance of an adequate partial pressure of oxygen. Haldane and Douglas say that the percentage of red corpuscles and total quantity of the hæmoglobin increases, and maintain that the oxygen is actively secreted by the lung into the blood, but the CO method by which their determinations have been made has not met with unqualified acceptance. If waste products, which arise from oxygen want, alter the combining power of hæmoglobin, this alteration may not persist in shed blood; for these products may disappear when the blood is exposed to air. Owing to the combining power of hæmoglobin the respiratory exchange and metabolism of an animal within wide limits are independent of the partial pressure of oxygen. On the other hand, the process of combustion is dependent not on the pressure, but on the percentage of oxygen. Thus the aeroplanist may become seized with altitude sickness from oxygen want, while his gas engine continues to carry him to loftier heights.

The partial pressure of oxygen in a mine at a depth of 3000 feet is considerably higher than at sea-level, and if the percentage is reduced to 17, while the firing of fire-damp and coal-dust is impossible, there need be in the alveolar air of the lungs no lower pressure of oxygen than at sea-level. Thus the simplest method of preventing explosions in coal mines is that proposed by J. Harger, viz., to ventilate them with air containing 17 per cent. of oxygen.[1] There is little doubt that all the great mine-explosions have been caused by the enforcement of a high degree of chemical purity of the air. In the old days when ventilation was bad there were no great dust explosions. Mr. W. H. Chambers, general manager of the Cadeby mine, where the recent disastrous explosion occurred, with the authority of his great and long practical experience of fiery mines, told me that the spontaneous combustion of coal and the danger of explosion can be wholly met by adequate diminution in ventilation. The fires can be choked out while the miners can still breathe and work. The Coal Mines Regulation Act enforces that a place shall not be in a fit state for working or passing therein, if the air contains either less than 19 per cent. of oxygen, or more than $1\frac{1}{4}$ per cent. of carbon dioxide. A mine liable to spontaneous combustion of coal may be exempted from this regulation by order of the Secretary of State.

The regulations impel the provision of such a ventilation current that the percentage of oxygen is sufficient for the spread of dust explosions along the intake airways, with the disastrous results so frequently recorded. If the mine were ventilated with air containing 17 per cent. of oxygen in sufficient volume to keep the miners cool and fresh, not only would explosions be prevented, but the mines could be safely worked and illuminated with electricity, and miners' nystagmus prevented, for this is due to the dim light of the safety lamp. The problem possibly may be solved by purifying and cooling the return air, and mixing and circulating this with a sufficiency of fresh air.

Owing to the fact that the percentage of CO_2 is the usual test of ventilation and that only a very few parts per 10,000 in excess of fresh air are permitted by the English Factory Acts, it is generally supposed that CO_2 is a poison, and that any considerable excess has a deleterious effect on the human body. No supposition could be further from the truth.

The percentage of CO_2 in the worst ventilated room does not rise above 0·5 per cent., or at the outside 1 per cent. It is impossible that any excess of CO_2 should enter into our bodies when we breathe such air, for whatever the percentage of CO_2 in the atmosphere may be, that in the pulmonary air is kept constant at about 5 to 6 per cent. of an atmosphere—by the action of the respiratory centre. It is the concentration of CO_2 which rules the respiratory centre, and to such purpose as to keep the concentration both in the lungs and in the blood uniform (Haldane); the only result from breathing air containing 0·5 to 1 per cent. of CO_2 is an inappreciable increase in the ventilation of the lungs. The very same thing happens when we take gentle exercise and produce more CO_2 in our bodies.

At each breath we rebreathe into our lungs the air in the nose and large air-tubes (the dead-space air), and about one-third of the air which is breathed in by a man at rest in dead-space air. Thus, no man breathes in pure outside air into his lungs. When a child goes to sleep with its head partly buried under the bedclothes, and in a cradle confined by curtains, he rebreathes the expired air to a still greater extent, and so with all animals that snuggle together for warmth's sake. Not only the new-born babe sleeping against its mother's breast, but pigs in a sty, young rabbits, rats, and mice clustered together in their nests, young chicks under the brooding hen, all alike breathe a far higher percentage than that allowed by the Factory Acts.

To rebreathe one's own breath is a natural and inevitable performance, and to breathe some of the air exhaled by another is the common lot of men who, like animals, have to crowd together and husband their heat in fighting the inclemency of the weather.

In the Albion Brewery we analysed on three different days the air of the room where the CO_2 generated in the vats is compressed and bottled as liquid carbonic acid. We found from 0·14 to 0·93 per cent. of CO_2 in the atmosphere of that room. The men who were filling the cylinders and turning the taps on and off to allow escape of air must often breathe more than this. The men engaged in this occupation worked twelve-hour shifts, having their meals in the room. Some had followed the same employment for eighteen years, and without detriment to their health. It is only when the higher concentrations of CO_2 are breathed, such as 3 to 4 per cent. of an atmosphere, that the respiration is increased, so that it is noticeable to the resting individual; but percentages over 1 per cent. diminish the power to do muscular work, for the excess of CO_2 produced by the work adds its effect to that of the excess in the air, and the difficulty of coordinating the breathing to the work in hand is increased.

Haldane and Priestley found that with a pressure of 2 per cent. of an atmosphere of CO_2 in the inspired air the pulmonary ventilation of a man at rest was increased 50 per cent., with 3 per cent. about 100 per cent., with 4 per cent. about 200 per cent., with 5 per cent. about 300 per cent., and with 6 per cent. about 500 per cent. With the last, panting is severe, while with 3 per cent. it is unnoticed until muscular work is done, when the panting is increased 100 per cent. more than usual. With more than 6 per cent. the distress is very great, and headache, flushing, and sweating occur.

Divers who work in diving dress and men who work in compressed-air caissons constantly do heavy and continuous labour in concentrations of CO_2 higher than 1 per cent. of an atmosphere, and so long as the CO_2 is kept below 2 to 3 per cent. they are capable of carrying out efficient work. In the case of workers in compressed air it is important to bear in mind that the effect of the CO_2 on the breathing depends on the partial pressure and not on the percentage of this gas in the air breathed.

By a series of observations made on rats confined

[1] Trans. Inst. of Mining Engineers, 1912.

in cages fitted with small, ill-ventilated sleeping-chambers, we have found that the temperature and humidity of the air—not the percentage of carbon dioxide or oxygen—determines whether the animals stay inside the sleeping-room or come outside. When the air is cold, they like to stay inside, even when the carbon dioxide rises to 4 to 5 per cent. of an atmosphere. When the sleeping-chamber is made too hot and moist they come outside.

The sanitarian says it is necessary to keep the CO_2 below 0·01 per cent., so that the organic poisons may not collect to a harmful extent. The evil smell of crowded rooms is accepted as unequivocal evidence of the existence of such. He pays much attention to this and little or none to the heat and moisture of the air. The smell arises from the secretions of the skin, soiled clothes, &c. The smell is only sensed by and excites disgust in one who comes to it from the outside air. He who is inside and helps to make the "fugg" is both wholly unaware of, and unaffected by it. Flügge points out, with justice, that while we naturally avoid any smell that excites disgust and puts us off our appetite, yet the offensive quality of the smell does not prove its poisonous nature. For the smell of the trade or food of one man may be horrible and loathsome to another not used to such.

The sight of a slaughterer and the smell of dead meat may be loathly to the sensitive poet, but the slaughterer is none the less healthy. The clang and jar of an engineer's workshop may be unendurable to a highly-strung artist or author, but the artificers miss the stoppage of the noisy clatter. The stench of glue-works, fried-fish shops, soap and bone-manure works, middens, sewers, become as nothing to those engaged in such, and the lives of the workers are in no wise shortened by the stench they endure. The nose ceases to respond to the uniformity of the impulse, and the stench clearly does not betoken in any of these cases the existence of a chemical organic poison. On descending into a sewer, after the first ten minutes the nose ceases to smell the stench; the air therein is usually found to be far freer from bacteria than the air in a schoolroom or tenement.

If we turn to foodstuffs we recognise that the smell of alcohol and of Stilton or Camembert cheese is horrible to a child, while the smell of putrid fish—the meal of the Siberian native—excites no less disgust in an epicure, who welcomes the cheese. Among the hardiest and healthiest of men are the North Sea fishermen, who sleep in the cabins of trawlers reeking with fish and oil, and for the sake of warmth shut themselves up until the lamp may go out from want of oxygen. The stench of such surroundings may effectually put the sensitive, untrained brain worker off his appetite, but the robust health of the fisherman proves that this effect is nervous in origin, and not due to a chemical organic poison in the air.

Ventilation cannot get rid of the source of a smell, while it may easily distribute the evil smell through a house. As Pettenkofer says, if there is a dung-heap in a room, it must be removed. It is no good trying to blow away the smell.

Flügge and his school bring convincing evidence to show that a stuffy atmosphere is stuffy owing to heat stagnation, and that the smell has nothing to do with the origin of the discomfort felt by those who endure it. The inhabitants of reeking hovels in the country do not suffer from chronic ill-health, unless want of nourishment, open-air exercise, or sleep come into play. Town workers who take no exercise in the fresh air are pale, anæmic, listless. Sheltered by houses they are far less exposed to winds, and live day and night in a warm, confined atmosphere.

The widespread belief in the presence of organic poisons in the expired air is mainly based on the statements of Brown Sequard and D'Arsenval, statements wholly unsubstantiated by the most trustworthy workers in Europe and America. These statements have done very great mischief to the cause of hygiene, for they led ventilating engineers and the public to seek after chemical purity, and neglect the attainment of adequate coolness and movement of the air. It was stated that the condensation water obtained from expired air is poisonous when injected into animals. The evidence on which this statement is based is not only not worthy of credence but is absurd, *e.g.* condensation water has been injected into a mouse in a quantity equivalent to injecting 5 kilogrammes into a man weighing 60 kilogrammes. No proper controls were carried out. It is recognised now that any distilled water contaminated by bacterial products may have a toxic effect. Flack and I have for fourteen weeks kept guinea-pigs and rats confined together in a box and poorly ventilated, so that they breathed air containing 0·5 to 1·0 per cent. of CO_2. The guinea-pigs proved wholly free from anaphylactic shock on injecting rats' serum. Therefore they were not sensitised by breathing the exhaled breath of the rats for many weeks, and we are certain that no foreign protein substance is absorbed in this way. It has been proved by others, and by us, that animals so confined do well so long as they are well fed and their cages kept clean, light, cool, and dry. It is wholly untrue that they are poisoned by breathing each other's breath. The only danger arises from droplet contagion in cases of infective disease.

To study the relative effect of the temperature and chemical purity of the atmosphere, I constructed a small experimental chamber of wood fitted with large glass observation windows and rendered airtight.

On one side of the chamber were fixed two small electric heaters, and a tin containing water was placed on these in order to saturate the air with water vapour. On another side of the chamber was placed a large radiator through which cold water could be circulated when required, so as to cool the chamber. In the roof were fixed three electric fans, one big and two small, by means of which the air of the chamber could be stirred. The chamber held approximately 3 cm. of air. In one class of experiments we shut within the chamber seven or eight students for about half an hour, and observed the effect of the confined atmosphere upon them. We kept them until the CO_2 reached 3 to 4 per cent., and the oxygen had fallen to 17 to 16 per cent. The wet-bulb temperature rose meanwhile to about 80° to 85° F., and the dry-bulb a degree or two higher. The students went in chatting and laughing, but by and by, as the temperature rose, they ceased to talk and their faces became flushed and moist. To relieve the monotony of the experiment we have watched them trying to light a cigarette, and, puzzled by their matches going out, borrowing others, only in vain. They had not sensed the diminution of oxygen, which fell below 17 per cent. Their breathing was deepened by the high percentage of CO_2, but no headache occurred in any of them from the short exposure. Their discomfort was relieved to an astonishing extent by putting on the electric fans placed in the roof. Whilst the air was kept stirred the students were not affected by the oppressive atmosphere. They begged for the fans to be put on when they were cut off. The same old stale air containing 3 to 4 per cent. CO_2 and 16 to 17 per cent. O_2 was whirled, but the movement of the air gave relief, because the air was 80° to 85° F. (wet bulb), while the air enmeshed in their clothes in contact with their skin was 98° to 99° F. (wet bulb). If we outside breathed through a tube the air in the chamber we felt none of the discomfort which was being experienced by those shut up inside. Similarly, if one of those in the chamber breathed through a tube the pure air outside he was not relieved.

R. A. Rowlands and H. B. Walker carried out a large number of observations in the chamber, each acting as subject in turn.

They recorded the effect on the respiratory ventilation and on the pulse rate, both when resting and when working. The work consisted in pulling a 20-kilo. weight about 1 metre high by means of a pulley and rope.

In some of the experiments the exhaled carbonic acid was absorbed, and in others carbonic acid was put into the chamber. The subjects inside could not tell when the gas was introduced, not even if the percentage were suddenly raised by 2. The introduction of this amount of the gas made no sensible difference to them, but increased their pulmonary ventilation.

In every one of the experiments they suffered from the heat, and the putting on of the fans gave great relief, and in particular diminished the pulse rate during and after the working periods. The relief became much greater when cold water was circulated through the radiator and the temperature of the chamber lowered 10° F.

The subjects wore only a vest, pants, and shoes in most of these experiments. When they wore their ordinary clothing the effect on the frequency of the pulse was more marked and the discomfort from heat and moisture much greater.

I have made observations on men dressed in the Fleuss rescue apparatus for use in mines, and exposed in a chamber to 120° F. dry bulb and 95° F. wet bulb. The skin temperature rises to the rectal temperature and the pulse is greatly accelerated—*e.g.* to 150—and there arises danger of heat stroke. The conditions are greatly relieved by interposing on the inspiratory tube of the apparatus a cooler filled with carbonic acid snow. The cool inspired air lowers the frequency of the heart and makes it possible for the men to do some work at 95° F. wet bulb, and to endure this temperature for two hours.

The observations made by Pembrey and Collis on the weaving-mill operatives at Darwen show that the skin of the face may be 4° to 13° F. higher in the mill when the wet bulb is 71° F. than at home when the wet-bulb temperature is about 55° F. The tendency of the warm, humid atmosphere of the mill is to establish a more uniform temperature of the body as a whole (surface and deep temperatures) and to throw a tax upon the power of accommodation as indicated by the rapid pulse and low blood-pressure.

The mill workers are wet with the steam blown into the sheds, their clothes and bodies are moist, and the long hours of exposure to such uncomfortable conditions are most deleterious to physical vigour and happiness. The operatives asked that they might be allowed to work without steam-injectors and with diminished ventilation, so that the mill rooms became saturated with moisture evaporated from the bodies of the operatives. The old regulations, while forbidding more than 6 parts in 10,000 CO_2, put no limit to the wet-bulb temperature, and this often became excessive on hot summer days. The operatives were quite right. Less ventilation and a lower wet bulb is far better than ample ventilation and a high wet bulb. The permissible limit of CO_2 has now been raised to 11 parts in 10,000, and the wet-bulb temperature is to be controlled within reasonable limits.

The efficiency of workers in mills, mines, tunnels, stoke-holes, &c., is vastly increased by the provision of a sufficient draught of cool and relatively dry air, so as to prevent overtaxing of the heat-regulating mechanism. Mr. F. Green informs me that by means of forced draught the stokehole of an Orient steamer is rendered the coolest place when the ship is in the tropics.

The electric fan has vastly improved the conditions of the worker in the tropics. I would suggest that each clerk should have a fan just as much as a lamp on his desk. It will pay the employer to supply fans.

In the modern battleship men are confined very largely to places artificially lit and ventilated by air driven in by fans through ventilating-shafts. The heat and moisture derived from the bodies of the men, from the engines, from cooking-ranges, &c., lead to a high degree of relative moisture, and thus all parts of the ironwork inside are coated with granulated cork to hold the condensed moisture and prevent dripping.

The air smells with the manifold smells of oil, cooking, human bodies, &c., and the fresh air driven in by fans through the metal conduits takes up the smell of these, and is spoken of by the officers with disparagement as "tinned" or "potted" air. This air is heated when required by being made to pass over radiators. Many of the officers' cabins and offices for clerks, typewriters, &c., in the centre of a battleship, have no portholes, and are only lit and ventilated by artificial means. The steel nature of the structure prevents the diffusion of air which takes place so freely through the brick walls of a house. The men in their sleeping quarters are very closely confined, and as the openings of the air-conduits are placed in the roof between the hammocks, the men next to such openings receive a cold draught and are likely to shut the openings. To sleep in a warm moist "fugg" would not much matter if the men were actively engaged for many hours of the day on deck and there exposed to the open air and the rigours of sea and weather. In the modern warship most of the crew work for many hours under deck, and some of the men may scarcely come on deck for weeks or even months. Considering the conditions which pertain, it seems to be of the utmost importance that all the men in a battleship should be inspected at short intervals by the medical officers so that cases of tuberculosis may be weeded out in their incipiency. The men of every rating should do deck drill for some part of every day. In the Norwegian navy every man, cooks and all, must do gymnastic drill on deck once a day. In the case of our navy, with voluntary service, the men should welcome this in their own interest.

In a destroyer visited by me twelve men occupied quarters containing about 1700 cubic feet of air. There was a stove with iron pipe for chimney, from which fumes of combustion must leak when in use, and a fan which would not work. When the men are shut down the moisture is such that boots, &c., go mouldy, and the water drips off the structure. The cooling effect of the sea-water washing over the steel shell of the boat is beneficial in keeping down the temperature in these confined and ill-ventilated quarters. On the manœuvring platform in the engine-room the wet-bulb temperature reaches a very high degree owing to the slight escape of steam round the turbines. Commander Domvile was kind enough to send me the wet and dry bulb temperatures taken there on a number of days. The wet bulb was found to be never below 80° F., sometimes reaching 95° and even 98° F. It is impossible for officers to work at these temperatures without straining the heat-regulating mechanism of the body and diminishing their health and working capacity. If such wet-bulb temperatures are unavoidable, means should be provided, such as fans, which would alleviate the discomfort and fatigue caused thereby. A supply of compressed air fitted with a nozzle might be arranged and used occasionally to douche the body with cool air. I have tried this plan and found it very effectual.

and can recommend the compressed-air bath as the substitute for a bracing cold wind.

The suitability of the clothing is of the greatest importance, not only to the comfort but to the efficiency of man as a working machine, *e.g.* power of soldiers to march. On a still day the body is confined by the clothes as if by a chamber of stagnant air, for the air is enclosed in the meshes of the clothes and the layer in contact with the skin becomes heated to body temperature and saturated with moisture.

The observations of Pembrey show that himself and four soldiers, marching in drill order on a moderately warm day, lost more water and retained more water in their clothes than on another similar day when they worked with no jacket on. The average figures were loss of moisture 1600, against 1200 grms., and water retained in clothes 254, against 109 grms. With no jacket the pulse was, on the average, increased 28 against 41 in drill order, and rectal temperature 1° against 1·5° F. The taking off of the jacket or throwing open of the jacket and vest very greatly increase the physiological economy of a march. It is absurd that on a hot summer day Boy Scouts should march with coloured scarves knotted round their necks. Nothing should be worn for ornament or smartness which increases the difficulty of keeping down the body temperature. The power to march and the efficiency of an army depend on prevention of heart stagnation and avoidance of fatigue of the heart.

I conclude, then, that all the efforts of the heating and ventilating engineer should be directed towards cooling the air in crowded places and cooling the bodies of the people by setting the air in motion by means of fans. In a crowded room the air confined between the bodies and clothes of the people is almost warmed up to body temperature and saturated with moisture, so that cooling of the body by radiation, convection and evaporation becomes reduced to a minimum. The strain on the heat-regulating mechanism tells on the heart. The pulse is accelerated, the blood is sent in increased volume to the skin, and circulates there in far greater volume, while less goes through the viscera and brain. As the surface temperature rises, the cutaneous vessels dilate, the veins become filled, the arteries may become small in volume, and the blood-pressure low, the heart is fatigued by the extra work thrown upon it. The influence of the heat stagnation is shown by the great acceleration of the pulse when work is done, and the slower rate at which the pulse returns to its former rate on resting.

The increased percentage of carbonic acid and diminution of oxygen which has been found to exist in badly ventilated churches, schools, theatres, barracks, is such that it can have no effect upon the incidence of respiratory disease and higher death-rate which statistical evidence has shown to exist among persons living in crowded and unventilated rooms. The conditions of temperature, moisture, and windless atmosphere in such places primarily diminish the heat loss, and secondarily the heat production, *i.e.*, the activity of the occupants, together with total volume of air breathed, oxygen taken in and food eaten. The whole metabolism of the body is thus run at a lower plane, and the nervous system and tone of the body is unstimulated by the monotonous, warm, and motionless air. If hard work has to be done it is done under conditions of strain. The number of pathogenic organisms is increased in such places, and these two conditions run together—diminished immunity and increased mass influence of infecting bacteria.

The volume of blood passing through, and of water vapour evaporated from, the respiratory mucous membrane must have a great influence on the mechanisms which protect this tract from bacterial infection. While too wet an atmosphere lessens evaporation, a hot dry atmosphere dries up the mucous membrane. As the immunising powers depend on the passage of blood plasma into the tissue spaces, it is clear that a proper degree of moisture is important. The temperature, too, must have a great influence on the scavenger activity of the ciliated epithelium and leucocytes in the mucous membrane of the nose.

In the warm moist atmosphere of a crowded place the infection from spray, sneezed, coughed, or spoken out, is enormous. On passing out from such an atmosphere into cold moist air the respiratory mucous membrane of the nose is suddenly chilled, the blood-vessels constricted, and the defensive mechanism of cilia and leucocyte checked. Hence the prevalence of colds in the winter. In the summer the infection is far less. We are far more exposed to moving air, and the sudden transition from a warm to a cold atmosphere does not occur. I believe that infection is largely determined by (1) the mass influence of the infecting agent; (2) the shallow breathing and diminished evaporation from, and flow of tissue lymph through, the respiratory tract, in warm, moist confined air. Colds are not caught by exposure to cold *per se*, as is shown by the experience of Arctic explorers, sailors, shipwrecked passengers, &c.

We have very great inherent powers of withstanding exposure to cold. The bodily mechanisms become trained and set to maintain the body heat by habitual exposure to open-air life. The risk lies in overheating our dwellings and overclothing our bodies, so that the mechanisms engaged in resisting infection become enfeebled, and no longer able to meet the sudden transition from the warm atmosphere of our rooms to the chill outside air of winter. The dark and gloomy days of winter confine us within doors, and, by reducing our activity and exposure to open air, depress the metabolism; the influence of smoke and fog, gloom of house and streets, cave-like places of business and dark dwellings, intensify the depression. The immunity to a cold after an infection lasts but a short while, and when children return, after the summer holidays, to school and damp chill autumn days, infection runs around. The history of hospital gangrene and its abolition by the aseptic methods of Lister—likewise the history of insect-borne disease—show the great importance of cleanliness in crowded and much occupied rooms. The essentials required of any good system of ventilating are then (1) movement, coolness, proper degree of relative moisture of the air; (2) reduction of the mass influence of pathogenic bacteria. The chemical purity of the air is of very minor importance, and will be adequately insured by attendance to the essentials.

As the prevention of spray (saliva) infection by ventilation is impossible in crowded places, it behoves us to maintain our immunity at a high level. We may seek to diminish the spray output of those infected with colds by teaching them to cough, sneeze, and talk with a handkerchief held in front of the mouth, or to stay at home until the acute stage is past.

In all these matters nurture is of the greatest importance, as well as nature. A man is born with physical and mental capacities small or great, with inherited characteristics, with more or less immunity to certain diseases, with a tendency to longevity of life or the opposite, but his comfort and happiness in life, the small or full development of his physical and mental capacities, his immunity and his longevity of life, are undoubtedly determined to a vast extent by nurture.

By nurture—I use the word in its widest sense to include all the defensive methods of sanitary science—plague, yellow fever, malaria, sleeping-sickness, cholera, hospital gangrene, &c., can be prevented by eliminating the infecting cause; smallpox and typhoid by this means, and also by vaccination; and most of the other ills which flesh is supposed to be heir to can be kept from troubling by approximating to the rules of life which a wild animal has to follow in the matter of a simple, and often spare diet, hard exercise, and exposure to the open air.

There is nothing more fallacious than the supposition commonly held that over-feeding and over-coddling indoors promotes health. The two together derange the natural functions of the body. He who seeks to save his life will lose it.

The body of a new-born babe is a glorious and perfect machine, the heritage of millions of years of evolution.

> "Not in entire forgetfulness,
> And not in utter nakedness,
> But trailing clouds of glory do we come.
>
> . . . .
>
> Shades of the prison house begin to close
> Upon the growing Boy."

The ill-conditioned body, anæmic complexion and undersized muscles, or the fat and gross habit, the decay of the teeth, the disordered digestion, the nervous irritability and unhappiness are the result of "Nurture"—not Nature.

In institutions children may be disciplined to vigorous health. After leaving school they are set adrift to face monotonous work in confined places, amusement in music-halls and cinema shows in place of manly exercise in the open air, injudicious diet, alcohol, and tobacco—everything which the trainer of an athlete would repel.

> "And custom lie upon him with a weight
> Heavy as frost, and deep almost as life."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SHEFFIELD.—The council of the University of Sheffield has made the following appointments:—(1) Dr. H. R. Dean, to the Joseph Hunter chair of pathology, in succession to Prof. J. M. Beattie, who has been appointed to the chair of bacteriology in the University of Liverpool. Dr. Dean is at present assistant bacteriologist to the Lister Institute of Preventive Medicine. (2) Mr. Leonard Southerns, to the post of junior lecturer and demonstrator in physics, *vice* Dr. J. Robinson, resigned. Mr. Southerns is at present chief assistant at the Eskdalemuir Observatory, N.B. The council received the resignation of Prof. F. W. Hardwick of the professorship of mining, owing to his retirement from active work. Prof. Hardwick has been on the staff since October, 1891.

A COURSE of fifteen lectures on Indian sociology will be delivered at East London College (University of London), Mile End Road, E., by Mr. T. C. Hodson (late of the Indian Civil Service), on Wednesdays at 5.30, commencing October 23. The lectures are open to the public without fee.

DR. A. N. WHITEHEAD, F.R.S., University reader in geometry, will deliver at University College, London, a non-technical course of lectures on "The General Ideas of the Science of Geometry" during the first two terms of the session. The course will begin on Tuesday, October 8, at 5 p.m.

THE opening of the session at Edinburgh University will see the inauguration of the new scheme for engineering degrees by which the full resources of the University and the Heriot-Watt College are utilised for the first time to enable students to specialise in the three departments of civil, mechanical, and electrical engineering.

A REUTER message from Cape Town states that in view of the fact that there is no precedent for the Sovereign's holding office in any university of the Empire, the King has resigned the Chancellorship of the Cape University with which his Majesty was invested on the occasion of his visit to South Africa in 1901 as Duke of Cornwall. The Duke of Connaught has accepted nomination to the Chancellorship in succession to the King.

ANNOUNCEMENT is made of two courses of post-graduate lectures to be delivered at University College (University of London), by Prof. J. A. Fleming, F.R.S. (Pender professor of electrical engineering). One course, on "Electromagnetic Waves and the Theory of Electrons," will be delivered on Wednesdays at 5 p.m., beginning Wednesday, November 6, and the other, on "Electric Wave Wireless Telegraphy," will begin on Wednesday, January 22, 1913.

AT the University of Bristol, the calendar of which for the session 1912–13 has been received, the bachelor's degree can be taken in engineering, both by day and evening students. The final part of the curriculum may be in civil, mechanical, electrical, or motor-car engineering. At Bristol also, it is interesting to note, the Senate of the University is authorised to confer a testamur in social study and in journalism—a further indication of the desire of the modern university to assist directly every kind of professional work.

THE best criterion of the vitality of a university is the record of its members' contributions to knowledge. The magnitude of such a list cannot, of course, be taken as a measure of the importance of the original work accomplished, but it indicates the activity of the various departments of the university to which the list refers, and shows that attention is not being concentrated unduly upon examination standards. A list of memoirs, papers, &c., published during the years 1909–1912 by members of the teaching staff, scholars and fellows, research students, and others connected with the University of Glasgow has just been received, and it provides convincing evidence of the large amount of literary and scientific work published by members of the University. The uniform distribution of these products through all departments should be a particular cause of gratification to the principal.

THE needs of students of applied science receive increasing attention year by year from university authorities in different parts of the country. The new calendar of Armstrong College, Newcastle-upon-Tyne, one of the constituent colleges of the University of Durham, shows that here, for example, students, in addition to being able to obtain the degree of bachelor of science in pure science, may, if they prefer, offer instead one of seven branches of applied science. Degrees may, in fact, be obtained in agriculture, mechanical and marine engineering, electrical engineering, civil engineering, naval architecture, mining, or metallurgy. The calendar shows, too, that the active cooperation of engineering and shipbuilding firms in the district has been secured. Many manufacturers have promised to cooperate with the college by receiving pupils in the several departments of their works and in their drawing offices, and by permitting them to devote themselves exclusively during two or three sessions to their college studies.

THE prospectus for the session 1912–13 of the day and evening college for men and women at the South-Western Polytechnic, Chelsea, serves excellently to illustrate the very complete provision for higher education provided by the London polytechnic institutions. In both the day and evening classes at Chelsea students can prepare for degrees at the University of London under favourable conditions. In the day college those students who enter for technical instruction should have received previously, the prospectus points out, a sound English education and should have acquired an elementary knowledge of mathematics, and, if possible, of physics and chemistry. The courses are arranged to occupy three years. On entering the student states whether he wishes to be trained as a mechanical or electrical engineer, or as a consulting or industrial chemist. In any of these cases he will find mapped out for him a complete course of study, involving laboratory instruction and instruction in the workshops. Students, having completed a three years' course, should be in a position to obtain situations, in many cases without payment of premium, in important industrial firms. Similarly in the evening classes, instruction is provided in a wide range of scientific, technological, and other subjects.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 23.—M. A. Grandidier in the chair.—E. L. **Bouvier**: *Caridinopsis chevalieri,* and the genera of the Atyideæ peculiar to tropical Africa.—Henri **Douvillé**: The Orbitolines and their connections.—A. **Verschaffel**: The earthquake of the night of September 14–15, 1912. An account of the phenomena observed at the Observatory of Abbadïa.—**Claude** and **Driencourt**: The orthostathmescope or intrument for observing the passage through the zenith of the alignment of two stars on the celestial sphere.—Th. **De Donder**: The invariants of the calculus of variations.—N. **Lusin**: The absolute convergence of trigonometric series.—F. **Briner** and E. L. **Durand**: The conditions of formation of nitrous and nitric acids starting from the oxides of nitrogen and water; application of the law of mass action. Nitric oxide was compressed with solutions of nitric acid of varying concentrations; a general account of the changes noted is given, full details being reserved for a later paper.—Félix **Robin**: The crystallisation of metals by annealing. The metals examined included tin, lead, zinc, aluminium, copper, and iron. The grain developed by annealing was studied by etching with suitable liquids and microscopic examination.—H. **Jumelle** and H. Perrier de la **Bathe**: The cabbage palm of Madagascar.—M. **Chaillot**: The biology and anatomy of Labiates with subterranean stolons.—A. **Desmoulière**: The antigenic bodies in the Wassermann reaction. An account of the effects of the addition of cholesterol to the alcoholic extract of syphilitic liver. The sensibility and keeping powers are increased.—Maurice **Piettre**: The influence of some chemical compounds on the artificial melanines.

BOOKS RECEIVED.

The Simple Carbohydrates and the Glucosides. By Dr. E. F. Armstrong. Second edition. Pp. viii+171. (London: Longmans, Green and Co.) 5*s.* net. (Monographs on Biochemistry.)

Oxidations and Reductions in the Animal Body. By Dr. H. D. Dakin. Pp. viii+135. (London: Longmans, Green and Co.) 4*s.* (Monographs on Biochemistry.)

The Teratology of Fishes. By Dr. J. F. Gemmill. Pp. xvii+74+xxvi plates. (Glasgow: J. MacLehose and Sons.) 15*s.* net.

Wild Flowers as They Grow. Photographed in Colour direct from Nature. By H. Essenhigh Corke, with descriptive text by G. Clarke Nuttall. Fourth series. Pp. viii+300. (London: Cassell and Co., Ltd.) 5*s.* net.

Mind and its Disorders. By Dr. W. H. D. Stoddart. Second edition. Pp. xvi+518. (London: H. K. Lewis.) 12*s.* 6*d.* net.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

*" To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH.

NO. 2241, VOL. 90] THURSDAY, OCTOBER 10, 1912 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

THURSDAY, OCTOBER 10, 1912.

FIVE NEW SCHOOL GEOGRAPHIES.

(1) *Cambridge Geographical Text-books—Intermediate.* By A. J. Dicks. Pp. xi+362. (Cambridge: University Press, 1912.) Price 3*s.*

(2) *Physical Geography for South African Schools.* By Alex. L. Du Toit. Pp. xii+250. (Cambridge: University Press, 1912.) Price 4*s.* 6*d.* net.

(3) *A Geography of Europe.* By T. Alford Smith. (Macmillan's Practical Modern Geographies.) Pp. xi+272. (London: Macmillan and Co., Ltd., 1912.) Price 2*s.* 6*d.*

(4) *A Class Book of Physical Geography.* By A. T. Simmons and E. Stenhouse. Pp. viii+436. (London: Macmillan and Co., Ltd., 1912.) Price 4*s.* 6*d.*

(5) *The Marlborough Country.* Notes, Geographical, Historical and Descriptive, on Sheet 266 of the One-inch Ordnance Survey Map. By H. C. Brentnall and C. C. Carter. Pp. 171. (Oxford: University Press; London: Henry Frowde, 1912.) Price 2*s.* 6*d.* net.

THESE are five up-to-date geographies, each emphasising, more or less, the chief features of what has now for the last seven or eight years come to be known as the "New Geography."

(1) The Cambridge "Intermediate" is a general geography. It is worked on the lines of cause and consequence, the why and the wherefore. Each section dovetails into its immediate predecessor in logical order, thus:—

(*a*) Mathematical geography and relation of land and water *lead to* climate;

(*b*) Climate *leads to* flora and fauna;

(*c*) Flora and fauna *lead to* distribution of population, development of industry, &c.

These three divisions occupy one-eighth of the book proper. The remaining seven-eighths applies the principles enumerated to the great continental regions of the world in the old-time order—Europe, Asia, Africa, Australasia, America. This is exclusive of a large supplementary list of examination questions, and of a fairly copious index of place names. The questions are not all that could be desired. Too many are merely essay subjects, as "Of what value is the study of geography?" and "Write an essay on the German people, and their position in Europe at the present time." Some of the statements in the text, too, require qualification, *e.g.*, that the trans-Andine railway runs *through* the Uspallata Pass, and that the Egyptians belong to the Hamite race.

(2) Offers the usual contents of a physical geography—earth, air, water, fire, land-forms and life—but draws its examples, as well as its pictures, from South Africa, and adds a concluding chapter on the physical geography of South Africa itself. Its strong point is its geology, which becomes the weak point of its geography—for there is far too much of it. The human interest suffers. This appears to be a defect throughout. There is a maximum of man's environment and a minimum of its effects on man himself. The value of the book to *English* teachers will lie in the novelty of the South African examples, which at once takes it out of the ordinary run of our school books. Its style strikes one as very stiff for class work, and there are no exercises. A full, if somewhat pretentious, bibliography is given at the end.

(3) Attacks the regional geography of Europe on modern lines. The various "lessons" consist of (*a*) practical exercises, (*b*) descriptive matter, (*c*) questions. Teachers who know Macmillan's "Practical Modern Geographies," of which series this is one of the latest volumes, have nothing but praise both for the matter and for the method of the books. In dealing with Europe regionally, it is, of course, impossible to ignore the political divisions, but Mr. Alford Smith rightly lays great stress on their physical bases.

A special instance will show the method of treatment. Chapters xiv.–xviii. are allotted to Germany, and are headed: Climate and Vegetation, Races of People, Coalfields, The Rhine, North Sea Ports—five headings which pick out the salient features of the country. To ensure the inclusion, or at all events the non-exclusion, of the other features, practical exercises are added on allied subjects, *e.g.*, distribution along with races of people, manufactures with coal, commerce and trade with ports.

(4) An excellent book treats physical geography as an intensely practical subject. Here, too, exercises, descriptions, and questions follow each other. The value of an exercise lies in its stimulus for investigation; the boy must use his school atlas, his book of reference, his instruments. He must become, therefore, to a certain extent an independent observer—which is excellent, and very satisfactory to all concerned, and is the very *raison d'être* of all books of this type. But to work out his exercises he must be assisted here and there with *clear* accounts of geographical phenomena. The authors of this physical geography are to be congratulated on the clarity of their descriptions. The section on winds, even though "wind roses" may not give a wholly correct idea of the winds of a given district, may be turned to as an example. He would be a dull boy, or girl, who could not grasp the principles of

the monsoons and the influence of the heat equator from these pages.

(5) "The Marlborough Country" should be as interesting to a tourist with a bent for geology, or archæology, or nature study, as it is useful to a teacher who wants to deduce from an ordnance map the immense amount of information which lies hidden beneath its signs and symbols. The Marlborough district map (sheet 266 of the one-inch ordnance survey map) is in this little book made to yield up as subject-matter for observation the reading of relief maps in general, the physical divisions of the "Marlborough Country," its geology, climate, farm life, communications, distribution of population, history and archæology, let alone such specialities as the Downs, the Vale of Pewsey, Savernake Forest, and a host of miscellanous local topics. The book is a novelty, and has more than a local interest. It is a pioneer, an exemplar, in the science of home geography.

Summarising generally, all five books are suitable for the middle and higher forms of a secondary school. No. 1 is well got up, of taking appearance, but rather sketchy, and inferior, in our opinion, to its "Oxford" rivals. No 2 must fill a great void in South Africa, but is naturally not so well adapted for British schools. Nos. 3 and 4 are on similar lines, and belong to the excellent type of book of which Simmons and Richardson's "Introduction to Practical Geography" was the first exponent. No. 5 has for its staple just the kind of information that a guide-book relegates to its introductory pages, and as for its interjectory questions—well, the ordinary man may ignore them, while the teacher will find them extremely useful.

LABORATORY CHEMISTRY.

(1) *Outlines of Inorganic Chemistry.* By Dr. E. B. Ludlan. Pp. xv + 365. (London: Edward Arnold, 1911.) Price 4s. 6d.

(2) *A Handbook of Organic Analysis, Qualitative and Quantitative.* By Hans Thacher Clarke, with an introduction by Prof. Norman Collie, F.R.S. Pp. viii + 264. (London: Edward Arnold, 1911.) Price 5s. net.

THE methods of teaching chemistry, particularly inorganic chemistry, are so diverse and depend so much upon the individuality of the teacher that it is no wonder there are a large number of books on elementary chemistry, and that their number is still increasing.

(1) Mr. Ludlan's book is very readable, and is illustrated with portraits of Lavoisier, Priestley, Scheele, Faraday, Dalton, and Humphry Davy. We like the introduction of such portraits in a book on science because it helps the student to remember historical facts, and impresses upon his memory the importance of the work of the persons whose portraits appear.

The author commences with a brief discussion on early notions which for many reasons, mainly for the want of the balance, were incorrect. The moral impressed is: "Be sure of your facts before trying to explain them." Some of the questions at the end of the chapters are unusual; for example, "How would you attempt to establish the truth or inaccuracy of the following statements: 'Sunshine puts the fire out'; 'Sunshine makes colours fade'; 'A watched kettle never boils'?" These questions may be suitable in a class, but are somewhat puerile in a book, more particularly as the chapter in question does not deal with them—it happens to be "On the Rusting of Iron." But anyone who works carefully through the book will obtain a good foundation of elementary chemistry.

(2) The second book is of a very different character, being on organic analysis. It is only fairly recently that books on organic analysis have been published in which any attempt has been made at classification. Of course, the difficulties of classifying substances of such diverse nature and properties as occur in organic chemistry are very great, and when all is said and done organic analysis is not in general so exact as inorganic analysis.

Prof. Collie, who writes an introduction to the book, remarks that "The examination of inorganic ions too often tends to degenerate into a series of arbitrary tests, memorised and applied without much consideration of their theoretical bearing." Some years ago, when everything was worked by the "chart," this was to some extent true, but the more modern books almost always insist most strongly on a mastery of the theoretical as well as the practical aspect. It is a strange fact that an organic chemist is apt to think lightly of inorganic chemistry and *vice versa*, and yet each branch has its own difficulties and importance.

The first chapter of the book before us deals with the preliminary investigation of the substance or substances to be analysed. Tests for purity, such as melting point, boiling point, and fractionation, are enumerated—we say enumerated instead of given, because the description is rather inadequate; for example, Distillation under reduced pressure: this is followed by tests for carbon and hydrogen and further preliminary tests with the object of sorting into groups such as phenolic, acidic, neutral, &c. The next chapter deals with the examination for radicles; it is well written, and the facts are grouped together in a very useful manner. The third chapter practically completes the qualitative portion of the book, and is followed by tables of organic compounds in which the properties and physical constants of a large number of the most generally met with organic compounds are compiled—it is, in fact, a short dictionary. This section will most certainly be found very useful in the laboratory, and has been very painstakingly compiled.

The rest of the book deals with quantitative analysis, combustions, nitrogen determinations, vapour densities, optical rotation, and other methods which are employed in the laboratory.

LOCAL AND GENERAL GEOLOGY.

(1) *Transactions of the Paisley Naturalists' Society.* Vol. i. Notes on the Mineralogy of Renfrewshire. By Robt. S. Houston. Pp. 88. (Paisley: Alexander Gardner, 1912.) Price 2*s.* 6*d.* net.

(2) *Physiography for High Schools.* By Albert L. Carey, Frank L. Bryant, William W. Clendenin, and William T. Morrey. Pp. vi+450. (Boston, New York, Chicago: D. C. Heath and Co.; London: George G. Harrap and Co., 1912.) Price 4*s.* 6*d.*

(3) *Structural and Field Geology. For Students of Pure and Applied Science.* By Prof. James Geikie, F.R.S. Third edition, revised. Pp. xxiv+452. (Edinburgh: Oliver and Boyd; London: Gurney and Jackson, 1912.) Price 12*s.* 6*d.* net.

(1) MR. HOUSTON'S volume, attractively produced and excellently printed, cannot fail to arouse interest in local mineralogy. A preface is given on the geology of Renfrewshire, and we are reminded of the famous specimens of prehnite and analcite from the Boylestone Quarry, near Barrhead. New analyses are given of several minerals, including phosphatic nodules (p. 72) from three localities, and a greenish kaolin (p. 71). The name "lithomarge" is misprinted in three places, and we do not like the term "carbonated" on p. 78 in place of "carbonised." But considerable care has evidently been given to the book, which serves as a model for the work of local naturalists.

(2) We now possess several good English books on physiography, and have received much stimulating aid from the United States. Hence it is questionable if another American work is likely to find a free place in our schools. Four high-school masters, however, have collaborated in New York City in producing a clearly written account of natural phenomena, illustrated with views and maps from the wide field available in the United States. Unlike Huxley, they set aside the biological aspects of physiography, and they omit in consequence a good deal that would interest a schoolboy in the surface-features of his country. The work is terse and lucid, but seems somewhat cold and uninspiring; its method of construction has prevented any one of the authors from impressing on it the mark of personality. A few good books of scientific travel would probably set young pupils thinking to far more purpose about the earth. Physical geography in the high-school stage already runs the risk of becoming stereotyped. Certain set names for phenomena require certain definitions. Meanwhile, the rock is removed out of its place and the waters wear the stones, while the eye of the pupil, made for wonder, remains fixed upon the printed page.

(3) Prof. James Geikie's "Structural and Field Geology" now reaches a third edition. In its fine use of full-page photographic plates it aims at accurate illustration of what will be encountered in the field. No one can convert these pictures into diagrams for the note-book; they are, as the author intends, direct encouragements to observe. Rocks are photographed from actual specimens, and the landscapes and field examples are largely derived from the series of views brought together by the Geological Survey. The book is a broad treatise on physical geology, written with a remarkable absence of technicalities. It goes, perhaps, too far in avoiding chemical considerations, such as those involved in the formation of laterite (p. 58) and cornstones (p. 70), and in omitting even chemical formulæ, which would be helpful in the description of the silicates. Methods of testing minerals and rocks are introduced as they happen to be required, and it is clear that the work should be read continuously. Among its best features are the drawings of block-models of faulted strata (pp. 162 and 166), which explain many of the puzzles of geological maps. The trough-faults in Fig. 53 might gain by a cross-reference to their explanation in Fig. 54.

The principles of geological surveying receive unusually full treatment, and attention is given to economic questions and to the broad characters of soils. Chapter xxv., on geological structure and surface features, might, of course, be greatly elaborated. The twenty-three lines devoted to coast-lines seem inadequate in comparison with forty-five pages given to ore-formations in chapter xvi., a subject not closely related to structural geology. Prof. James Geikie's book, so handsomely set before us, will long remain our best introduction to geological phenomena as they actually present themselves to the observer.

Grenville A. J. Cole.

WHAT IS INSTINCT?

The Evolution of Animal Intelligence. By Prof. S. J. Holmes. Pp. v+296. (New York: Henry Holt and Co., 1911.)

THE study of animal behaviour has two problems, description and interpretation. Both give opportunities for error. Thus on the one hand Binet's discussion of the mental life of Protozoa is largely based on a mistaken view of the facts. Didinium does not "hunt" its prey or "cast darts" at it. On the other hand Thorndike, on the basis of his well-known experiments, argued that his animals showed no high degree of intelligence because there was no sudden drop in their learning curves; Hobhouse opposed this conclusion on the ground that the curves did show a sharp drop. But in a recent article comparing human adults, children, and rats in learning a maze, Prof. Hicks finds that "the relation between the abruptness of slope and the degree of rational ability is just the inverse of that assumed by Thorndike and Hobhouse."

As this example suggests, problems of interpretation lead inevitably to questions of human psychology. Now we know considerably less about human methods than the old naïve anthropomorphism assumed. Nevertheless, the work already done by general psychology upon many of the problems of interpretation occurring in animal psychology cannot profitably be ignored. The failure to recognise this fully somewhat detracts from the value of Mr. Holmes's discussion of that central problem, the nature of instinct. His treatment seems to imply that the distinction between reflex action and instinct is merely one of degree or complexity.

Spencer's view is, of course, one for which many arguments may be found, but, in any attempt to discuss the matter at all fully, it should surely be made clear that a very different opinion has been taken by most of those approaching the question from the psychological, rather than the biological, viewpoint the opinion, namely, that instinct is essentially conscious, involving elements of striving, feeling and cognition. Curiously, Mr. Holmes quotes with approval a well-known passage from James which insists on the essential kinship of animal instincts with human impulses, without apparently seeing how incompatible this conception is with any attempt to define instinct in terms of mere movement. Certainly, unless all interpretation is delusive, it seems clear that in many cases consciousness is necessarily involved. A bird building a nest or feeding its young is not merely executing a series of movements which happen to produce a given result. On different occasions this result remains the same while the exact movements and their order are continually varying; that is, the result is not merely an effect but also a cause: we have not merely movement but action.

In discussing puzzle-box tests of intelligence Mr. Holmes rightly agrees with Prof. Hobhouse that the frequent variation of method in lifting the latch, &c. (*e.g.*, using either paw), is conclusive against attributing everything to sensori-motor association. But the same argument seems decisive against regarding instinct as a complex of reflexes. Its framework is fixed; the gaps, however small, have to be varyingly filled in by conative and intellectual processes of at least the perceptual level.

Into the relation of instinct to intelligence it is impossible to enter. The use of intelligence as equivalent to the power to form associations may be justified if one means merely that which is opposed to instinct, but it fails to find any place for that perception of relations which is to be found selecting means to ends whether given by congenital or experiential orientation.

If Mr. Holmes's discussion of central theoretical questions is not altogether satisfying, his book is extremely interesting if only because of the amount of concrete illustration. It is unfortunate that a number of slipshod phrases has been allowed to pass.

OUR BOOKSHELF.

Their Winged Destiny, being a Tale of Two Planets. By Donald W. Horner. Pp. 240. (London: Simpkin, Marshall and Co., Ltd.) Price 2s. net.

THERE are about one hundred million suns in space; and it is reasonable to suppose that many of them have planets revolving round them similar to those which form our own solar system. Whether life exists upon any of these bodies is a matter of legitimate speculation. It is, perhaps, possible that among so many bodies there is one which has gone through precisely the same stages of development as the earth, and upon which the same forms of life are in being. This hypothesis provides Mr. Horner with the basis of his fantastic romance.

As in Mr. Wells's impressive story of "The Star," a new star appears and threatens to destroy the earth. To avoid the calamity, a party leaves the earth in an "Electronship," which can travel with the velocity of light, and after four years arrives at the system of α Centauri, where black and white giants were at war on one planet, while another was found to be exactly like the earth, not only as regards the distribution of land and water, but also in its inhabitants, who spoke the same languages as the peoples of our globe. Slight differences of mechanical and social development led to difficulties when the travellers settled down upon the Centaurian planet; and eventually the party returned to the earth again to find that it had not been annihilated, the new star having passed outside our system.

There is, of course, a love story to give human interest to the adventures; and some amusing and exciting episodes lighten the monotony of a tiresome journey. As an attempt to combine fact with fiction, the story is not without merit; but the style is commonplace, and such a split infinitive as "to quietly and unostentatiously do" is enough to make any lover of good literature shudder. R. A. G.

Catalogue of the Periodical Publications in the Library of the Royal Society of London. Pp. viii+455 (London: Printed for the Royal Society at the Oxford University Press and sold by Henry Frowde, 1912.)

Catalogue of the Periodical Publications, including the Serial Publications of Societies and Governments, in the Library of University College, London. By L. Newcombe. Pp. vii+269. (Oxford: Printed for University College, London, by Horace Hart, 1912.)

The general plan of both these catalogues is similar, and this is natural, since the Royal Society catalogue has been compiled by Mr. Newcombe, sub-librarian of University College, London, and Mr. L. Ellston.

A catalogue of periodical publications in the library of the Royal Society was last printed in 1881, and the large number of accessions to this section of the library in the succeeding thirty years rendered a new catalogue imperative. Instead of adopting the plan of the old catalogue, with its classification under eight separate alphabets, the present has been arranged under one alphabet and restricted as closely as possible to periodical works.

The catalogues will prove invaluable to scientific workers who make use of either library, for the task of discovering a volume has certainly been made as light as possible.

Bacon's New Globe with Contour Colouring. Natural Scale 1/37,000,000. Price 25*s.*

The globe is nearly fifteen inches in diameter, weighs about four and a half pounds, and is consequently easily portable. It is provided with a brass graduated semi-meridian and a conveniently-arranged compass. The colour scheme is based on that of the International Map Committee, and the relative land levels and sea depths are both indicated.

The large number of names included has made the size of type very small, and few places can be read even at a short distance. This will interfere with the use of the globe for class purposes. For individual study the globe will prove useful, and its use may be recommended to correct the wrong impressions formed by an exclusive examination of flat maps.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

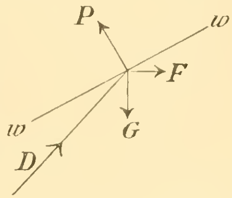
Sailing Flight of Birds.

Coming out from Queenstown on September 10 on her way toward Boston, the ss. *Arabic* was accompanied for some hours by a large flock of gulls. For the most part these birds were visibly working, flapping their wings, but occasionally a few would cease flapping and merely sail along for considerable distances, keeping up with the ship or even gaining upon it, sometimes descending, sometimes ascending, apparently at will, with no perceptible action of their wings except, now and then, a slight effort which seemed to be needed for preserving equilibrium, not for support or for propulsion. The wind was of such direction and velocity that the smoke from the ship's funnel went astern in a trail making an angle of, perhaps, 30° with the keel.

Having at first no reasonable theory of the sailing which the gulls practised, I watched them intently for some time, and made the following observations:—

(1) The sailing occurred almost wholly, if not quite so, over or near the windward side (the starboard) of the ship, at moderate heights, 20 to 40 ft. perhaps, above the level of the uppermost deck, and not very near the bow.

(2) When a bird was sailing parallel to the course of the ship, the line from beak to tail was very nearly, if not quite, parallel to the trail of smoke from the funnel. If the gull turned so as to make his own axis more nearly parallel to the keel of the ship, he drifted to leeward; if his axis was turned somewhat farther from the direction of the keel than at first, he went to windward.



Apparently the head and neck served as a bow rudder for small changes of direction, the whole body soon following the course indicated and initiated by this part.

(3) When a bird was sailing along with the ship his head was held rather low. If he raised his head and lowered his tail, he was carried to leeward or astern with great velocity; this frequently happened, for it was evident that most of the food was discovered by the gulls behind the sailing ones, and the greater part of the flock was usually there.

(4) When, through a shift in the wind or in the course of the ship, the smoke began to trail out nearly astern, a change which occupied a few minutes only, the sailing of the birds ceased, each one being then obliged to make visible effort to keep up with the ship.

An explanation of the ability of the birds to sail, under the conditions described above, is, I believe, found in the upward course of the wind which has struck the weather side of the ship and must rise in order to pass over it. Given a brisk, steady, upward current of air, a gull, with its highly practical knowledge of mechanics, can, of course, sail in any direction. Thus, in the figure here given, if *ww* represents a wing-plane, D the direction of the current of air, P the net wind-pressure on the wing-plane, G the pull of gravity, the bird's weight, and F the frictional resistance[1] encountered by the bird in moving through the air, we have indicated a solution of the problem of support and of propulsion, propulsion in a direction opposite to that of the horizontal component of the wind's velocity.

As the trail of smoke marks the direction of the wind with respect to the moving ship, the bird must, in order to sail with the same velocity and direction as the ship, have a motion relative to the air equal and opposite to the motion of the smoke relative to the ship. Accordingly, the bird's axis is kept parallel to, and opposite to, the course of the smoke as indicated by its trail from the funnel.

With a head-wind, though there must be an up-current near the bow, this current must be much more narrowly local, and therefore less advantageous for the bird's use in sailing, than the up-current produced by a wind abeam.

It would appear that the gulls when sailing are not directly seeking food, but are merely resting, loafing for the time being, with ears intent, however, for any indication of a find by their more industrious brothers astern.

Having shown this discussion to a number of well-known physicists aboard the *Arabic*, I find no opposition to the theory proposed for the facts as noted, but a very general doubt as to whether gulls do not sometimes sail on the leeward side of a ship or too far astern to get the benefit of the upward air current from the windward side. When I ask seafaring men about the matter, they at first say confidently that the birds sail on either side of the ship, but after a little consideration they waver in this statement and admit that they have never taken particular note of the facts in the case. Accordingly I have thought it worth while to write this letter, in the hope that its publication in NATURE, if room be found for it, may stimulate further observation of an interesting phenomenon and perhaps prevent some inventors from wasting their time and money in vain attempts to accomplish motor-less flight.

The westward course from Queenstown may be an especially favourable place for studying the question here raised. Four years ago I made there some observations which, so far as I can now recall them, agreed in essential particulars with those which I have made recently, but I did not at that time see the full significance of the facts noted.

EDWIN H. HALL.

Cambridge, Mass., September 20.

[1] Perhaps D should be taken in the direction of D, but uncertainty here does not affect the main argument.

Errors of the Computed Times of Solar Eclipse Phenomena.

THE final reports of two of the observers of the total solar eclipse of April 28, 1911, have recently been published, giving detailed accounts of their experiences at Vavau, Tonga Islands. Father Cortie's report appears in Proceedings, R.S., No. A595; that of Dr. W. J. S. Lockyer in a publication of the Solar Physics Committee. In reading these reports I have been much struck by the circumstance that both writers appear to have been taken aback by the (to them) unexpected effect of the errors of the lunar tables on the computed times of the various phases of the eclipse. But I wish to point out that they were not left without warning. In Monthly Notices, R.A.S., vol. lxix., p. 31, I stated that with the existing errors of the lunar tables the times of the contacts in this eclipse as there given would be several seconds too late. And as a means of estimating the true times I gave the intervals from the instant when the cusps subtended an angle of specified value at the sun's centre to the commencement of totality. The shift of the moon's actual position relatively to its tabular place would, of course, alter the predicted duration of the eclipse. At the time of publication of my paper (November, 1908), it was not possible to give definite information as to the magnitude of the errors in question, as Newcomb's latest corrections were not then available. But, so far as appears from these reports, the intending observers did not make any further inquiries on the subject before proceeding to draw up their definite programmes of observation. In the circumstances this, surely, would have been a wise precaution.

A. M. W. DOWNING.

September 27.

WITH regard to Dr. Downing's remarks, I was aware from his published statement that the predicted time of totality would probably be "several seconds too late," but little thought that the error would amount to so much as *twenty seconds* of time. The precaution was naturally taken to observe closely the diminishing cusp and to arrange to give the necessary time signals from the cusp data mentioned by Dr. Downing in the above letter. Unfortunately, however, while the cusp was visible nearly up to second contact, the image of it on the screen had been oscillating so violently (due to air tremors) that the officer in charge had previously decided to give the necessary signals at the computed times from the chronometer. (See page 17 of my report for details of the actual procedure.) It is true that no inquiry was made by me to find out what error might be expected, but it was assumed that if such a large error had been approximately known it would have been published. It would be advantageous if the present director of the Nautical Almanac could find his way to make generally known the approximate values of such errors a short time previous to the setting out of eclipse expeditions.

The facts that Father Cortie's camp was in the same clearing as that of my party and that he made use of my time signals explain why he experienced the same error.

WILLIAM J. S. LOCKYER.

Solar Physics Observatory, October 1.

A Flower-sanctuary.

IT seems to me that Sir Edward Fry takes a rather narrow view of the by-law under discussion; for surely it may be held that the removal of any of the special Cheddar plants, in such quantities as to leave a blank where there was formerly a mass of colour, would constitute a "disfigurement" or "damage" within the meaning of the enactment: and I suggest that any bench of magistrates anxious to preserve the beauty of the gorge should find no difficulty in convicting under the by-law. If, however, it be held that the existing by-law is inadequate, it seems clear that county councils have full power to enact far more stringent and specialised by-laws.

I remember that on the commons under the jurisdiction of the London County Council there used to be—and doubtless still are—notices forbidding anyone, under a penalty of five pounds, to pluck even a single blossom of any wild flower; and I think that Sir Edward Fry will find on St. Vincent's Rocks, at Clifton, notices announcing a similar penalty against anyone who shall gather the rare *Arabis stricta*: at any rate, there were such notices a few years ago, and it was well understood that the protection of *Arabis stricta* was the motive, or a chief motive, of the authorities. FRANK H. PERRYCOSTE.

Higher Shute Cottage, Polperro, Cornwall, September 29.

MR. PERRYCOSTE is quite right in suggesting that the special flora of Cheddar might be destroyed in such a way as to bring the offender under the by-law in question, but this does not interfere with my statement that the flora might be destroyed without any contravention of the by-law; it is much more probable that the flora will be gradually extinguished than by a single act of vandalism. EDW. FRY.

IN addition to the existence of a local order for the protection of wild flowers in Cornwall, extending only to the highways, there are other counties, such as Essex, Surrey, Sussex, and Devon, that have already availed themselves of the power to frame a by-law applying to a separate county.

Though these means of restricting hawking and excessive collecting exist on a limited scale at present, it is the aim of the Plant Protection Section of the Selborne Society to obtain the cooperation of all county councils in the framing of by-laws throughout the country. This, indeed, it must be stated, is apparently the only course left, for the experience of county councils in applying singly for this power to the Home Office has been distinctly discouraging. In fact, the Home Office has refused to increase the number of local orders; so that the only method to adopt is to get every county council to apply simultaneously, when the force of public opinion thus expressed will not fail, we hope, to have the desired effect.

Of course, the securing of a local order for Somerset, as advocated by Sir Edward Fry, would not be equivalent to the establishment of a flower-sanctuary. Unless land were purchased by the National Trust, or some kindred public-spirited body, or by private enterprise, the making of a reservation of any tract without the owner's consent is out of the power of the Government. At least, we have not come to land nationalisation as yet (save the mark!).

The desirability of the formation of wild-flower reservations is undeniable. It is one of the projects kept in view by the Plant Protection Section. One of the methods of securing this end will be the obtaining of the support of the scientific societies of the country, and the appointment of a corresponding secretary in each district to advise upon what tracts require reservation and what facilities exist locally for their formation. The writer's investigation into the voluminous causes of extermination of plants has shown that there are numerous localities in every county of the British Isles which require reservation or protection. It is obvious that no one body such as the Selborne Society could undertake to carry on single-handed the enormous amount of organisation required to protect actively plants locally without effective assistance from such bodies, or without some organised effort. This question is on the *tapis* at the next meeting of the section, which I hope Sir Edward Fry will attend, and it is hoped to prosecute this part of the campaign very actively during the coming winter. The assistance of any who can render service in this matter of enlisting the sympathies of the scientific societies will be very gratefully received. The result of an appeal to the county councils last year to aid in the creating of a public protest against exterminating wild flowers, especially addressed to the schools, in which the collecting necessary to the pursuit of nature-study was involved, was very encouraging.

The whole question resolves itself, in fine, to the obtaining of State protection of wild plants (and animals) in this country, as in Prussia. This is the prime object the section has in view. In the meantime, it is endeavouring to create a public opinion in favour of the movement, until such time as the occasion is ripe for making a concerted appeal for Government control. A. R. HORWOOD,

Recorder, Plant Protection Section of the Selborne Society.

Leicester Museum, September 27.

The Summer of 1912.

IN NATURE of September 19, Mr. Harding concludes a very interesting article on the recent summer in the British Islands, by recording the fact that "the temperature of the sea-surface in the North Atlantic and in proximity to our own coasts has for some time past been much below the average." This seems to bear out what I have been telling people for weeks past—that the abnormal chilliness of the past summer, and especially of the month of August, was in all probability due to the cooling of the Gulf Stream by the abnormal ice-drift on the other side of the Atlantic, to which the disastrous fate of the *Titanic* forced the tardy attention of even the great shipping companies. A reference to such a thorough-going atlas as that of Diercke and Gaebler (p. 21) will show what this must mean, when not only icebergs but extensive icefloes in such numbers were melting away in the latitudes of the Spanish peninsula, and even further south than the latitude of Gibraltar, in the very path of the Gulf Stream Drift, and even of the return North Equatorial current, with the natural result that these islands, within the same latitudes as Labrador, should have a taste of something like a Labrador summer.

If we make a little scientific use of the imagination, asking ourselves what would be the climatic results to north-western Europe of the obliteration of the Gulf Stream altogether, we may arrive at some inferential results as to the importance of such a causal factor among the conditions which existed in the Pleistocene period of glaciation, when—as Prof. J. W. Spencer (Bull. Geol. Soc. America, vol. vi.) has shown —the elevation of the Antillean Continent was such that we may infer the impossibility of the existence of the Gulf Stream as such for the greater part of that period.

That would leave us no more than such a mere *wind-drift* of surface ocean-water as is seen in the "Kuro-Siwo" of the North Pacific at the present time (*op. cit.*, p. 13). See further, Tarr, "Physical Geography" (pp. 182–191) and "The International Geography" (p. 69), both published by Messrs. Macmillan and Co. A. IRVING.

Hockerill, Bishop's Stortford, September 30.

Turkish Earthquake of September 13.

THE bulletin from Pulkowa has just reached me, and from this it appears that the azimuth of the epicentre from Pulkowa was 9° 12′ west of south. Two estimates of the distance are given, leading respectively to 41·1° N., 26·4 E., and 40·1° N., 26·3° E. The epicentre determined here was 40·4° N., 26·9° E., and the azimuth was 65° 33′ east of south.

From the two azimuths alone I find the epicentre to be 40·7° N., 26·5° E. GEORGE W. WALKER.

The Observatory, Eskdalemuir, Langholm, Dumfriesshire, October 1.

THE NORTHERN ELEPHANT SEAL.

A VALUABLE paper on the northern elephant seal (*Macrorhinus angustirostris*, Gill), by Mr. Charles H. Townsend, director of the New York Aquarium, has been published in "Zoologica"—scientific contributions of the New York Zoological Society vol. i., No. 8. The paper is No. 2 of the scientific results of the expedition to the Gulf of California, in charge of Mr. Townsend, by the U.S. Fisheries steamship *Albatross* in 1911. It consists of fourteen pages, accompanied by twenty-one illustrations, and relates to a species concerning which there has been comparatively little information obtained during the past forty years.

The northern elephant seal has long been on the verge of extinction, and is now found only on Guadalupe, an uninhabited island lying in the Pacific Ocean 140 miles off the northern part of the peninsula of Lower California. It formerly had a range extending for about 1000 miles along the coast of Upper and Lower California, and has never been recorded from any other region of the north Pacific. It is the largest of all seals, and owes its name to its great size and to the remarkable snout or proboscis developed in the adult male.

Being valuable for its oil, the seal was killed in large numbers for commercial purposes as late as the year 1852. Since then it has seldom been seen. During the winter of 1911, while in charge of the deep-sea investigations of the United States steamship *Albatross*, Mr. Townsend called at Guadalupe Island and was fortunate enough to secure the specimens, photographs, and data upon which the present paper is based. In addition to the museum specimens obtained, six yearlings were shipped alive to the New York Aquarium.

The seals had little fear of man. While the large specimens were being skinned and skeletonised, some of the animals slept undisturbed within thirty feet of where the men were working. A few of the females were accompanied by newly born pups, indicating that the breeding season was just commencing. The author did not observe any male with more than one female.

The three adult males which were killed were found to have an average length of sixteen feet, with a girth of eleven feet. The adult female obtained was eleven feet long. The new-born pups were distinguishable in colour from the yearlings, being dusky black, and were apparently about a week old (March 2). The colour of the adult is yellowish-brown, the young animals being greyish-brown.

The skin of the adult male is very thick, and the carcasses were so heavy that it required all the strength of half-a-dozen men to turn one of them over. Unless actually annoyed by members of the party, the animals did not attempt to leave the beach. The large males that accompanied the nursing females were frequently engaged in fights with unattached males. There had evidently been considerable fighting, as their necks were more or less raw.

In fighting, the large males crawl slowly and laboriously within striking distance, and then, rearing on the front flippers, and drawing the heavy, pendant proboscis into wrinkled folds well up on top of the snout, strike at each other's necks with their large canines. The skin of the under surface of the neck and fore-part of the breast is greatly thickened; it is practically hairless, and years of fighting give it an exceedingly rough and calloused surface. This *shield*, as it may be

FIG. 1.—View of north end of elephant seal rookery, Guadalupe Island. Males, females, two-year olds and yearlings. The males with heads erected are in fighting attitude, with proboscis retracted and mouth wide open. U.S.S. *Albatross* in distance.

called, is the part of the animal most exposed to attack when fighting. The proboscis is broad and fleshy to the tip, and its length forward from the canines is about equal to the distance between the canine and the eye. It is exceedingly thick and heavy, and its width is about equal to the space between the eyes. In one specimen taken, it was nine inches long. When the animal is crawling, the proboscis is relaxed and pendant.

The author found that the proboscis is not capable of inflation. When withdrawn, it is simply massed into compact folds on top of the head. There is little indication of the proboscis in the half-grown male, and it is probable that it does not develop until sexual maturity is reached.

The specific distinctness of the northern elephant seal is well shown in photographs of the skulls of *Macrorhinus angustirostris* and *M. leoninus*, the skulls of both species exceeding twenty-two inches in extreme length, *angustirostris* being longer, while *leoninus* has the greater zygomatic width.

Mr. Townsend has directed the attention of the Mexican Government to the existence of this unique herd, and the Mexican authorities have already taken steps to prevent its destruction.

FIG. 2.—Male elephant seals approaching to fight. When within striking distance, both rear high on fore flippers, retract proboscis and open mouth very wide.

THE NATURAL HISTORY OF THE DEAD SEA AND JORDAN VALLEY.[1]

IN the volume before us Dr. Blanckenhorn has collected the results of his researches into the geology and natural history of Palestine, the latest of which occupied the first half of 1908. These have enabled him to give a much more minute account of the geology of the region than any of his predecessors, to lay down more accurately the boundaries of the several formations, and to trace a number of important faults. As his map shows, the Syrian upland on either side of the Jordan valley from the southern end of the Dead Sea almost up to the Lake of Gennesaret consists of Cretaceous rocks chiefly of Senonian and Turonian age, with an occasional exposure of the underlying Cenomanian.

At the beginning of the Senonian were slight and local volcanic outbreaks, and this formation is sometimes bituminous. Marine deposits of Eocene age are first seen on the west side of the Jordan about the latitude of Jaffa, and become more extensive in proceeding northward. No marine beds of Miocene or Pliocene age occur in the hill country; the deposits in the Jordan valley are mapped as *diluvium* (when will foreign geologists abandon this discredited and misleading term?), and the latest therein, with those in the Kishon valley and on a large part of the coast, are "alluvium." Then came the volcanic discharges which built up the great basalt mass of the Hauran with the minor outbreaks west of the Jordan, which are obviously subsequent to the formation of its valley. On a separate sheet Dr. Blanckenhorn exhibits in a tabular form (very convenient to the reader) his conclusions in regard to the dates of the later movements and deposits, and their correlation with those in Europe. According to this, a continental elevation, causing a steeping of the general slope and the first great erosion-phase of the rivers, began about the middle of the Pliocene. Dr. Blanckenhorn places the second phase of earth movements, bringing about the first fractures running from north to south,

[1] "Naturwissenschaftliche Studien am Toten Meer und im Jordantal: Bericht über eine im Jahre 1908 unternommene Forschungsreise in Palästina." By Prof. Max Blanckenhorn. With geological map in colours, 6 plates from photographs, and 106 figures in text. Pp. vii+478. (Berlin: R. Friedländer & Sohn, 1912.) Price 1*l.* 4*s.*

i.e., the trough faulting which gave rise to the Red Sea and the Gulf of Akabah, the Wady Arabah and the Jordan valley, at the beginning of the Pleistocene, and with this he associates the great basaltic discharges already mentioned.

A large fresh-water lake was next formed in the Jordan valley, which he considers to be a record of a pluvial phase and contemporaneous with the Günz glaciation of the Alps. Towards the end of this began a third epoch of earth movements, producing some folding and faulting in a north to south and north-north-east to south-south-westerly direction and bringing up some older strata, among them probably the Cambrian, which he discovered south of the Dead Sea. These caused some more eruptions. A short dry period followed, in which the level of the lake was lowered, the water became brackish, and the salt beds of Jebel Usdum (the top of which is about 600 feet above the present level of the Dead Sea) were deposited. This corresponded with the first interglacial phase of the Alps. The Mindel glaciation of that region brought on a pluvial phase in Palestine when the Jordan valley-lake was at its greatest, extending from the north of the Lake of Gennesaret to some distance south of the Dead Sea, and small glaciers formed in the Lebanon. A long dry phase succeeded, corresponding with the second interglacial of the Alps, during which the Jordan lake sank nearly to the present level of the Dead Sea; all the valleys were much eroded, and some streams of lava (the last in this region) were ejected.

The Riss ice age of the Alps (that when the glaciers attained their greatest size) corresponded with a third pluvial phase which produced the middle terraces in the Jordan valley. The lake again retreated in another dry period, representing the third interglacial of the Alps, but the lower terraces in the Jordan valley are records of the Würm glaciation, after which the climate gradually changed to its present condition. Valley erosion went on throughout, and an elevation of the coast occurred just before the Würm ice age. This, according to Dr. Blanckenhorn, corresponds with the Mousterian, Aurignacian and Solutrian ages of man, the Chellean and Acheulean being placed in the preceding interglacial phase and the earliest of our forerunners at present acknowledged (the Reutelian) being regarded as contemporaries of the glaciers of the Lebanon.

The tabulation is undoubtedly a neat one, but it does not seem clear how Dr. Blanckenhorn explains the separation of the Dead Sea (and the greater part of the Jordan valley) from the Gulf of Akabah. The watershed between these is about 700 feet above the latter and is suggestive of movements transverse to the Jordan-Akabah trough. It is also singular that the period of greatest cold in Palestine—that of the Lebanon moraines—should correspond with the Mindel glaciation of the Alps, and that both the times of heaviest precipitation should be contemporaneous with the two smaller advances of the Alpine ice and not with the two greater, the Riss and the Würm. It is, of course, possible that the zone of heaviest precipitation did not shift southward with that of lowest temperature, but some explanation, we think, might have been offered of this rather obvious anomaly.

Perhaps also scepticism may be still permitted as to some of the subdivisions in the relics of primitive man, and even the identification of the earliest among them, but this we know is thorny ground.

The book, we think, would have been improved if the author, instead of retaining the form of a diary, had been content to give his itinerary in the fewest possible words and to group together his results so as to give continuous accounts of the stratigraphy and of his views about the physical geology, with the reasons for them. The reader at present loses his way in the mixed multitude of personal and scientific details, and perhaps sometimes fails duly to appreciate the latter. The illustrations also leave something to be desired, the sketches of sections generally being very rough. Still, Dr. Blanckenhorn has spared no pains in collecting a great quantity of information on the geology of Palestine, besides giving lists of the fauna and flora of the country, so that his book will be a very valuable addition to our knowledge of that interesting region.

T. G. B.

THE MEDICAL NEW YEAR.

ON October 1, our medical schools begin their winter session; and in many of the chief medical schools this New Year's Day is observed by giving a ceremonial address to students and others. This good custom shows some signs of old age. The need is less than it was that medical students should be warned against idleness, off-hand manners, or unkindness. The introductory address tends to have an old-fashioned air; and, it may be, the time is coming for some kind of ceremony more in accord with our present ways. The like embarrassment seems to attend the annual orations in praise of Harvey and of Hunter at the Royal Colleges of Physicians and Surgeons of England. Harvey and Hunter, we begin to think, would be glad to know that their immortal names were given a rest, in favour of the praises of some of their successors.

Still, one would be sorry that the First of October addresses should be abandoned at our medical schools. The reports of some of them, published last week in *The Lancet* and *The British Medical Journal*, are of notable interest, and cover a wide range of thought.

At St. George's Hospital, Mr. Grimsdale spoke on the present duty of the medical citizen; and the very phrase "the medical citizen" tells how far we have come from the old professional individualism of the doctor. Imagine the feelings of the physicians of King George III. if they had been told they were medical citizens. Still, there was no National Insurance Act in those not very spacious times; and Mr. Grimsdale was mostly concerned with the National Insurance Act. He put clearly and well the reasons why the doctors cannot and will not work under the Act as it stands at present; and the doctors will be glad that he reminded them of that delightful fable of the elephant and the partridge's nest.

At the Middlesex Hospital, Dr. Lazarus-Barlow chose a very different theme—the genius of the infinitely little. Why genius? Whatever attributes we may be able to assign in our imagination to the infinitely little, genius is not one of them. He ought to have said the kingdom, or the work, of the infinitely little. But he gave an admirable address. It was Pasteur, of course, of whom it was said that he had discovered the kingdom of the infinitely little. But, as Dr. Lazarus-Barlow told his audience, beyond the kingdom of the bacteria there is the kingdom of the radium emanations, which are infinitely littler; and beyond the kingdom of the radium emanations there is the kingdom of the enzymes, which are infinitely littlest. Not thought, but wonder alone, is possible in the presence of the facts of these kingdoms. It takes a very metaphysical mind to be near them.

With a sort of shock we come to Dr. Jane Walker's address to the London School of Medicine for Women. Her theme was common sense. It is a fertile subject for a medical address, and she treated it with delightful simplicity and directness. She began with those two prophets without honour in their own country, MacCormac of Belfast, and Boddington of Sutton Coldfield, who advocated the open-air treatment of consumption when as yet there was no clear understanding as to the cause and the nature of that disease. Next she praised, for the splendour of their common sense, St. Francis, Ambroise Paré, and Dr. Johnson. We think that St. Francis would rather be excused; and Dr. Johnson, like the doctors in the line "Who shall decide where doctors disagree?" was not a medical doctor; but Ambroise Paré is all right; his common sense is magnificent and unfailing. Dr. Walker gave many other pleasant and memorable examples of the sovereignty of common sense in the wisdom of life. It may be permitted to quote one out of many.

> Take the case of the "mentally defective" problem. Are we not just a little lacking in common sense in our dealing with that? Surely our attention ought to be more earnestly directed to the so-called normal people, that they do not tempt their feebler brothers and sisters, who, left alone, would do them little harm. When one reads the flood of literature that is constantly being poured out about the "menace of the feeble-minded," one is tempted to feel that a good deal of it is mere nonsense.

Indeed, we hope that all the women students who heard Dr. Walker's lecture will follow her good advice; and it is a good thing for our lady doctors in this country that they have this keen eye for the importance of common sense in medical and surgical practice.

Dr. Humphrey Rolleston's address at Manchester University is perhaps the best of all in regard to thoroughness and careful weighing of his words. He took for his subject "Universities and Medical Education." As a Cambridge man, who is likewise an examiner in Manchester University, he was able to speak with authority of the complex and ever-shifting relations between all that is called Literæ Humaniores, the medical sciences, and medical and surgical practice. It would be hard to beat his ideal of the first years of medical education.

> The education best suited for a medical student before beginning his professional subjects should be on the following lines. The subjects ordinarily taught in schools, including Latin and Greek, should be pursued until the age of about 15½ years, when the student's proficiency should be tested by an examination, the results of which should count at the university matriculation. After passing this examination the student should spend the next 2—2½ years in obtaining a sound knowledge of French and German, literature, English composition, physics, and chemistry, and the necessary mathematics. At the end of this time, when he is from 17½ to 18 years of age, he should be able to pass an examination on these subjects, and then begin the study of biology and of anatomy and physiology. This compromise would ensure general culture with a modicum of classical training, and a knowledge of French and German at a time when it can be readily acquired, and yet would not encroach unduly on the time necessary for strictly professional instruction. This education, which is somewhat on the lines provided on the modern side, would be far better than that given on the classical side at public schools, and by providing a good basis of physics and chemistry would do much to remedy the prevailing difficulty of the early science examinations in the medical curriculum.

While introductory addresses remain as good as these four, it would certainly be a pity to desert this way of observing the opening of our medical schools.

THE CHURCH CONGRESS AT MIDDLESBROUGH.

DURING the week ending on Saturday, October 5, the Church Congress has been holding its annual gathering at Middlesbrough, the great industrial centre of population which has grown up at the mouth of the Tees. The choice of such a meeting-place is at once a declaration and a challenge a declaration that the Church considers the problems of industrialism to be also the problems of religion, and a challenge to those people who would solve the riddles of capital and labour without reference to a spiritual basis for the aspirations of both parties in the conflict. It is well that any body of men and women joined together to discuss the outstanding difficulties of a common faith should feel able at times to dispense with the inspiration of mediæval architecture and academic hall and should go forth boldly to conduct their deliberations on the edge of a populous and rapidly depleting coal-field, illuminated with the glare of titanic blast furnaces.

On the whole, the choice of subjects and their treatment by the selected speakers has justified the action of the organising committee. We do not look to such meetings to produce any contribution to knowledge, but rather to express an attitude of mind and to set an example of a right method of approach to the vexed questions of the day. The eminently sane and statesmanlike influence of the Archbishop of York was felt throughout the proceedings, and his opening address contained an excellent summary of the ground to be traversed in these meetings of the Congress, and indicated the point of view from which he desired that it might be surveyed.

The papers and discussions on town planning and rural housing showed signs of a healthy realisation of the economic aspects of that question. Cottages never will and never ought to be built in any number and let at rents less than their true economic value. Such a course of action, from whatever motives it be adopted, leads in the end to a depreciation of wages. It is, in fact, a return by a circuitous route to the old and evil plan of a subsidy to wages through a widespread extension of a method of outdoor relief—a system which, under the old ante-1834 Poor Law, proved to be pauperisation in one of the worst forms. Only when it is realised that, as Mr. Raymond Unwin declared was already the case, it pays to provide good housing accommodation and that garden villages are a better form of investment than potential slums shall we see the end of the long series of lamentable mistakes in housing, some of which have recently been perpetrated afresh in connection with the opening up of the new industrial areas at Doncaster and Dover.

The question of the falling birth-rate, a fall which is very marked in the manufacturing cities of the northern provinces, wherever women are employed in factories, was dealt with by Mr. W. C. D. Whetham, F.R.S., who again emphasised the frequent opposition in present circumstances between the economic and the religious aspect of normal family life. The Church of England, unlike the Church of Rome, has not yet grasped the fact that the number and quality of her future members, indeed, her very corporate existence, can be made the plaything of social, industrial, and moral forces with which she has neglected to concern herself.

From the academic point of view, the most interesting morning was that devoted, on Thursday, to a discussion of the relation of miracles to the Christian faith, a contribution towards the agelong effort to reconcile intuitive belief and intellectual reason and to assign to each their true importance in the religious life. The subject was opened by the Dean of Christ Church (Dr. Strong) with an admirable attempt to determine how far, in the light of all knowledge at present available, it was practicable to answer the question: "Are miracles possible at all?" The Dean gave an excellent account of modern thought relating to the purely mechanical theory of life, which would regard the world as a closed system, controlled by unerring laws of matter and motion, and in which the appearance of a miracle could only be explained as the result of imperfect observation or incorrect deduction. But he pointed out that recent tendencies, both in philosophy and biology, would seem to lead away from and not towards the acceptance of such a mechanical view of nature as the complete and ultimate solution of the whole problem of existence and consciousness.

Prebendary Webb-Peploe's contribution, which was much applauded, served to remind us that for those people who are prepared to adopt intact into their theological belief the experiences attributed to Job, Daniel and Jonah, the efforts of learned professors and others to alleviate their lot are both officious and ill-judged. The discussion was closed by the Archbishop, who referred to some of the papers read at the recent meeting of the British Association for the Advancement of Science, held at Dundee, and concurred with the Dean that at the present moment it was the mechanical theory of the universe, quite as much as the miraculous basis of Christianity, that was on its trial in the world of thought. His Grace's closing sentences, as reported in *The Times,* may perhaps be given to sum up the general trend of the whole discussion. "The real meaning of the miraculous was that it was an assurance given to them that, ultimately, the Divine Being was free and master in His own house; and it was the coming forth of that fact into the world that carried with it the consequences that they called miracles."

NOTES.

THE meeting to be held at the Mansion House on October 23, in connection with the proposed memorial to the late Lord Lister, is the outcome of a movement which was set on foot by the presidents of the Royal Society and the Royal College of Surgeons. A large and influential committee has been formed, representative of scientific, medical, and general interests, both in this country and abroad, and the various possible schemes, including a memorial in Westminster Abbey, and others of an international character, will be laid before the meeting, which it is hoped will be largely attended.

THE Royal Microscopical Society has arranged to hold a conversazione at King's College, London, on Wednesday, October 16, from 8 to 11 p.m.

THE extension to the Manchester Museum will be opened on the afternoon of Wednesday, October 30, by Mr. Jesse Haworth. An address will be delivered by Prof. W. M. Flinders, F.R.S.

MR. E. GRANT HOOPER, superintending chemist, Government Laboratory, and vice-president of the Society of Chemical Industry, has been appointed Deputy-Government Chemist, in succession to Mr. H. W. Davis, who has retired.

SIR GEORGE DARWIN, K.C.B., F.R.S., Plumian professor of astronomy at Cambridge, who, we regret to learn, has been ill for two or three weeks, underwent a severe operation on Thursday last. On Sunday he spent a bad night, but we are glad to be able to state that he is now making good progress.

The Home Secretary has appointed a committee to inquire and report as to the precautions necessary in the use of celluloid in manufacture and the handling and storage of celluloid and celluloid articles. The members of the committee are:—The Earl of Plymouth (chairman); Prof. J. J. Dobbie, F.R.S., principal Government chemist; Captain M. B. Lloyd; Mr. H. M. Robinson, Deputy Chief Inspector of Factories; and Mr. E. O. Sachs, chairman of the executive of the British Fire Prevention Committee.

We notice with regret the announcement of the death on Sunday, October 6, at seventy-six years of age, of Prof. W. W. Skeat, professor of Anglo-Saxon in the University of Cambridge, and of world-wide distinction among philologists. In his early years he showed talent in mathematical studies, and he took his degree at Cambridge in the Mathematical Tripos, where he was placed as fourteenth Wrangler in 1858. After a few years spent in country curacies, he returned to Cambridge in 1864, and was appointed a mathematical lecturer at his own college, Christ's. He then commenced the etymological studies represented in the long series of publications upon the English language which forms an imposing monument to his knowledge and industry.

The third International Archæological Congress was opened in Rome on Wednesday, October 9. We learn from *The Morning Post* that no fewer than twenty-four Governments are officially represented, but the British Government is absent from the list, though one department—the Board of Education—is represented by Dr. Ashby, the resident director of the British School at Rome. British universities and other learned societies, however, are well represented. The congress will be divided into twelve sections, according to subjects. Among the themes to be discussed are:—The Iron age in Italy, the prehistoric civilisation of Sardinia, the monuments of Egypt and Asia, Minoan civilisation, the origins of Etruscan culture, the territories of the old Italian cities, Roman epigraphy, numismatics, the roads of the Roman Empire, and the question of archæological bibliography.

An interesting and important step towards systematised nature-protection has been taken by the Royal Society for the Protection of Birds. This is the taking over of the remarkable Somerset headland, Brean Down. For permission to establish this sanctuary the society is indebted to the wisdom of the Somerset County Council, the action of which may well form a precedent for county councils throughout the kingdom. The society has the "shooting rights," and has appointed a watcher, but the general maintenance of the place will depend largely on the support given to the society. Subscriptions for this or other work of the society may be sent to the secretary, 25 Queen Anne's Gate, S.W. The joint action of local governing bodies, of protection societies, and of private individuals is the kind of method that should succeed in this country. "Our Dumb Friends' League" will hold a meeting at the Whitehall Rooms on October 15, at which Mr. James Buckland, the promoter of the Plumage Bill, Colonel Sir Mark Lockwood, M.P., and Mr. George Greenwood, M.P., will speak. The Ranee of Sarawak will preside. Brean Down is a bare grassy promontory with broken cliffs. It is well known to botanists as a habitat of the white rock rose. Its chief bird—there are three specially protected—is the beautiful sheldrake. Of the other two, the raven has built here for fifty years. Lately the peregrine, so often found near the raven, has established itself. Mr. Harry Cox, to whose zeal the new sanctuary mainly owes its institution, last year rescued the only young one. Kingfishers, sparrow-hawks, daws, kestrels, shrikes, linnets, rock-pipits, and wheat-ears are also natives.

Three important plaster casts have been added to the exhibition of fossil reptiles in the department of geology in the British Museum (Natural History). A copy of the skull of the gigantic carnivorous dinosaur, *Tyrannosaurus rex*, is interesting for comparison with the fragmentary remains of Megalosauria found in England. The original specimen was obtained by the American Museum of Natural History from the Upper Cretaceous (Laramie Formation) of Montana, U.S.A., and as it measures no less than 4 ft. in length, the carnivore to which it belonged would be able to prey on the contemporaneous herbivorous dinosaurs, Trachodon and Triceratops. A copy of the skeleton of a pterodactyl, with large slender teeth, lately discovered by Mr. B. Hauff in the Upper Lias of Würtemberg, shows again how completely developed were the flying reptiles even in the early part of the Jurassic period. A cast of a nearly complete skeleton of the Permian labyrinthodont, *Archegosaurus decheni*, in the museum of the Prussian Geological Survey at Berlin, is a useful acquisition in view of the researches now in progress concerning the origin of reptiles and their connection with amphibians.

By the tragic death of George Herbert Grosvenor, who was drowned at Polzeath on September 4, whilst endeavouring to save the life of a friend, biology has lost one of the most promising of her younger workers. After a brilliant career at Harrow, Mr. Grosvenor was elected to a biological exhibition at New College, Oxford, subsequently taking a first in his Final School. Elected to the Oxford table at Naples, he confirmed, by a brilliant piece of work, Strethill Wright's almost forgotten suggestion that the nematocysts of Æolids were derived from their prey. His work was awarded the Rolleston prize in 1904. On his return to Oxford he became busily engaged in founding a new school of economic entomology, and with his characteristic thoroughness had acquired a wide knowledge of insects. His regular work left him but little time for research, though it is hoped that the results of some of his investigations may yet be published. Of his great personal charm this is not the place to speak. He combined an exceptional power of concentration and clearness of thought with a singularly modest and retiring disposition, and his loss will be long and deeply felt by those whose good fortune it was to be his associates.

The statue of Captain James Cook presented to the town of Whitby by the Hon. Gervase Beckett, M.P., which was unveiled on October 2, will be welcomed as a fitting memorial to a man who succeeded, where many others had failed, in laying open the secrets of the Pacific Ocean, thanks mainly to inborn determination and courage. Cook was not a man of many or varied attainments. He was born of lowly parents, and from his earliest years his whole energy was directed towards perfecting himself in the work of his calling on the sea. The same energy and stedfastness of purpose, joined to his temperance and his mastery of every detail of his profession, enabled him to carry through the journeys which elucidated the questions as to the amount and extent of the lands in the Southern Ocean, the answer to which had eluded so many less competent and persevering explorers. It is on his work as a voyager and discoverer that Cook's chief claim to fame is based, but the fact that he was the first to take scientific preventive measures against scurvy, the disease which has wrecked the hopes of so many explorers, earned him the gratitude of voyagers. It was for his splendid work in this direction that he was unanimously elected a fellow of the Royal Society after his return from his second voyage in 1775. On this he had kept the sea for three years, and but one of his crew of 118 men was lost.

In the report of the Rhodesia Museum—which is now under the joint control of the Bulawayo municipality and the Rhodesia Scientific Association—for 1911, it is stated that the building opened by H.R.H. the Duke of Connaught in 1910 is already well-nigh filled, and that proposals for enlargement are already under consideration. There is the usual complaint as to the insufficiency of funds, even for ordinary purposes.

The hundredth volume of the *Zeitschrift fur wissenschaftliche Zoologie* was completed with the part published on June 25 last, and already three parts of the hundred and first volume have appeared since that date. The degree of elaboration to which it is possible to bring the study of invertebrate anatomy is well illustrated in recent volumes of this valuable series. The last part issued (vol. ci., part 3) contains the first continuation of the fifth part of Dr. Friedrich Voss's memoir on the thorax of the domestic cricket, and this continuation alone contains no fewer than 134 pages. Truly the accumulation of detailed information with regard to the animal kingdom goes on at a great rate, especially in Germany.

Canada, it appears from the report of the Commissioner of Dominion Parks for 1911, published by the Government Printing Bureau at Ottawa, now possesses seven public parks in which native animals are preserved. Some of these, which contain hotels and medicinal baths, are to a great extent self-supporting, and all are stated to be making rapid and satisfactory progress. In the Rocky Mountain Park at Banff, where the use of firearms, save in exceptional circumstances, is prohibited, the animals are becoming increasingly tame, deer visiting the lawns of the residences, and bighorn sheep wintering within half a mile of the Pacific Railway. The bison (buffalo) in the Buffalo Park at Wainwright are in a thriving condition, and promise a large natural increase in the future.

The last report of the Madras Museum records steady progress in the arrangement of this important collection and in the acquisition of new specimens. The great series of bronze images has been re-classified, and a considerable number of fresh copper plates has been added. The numismatic department has received large additions in the shape of pagodas, fanams, and six Venetian sequins. Among the accessions to the natural history collections may be mentioned the first Indian specimen of Swinhoe's snipe (*Gallinago megala*), shot recently in the Chingleput district, a bird which breeds in Eastern Siberia and Northern China, and migrates in the cold season to Southern China and the Malay Peninsula, the few existing specimens having been procured from the Malay Peninsula, Burma, and Assam.

In the August number of *The National Geographic Magazine*, Mr. Carl E. Akeley narrates, with a great wealth of photographic illustration, his experiences during an expedition to East Africa for the purpose of obtaining a series of elephants to form a group in the American Museum of Natural History. The main note of the article is the growing scarcity of old bulls with tusks of more than 50 lb. in weight. The best specimen obtained was a young bull standing 11 ft. 3 in. at the shoulder, with tusks weighing respectively 100 and 102 lb. These tusks were comparatively young ivory, and it is estimated that if the animal had been suffered to live another fifty years it would have developed tusks of something like 200 lb. weight, such tusks being by no means abnormal, but merely the ordinary development of mature bulls of the Uganda race. When, however, a bull grows tusks of 50 lb. weight, which he does in about twenty-five years, he becomes the target of every hunter in the country, and it is consequently only a few individuals, which obtain protection by living amid large herds of cows or in dense forests, that can attain full maturity. Large tusks must therefore become very rare in the near future. Attention is also directed to the damage to forests and cultivation due to herds of elephants from which tuskers have been killed off, damage which may lead to reprisals from proprietors as the country becomes opened up.

The forty-third annual report of the American Museum of Natural History for the year 1911 begins by recording that the trustees have resolved to complete the building of the southern half of the museum in time for the celebration of the jubilee in 1919. Special halls will thus be provided for whales, fishes, oceanography, and geography, while numerous rearrangements for the more adequate display of the collections will be possible. With characteristic energy, and with the aid of private benefactions, the museum employed no fewer than forty-four parties for the collection of specimens in various parts of the world. It is, therefore, making haste to rival in opportunities for natural history research the older foundations, the growth of which has been more gradual. Among notable accessions thus obtained during 1911 may be mentioned mammals and birds from Lower California and the northern part of South America, invertebrates from the West Indies and British Guiana, fossil mammalian remains from Cuba, and a glacial pot-hole from St. Lawrence County, New York. The Williston collection of tropical Diptera was also purchased. Among new exhibits illustrated in the report, the group of skeletons of extinct ground-sloths from South America is especially important, while a set of restored models of Devonian fishes arranged in the form of an aquarium is at least striking. Probably on account of the intimate association of the museum with elementary education, most of the exhibits seem to be more pictorial in character than those to which we are accustomed in European museums. The American museum is to be congratulated on being able at the same time to occupy a foremost place in the advancement of knowledge by its valuable publications.

Mr. L. L. Woodruff (Proc. Soc. Experimental Biology and Medicine, vol. ix., p. 121) has now continued his pedigreed culture of the common ciliate infusorian, *Paramoecium aurelia*, for five years. The culture was started in May, 1907, with a wild individual isolated from a laboratory aquarium. From the progeny of this specimen individuals have been isolated practically daily, and cultivated in sterilised infusions of hay and other vegetable substances. During the five years to May, 1912, 3029 generations have been produced without any conjugation having taken place, and the organisms are still in as normal condition, both morphologically and physiologically, as the original wild ancestor. The author concludes that the original individual cell possessed the potentiality of producing descendants the number of which is represented by at least 2 raised to the 3029th power, and that senescence and the need of fertilisation are not primary attributes of living matter.

In No. 6 of the Kew Bulletin, Mr. W. J. Bean gives an extremely interesting account of various gardens and parks in South Europe, including the famous garden at La Mortola, the acclimatisation garden at Hyères, the Villa Thuret and Eilen Roc gardens at Cap d'Antibes, and the fine gardens at Milan, Pallanza, Florence, Naples, Bologna, Padua, and various towns on the Adriatic coast. These notes, based on a tour made by the author in early summer of this year, should prove most useful to botanists who may wish to visit Italy and the adjacent parts of South Europe. The same number contains descriptions and plates of two recent additions to the Kew collection—a spurge (*Euphorbia meloformis*) and a cycad (*Cycas Micholitzii*). The former is one of the most remarkable South African spurges, and bears such a striking resemblance to *Echinocactus* that a non-botanist would never suppose that they belonged to two totally different families of plants.

Dr. R. R. Gates, who has contributed so much to the recent literature of mutation by his cytological work on Œnothera, describes in *The New Phytologist* (vol. xi., No. 2) a peculiar development which occurred in his cultures of evening primroses obtained originally from the Lancashire coast. In some of the forms the stem internodes remained undeveloped, though growth continued and new cycles of rosette leaves were continually added above while the older ones died away below. In this way a stem was produced which was covered with leaf-bases and bore a crown of leaves at the top, giving a striking resemblance to a cycad. From these and other forms it is hoped by further work to learn something more regarding the manner of origin of the various Œnotheras, and in particular to analyse the De Vriesian factor of evolution and ascertain in how far it is merely a process of hybrid-splitting and in how far it is a more deep-seated germinal disturbance—resulting in part from effects of previous crossing, from the direct influence of changed environment, or from some internal and unknown cause.

Mr. Neil E. Stevens has sent us a reprint of his recent paper (*Botanical Gazette*, April, 1912) on the cytology of heterostyled plants, containing observations on buckwheat and *Houstonia coerulea*. Zoologists have shown that in various insects the sperms are of two kinds, equal in number, and differing in respect of one or more of their chromosomes, and it has been shown that fertilisation of the eggs by one kind of sperm produces males, by the other kind females. This remarkable discovery has suggested the possibility of a similar condition in other organisms having separate sexes, but so far no evidence of such a "sex determinant" has been obtained in diœcious plants. In buckwheat, Stevens finds that in the mitosis of the pollen mother-cells the chromosomes of the short-styled form are much larger than in the long-styled form, also that there is a characteristic and constant difference in the arrangement of the chromosomes at one stage (anaphase) of the reducing nuclear division. In *Houstonia coerulea* the difference in size of the chromosomes is less marked, and there is apparently no difference in arrangement.

In our issue of July 25 we referred to a useful series of wind charts relating to the monsoon area of the North Indian Ocean, published by the U.S. Weather Bureau. This has been supplemented in its meteorological chart of the Indian Ocean for October by an interesting discussion, "Weather of India and her Seas," by the same writer (Mr. W. E. Hurd). He points out the close connection between the meteorology of India and the adjacent seas. Apart from the seasonal effects of insolation, the weather is directly associated with the distribution of atmospheric pressure in various regions, the changes in which produce the summer and winter monsoons. The writer traces the effects of these over various districts in a clear and instructive manner, some of the data being naturally drawn from the records of the Indian Meteorological Department. In the October charts of the North Atlantic and North Pacific oceans the Weather Bureau directs attention to recent alterations in the Act regulating wireless telegraphy, one provision of which enacts that no vessel licensed to carry fifty or more persons shall leave the shores of the United States from October 1 unless equipped with efficient apparatus for radio-communication, to be used during day and night, and capable of transmitting and receiving messages over a distance of at least one hundred miles.

In "Relative Bestimmungen der Intensität der Schwerkraft" (Karlsruhe: G. Braun), Dr. E. Becker gives the results of a series of pendulum experiments conducted during the years 1900–05 in Alsace-Lorraine. The work of the group of experimenters concerned appears to have been very carefully performed and the reductions of the observations have been carried out with a due recognition of the systematic errors likely to be present. Using Helmert's system of corrections to sea-level and giving to the ideal surface layer of land a density of 2·4, the experimenters find the western Rhine valley to be a region where gravity has its normal value. In general the higher land to the west is a region of gravity-excess. The map which accompanies the work would enable the reader to make a more intelligent use of the tabulated results if by shading or otherwise it gave an idea of the level contours or of the geological distribution. That would at once confirm or disprove the idea left by the table that no marked correlation between gravity-variation and height or geological conditions has been found. Another useful addition to the work would have been some illustrations of the apparatus used and described. It is to be hoped that the experiments will be extended as suggested in the last sentence of the memoir.

The volume of Contributions from the Jefferson Physical Laboratory of Harvard University for the year 1911 extends to nearly 400 pages, and contains eight memoirs, several of which we have already noticed in these columns. More than half the present volume is occupied by the important papers of Bridgeman on the properties of water and of mercury at pressures up to 20,000 kilogrammes per square centimetre, and at temperatures between $-80°$ and $+80°$ C. In addition to the new information these papers supply as to the various modifications of ice and the conditions of equilibrium amongst them, they show that the laws of change of state from solid to liquid are much simpler than the theories and observations of Tammann and of van Laar have led us to believe. Each melting point, for instance, changes with pressure in the same direction at these great pressures as it does at lower pressures, so that there is no maximum melting point in the case of mercury or minimum in the case of water. It seems probable that the maxima observed by Damien were due to slight impurities, too small to have observable effects on the melting points at low pressures, but which appear to have considerable effects at these high pressures.

A copy has been received of the third edition of "The Record of the Royal Society of London," prepared in connection with the celebration of the 250th anniversary of the foundation of the society. The volume, which may be obtained of Mr. Henry Frowde, Amen Corner, E.C., price 15*s*. net, is much larger and more complete than previous editions, and is a valuable official statement of the development and position of our leading society for the promotion of natural knowlege. The chapter of greatest general interest is that with which the volume opens, on the foundation and early history of the society. This has been re-written by the president, Sir Archibald Geikie, who has also supervised and edited the whole work. The three charters are printed in full, with translations, while other chapters are devoted to the statutes, trusts, benefactions, medallists, committees, and like matters. There is a chronological register of fellows, as well as an alphabetical list, with dates of election. The volume is illustrated by twenty excellent plates, mostly from portraits of former fellows in the society's possession. Among the additions to the new edition are portraits of Lord Kelvin, Lord Lister, and Charles Darwin. The officers and the clerical staff have been successful in producing an attractive volume of more than domestic interest.

Mr. C. Baker, 244 High Holborn, has just issued a new classified list of second-hand instruments for sale or hire. The catalogue contains particulars and prices of more than fifteen hundred optical and other instruments and accessories offered at low prices. Every instrument is guaranteed to be in adjustment, having been put in order where necessary in Mr. Baker's workshops or in the works of the original makers.

Fifty volumes of the "Cambridge Manuals of Science and Literature" have now been published by the Cambridge University Press. Among the most recent additions may be mentioned "The Work of Rain and Rivers," by Prof. T. G. Bonney, F.R.S.; "Brewing," by Mr. A. Chaston Chapman; "The Individual in the Animal Kingdom," by Mr. Julian S. Huxley; "House-flies and How they Spread Disease," by Dr. C. G. Hewitt; and "The Psychology of Insanity," by Dr. Bernard Hart. We notice, too, that Mr. L. Doncaster's volume in the series, "Heredity in the Light of Recent Research," has reached a second edition, in which a chapter on heredity and sex has been added.

OUR ASTRONOMICAL COLUMN.

Gale's Comet, 1912*a*.—No. 4602 of the *Astronomische Nachrichten* contains new elements for comet 1912. A set by Mr. H. E. Wood puts the perihelion passage back to October 1·86, and reduces the inclination of the orbit to 51° 54′; another by Mr. Merfield agrees fairly well with that published by Dr. Ebell, who gives a new ephemeris, derived from corrected elements, from which the following is taken:—

Ephemeris, 12h. M.T. Berlin.

1912	α (true) h. m.	δ (true) ° ′	log r	log Δ	Mag.
Oct. 13	15 43·4	+8 27·1	9·8673	0·0454	6·3
15	15 46·2	+10 28·3			
17	15 48·7	+12 23·9	9·8806	0·0588	6·4

It will be observed that this ephemeris gives the declination for October 13 nearly 1° more northerly than that we gave, from the earlier ephemeris, last week; the calculated magnitude is also considerably fainter. An observation by M. Gonnessiat at Algiers on September 26 gave the magnitude as 8·0.

SUN-SPOT ACTIVITY.—There has recently been some slight suggestion of a recrudescence of sun-spot activity, although one scarcely expects the actual minimum to have passed yet.

In the earlier part of the year very few spots were seen, and those that did appear were very small and seemed to be very shallow, for they generally filled up and disappeared while the region was still on the visible hemisphere. One exception was a fairly large black circular spot, which endured from June 17 to 28, and on Saturday last there appeared a small group, containing two intense nuclei, just south of the sun's centre, on the central meridian; this is now a fair-sized group, and should be seen near the western limb about October 11 or 12.

THE SYSTEMATIC MOTIONS OF SUN-SPOTS.—Acting on a suggestion conveyed to him by the statement that "the rotation periods given by different spots in the same zone of latitude differ more widely than do the mean rotation periods for different zones of latitude," given in Mr. and Mrs. Maunder's paper on the solar rotation period, Prof. Hirayama has analysed the motions of spots given in the Greenwich, Carrington's, and Spörer's publications, and finds that apparently there are two drifts of sun-spots exhibiting distinctive systematic motions. The angular velocity of drift i. is represented by $\xi = 14{\cdot}37^\circ - 2{\cdot}97^\circ \sin^2\lambda$ (where λ = the heliographic latitude), and of drift ii. by $\xi = 14{\cdot}69^\circ - 2{\cdot}65^\circ \sin^2\lambda$; the former agrees fairly well with the mean values found by other investigators, while the latter exceeds it, showing a mean rate about $0{\cdot}35^\circ$ greater than that indicated by drift i. For the lower latitudes, the rotation period proper to drift ii. agrees fairly well with that found spectroscopically by Messrs. Storey and Wilson, and Prof. Hirayama suggests that possibly certain groups of spots, by a proper motion of their own, come to the same level as the chromospheric layer investigated spectroscopically, and attain its angular velocity. He also suggests that this idea of two drifts may explain the distribution of sun-spots with different rotation periods in any particular zone of latitude. The data considered by him show that there are about twice as many sun-spots collected in drift i. as in drift ii. (Journal of the College of Science, Imperial University, Tokio, vol. xxxii., No. 7.)

THE PARALLAX OF NOVA LACERTÆ.—In No. 52 of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo*, Herr Balanowsky discusses the attempt made at Pulkowa to determine the parallax and proper motion of Nova Lacertæ. Sixteen plates were taken between January 4, 1911, and February 19, 1912, but two had to be rejected because the images were poor. The first solution from the remaining fourteen plates gave values which were small as compared with their probable errors, but indicated that the proper motion in declination was probably zero. The final solution gave for the value of the parallax $0{\cdot}005'' \pm 0{\cdot}020''$, which practically means that it was zero, and indicated that the proper motion in right-ascension did not exceed $+0{\cdot}01$s.

THE ROYAL HUNGARIAN ASTROPHYSICAL OBSERVATORY.—In No. 14 of the *Kleinere Veröffentlichungen des Königl. Ungarischen Astrophysikalischen Observatoriums*, Dr. Konkoly gives a very detailed description of the instruments added to the equipment of the observatory between the beginning of 1908 and the end of 1911. Many of the instruments have been made for special purposes, and the book, consisting of 166 pages, fully illustrated, should prove exceedingly useful to anyone desiring to set up instruments for astrophysical researches.

OBSERVATIONS OF VARIABLE STARS.—In No. 9 (vol. i., second series) of the *Memorie della Società degli Spettroscopisti Italiana*, Signor E. Padova publishes the values and light curves determined from observations of variable stars during the years 1907–11. Eleven stars are dealt with, and these are divided into three groups, viz. Algol variables, short-period, and long-period variables. In several cases the light-curves are compared, graphically, with those drawn from published elements, or determined by other observers, and the differences between them are discussed. For Mira Ceti the observer found a minimum of magnitude 9·36 on January 15, 1912.

BIRD NOTES.

IN the August *Zoologist* Mr. Collingwood Ingram points out that four races of the furze-warbler are recognisable, namely, the typical *Sylvia undulata* of the northern Mediterranean countries, *S. u. aremoricus* of the Atlantic coast of France and Spain, the north African *S. u. toni*, and the British *S. u. dartfordiensis*, a Dartford warbler, the last being distinguished by its brown back and the smaller development of the white tips to the throat and breast feathers.

The migratory birds visiting the Buffalo River district form the subject of an article by the Rev. R. Godfrey in the June issue of the Journal of the South African Ornithologists' Union. Among the species observed were the white and black stork, the European swallow, and several kinds of cuckoos.

In the July issue of *The Emu* Dr. J. B. Cleland continues his account of the results of an examination of the contents of the crops and stomachs of Australian birds, the total number of species which have passed through his hands being 305. Farmers and gardeners should now be able to discriminate without difficulty between beneficial and harmful birds.

A hand-list of the birds of Formosa, by Mr. S. Uchida, is included in vol. iii. part i., of *Annotationes Zoologicae Japonenses*. In a list published in 1907 by Messrs. Ogilvie-Grant and La Touche, 260 Formosan species were recognised; the author has been able to raise the number to 290. The discovery of a species of Dicœum has introduced an additional family into the avifauna of the island. We notice that on page 169 *Cuculus canorus* is misprinted *Cuculus canolus*, the error being repeated on page 209 of the distributional list.

No. 23 of *Harmsworth Popular Science* contains an article on the difficulties of bird-classification, although its contents scarcely bear out the title. There are, moreover, statements which do not represent the facts, as, for instance, the assertion that the seriema was originally grouped with the secretary-bird. Again, we find it stated on page 2736 that "the boat-billed heron, . . . the whale-headed stork, . . . and the hammer-head are famous members of the heron tribe," whereas these three birds severally represent the same number of distinct families, which in the British Museum Hand-list are assigned to as many suborders.

In *British Birds* for September, Mr. H. W. Robinson states that two nests of the eider were observed on June 2, 1912, on a small island just off the coast of Ireland. Hitherto eiders have been known in Ireland only as occasional stragglers. It is a matter for regret that in each instance the eggs were taken.

In Reichenow's *Ornithologische Monatsberichte* for July and August, 1912, Mr. J. Thienemann records that a laughing gull (*Larus ridibundus*), marked at Rositten, was shot on a swamp in the West Indies in November, 1911. R. L.

EXPERIMENTAL WORK AT AN AGRICULTURAL COLLEGE.[1]

THE bulky annual before us consists of reports from the various departments of the South-Eastern Agricultural College, prefaced by editorial notes, which summarise the present position of the college. This appears to be satisfactory, and progress in several directions is being made. The editor is dissatisfied with the recognition of Long Ashton by the Development Commissioners as the chief fruit research station for England and Wales. But it must not be forgotten that Long Ashton serves the most important fruit area in the country, extending from Devonshire to Herefordshire and Worcestershire. Wye, however, is to have a research plantation for fruit and hops.

(1) *Farm and Dairying.* The chief point of interest mentioned by Mr. Mackintosh has reference to the good results obtained by spraying potatoes: "the yields from sprayed and unsprayed plots showing a balance of four tons per acre in favour of the former." The sugar-beet experiments proved, as elsewhere, that the crop can be successfully grown in this country, but it remains to be shown whether the manufacture of beet-sugar is destined to become an important British industry. Sugar-beet slices and coconut cake were found to be useful artificials.

(2) *Hops and Horticulture.* The article by Messrs. Smith and Wellington on the packing of apples is particularly interesting, especially in relation to the establishment of a commercial fruit show in Kent.

(3) *Economic Zoology.*—Prof. Theobald's report is of considerable length, and, as usual, contains a large amount of familiar matter as well as valuable additions to knowledge. The illustrative plates are excellent. The author has spent much time in investigating aphides, of which 174 species (ten hitherto undescribed) have been found in Kent. The egg-laying of the pear-midge (*Diplosis pyrivora*, Riley) is for the first time described in detail; an excellent account is given of the narcissus-flies (*Merodon equestris*, Fbr., and *Eumerus strigatus*, Fln.); and the house-fly as a carrier of disease germs is described in unsavoury detail.

(4) *Chemistry.*—The two most important articles in Prof. Auld's report have reference to the formation of prussic acid from linseed cake and other feeding stuffs, indicating a certain necessity for care in their use; and the extraction of nicotine from tobacco, with a description of experiments in denaturing.

(5) *Botany.*—Prof. Parkinson contributes an interesting note, in continuation of previous work, on the forcing of plants by warm-bath treatment, *e.g.* bulbs of hyacinth and narcissus soaked in water at a temperature of 88° F. for twelve hours rapidly outstripped untreated ones (Fig. 1). Mr. Garrad gives his second report on the growing of tobacco for nicotine extraction, and the Principal contributes a note on the smoking qualities of the tobacco, which would seem to be remarkably good.

FIG. 1. Narcissus. D—"Dipped" plants. C—Undipped or control plants. From the Journal of the South-Eastern Agricultural College.

(6) *Economic Mycology.*—Prof. Salmon's invaluable report deals with the use of lime-sulphur wash and with American gooseberry mildew; and a reprint is given of the important presidential address on "Economic Mycology and some of its Problems" which he delivered to the British Mycological Society last year. Among other things, the significance of "bridging species" is pointed out, *e.g.* the spores of grass-mildew (*Erysiphe graminis*) taken directly from *Bromus racemosus* cannot infect *B. commutatus.* They can, however, infect *B. hordeaceus*, and the spores developed in this species germinate effectively on *B. commutatus.* The methods of combating fungoid disease are also discussed in a luminous fashion.

(7) *Notes on Hops.*—Prof. Salmon describes in detail the work done by way of raising new varieties of hops, and the sending out of male hops to growers.

(8) *Veterinary Science.*—Prof. Cave decides against preventive treatment, on the lines so far devised, in the case of "struck sheep," and gives an account of Jöhne's disease; while Mr. Bruce Gardener communicates the results of his useful research on parasitic gastritis in sheep and cattle ("Lincolnshire lamb disease"), due to species of the nematode genera Hæmonchus, Ostertagia, and Trichostrongylus. As these pests are common to sheep and horned stock, it is clear that the common practice of turning cattle on to pasture dangerous for sheep should not be pursued, though horses and pigs will take no harm.

J. R. AINSWORTH-DAVIS.

Roberts, illustrated. *Sampson Low and Co., Ltd.*—Outlines of Moral Philosophy, Prof. D. Stewart, with a Memoir, &c., by Prof. J. M'Cosh, new edition.

THE BRITISH ASSOCIATION AT DUNDEE.

SECTION K.

BOTANY.

Opening Address by Prof. Frederick Keeble, Sc.D., President of the Section.

It is with more than the normal trepidation natural to presidents that I, who have worked on the borderlines of several biological sciences, undertake the task of addressing the members of this section. As well might a rogue and snapper-up of unconsidered trifles recite his doggerel songs before a bench of learned magistrates.

Therefore, although I have studied from their works the ways of presidents, and although I shall strive to keep the path which they have mostly trod, yet should I stray I plead with Autolycus that—

"When I wander here and there,
I then do most go right."

The addresses which I have consulted show me two alternative models.

I may take all knowledge for my province and discourse on the progress of our science as a whole. This is Ercles's vein, a tyrant's vein. Or as a lover of a department of the science and more condoling, I may confine my address to a special branch of botany. Each method has its merits and its drawbacks, and the one is corrective of the other.

The departmental method depicts the tree of knowledge in sympodial symmetry. The branch which the president of one year holds out for our inspection is seen arising from an erstwhile dormant lateral bud far back from the growing point of the branch exhibited by his predecessor. Under the magic of the presidential hands the new branch grows as grows the enchanted mango. Like the lean kine, it eats up the fat kine, and by the end of the address it dominates all other branches.

The general method shows the tree in other guise. As an artist is wont to paint a tree, so the historian draws it on monopodial lines, with branches standing in due subservience to the leader and in strict coordination with one another. Together these methods tell the truth, which is that the tree of knowledge grows, like many another broad-leaved tree, by a mixed process of monopodial sequences following upon sympodial developments.

What is to the specialist, and indeed for a space is, the luxuriant predominance of his branch appears in historical perspective but as a new lateral for the extension of all the sublateral shoots of science.

Such a new basis for the further growth of all the branches of botany is provided by the lusty shoot of Mendelism, and after weighing the alternatives, and with the reserves announced already, I propose to try to show that this recent outgrowth of the tree of knowledge is destined not to mar its symmetry, but to aid the growth of the whole crown. This, my chief task, should have been my first care had not an event occurred since the last meeting of this Association which compels me, in common with all botanists, to divert thought from its preoccupation and to look back along the route which our science has travelled during the last few decades.

That event, I need not say, is the death of Sir Joseph Hooker, a former president of this Association and twice president of this section. The most venerable and distinguished of British botanists, Sir Joseph Hooker was well-nigh the last survivor of that band of Victorian naturalists who helped to lay the foundations of biology and to disseminate broadcast the knowledge which they made. The story of the labours of that group of naturalists—Lyell, Darwin, the Hookers, Wallace, Huxley, Galton, and others scarcely less distinguished—has been told so often that there is no need to re-tell it now. Nor need I recount the work of Hooker. His discoveries are known and require no re-enumeration. They are incorporated with the common fund of knowledge. British botanists will determine, doubtless, to consecrate a special occasion to the commemoration of Hooker's services to science and to the perpetuation of his memory. My duty it is to express, on behalf of native botanists and of our guests who honour us with their presence, our sense of loss in the death of Sir Joseph Hooker and our admiring recognition of his achievements.

And with the example of that long life devoted until its latest hour to the pursuit of science, I would fain address myself forthwith to my special task; but despite my will I find my thoughts enchained in the contemplation of the life and times of Hooker. Systematist, explorer, critic, writer, administrator, Sir Joseph was first and last a botanist. The versatile Hooker was a specialist.

Thus I find myself turned again to the thoughts which vexed my mind at the outset of this address, urged now to ask outright whether the specialisation of our times has the quality which distinguished that of Hooker and his contemporaries.

This is the uneasy phantom that has been haunting me and luring me to the ramparts when I should be wooing my chosen theme. It haunts me, refusing to be laid. Reason fails to exorcise that ghost. Its uneasy presence lingers near me even though I conjure it with specious argument; urging that these days are days of specialisation *à outrance*: that nowadays both in the art and practice part of life we live by the intensive cultivation of small-holdings; that the fields of science are parcelled out in small allotments. Were I—a simple officer—the sole subject of this visitation I should attribute it to fantasy, and with Horatio cry "Tush!" but beside this poor Bernardo, Marcellus, officer and scholar, has likewise seen it "in the same figure like the King that's dead," and who may refuse to entertain a ghost presenting this—the highest of credentials?

Therefore I offer it again my arguments, insisting that at least among our elders we have specialists as versatile as any of the Victorians. The ghost is not impressed. Instead, it rises to a fuller height, and lays its incorporeal finger on the row of volumes which line the shelves above my head. My obsequious eye follows the direction, and beholds Lyell's "Principles," Darwin's "Voyage," Hooker's "Journal," Huxley's "Essays," Wallace's "Island Life," Galton's "Natural Inheritance," and the other classics from his clients' pens. With the dawn of my comprehension the spectre vanishes, and I am alone, but not in peace. The message left with me appears to translate as follows: The present generation has become expert in intensive cultivation of scientific knowledge, but it has forgotten how to market its produce. In the preoccupation of specialisation it neglects the art of expression. It sinks the artist in the artisan. Each specialist exchanges "separates"—hateful term—with other specialists, but few among us are on speaking terms with the cultured general public curious to know what science is achieving.

The translation into common English of our scientific works is done, like that of foreign classics, too much by hacks and amateurs, and too little by skilled hands. The present generation lets its modesty wrong it; for the science of our day is no less full—nay, many times more full—of interest and wonder than that of fifty years ago.

Still worse: to fail to cultivate the art of expression is to blunt the power of thinking, for the adage "clear thinking means clear writing" stands though the subject and object be transposed.

Such is the nature of the charge which my visitant left with me; and though, as it must have known, my rough translation fails to convey the sober grace of the original, I think that I shall not be alone in pleading guilty to that charge.

Nor perhaps will my fellow-specialists resent an attempt to trace the origin of our lack of literary grace. This defect is in part inevitable and in part remediable. Inevitable because of the increasingly engrossing nature of scientific investigation, because of the relatively small natural gift of expression which nature has vouchsafed to the English race, and because, as science becomes more complex, its followers think more and more in symbols, and those who think in symbols are apt to write in shorthand. The defect is remediable because it is traceable in some measure to the training to which we submit our youth. That training neglects too much the literary side of education.

As it seems to me, there is a fundamental error in our mode of training men of science. The error consists in this: that students who come to English universities are treated in intellectual matters not as youths but as men of mature minds. The professorial potter takes the clay as he finds it, and, no matter what its state, fires it forthwith, and lo! in course of time it is converted into earthenware. Were the assumption on which he acts well-founded, the method might be justified. If our undergraduates were, as we assume they are, well found in general culture, trained already in scientific method, familiar with the language of our fathers, and apt also to read and speak and write some other tongue, then let us take them straightway and bake them in the oven of specialisation.

But I at all events have never met those students, and, outside the ranks of genius—which training toucheth not—I believe they do not exist. The error, as I conceive it, lies in our failure to apply, in drafting schemes of training, the biological law that as society grows older its young men grow younger. Undergraduates call themselves men, not solely from a sense of pride, but also in obedience to tradition. Centuries ago they went up to the university as men of fifteen or sixteen; now they go up as youths of eighteen or nineteen. With respect to moral discipline we are not unforgetful of their youth, but with respect to intellectual education we treat them as though they were grown up. Even the saving second subject has, I am told, been discarded from the final honours course. Let me give an example in illustration of our methods. It is found that a student in his second or third year knows no German, and we advise him to learn it. But in what a way, with our tacit approval, does he set about the task! So that he may tear the meaning from a scientific text as John Ridd clutched the arm of Carver Doone and tore the muscle out of it as the string comes out of an orange!

This barbarism we permit, because we know that it is no barbarism but expediency for a trained workman to take up any tool he needs and to use it as he wills. In the elegant language of modern literature, "and what he thought he'd most require he went and took the same as we."

Yet, unless we hold that mental training is a scholastic fiction, and that the teacher's sole business is to supply carefully selected and copious provender for the stuffing of students like Surrey fowls, it must be our care to encourage general as well as special culture in our students.

A further criticism which I have to make upon our university methods will seem to some far-fetched. We are prone to forget that the twin gifts of youth are enthusiasm and idleness. The former we encourage, but the latter, falling within the category of morals, we visit with our displeasure. There is, however, an idleness which is not laziness, but a resting period of the organism tired with the trouble of growing up. I could wish that our English universities understood intellectual liberty as well as German universities understand it. We are apt to mind our sheep too much, and to overrate the virtue of docility.

I would plead for more breadth and less special knowledge, for more licensed freedom, a lesser uniformity, a wider search for gifts, and a slighter regard for specialist attainments. It is never too late for a well-trained mind to master a new subject, but he who neglects the substance of education for the shadow of mere knowledge robs himself of half the pleasure of his work and of every chance of greatness.

In attempting thus to diagnose a complaint which some may think is non-existent, I have laid myself open to attack at every point; yet I have a flickering hope that I may be dealt with after the manner prayed for by an examinee whose paper, which I read, contained the appeal: "Mr. Examiner, please temper justice with mercy, for I am so young in mind." This hope I base upon the facts that modern science has at least taught tolerance, and that I have ever found my botanist colleagues conspicuous for this virtue. They understand that even the most minor among prophets prefers the stake to silence, and their good humour acquiesces in the interchange of rôles whereby the martyrdom which should be his is borne by them in listening to his wrathful words.

Anticipation of toleration so undeserved leads me to regret almost that I ever introduced that ghost at all. For now that it has served my purpose I am free to admit that I might have laid it long ago by other and *tu-quoque* arts.

I, too, might have pointed to those shelves, and at the sight of Mendel's work it would have vanished with a blush. For with all their gracious gifts the Victorians whose just praises I have sung failed to discover that Mendel was alive among them, and showing a way to solve the problems over which they themselves were puzzling.

The merit of the discovery of the greatness of Mendel's work belongs to our generation, and those of us who had no share in it have at least the right to applaud the discoverers and to score the discovery to our side.

So I may conclude the contrast of Victorian with modern naturalists with the reflection: theirs, the higher meed of culture; ours, perhaps, the greater perspicacity.

If, as I am prepared to maintain, the greatest gift which an experimental science may receive is that of a new, serviceable, general method, then to no man are biologists more indebted than to Mendel, for such a method he gave to our science. If, further, this claim can be established, I am absolved from the task of answering the critics of Mendelian doctrine.

Who does not recollect the answer which John Hunter gave to someone—Jenner, perhaps—who wrote to that great experimenter expressing doubt of the validity of an hypothesis? "Don't think—try," was Hunter's fine response.

If it were my purpose to discourse on Mendelian doctrine, it would be my duty to carry on that work—like the early builders of that doctrine—with sword in one hand and trowel in the other, and to try in emulation of the pioneers to take an equal joy in using either implement. But my work concerns the method and facts accomplished by its use, and, as I understand philosophy, the writ of criticism does not run in the domain of accomplished fact. A homely illustration will serve to define my attitude. Here is a new knife, and there an old loaf, the crust of which has turned the edge of other implements. If with this knife I cut that loaf, it is idle to tell me that my knife is blunt. One form of criticism, and one only, is valid in such circumstances, and that is the constructive criticism of offering a better instrument. If I want bread, and Mendel's knife can give it to me, I shall go on cutting, indifferent to the stones of destructive criticism.

My business, therefore, is to meet criticism, not by dialectics, but by confronting it with the facts accomplished by this method and by showing that its use opens new pathways on the borders of the unknown.

Now, if we scrutinise the method of Mendelian research, we may see that there can be no criticism of it.

Give a chemist a complex mixture of many compounds to describe: how does he proceed? The chemist sorts out the ingredients, and submits them severally to analysis. Such, also, is the method of the Mendelian analyst. Give him that complex mixture which is called an individual, and he sorts out the ingredients and submits them to analysis. Ask him how two complex mixtures behave when they are bred together, and he re-defines the question in such terms that it ceases to be enigmatical, and becomes susceptible of solution by experiment.

I am not concerned to claim for the Mendelian method the exclusive possession of these virtues. All I claim is that for the work of making a physiological analysis of individuals, and of thereby establishing a physiological classification of plants and animals, the Mendelian method has proved its value. It effects the service by a simultaneous analysis of germ and soma.

Let it be conceded at the outset that this analysis is made, not by direct but by indirect methods. For so long as the physical nature of living substance remains unknown we can scarcely hope to resolve an individual into its physical components. All that can be done is to make comparative analyses of individuals and to discover how their several components differ from one another.

For our present purpose we may represent the individual by an equation:—Individual $= x + c$; where c represents the sum of a long series of characters of the individual and x an imaginary or real groundwork left after all the Mendelian characters the sum of which is c have been removed by analysis from the individual. The Mendelian method is concerned directly with the resolution of c into its components. Indirectly it is concerned also with x; for by the pursuit of the method the full value of c may be determined, and hence that of x may be inferred. This concession made, it is permissible to concentrate our attention on the term c.

Thus the business of the Mendelian is to resolve the complex of characters which is possessed by an individual into its constituent unit characters. As a consequence of this experimental analysis Mendelism is enabled to restate the problem of the behaviour in inheritance of two individuals in these terms:—

The complex of characteristics which distinguishes an individual is the expression of the sum of a long series of characters. As the individual arises from germ cells so each character arises from a germ within the germ cells. Such germs of characters are called factors. When two germ cells unite to form an incipient individual or zygote they bring together the similar factors of a given character—one factor from the one germ cell and the other from the other. As the zygote forms the mature individual, so the paired factors give rise to a character of the individual.

The body characters are the flowers of the factorial seeds implanted in the germ cells.

Some characters are simple and derive from one pair of factors only; others are of an ascending order of complexity and may be traced to the co-operative agency of two, or more than two, pairs of factors. In the case of a complex character the determining factors may be unlike one another or they may be alike. Thus two pairs of different factors are required to produce the character of colour in certain flowers; on the other hand, it is at least probable that certain characters are the outcome of repeated doses of the same factorial stimulant. Further, the individual is a dual thing—a double-barrelled gun. Each barrel is loaded with the factorial charge supplied by one of the two gametes by the union of which its duality is constituted. Conversely and consequently a gamete or germ cell is, in comparison with the individual, of single and not of dual nature. It has one barrel only, and therefore can carry or give effect to one, and only one, of the two factorial charges with which the individual was supplied at the time of its formation.

Our image of the double-barrelled gun serves also to illustrate the several states in which an individual may find itself with respect to its charge of factors of any given simple body character.

Both barrels of the gun may be loaded. An individual in like state possesses two factorial charges and produces gametes, all of which are alike in the possession of one of these factors. Therefore, such an individual, when self-fertilised, or mated with its like, produces gametes which are all alike in this respect, and these gametes, fusing in pairs, give rise to individuals which all possess the character in question. Such individuals are homozygous, they breed true to the character.

Neither barrel may be loaded; and an individual in like state is also homozygous. It breeds true to the absence of the character. If a gamete of the former individual meet with one from the latter individual, the resulting zygote is in like case with that of a double-barrelled gun of which one chamber only is loaded. The zygote is heterozygous for the character. Unlike the homozygotes, which breed true, the heterozygous individual does not breed true to the character in question.

By the application of the foregoing propositions and a little arithmetic, it may be predicted that the offspring of the heterozygote fall into three groups—one homozygous for the character, and another heterozygous, and a third homozygous for the absence of the character—and that, further, these types of individuals occur in the proportion of 1 : 2 : 1. Needless to say, the prediction is susceptible of verification by experimental breeding from the heterozygote. These are Mendelian commonplaces with which I should have hesitated to occupy our time were it not for the fact that I desire to emphasise the epoch-making nature of Mendel's method. The magic wrought by genius is potent because it is simple. The rules of Mendelian method are simple. If it be urged that I have broken my promise and strayed from method to doctrine I would ask which of the simple propositions I have stated may be demurred to by any student of biology?

The supreme importance of Mendel's contribution to science consists in this: that instead of mixing anything with anything "in the gruel thick and slab" of a witches' cauldron, he has taught us to cast the horoscope of Fate by the method of genetical analysis of individual characters. Thus the first part of the Mendelian restatement of the old problem of heredity reads: Investigate one by one the modes of inheritance of the several characters of an individual. Choose for this purpose organisms which are as far as possible alike in all respects except for the character under investigation. Carry the experiment to its conclusion, even to the third or fourth generation. If uncertain results are obtained, ascertain before discarding the method whether the uncertainty may not be due to the interference of other characters not to be suspected *a priori* of exercising an influence upon the expression of the character under investigation.

Who, for example, would suspect a morphological character like thickness of stem of exercising an influence on the time of flowering of a plant? Yet such is the case with the pea (*Pisum sativum*), and there is evidence that when this disturbing influence is removed inheritance of time of flowering follows Mendelian rules.

The second part of the restatement of the problem of genetics may be expressed as follows: Only by the use of individuals of proved constitution with respect to a given character may the effect of external conditions on organisms be determined. The study of variation must be preceded by Mendelian analysis and synthesis. Let me illustrate this theme by an example.

The species, *Primula sinensis*, the Chinese primrose, has given rise to many distinct varieties. Among these varieties are some with white flowers and others with magenta, blue, red, or other coloured flowers. Each of these varieties may be obtained of florists in a pure strain—that is to say, in a strain which breeds true to flower-character. For our immediate purpose we will group these varieties into white and coloured forms.

It has been shown, however, that this apparently natural mode of grouping is inadequate to give a correct idea of the genetic constitutions of these races. It would seem self-evident that the white races differ from the coloured races by the lack of flower-pigment; yet Mendelian analysis demonstrates that there are more subtle differences between the different races. These differences become apparent when true-breeding white and coloured plants are crossed with one another; for it is then discovered that two types of white-flowered plants exist, and it is only by their fruits—their offspring—that ye may know them. Thus if certain white-flowered races are chosen for the experiment, the result of crossing white and colour is a coloured F_1 generation. If certain other white races are used and mated with the coloured form the offspring of the cross all bear white flowers. The different genetical behaviours of these heterozygous first generations give the clue to the difference between the two forms of white used as parents. In the former case—that in which the first (F_1) generation consists of coloured offspring—the second (F_2) generation, raised by self-fertilising F_1 individuals or by crossing them with one another, consists of coloured : white in the proportion of 3 : 1.

Whence we conclude that the white used in this experiment owes its character of whiteness to lack of the pigment-producing factor which is present in the coloured parent race. This conclusion is confirmed by the genetical behaviour of the whites of the F_2 generation. Such extracted whites breed true to flower-character—that is, give rise to white-flowered offspring only. White-flowered races which behave in this manner are termed recessive whites.

In the second case—that in which the F_1 generation consists of white-flowered offspring—the F_2 generation, from selfed or intercrossed F_1 plants, consists of three white : one coloured. The coloured offspring breed true. Of the three whites one breeds true to whiteness and the other two give rise, like the white F_1 generation, to three white : one colour. White races which thus impose their whiteness on the offspring of their union with a coloured race are known as dominant whites. Mendelians account for the genetical behaviour of dominant whites by assuming that they carry the character for colour and also a character for colour-inhibition. This hypothesis, which is novel to biology, is amply justified by genetical results. It propounds a series of questions to the physiologist and biochemist, and in so doing exemplifies the fruitfulness of Mendelism. We shall see immediately whether the biochemist is able to take up this Mendelian challenge and what answer he can give to it.

At present, however, we are concerned to show by an example the necessity of prefacing the study of variation by Mendelian analysis. It was stated just now that the cross, dominant white by colour, results in a white F_1. That statement requires amplification. Grown under normal conditions the F_1 individuals bear pure white flowers; but if grown in somewhat higher temperatures the flowers develop a distinct though pale flush of colour. It is easy to show that the factor for colour is unaffected by the changed conditions, for the flushed F_1 individuals yield offspring of the same kind and in the same proportions as those produced by white F_1 plants.

It is fairly evident that the flushing is produced by the destructive action of heat on the inhibitor. In pre-Mendelian times this response to temperature would have been added without more ado as yet another ornament to dress the window of that old curiosity shop which is stocked with miscellaneous and heterogeneous articles all ticketed with the label "variation."

But in the light of Mendelism we may see in this effect of temperature the result of the casting-vote of circumstance on a heterozygous constitution. We may recall instances—as, for example, those provided by the well-known experiments on the effects of high temperatures on insect larvæ—which seem to show that environmental agencies may single out not only characters but also factors for attack. Thus we may begin to cohere in series the hitherto sundered and scattered phenomena of variation.

It is not yet possible to say how much of variation is to be put down to the interplay of characters, or, rather, to the differential effects of external conditions on characters which tend to balance one another; but this at least may be said—that the old and worn controversy on acquired characters was so much waste of words, because the problem purporting to be discussed had never been defined. Like the half of human quarrels, it was a quarrel about words.

It is stated in the books that the formation of peloric (regular) flowers may be induced by uniform illumination. Was the material used in the research homozygous or heterozygous? Does uniform illumination just prevent the unpaired factor from inducing normal growth? If so, what is the effect on the homozygous normal? These are examples of questions which suggest themselves at every turn, and they will abide the answer of experiment. The time is approaching when it will be possible to test the validity of the hypothesis on which the superhypothesis of natural selection rests apparently secure from verification or disproof.

That hypothesis maintains that everything is in a state of flux; that variation occurs at all times and affects all parts. This may be true of multiple mongrels; of organisms which are heterozygous for many characters. On the other hand, nothing is more surprising than the stability of forms which are pure-bred for a fair number of characters, and it is at all events a suggestion not to be rejected summarily that plants pure bred for a considerable number of characters may exhibit a constancy and stability not usually associated with our ideas of living things.

In any case, it is open to the biologist to provide himself with suitable material wherewith to study the range and scope of variation and to investigate the conditions under which the organism discards old characters and regresses or acquires new ones and progresses. It is open to the Mendelian breeder to standardise creation.

Thus in fulfilling the first part of its task—that of defining the pure-bred—the Mendelian method has provided the material for the fulfilment of the second part—namely, the investigation of the conditions which make for the stability and instability of the organism. I think the time has come when this latter task might be undertaken on a large scale and with good prospects of success.

So far I have played the part of one of those street-corner watchers of the skies who offer a telescope for the inspection of the heavens. I have now to take a turn myself, and by means of the binoculars of Mendelism and physiology survey, not the celestial bodies, but certain new features of a small and narrow terrestrial field which this instrument brings within our ken. My survey has reference to the phenomena of the pigmentation of plants, and is confined to those presented by the anthocyan or sap pigments to which the colours of many flowers are due.

Until recently knowledge of the processes of pigmentation advanced along two main and independent lines. One line of advance—that followed with such brilliant success by Bateson and the Cambridge school, as well as by other students of genetics—has led to a wealth of exact knowledge with respect to the factors and characters which determine coloration. The other line of advance, pursued with no less brilliant results by Chodat and Bach and by Palladin and his associates, has resulted in a great increase of our understanding of the biochemistry of pigmentation.

The merit of being the first to combine the genetical with the biochemical method belongs to Miss Wheldale, to whom, moreover, we owe a good working hypothesis of the nature of the processes involved in pigment-formation. The work of Palladin and of Chodat and Bach is so well known that I need not review it in any detail. To Palladin we owe in large measure the conception that respiration consists in a sequence of enzyme-like actions, the later of which result in oxidations and are ascribed to oxydases. To the same observer we owe also the suggestion that chromogens play a part in the oxidations set up by oxydases, and that these colourless chromogens may undergo either alternate oxidation and reduction and so take a continuous part in oxydase action, or undergo permanent oxidation and so constitute the pigments of the plant.

Chodat and Bach have given us a serviceable conception of the nature of oxydases. According to the Chodat-Bach hypothesis, oxydases are of dual nature; the complete oxydase consisting of two parts—a peroxydase and an organic peroxide. An oxydase reacts with oxidisable reagents, such as guaiacum, to produce a characteristically coloured product. Hence these reagents may be termed oxydase-reagents. Peroxydases react with oxydase reagents only if there be added, as a substitute for the organic peroxide of the complete oxydase, a source of active oxygen in the form of hydrogen peroxide. Both oxydases and peroxydases occur in the cells of plants, and may be identified in extracts therefrom.

The work of Görtner on the pigments of insects adds confirmation to the view that pigments are the product of the action of oxydase on chromogens. Thus he has shown that the black or brown melanin of the integuments of insects is produced by the action of an oxydase, tyrosinase, on some such product of protein-hydrolysis as tyrosin.

Miss Wheldale's studies have led her to formulate the hypothesis that the anthocyan pigments of plants are the outcome of a series of chemical changes of the following order: Glucosides hydrolysed by emulsin yield chromogens which, acted on by oxydases, give rise to anthocyan pigments. The difficulty in the way of further advance lay in the unsatisfactory nature of the methods for identifying oxydases derived from plant tissues. Hence when we turned our attention to this subject Dr. E. F. Armstrong and I made it our first task to search for means whereby we should be able not only to identify, but also to locate, oxydases and peroxydases in plant-tissues. Clarke had tested already numerous oxydase-reagents and found that certain among them are adapted for microchemical use. As the result of a considerable number of trials of known reagents we have found that α-naphthol and benzidine are each adapted admirably for the purpose of locating oxydases. By means of these reagents we have been able to map out the distribution of oxydase and peroxydase in the flowers and other parts of various plants, and although the work is laborious and the technique as yet imperfect, the results afford strong confirmation of the current hypothesis of the mode of formation of anthocyan pigments. This confirmation, however, was rendered possible only by reason of the fact that we worked with races of plants bred on Mendelian lines, and hence of known genetic constitutions.

Our method of investigation is briefly as follows. The oxydase-reagent is used in weak alcoholic solution, the part of the plant to be tested is incubated in the solution for a suitable time, and if no oxydase action takes place—that is, if no characteristic coloration of the tissues occurs—the material is tested for peroxydase by the addition of hydrogen peroxide. The method may be employed for intact corollas or petals or for sections of plant-tissues.

It is important to mention that the first result of immersing a sap-pigmented tissue in either reagent is the decolorisation of the tissue. For example, a corolla of a coloured-flowered race of *Primula sinensis* loses its colour completely after being immersed for an hour or two in either reagent. The decolorised corolla, which in the case of *P. sinensis* remains colourless, is treated with hydrogen peroxide, with the result that a well-marked peroxydase reaction is obtained. The reaction is confined to the non-chlorophyllous parts of the corolla, and does not occur, except in the epidermal hairs, in the region of the yellow or green eye, the tissues of which contain chlorophyll. Indeed, there is good reason to believe that chlorophyll inhibits oxydase action.

By treating similar flowers with each of our two reagents we find that the action of α-naphthol and benzidine are, in a considerable measure, supplementary one of the other. Thus the lilac-blue α-naphthol reaction is confined, or almost confined, to the veins of the corolla, the brown benzidine reaction is exhibited by the superficial (epidermal) cells and also by the veins. In order to emphasise the facts of distribution we speak of the peroxydases of *P. sinensis* as epidermal peroxydase and bundle oxydase. The former occurs in the epidermis and in the epidermal hairs, the latter in the bundle sheath which accompanies the veins.

Similarly, if sections of a stem of *P. sinensis* be investigated they are found to contain a superficial peroxydase and a deep-seated peroxydase. As the result of investigating the peroxydases, not of any unknown variety taken at hazard, but of the several varieties characterised by constant differences of depth and extent of pigmentation, we have been able to show that the distribution of peroxydase in any one race coincides broadly with the distribution of pigment in the most pigmented races. In other words, in *P. sinensis* the peroxydase framework for pigmentation occurs throughout the species, and the building of the several colour varieties is determined by the activity of the factor for chromogen production. If we conceive of this factor as administered in a series of doses we can form a fair picture of the mode of evolution of the series of varieties characterised by increasing or decreasing amount of pigmentation of their vegetative parts.

On turning to investigate the peroxydases in white-flowered races of *P. sinensis*, we shall expect to find from analogy with the peroxydases of the stem that these agents of pigment-formation are not lacking from the corollas of recessive whites. The application of our reagents shows that this expectation is correct, and that those white-flowered races which lack the factor for colour contain epidermal and bundle peroxydase. Hence we conclude that the absence of colour from recessive white flowers is due, not to the absence of peroxydase, but to absence of chromogen. This conclusion is in conformity with that arrived at previously by Mendelian methods; for, as we have noted already, these methods demonstrate that anthocyan pigmentation of the flower of *P. sinensis* depends on the presence of one factor only, and that the absence of pigmentation which is characteristic of recessive whites is due to the absence of that single colour-factor.

The result of our investigation of the peroxydases of dominant white flowers is, on the other hand, quite different from that given by recessive whites. When corollas of dominant white races are treated with α-naphthol or benzidine and subsequently with hydrogen peroxide, they show no sign of peroxydase neither in epidermis nor in bundles. Hence such flowers either lack peroxydase or else they contain a substance which inhibits peroxydase from exercising its oxidising action on our oxydase-indicators.

That oxydases may be inhibited *in vitro* has been demonstrated already by Görtner, who has shown that the addition of certain phenolic compounds—orcin, resorcin, &c., prevents tyrosinase from exercising its characteristic action upon tyrosin.

Assuming that an inhibitor of peroxydase occurs in dominant white flowers, it may be supposed to act either by destroying peroxydase or by setting up conditions under which the activity of peroxydase is arrested. Assuming further that the inhibitor acts in the latter way, it follows that if means of destroying or removing the inhibitor be discovered and employed, the peroxydase released from the inhibitory grip should be free to effect the oxidation of our reagents.

This train of reasoning gave us a point of departure for experiment. Starting from this point Dr. Armstrong and I have found in hydrogen cyanide a means of removing peroxydase-inhibition. Thus if dominant white flowers are immersed in a 0·4 per cent. solution of hydrogen cyanide for twenty-four hours, washed, and treated with either of our reagents together with hydrogen peroxide, pronounced peroxydase reactions are obtained, both in the epidermal and bundle tissues of the corolla. Carbon dioxide in aqueous solution produces a like, albeit a less pronounced effect.

Now, it so happened that we had at our disposal a race of primulas, the flowers of which lend themselves peculiarly well to the purpose of confirming these observations. The race in question is characterised by blue flowers with fairly symmetrically placed paired white patches on each petal. We have reason to believe from the known ancestry of this race that these white patches are produced by a localised inhibitor.

Corollas of these flowers treated with α-naphthol or benzidine become quite colourless. When, however, hydrogen peroxide is added the natural pattern is restored. The parts originally blue are stained lilac-blue or brown, according to the reagent used, and the inhibitory patches stand out as in the intact flower as white areas on the coloured ground.

If instead of submitting the parti-coloured flowers directly to the oxydase reagent they are treated first with hydrogen cyanide, and then treated with the reagent and subsequently with hydrogen peroxide, the inhibition located in the white areas is found to have been removed, and the peroxydase reaction is produced over blue and white areas alike.

Hence the Mendelian hypothesis of the inhibitory nature of dominant whites is confirmed by biochemical methods. Moreover, these methods demonstrate that the inhibitor acts not by destroying but by preventing the action of oxydase upon the chromogen.

There are many other aspects presented by the phenomena of oxydase distribution in *P. sinensis* and other plants which we have investigated. Some I may enumerate, but lack of time must be my excuse for not dealing fully with any of them.

The close proximity in the flower of the superficial and deep oxydases suggests that the latter may co-operate with the former in producing flower-pigments. This possibility entails the hypothesis of a translocation of oxydase from the region in which it is secreted to that in which it acts, and there are not a few facts which are in favour of this view; for example, the lines of deep colour which occur along the veins of many flowers, the frequency with which the walls of cells appear to contain oxydase, the occurrence of oxydase in the mesophyll cells which adjoin the bundle sheath, and the evidence provided by the mutual influence of stock and scion in grafted plants and in graft hybrids. Though these and other subjects must be passed over, I cannot resist giving what appears to me to be the most elegant mode of demonstrating the relation between oxydases and pigmentation which we have as yet observed. The plant which has served for this purpose is the sweet William (*Dianthus barbatus*), and any of the old-fashioned races of this plant common in cottage gardens suffices, provided that it be an ever-sporting race. Such a race is known by the fact that it bears, on one and the same head, flowers of different colours. The race which we have used is very sporting, a single plant bearing in one inflorescence deep magenta, pale magenta, white with limited rose flush, and all but pure white flowers.

If a petal of each of these flowers be treated with the benzidine reagent, it is found that the extent and amount of the oxydase reaction, as measured by the distribution and depth of brown coloration indicative of oxydase, coincide precisely with the extent and amount of pigmentation. The full-coloured petal gives a uniform deep brown reaction, the light magenta a uniform but paler reaction, the petal with a limited rosy flush gives a slight reaction, limited to the pigmented area, and the all-but-white petal gives none but the slightest reaction, and that only in the part of the petal which contained traces of pigment. Thus—unless the results are due to a partial inhibition which has eluded our attempts at demonstration—it would seem established that the ever-sporting habit is due to differences in the amount of oxydase in the diversely coloured flowers.

The sweet William is also noteworthy in that it contains white races, some of which give an oxydase reaction in their petals, and some of which give no oxydase reaction. Breeding experiments now in progress will decide whether or no these white races, like those of sweet peas investigated by Bateson and Punnett, mated together yield coloured progeny. If so, the factors for colour, long wandering yet not lost, which meet again in reversionary coloured cross-breeds, may prove to be a chromogen factor and an oxydase factor.

Finally, a brief reference must be made to our observations on the periodic fluctuation of oxydase in plants. Various observers have noticed that plant tissues give the peroxydase reaction much more generally than the oxydase reaction. The observations now to be described indicate that this is due to the greater stability of peroxydase as compared with the organic peroxide.

In certain circumstances a tissue which gives only the peroxydase reaction may exhibit the direct oxydase reaction. Moreover, the extent of the peroxydase reaction, as judged by the depth of coloration of the reagent, varies in similar plants at different times.

Inquiry into the meaning of these fluctuations led us to the discovery that the nature and amount of oxydase contained in a plant tissue varies in an orderly manner according to external conditions.

Among the conditions which determine this fluctuation are light and darkness. Plants subjected to normal illumination possess less oxydase than those which are kept in darkness. After one or two days' exposure to darkness plants of *P. sinensis* contain more peroxydase than sister plants kept under normal conditions of illumination. Moreover, after such an exposure to darkness tissues which under normal conditions give only peroxydase-reactions yield distinct oxydase-reactions.

Whether these phenomena are general among plants we are not yet in a position to say; but repeated experiment enables us to vouch for them in the case of *P. sinensis*. Should the results of similar investigations with other plants show that this diurnal variation of the oxydase-content of plant tissues is of general occurrence, we may perhaps discover therein the means whereby many of the phenomena of periodicity exhibited by plants are maintained and regulated. We know that the light and darkness of the day and night set up rhythms in the plant; for example, that the leaves of various plants assume nocturnal and diurnal positions. We know further that the rhythm thus established may be maintained for a certain time under uniform conditions of illumination. This is the case with the sensitive plant and many another.

Animals also exhibit a like periodicity. Thus some years ago Dr. Gamble and I showed that certain shrimp-like animals, *Hippolyte varians*, roll up their brilliant chromatophores at night and assume a sky-blue colour. When daylight comes they put on their daytime dress by spreading out the pigment of their chromatophores in far-reaching superficial networks. Kept in the dark, these animals retain for many days this periodic habit, and when the hour of night arrives, although they have no light to tell it by, they lay aside their daily garb and put on the uniform of night. So also the plant-animal *Convoluta roscoffensis*, which lives on the seashore, orders its behaviour by the sun and moon. It lies on the sand till the waves of the making tide are upon it, and then descends to security and darkness. When the tide recedes it rises to the light. Even the uncongenial surroundings of a teacup and a laboratory fail to break this habit; for in these surroundings its uprisings and down-lyings keep time with the tides.

To one who has scrutinised with perplexed mind these mysteries of biology, the speculation may be permitted that light and darkness may work these wonders through the control of chemical agents such as oxydases. But though it be legitimate to make a speculation of this kind, it is idle to hunt the unknown to the death without the lethal weapon of experiment, and so I leave it for the present unpursued, and with it my address. We have it on the authority of a poet and philosopher that to the traveller on a lonely road each bush becomes a bear, and I am not oblivious of the fact that oxydases have obtruded themselves with a certain obstinacy in the course of my address. Nevertheless, obsession has its uses and significance, for it is the after-effect of enthusiasm; and though I have dealt, perhaps at undue length, with special problems and with suggestions, I venture to think that I have made out my case for the opportuneness of an *entente cordiale* between physiology and Mendelism.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Henry Sidgwick memorial lecture at Newnham College will be given by Prof. Ward in the College Hall on Saturday, November 9, at 5 p.m., and will be open to all. The subject will be "Heredity and Memory."

The prize of 50l. out of the Gordon Wigan Fund for a research in chemistry has been awarded to D. H. Peacock, of Trinity College, for investigations on "Hydroxyhydrindenehydrazine and its Resolution," "1:2:4-Triketopentamethylene," and "The Theory of Molecular Volumes."

The next combined examination for fifty-seven entrance scholarships and a large number of exhibitions, at Pembroke, Gonville and Caius, Jesus, Christ's, St. John's, and Emmanuel Colleges, will be held on Tuesday, December 3, and following days. Mathematics, classics, natural sciences, and history will be the subjects of examination at all the above-mentioned colleges. A candidate for a scholarship or exhibition at any of the six colleges must not be more than nineteen years of age on October 1, 1912. Forms of application for admission to the examination at the respective colleges may be obtained as follows:—Pembroke College, The Master; Gonville and Caius College, the Master; Jesus College, A. Gray; Christ's College, the Master; St. John's College, the Master; Emmanuel College, the Master; from any of whom further information respecting the scholarships and other matters connected with the several colleges may be obtained. The forms of application must be sent in on or before Saturday, November 23.

Colonel Harding, of Madingley Hall, has offered to the Vice-Chancellor to hand over to the University a sum which will produce an annual income of between 50*l*. and 60*l*. a year, to be devoted to the payment of a lectureship in zoology.

A SERIES of ten free public lectures upon natural history, folk-lore, and related subjects will be given in the new Lecture Hall of the Horniman Museum, Forest Hill, S.E., at 3.30 o'clock on Saturday afternoons, commencing October 12.

IT is stated in *Science* that at the September meeting of the Yale Corporation it was announced that since the last meeting three wills have been filed for probate from which Yale University will probably receive during the year about 150,000*l*. These bequests include 50,000*l*., unrestricted, by bequest of Mr. Matthew C. D. Borden, and the McPherson fund of between 80,000*l*. and 100,000*l*., "to be employed in assisting worthy indigent students."

A COPY of the second issue of the "Register of Old Students of the Royal College of Science, London," compiled by the Old Students' Association, has been received. An excellently reproduced photograph of Sir William Crookes, O.M., F.R.S., the president of the association, serves as a frontispiece to the register. The names of 876 old students are given; of these 729 are associates of the college, and in their cases the subjects in which they took their diplomas are enumerated. Copies of the register may be obtained, price 1*s*. net, from Messrs. Lamley and Co., Exhibition Road, South Kensington.

THE Secretary of State for India in Council has made the following appointments to the Indian Educational Service:—Dr. W. N. F. Woodland to be professor of zoology at the Muir Central College, Allahabad; Dr. A. N. Meldrum to be professor of physics and chemistry at the Institute of Science, Ahmedabad; Mr. W. S. Rowlands to be professor of philosophy at the Government College, Jubbulpore; Mr. G. H. Luce to be professor of English at the Government College, Rangoon; and Mr. C. S. Gibson to be additional professor of chemistry at his Highness the Maharaja's College, Trivandrum, in the Travancore State Service.

AT the University of Leeds on October 3 honorary degrees were conferred upon Mr. Arthur Cooper, president of the Iron and Steel Institute; Sir Robert Hadfield, F.R.S., a past president of the institute; M. Adolphe Greiner, of Liége; Herr Friedrich Springorum and Mr. J. E. Stead, F.R.S., members of the council of the institute; Mr. Corbet Woodall, Mr. Charles Carpenter, and Mr. Thomas Newbigging, for their services to science in the gas industry; and Sir Swire Smith, Mrs. R. W. Eddison, Mr. W. E. Garforth, and the Rev. W. H. Keeling, headmaster of Bradford Grammar School, for their services to science and education in Yorkshire.

THE students of forestry in Edinburgh University, as part of their practical training, have during August and September been camping out at the Drumbuick Wood, Methven, Perthshire, and part of the Logiealmond estate of the Earl of Mansfield, so as to have the opportunity of measuring timber. The trees were principally Scots pine, larch, and spruce, and these were numbered and measured. The accessible trees were dealt with in detail in 10-ft. sections, while every tenth was barked so as to obtain the allowance necessary to be made for bark. The work of the students was supervised by Mr. Lyford-Pike, junior lecturer in the University, who was assisted by a few recent graduates in forestry.

DR. L. SILBERSTEIN will commence a course of twelve lectures on "The Theory of Relativity" at University College, Gower Street, W.C., to-morrow, October 11, at 5 p.m. The first part of the course will be historical, beginning with Maxwell's electromagnetic theory, and the Hertz-Heaviside equations; the second part will be concerned with the principle itself; and the third with its applications and recent extensions. Much attention has been paid to the subject since Einstein founded the modern theory in 1905, but the arguments for the principle, and the conclusions to which they lead, are not well understood. There must be many students of physics who will be glad to have a clear and connected statement of a theory which, carried to its furthest extent, would declare that "the phenomena of physical science do not lead us to any knowledge of a permanent and unique frame of reference relative to which the motions of bodies may be determined."

COPIES of the calendar for the academic year, 1912–13, of the University of Leeds are now available. As is natural in the case of a great modern university, the faculties of science and technology take a prominent place in the activities connected with the institution. The degree of bachelor of science, whether with or without honours, may be taken in pure or applied science. The student wishing to graduate on the technical side may study mechanical, civil, electrical, mining, or gas engineering, fuel and metallurgy, agriculture, colour chemistry and dyeing, or the chemistry of leather manufacture, and, if successful, secure his degree. In addition, the University grants diplomas in certain circumstances in the branches of applied science in which degrees are awarded, and also in textile design and cloth finishing, in woollen and worsted spinning, cloth manufacture, and textile chemistry. Evening classes in a wide range of subjects are also provided for students whose time is occupied in industrial pursuits during the day.

AN interesting short history of Bedford College for Women is included in the calendar for the sixty-fourth session, that of 1912–13, of the college, which was recognised in 1900 as a school of the University of London in the faculties of arts and science. It will be remembered that a bequest in 1908 of 11,500*l.* from the late Mr. R. J. Turle enabled the council in the same year to purchase the end of the lease of South Villa, Regent's Park, for the sum of 15,000*l.*, a promise from the Crown having been obtained of a new lease for 99 years. The site is an ideal one. New buildings, for which Mr. Basil Champneys has been appointed architect, and will include a library, laboratories, lecture rooms, and a residence for students, are now in course of erection, and it is hoped that they will be ready for occupation by next Easter. It is estimated that the cost of the undertaking will amount to about 115,000*l.*, including 18,000*l.* which has been expended in connection with the purchase of the lease of the new site. The total sum given and promised amounts to 130,000*l.*, which leaves 15,000*l.* to form the nucleus of an endowment fund.

THE calendar of the North of Scotland College of Agriculture for the session 1912–13 points out that the classes of the college are held in the University of Aberdeen, with the exception of the class in agricultural engineering, which meets in Robert Gordon's Technical College. The courses of instruction provided are arranged for the benefit of every section of the agricultural community. The lectures, in the branches of agriculture and agricultural chemistry, are arranged in a series of three years with the view of giving full treatment to these subjects. Students unable to spare the time for a long course in agricultural science, but who can spare five months in winter, have an opportunity of obtaining a diploma in agriculture conferred by the University. Young men and women who wish to qualify themselves as agricultural teachers or as specialists in some branch of agricultural science may obtain the degree of bachelor of science of the University on passing the preliminary examination of the University and two professional examinations. Extended courses of lectures in forestry are arranged for those desirous of training as factors and land stewards; courses for teachers in school gardening and other subjects required in rural districts are provided, and every effort is being made to supply suitable technical education for the district.

THE *London University Gazette* for September 25 announces a number of courses of advanced lectures in various subjects, among them being a course of three or four lectures on "The Theory of the Solid State," by Prof. W. Nernst, professor of physical chemistry and director of the Institute of Physical Chemistry in the University of Berlin. Other courses to be delivered during the session are :—The fundamental chemical processes of plant life, Prof. H. E. Armstrong, F.R.S.; the Gnetales, Prof. M. J. Benson; the permeability of protoplasm, F. F. Blackman, F.R.S.; the activities of green plants in relation to light, Harold Wager, F.R.S.; meteorology in relation to the navigation of the air, Dr. W. N. Shaw, F.R.S.; the action of enzymes, Prof. W. M. Bayliss, F.R.S.; the physiology of the mammalian heart, Dr. F. S. Locke; protozoa, Prof. E. A. Minchin, F.R.S.; the growth of the vertebrate embryo, R. Assheton; recent work on experimental embryology, Dr. J. W. Jenkinson; mimicry and protective resemblance, Prof. E. B. Poulton, F.R.S.; the evolution of the mammary apparatus in the mammalia, Prof. E. Bresslau, of Strassburg; growth and form, Prof. D'Arcy Thompson, C.B.; the advanced metallurgy of gold, silver, copper, lead, &c., Prof. W. Gowland, F.R.S.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 30.—M. Émile Picard in the chair.—Edmond **Perrier**: The skull known as that of Descartes in the museum. Reasons are given for the probable authenticity of this skull.—Pierre **Termier**: The scientific results of the Alpine excursion of the Geologische Vereinigung; the lepontine strata to the west of Innsbruck.—M. **Gouy**: A particular kind of electric currents. A non-electrified body is usually regarded as carrying equal charges of the two kinds of electricity. The latter, according to current views, are carried by particles possessing a certain independence, and under certain conditions may move with different velocities. If this is the case, the movement of a non-electrified body may give rise to an electric convection current, producing its ordinary effects. This view is applied to the case of incandescent gases in motion.—M. **Arnaud**: Astronomical refraction in the neighbourhood of the horizon.—Em. **Bourquelot** and Mlle. A. **Fichtenholz**: The presence of quebrachite in the leaves of *Grevillea robusta*. The fresh leaves contain more than 4 grams of quebrachite per kilogram, or four times the amount extracted from the bark of

C. tanret. Details are given of the method of extraction and of the chemical and physical properties of the quebrachite.—A. **Fernbach**: A new form of soluble starch. Weak solutions of starch in water, not containing more than 2 per cent. of starch, are poured into a large excess of acetone, and the precipitate extracted with pure acetone, and dried in a vacuum. The starch thus obtained is distinguished by the property of dissolving easily in cold water, and this solution yields with iodine very pure blue colorations.—J. **Wolff**: Some new properties of the peroxydases and their mode of working in the absence of peroxide.—Jacques **Parisot** and M. **Vernier**: Researches on the toxicity of fungi. Their hæmolytic power. It is shown that the hæmolytic power of fungi, when it exists, is very strong, both *in vitro* and *in vivo*. This property is possessed by some of the edible fungi, and it is pointed out that a very long exposure to a high temperature during cooking is required to destroy this poisonous property.—Maurice **Lugeon**: The tectonic of the Morcles strata and its consequences.—De Montessus de **Ballore**: Seismological observations made at the island of Pâques.—Henry **Hubert**: The aërial currents in western Africa.

NATURE IN ROMAN LITERATURE.

The Love of Nature among the Romans during the Later Decades of the Republic and the First Century of the Empire. By Sir A. Geikie, K.C.B., F.R.S. Pp. xi + 394. (London: John Murray, 1912.) Price 9*s.* net.

THIS is indeed a delightful book, full of contagious zest and charm. The love of nature, the love of science, the love of the best literature both of the past and the present, all combine to make it so. It represents the happy adventure of one of our very foremost men of science, the President of the Royal Society, and the *doyen* of British geology, into the realm of classical scholarship and Roman literature. The "classics," as they are commonly called among those who love them and write about them, suffer too often by being made a business of. The affection of the schoolmaster or the classical professor is discounted as being professional, and its sincerity is a little doubted. It is only when some old statesman or soldier, some lawyer or physician, some original modern poet who has made his own name, after experience of the world, turns again, as Cardinal Newman in the famous passage in the Grammar of Assent describes him doing, to the Homer or Horace of his schoolboy hours, that we feel that the classics are being taken at their real value and that their natural undying charm is once more powerfully vindicated.

Specially is this the case when their beauty is avowed, *quod minime reris,* by a man of science. But, indeed, there should be no feud between the love of natural knowledge and of literary art, and, above all, of poetry, the best of which rests so much upon the close observation and faithful presentment of nature. There used not to be such a feud. It may be hoped that we are returning to a more healthy condition both of science and of scholarship when a book such as this comes into being. What were its occasion and origin Sir Archibald Geikie tells us in his modest, pleasant preface. He was asked by the Classical Association to become their president, and he chose, he tells us, for his address a subject which "seemed in some measure to combine the classical interests of the members with his own deep love of nature." This book is the expansion of the address which he then gave—an address which came, perhaps, as somewhat of a surprise to some, but not to those who knew Sir Archibald well or who remembered his Romanes Lecture at Oxford, or his book on "Landscape in History."

Such readers will not be surprised to hear that this new volume is excellently written. The great masters of science have usually written well, but this is more than well written. It is eminently readable, in a style at once lucid and sustained, and sympathetic with its subject. Indeed, it might be used to point the moral that an acquaintance with the masterpieces of antiquity is not without its uses to the modern student or exponent of science.

What may surprise, is that the President of the Royal Society should prove himself so well informed a scholar and, to use the classical phrase, so "ripe" a scholar. For not only is he well "posted up," not only has he read his monographs, his Pelham on the Italian *pascua,* or his Boissier's "Varron"—a rare book—but, still more, to the accuracy and completeness which his science might teach him, he adds a judgment, tact, and taste, pre-eminently considered, mellow, and mature.

It may be noted that he has for the most part translated himself, and often into verse, the many quotations which he makes from the Latin poets. This is a bold course, but justified both by the general good level of the renderings, and still more because it secures two advantages, the first, that of exactness of understanding for the writer himself; the second, that of consistency of presentment for his readers.

The volume, then, is essentially a "humane" book. It is written with real feeling and *con amore.* Geology, notwithstanding its "stony names," of which Tennyson made such ingenious poetic use,

> Of shale and hornblende, rag and trap and tuff,
> Amygdaloid and trachyte,

is really a humane study, for it deals with the structure of the dwelling in which we live, the history and character of the home of our race so far back as we can trace its chronicle.

When Sir Archibald looks at the literature, the poetry, the mode of life, the tastes of the Romans with the "modern eye," the scientific eye, he naturally first sees Italy as a geologist, and, so doing, throws a new light on the figures and epithets, the descriptions and the criticisms, with which the scholar is so familiar.

Italy, the Italy of Cicero and Virgil, the

> Magna parens frugum, Saturnia tellus
> Magna virum,

was always, in the broad geological and geographical sense, the Italy she is now; her kindly and temperate skies with their *indulgentia caeli*; her double sea, largely the secret of her skies; her northern wall and spinal chain of mountains; her lakes; her short rivers, here torrent, here stagnant, now in "spate," now parched threads, the consequence of these mountains; her volcanic energies, slumbering or active—these have always been the same. They make the *mise-en-scène*; they give the colour and the form to the pictures which her poets have drawn in all ages. They are the eternal factors on which the tillers of her soil, the cultivators of her woodlands, have counted, and with which they have contended, from age to age.

The Romans and the ancient Italians were a race of "country men" and "country gentlemen." The rich and fashionable loved to go to "town" for the season. The poorer, when they could get so far, loved more and more the excitement of the city shows and spectacles too, but there were many among both who also loved the country, and not a few who, especially in middle and later life, loved the country more. Like Burke at Beaconsfield or Warren Hastings at Daylesford, like Gladstone at Hawarden or Disraeli at Hughenden, Cicero and Hortensius enjoyed, even if they kept one eye ever on Rome, the refreshment of their *villegiatura*. Horace, though for a time, like Browning, a lover of society, a dandy, and a diner-out, yet more and more came to prefer his Sabine farm. Virgil, like Tennyson, made rare and shy incursions into the metropolis, but like Tennyson again at Farringford or Aldworth, so Virgil at Naples or Nola preferred the *secessus*, the solitude of sea and upland.

Sir Archibald has brought out another resemblance between these two poets, for just as Tennyson never forgot the smallest detail of the "wold" and "marsh" and "table-shore" of Lincolnshire, so Virgil, as he points out, drew from memory, but with astonishing fidelity, the scenery of the northern home he had long left. It is true that in his early poems he introduces, by a sort of *mirage*, the scenery of Theocritus' Sicily, into the plains of Lombardy, but the greater part of his drawing is, as Sir Archibald Geikie points out, "from the life." For Virgil was by birth and nurture a countryman—indeed, a peasant. He was "brought up among orchards and woodlands." He knew the country, and he was a most accurate observer of nature. Sir Archibald Geikie quotes as an instance the famous passage in which he describes the wave rushing up, breaking in foam, flooding the sandy coves, then retreating, at first dragging the spinning pebbles with it, then finally thinning out, as it retires, into a sliding, shallow tide—"picturing," as he says, "in four pregnant words, one of the great dynamical processes of the sea." "Virgil," he adds, "knew nothing of the scientific meaning of the facts he noted, but no man of science could have observed them more accurately or described them with more concise precision." He dwells, too, on the appeal to another sense, the ear: the representation by an alliteration of rough "r's"—"*nunc rapidus retro atque aestu revoluta resorbens*," of what Tennyson, as he recalls, describes as "the scream of the maddened beach dragged down by the wave."

Sir Archibald Geikie doubts whether Virgil had seen the Lake of Como. He thinks that he probably knew the Lake of Garda, from which his own Mincius takes its course. Another scientific poet and lover of nature had no doubt. No one who has read it will forget the passage in which Goethe describes how, at the beginning of his "Italian Journey," he came to the shores of Garda; how he found the south wind blowing up the lake, lashing it into loud and dangerous waves; and how, as he waited and listened to their murmur, he realised after eighteen centuries the fidelity of Virgil's line:—

Fluctibus et fremitu assurgens Benace marino.

The truth is, Virgil was a great "naturalist," and must always furnish the greater part of the material for any writer who tries to estimate the Roman appreciation of nature. That he does so for Sir Archibald Geikie, a glance at the index will show. One of the best passages in the volume is a page of eloquent, if condensed, prose summing up Virgil's love of woods and woodlands. But Virgil was something more than an observer. He was by education not a little of a philosopher also. It is here that he joins hands with Lucretius, whom Sir Archibald Geikie calls a philosopher and man of science, and of whom he says:—

"Among all the poets of ancient or modern times he stands out as the one who may perhaps most fittingly be called the poet of nature."

If Virgil sprang from a peasant stock, Lucretius was of a noble family. His vivid pictures of the *blasé* Roman noble ordering his smart team of "jennets" and tearing from Rome to his place in the country, and then as rapidly back again, is drawn from habits with which he was familiar. But he himself, as these pages remind us, loved the country, mountain, sea and shore, and was in particular specially fond of animals. He loved still more the scientific speculations which these sights, or the contemplation of sun and moon, or the "wide and starry sky," suggest to the thoughtful student. His science he derived, like all Romans, from Greece.

It is not part of Sir Archibald's scheme to include the "love and knowledge of nature among the Greeks," except in so far as this is implied and contained in Roman thought and writing. That measure is, of course, a large one. The Alexandrines in particular, only partly Greek, and living and learning in cities and university towns, amid libraries and observatories, first developed the modern love alike of nature and of natural science. From them it passed to Rome. Aratus, the poet and fellow-countryman whom St. Paul quoted at Athens, was one of the most popular poets at Rome, and influenced, as the President of the Royal Society points out, Cicero and Virgil; he might have added, through Cicero, Lucretius also. Both Lucretius and Virgil, however, owed more still to the prevailing Epicureanism, which from the Greek schools of their time passed over to and permeated Italy. Catullus and Horace and Ovid fell under the same Greek influences.

But this is not the true, genuine native Roman love of nature. That love, a more superficial yet in some ways more natural and pleasing thing, is, as these pages show, to be found in almost all the poets from Catullus to Statius and Martial, in the prose-writers from Varro to Seneca. Its varied expressions and manifestations constitute a rich and copious subject, but Sir Archibald deals with this very skilfully by arranging it under different headings: the love of flowers; the love of animals; Roman gardens; flowers and foliage in Roman art; day and night; the seasons; springs, rivers, and lakes; mountains; the sea-shores; and so on. The result is that he is never tedious. The reader can take up any chapter and almost any page separately, and find something to interest him—the character of the melancholy, amorous Propertius, asking to be "put among the girls"; the clever, frivolous, querulous Ovid; the intense, direct Catullus; the pretentious and somewhat hypocritical Seneca; the importance and the character, almost personal in its significance, of winds and stars to the ancient farmer and seaman; the testimony of the Pompeiian wall-frescoes, half foreign, half local and native, their figures Greek, their landscapes Latin—each is touched in succession with a fresh eye and firm hand.

Incidentally, also, as might be expected, there are references to modern writers—not only to Tennyson, already alluded to, but to Spenser and Shakespeare, to Cowley and Cowper, to Coleridge and Keats, and, of course, to Wordsworth. Perhaps one of the most striking points which is made in these pages, is that the ancients too possessed that

> "inner eye
> Which is the bliss of solitude."

Indeed, the Romans had the very expression, for does not Ovid in his "Metamorphoses," as Sir Archibald Geikie points out, write:—

> Quae natura negabat
> Visibus humanis, oculis ea pectoris hausit?

To conclude, the theme is one which has been touched before, notably by Prof. W. R. Hardie in "Lectures on Classical Subjects," published about a dozen years ago, but never has it been handled so thoroughly or with more freshness and suggestiveness than by the President of the Royal Society in this volume, which we confidently commend to scholars and men of science, but still more confidently to the general reader.

T. Herbert Warren.

PHYSICS—POPULAR AND APPLIED.

(6) *Physik.* Zum Gebrauch bei physikalischen Vorlesungen in höheren Lehranstalten sowie zum Selbstunterricht. By Prof. H. Böttger. Erster Band: "Mechanik, Wärmelehre, Akustik." Pp. xiii+983. ("Das Buch der Natur," Dreiundzwanzigste Auflage. Dritter Teil, Zweite Abt.) (Braunschweig: F. Vieweg und Sohn, 1912.) Price 15 marks.

(1) IT is always difficult for the reviewer of a book who naturally possesses a more or less intimate knowledge of the subject under review to write with confidence concerning a popular treatise. There is always the possibility that his previous knowledge enables him to appreciate many points which may not be so easily grasped by others less acquainted with the sub-

ject. And, after all, it is for this latter class that such books are primarily intended. But in the present case there is scarcely room for doubt that Prof. Soddy has successfully accomplished the very difficult task of making physics of absorbing interest on popular lines. This has been done without any of that sacrifice of exactness of statement which so often mars works of this kind; thus the trained physicist and the novice may read the book with equal pleasure. It is quite surprising how many phenomena the author has been able to deal with in this fashion, and what up-to date work he has been able to introduce. There is no space available to detail the various contents more than to say that such subjects as the kinetic theory of matter (including reference to Perrin's beautiful experiments on Brownian movements) and radioactivity, among others, are treated with admirable lucidity. A book of this kind deserves a longer review; it is to be hoped it will have a large circulation, for it forms a worthy addition to the excellent series to which it belongs.

(2) This consists of a series of descriptions of experiments which Prof. Burch has compiled, based upon the work of practical classes in the Physiological Laboratory, Oxford. About sixty experiments are described, dealing with the dioptrics of the eye, judgments of the eye, sensations of the eye, the measurement of colour sensations, and experiments with flashing light.

(3) From time to time during the progress of physical science a book appears the author of which is thoroughly dissatisfied with everything that has been accomplished, and desires to begin again on an entirely new foundation. This book is the latest of the kind. The author, in this case, claims to have made an intimate study of natural phenomena, and to possess a lengthened experience in physical research. Such a claim is, however, scarcely borne out by a perusal of his book. One cannot help thinking that his dissatisfaction with things in general arises rather from his own lack of acquaintance with the exact nature of physical science than from any fundamental error in present-day theories. It is really impossible to take the book seriously; at any rate, the present writer finds it so.

(4) This is a little book dealing with various applications of the kinematograph to scientific research. The author directs attention to what has already been achieved, and throws out suggestions as to the lines upon which further progress could be made.

(5) This is a treatise of a rather advanced character, though very much compressed, upon wave-motion, &c., particularly in its applications to sound and light. It is rather poorly printed, and the diagrams are not well produced.

(6) Like many similar German text-books of physics, the treatment in this one is very full—surprisingly so when it is remembered that it is intended for use in schools. This is the first volume, and comprises mechanics, heat, and sound. The type and diagrams are good.

MICRO-ORGANISMS AND THE HOMESTEAD.

(1) *Microbiology for Agricultural and Domestic Science Students.* Edited by Prof. C. E. Marshall. Pp. xxi+724. (London: J. and A. Churchill, 1912.) Price 10*s*. 6*d*. net.

(2) *Microbes and Toxins.* By Dr. E. Burnet. With a preface by Elie Metchnikoff. Translated from the French by Dr. C. Broquet and Dr. W. M. Scott. Pp. xvi+316. (London: William Heinemann, 1912.) Price 5*s*. net.

(3) *Bacteria as Friends and Foes of the Dairy Farmer.* By Wilfrid Sadler. Pp. xv+112. (London: Methuen and Co., Ltd., 1912.) Price 1*s*. 6*d*.

(1) MICRO-ORGANISMS are of far-reaching importance in agriculture, and the domestic science student cannot afford to neglect them, and the appearance of a work dealing with these branches of bacteriology, particularly the latter, is therefore opportune.

A number of well-known authors, specialists for the most part in their various subjects, have collaborated to produce the book under review. The editor, Prof. Marshall, fully recognises the weakness of this system of compilation, and has attempted, with success we think, to coordinate the whole. He points out that the term "bacteriology" has come to include many groups of micro-organisms other than the true bacteria, and the term "microbiology" has therefore been employed as a title for the present book.

The scheme of the book is comprehensive and well conceived, and ranges over a wide field. The subject-matter is divided into three parts: the first deals with the morphology and culture of micro-organisms, including the Protozoa; the second with the physiology of micro-organisms; and the third with applied microbiology. The last includes sections on air, water and sewage, the soil, milk and milk products, the preservation of foods, alcohol, vinegar and other fermentation products, and the microbial diseases of plants, man, and animals. We have found practically nothing in the contents to criticise, and the book is well illustrated with 128 figures in the text and one coloured plate of the malaria parasite.

(2) This book fills a lacuna in bacteriological

literature, inasmuch as it deals with the general physiology and functions of micro-organisms. While appealing more particularly to the specialist, the general reader who has some biological training and desires to obtain a general survey of the activities of micro-organisms may peruse it with advantage. The third chapter, which deals with the form and structure of microbes, contains a brief but sufficient account of recent work on these subjects, and the section on reproduction and sexual reproduction of these lowly organisms is particularly good. The chapters on infection, immunity, and supersensitivation are models of judicious selection from the voluminous literature, and give excellent summaries of the subjects.

The author, being a member of the staff of the Pasteur Institute, naturally gives considerable prominence to the views of the French school on the physico-chemical nature of the toxin-antitoxin reaction, but the other hypotheses are fully and fairly stated. Final chapters deal with the applications of bacteriology, vaccines, and curative sera and chemio-therapy. We demur to the statement (twice repeated) that because an animal's serum may naturally possess some antitoxic power towards diphtheria or tetanus toxin, such an animal *must* therefore have harboured the diphtheria or tetanus bacillus. Though this may be the explanation in some cases, we do not think that it is necessary to postulate such an infection in all instances. If antitoxin be generated during artificial immunisation by the detachment of *natural* side-chains from cell-protoplasm, there is apparently no reason why similar side-chains should not *normally* become detached by ordinary physiological processes, constituting the small amount of antitoxin sometimes found in a non-immunised animal.

We have read this book with much interest, and can recommend it as giving an excellent account of the subjects of which it treats.

(3) As Mr. Golding says in the introduction to this little book, "it has become an absolute necessity that the dairy farmer should be acquainted with some knowledge of the world of microscopic beings with which he is beset on all sides, and be able to distinguish his friends from his foes among this host which he cannot see, but to which he owes, and from which he fears, so much." We think that this book will well supply this kind of knowledge to the producer, the purveyor, and the consumer of milk. After a simple introductory statement of what bacteria are and how they grow and multiply, the use of starters for butter- and cheese-making is considered. The production of a pure milk is then discussed, and the sources and nature of contamination are described, the cow and milking, transit, distribution, and consumption of milk all being considered. A few pages are devoted to disease germs and the sour-milk treatment, and the book concludes with a short bibliography for the use of those who desire further information on the subject.

R. T. HEWLETT.

OUR BOOKSHELF.

Nature Photography. What to Photograph, Where to Search for Objects, How to Photograph Them. By Stanley C. Johnson, M.A. Pp. 115. (London: Hazell, Watson and Viney, Ltd., 1912.) Price 1s. net.

"NATURE" is a very wide term. It is not possible to state concisely the meaning that the author attaches to it. He does not refer to the larger animals, and though he gets down to beetles and butterflies, he does not include the smaller creatures that are generally called microscopic. He deals with fishes, birds, flowers, trees, reptiles and some of the larger insects, giving what is evidently his own experience in connection with the photography of such things. This personal character of the book gives it a value that a more inclusive compilation might not possess. He has very little to say about the actual photography, but treats rather of the selection and arrangement of the subjects, where and when to look for them, and so on, and in this connection gives advice that will be found of great value by those who do work of this kind.

In dealing with the bright colours and delicate shades that some of these objects present, the author's practice of using only stained plates ("non-filter," as they are called) cannot be regarded as thoroughly sound. His own illustrations of coloured objects are not good, but it is possible that the chief fault here lies with the maker of the blocks. The truthful rendering of various colours in monochrome is now fairly well understood by those who care to study the matter, and is not to be dismissed in a line or two by the simple recommendation to use any particular plate.

Dactylography, or the Study of Finger-prints. By Henry Faulds. Pp. 127. (Halifax: Milner and Company, n.d.) Price 1s. net.

THIS little book is the latest addition to the "Twentieth Century Science Series," which includes volumes that treat scientific subjects in a popular manner for the general reader. Mr. Faulds here writes in an interesting way on a subject with which his name has long been associated as an authority, and the reader is provided with a trustworthy account of the technique of printing and scrutinising finger-patterns and of classifying them. The practical results which followed the study of finger-prints are enumerated, and the future prospects of the subject outlined.

The Transactions of the American Institute of Chemical Engineers. Vol. iv., 1911. Pp. iv + 514. (New York: D. Van Nostrand and Co.; London: E. and F. N. Spon, Ltd., 1912.) Price 30s. net.

Two addresses delivered by the president, Dr. F. W. Frerichs, at Chicago and Washington are chiefly devoted to descriptions of six problems in chemical engineering practice. One of these, the extraction of bismuth from carbonaceous ores, consists of a complete account of the recovery of this metal from ores containing 1 oz. of lead, 15 oz. of silver 5 per cent. lead, and 5 per cent. of bismuth. The metal can be produced greatly in excess of the consumption, which in 1910 was about 200,000 lb for the United States. It is used almost exclusively for medicinal purposes.

Mr. Clarence Hall, explosives engineer, United States Bureau of Mines, contributes an interesting paper on explosives used in engineering and mining operations. The apparatus used at the Pittsburg testing station for the determination of the relative energy and efficiency of various explosives, such as black powder, granulated nitroglycerine powders, and nitro-glycerine and ammonia dynamites, is described. Mettegang's recorder for determining the rate of detonation is used, and velocities of detonation up to 6240 metres per second have been found for 60 per cent. nitroglycerine dynamites. The recorder has a soot-covered bronze drum 500 mm. in circumference which can be driven up to 105 revolutions per second, and marks are made thereon by electrical contact devices.

The manufacture of gelatine is described by Mr. Ludwig A. Thiele. The raw materials are bones, from which osseine is derived, and hidestock. The process is the same for the osseine and hidestock, the former being got from the bones by treatment with either hydrochloric, phosphoric, or sulphurous acid, during which process a valuable by-product, acid phosphate, is produced. A report of the Committee on Chemical Engineering Education is included in the volume, together with other papers on manufacturing processes.

Science French Course. By C. W. Paget Moffatt. Pp. x + 305. (London: W. B. Clive, University Tutorial Press, Ltd., 1912.) Price 3s. 6d.

THE object of this book is, the author says, to provide students of science who desire to read French scientific literature with the necessary minimum of French grammar, and a selection of extracts from which some practice may be obtained. For students with no knowledge of French at all the amount of assistance given in translation appears rather inadequate, but for those who have forgotten what was learnt at school and wish to revise rapidly, the book should prove of great assistance. The extracts will form excellent reading in French for boys and girls in the upper forms of secondary schools who are taking a course of work in science.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Synthesis of Matter.

IN the issue of NATURE for July 18 last, there appears an important letter from Sir William Ramsay dealing with the appearance of hydrogen, helium, and neon in the glass of exhausted X-ray bulbs. This result is of great interest, and may have an important bearing in addition to that mentioned by the author.

It is well known that X-ray bulbs only possess a limited period of life and go "soft," as it is termed, as if a small amount of gas previously adsorbed by the glass had been set free. The thought occurred to me some time ago that the softening might not be due to this cause, but to rare gases, such as helium, actinium, &c., produced from the æther of the vacuum becoming charged with energy from the kathode. It is such gases which are found in the process known as inorganic evolution in the hottest stars and nebulæ, and discovered there first by Lockyer, before their terrestrial occurrence in cleveite and elsewhere was detected by Ramsay.

If elements can decompose with evolution of energy as in radio-activity, it would seem not impossible that matter might be synthetised with absorption of energy, and that a first stage in such a process might be the formation of electrons by the charging of æther with a permanent form of energy, followed by a synthesis of ordinary matter in which such gases as helium would be a first product.

Attempts were made by me at the time to obtain evidences of helium from exhausted X-ray bulbs, but failed, as I now believe, from the small quantity of gas available and my lack of training in this very specialised field of manipulation. It would be interesting to carry out a prolonged experiment with an X-ray bulb run for days, and pumped out at intervals, in order to ascertain whether such development of helium took place.

It is, of course, possible that any gas so arising might come from the electrodes and glass undergoing atomic disintegration, but the possible origin of matter from æther when there is an available supply of energy at high potential should not be lost sight of. Theory suggests that such a formation is possible, if matter consists of vortex rings or other permanent forms of periodic movement of the æther, and it may be that in the chromosphere spectra there is evidence of production of matter occurring at the present time.

BENJAMIN MOORE.

The Jaw from the Stalagmite in Kent's Cavern.

I AM much obliged to Prof. Keith for his reply to my letter on the Kent's Cavern jaw, from the granular stalagmite. As my friend Prof. Boyd Dawkins, who read the paper, was a member of the Kent's Cavern Committee, and reported in 1869 on the fossils found up to that date, I naturally took for granted that all the facts of the case would be before Section H, and that Prof. Keith was challenging the evidence.

On referring to Prof. Boyd Dawkins's 1869 report I noted with surprise that the jaw was not even mentioned. To those acquainted with the history of Kent's Cavern this omission is easily explained.

Throughout the explorations of the cavern, beginning in 1825, all the evidence in favour of the antiquity of man was challenged and explained away by outside critics. Objects in and under the stalagmite were accounted for in one of the following ways, viz.: (1) interments; (2) cracks or fissures; (3) the stalagmite was a comparatively recent invading magma!

For these reasons it would have been unwise, in 1869, to depend on any evidence so certain to be challenged. Indeed, the value of the evidence of the said jaw has not been publicly discussed up to the present time.

After Pengelly's death Sir John Evans published the second edition of his "Ancient Stone Implements," in which, alas! he seems to have followed the earliest explorers in the general assumption of fissures. Sir John observes that in the stalagmite there were few remains, "whether human or otherwise, and these for the most part may have fallen in from higher levels." He further observes that "concerning this long chapter in the history of human existence the records of the cavern are a blank." If I may venture to say so, the distinguished archæologist must have compiled his account of Kent's Cavern from early and late records as of equal authority.

So far as the weighty authority of the chairman of the Kent's Cavern Committee (but not on the committee when the jaw was discovered) is concerned, Prof. Keith would be fully justified in questioning the authenticity of the jaw in question.

In Pengelly's Glasgow lecture (1875) we find the words—"I have found teeth of the mammoth, teeth of the woolly rhinoceros, teeth of the cave hyæna, and teeth of the cave bear in the very uppermost part of the stalagmite; and a human jaw, with four teeth in it, at the base of the same deposit" (pp. 17–18).

In describing a bone pin found under the stalagmite, near the same spot as the jaw was found, Pengelly incidentally describes the stalagmite as "20 inches thick, perfectly intact, and *continuous in all directions*" (Report Brit. Assoc., 1867, p. 31). The italics are mine.

One item of evidence *per contra* must be noticed, viz. that "one of the artificially formed flints [from the stalagmite] has the appearance of being a fragment of a polished Celt or axe, and is the only specimen of the kind which has been found in the cavern." Nothing of the sort, we are told, was subsequently found.

It is much to be regretted that the British Association did not complete its sixteen years' exploration with a general summary of results, with plans and sections. There is, I believe, no general ground plan of the cavern in existence, except the rough sketch which I prepared for the last visit of the Geologists' Association (Proc. Geol. Assoc., vol. xvi., p. 437, 1900).

Torquay, October 7.

A Pearl from Nautilus.

The accompanying photograph shows a pearl (natural size), alleged to have been found in *Nautilus pompilus*, from the Sulu archipelago. It was lent to me for examination by Mr. T. H. Haynes, of the Montebello Islands, north-west Australia, one of the pioneers of the pearl-shelling industry in Australia and the East Indies, who is now in England. This pearl was given to Mr. Haynes, about 1884, by a half-breed Chinaman named Oto, brother-in-law to the late Sultan of Sulu, Mohamed Budderuddin.

Mr. Haynes tells me that the pearly Nautilus is occasionally taken alive by the pearl-shell divers, by whom the flesh is considered a great delicacy. Now and then a pearl is found in a Nautilus, but as these pearls are considered unlucky they are usually thrown away. There is a superstition among the natives that, if a man fights with a Nautilus pearl in a ring on his finger, he will be killed. It is probable, therefore, that few, if any, examples of these Nautilus pearls have found their way into the West.

A Nautilus pearl. Natural size.

The pearl, which is a perfect pear-shape, slightly flattened at the broader end, weighs 18 carats (72 grains), and is composed of the porcellanous (not the nacreous) constituent of the shell. It is somewhat translucent, white, with a slightly creamy tinge, rather suggesting fine Beleek china. The broad end, which has apparently been flattened by pressure of the shell upon the pearl sac, is rather more transparent and vitreous.

Errors of the Computed Times of Solar Eclipse Phenomena.

With regard to Dr. Downing's letter on this matter (Nature, October 10, 1912), may I be allowed to remark that I was fully aware of his warning that the computed eclipse times of second and third contacts were too late. In fact, I carried with me to Vavau the reprint of his paper to which he alludes (Monthly Notices R.A.S., vol. lxix., p. 31), which he had kindly sent me, and frequently consulted it. In addition, I had prepared an instrument for projection of the solar image so as to observe the angles of cusps given in his paper, but as Dr. Lockyer also had a similar instrument, we arranged that I should make use of his time signals.

As a further precaution, to obtain the time of the first flash, I had arranged a direct-vision spectroscope adjusted on the C line in the chromosphere at the angle of second contact. Unfortunately, the clouds at the time of second contact rendered all these precautions useless.

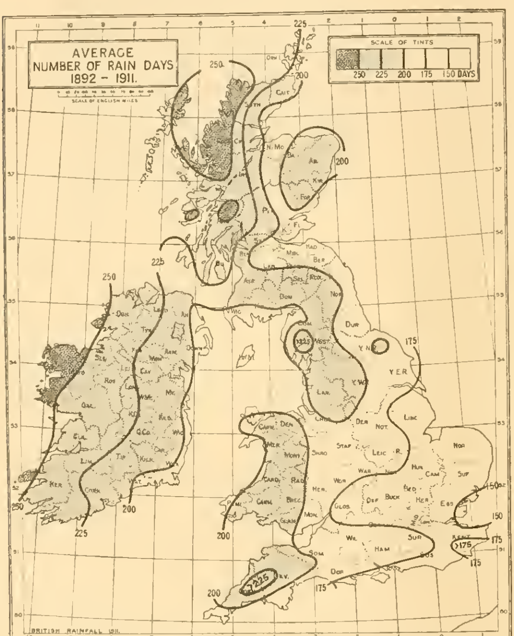
I trust that Dr. Downing does not read into my remark, "The total phase commenced about 20 seconds before the predicted time" (Proceedings R.S., No. A595), anything more than a mere statement of a fact.

A. L. Cortie.

Stonyhurst College Observatory, October 14.

BRITISH RAINFALL IN 1911.

THE Director of the British Rainfall Organisation is to be congratulated on the volume he has produced[1] dealing with the rainfall of the British Isles, and for the compilation of which he has the assistance of 5300 observers. As time goes on the value of the work undertaken is greatly enhanced, not only by the extension of the observations and the greater accuracy of the results, but also by the completeness of the discussions rendered possible by the accumulation of data. The thoroughness with which the work is carried out both by the voluntary observers and by Dr. Mill and his assistants merits the greatest admiration, and is a masterpiece as a private undertaking.



A discussion of the distribution of rainfall in time is given which will prove of very great value, and is a matter of considerable interest even to the general public endowed merely with average scientific craving.

In a former volume for 1902, a first attempt was made in the same direction, dealing only with the observations for ten years, and these embracing chiefly a dry period. Now a period of twenty years, 1892 to 1911, is dealt with, and the results at 100 stations of established accuracy have been collated, which may with some confidence be expected to furnish a trustworthy average.

There is naturally a relation existing between the frequency and amount of rainfall, the wetter western districts showing a greater frequency than the relatively drier Eastern districts.

The rain days for the year on the average of twenty years range from 250 in the north-west of Scotland and the west of Ireland to 150 in the estuary of the Thames; and England, with the exception of the north-western and western districts, has fewer than 200 rain days in the year.

The map of frequency, like that of quantity, suggests very clearly the controlling influence of the westerly winds which predominate, and which are laden with moisture from off the Atlantic on their arrival over the British Isles.

The abnormal year of 1911 was believed to have been unparalleled for its dry periods, and under the heading of "Droughts in 1911" a comparison is made between the results for 1911 and the records of the last twenty-four years, selecting one hundred well-distributed stations in the British Isles; this shows that the surmise about 1911 is not without foundation. 1911 had more absolute droughts than any other year except 1887, and it had the largest number of partial droughts. An absolute drought is no rain for more than fourteen consecutive days, and a partial drought a period of more than twenty-eight consecutive days with a mean rainfall not exceeding 0·01 in. per day. The absolute droughts in 1911 were more than double the average, and partial droughts little short of three times the average.

Dealing with heavy rains in short periods, an exceedingly interesting table is given showing the rainfalls of very rare intensity lasting for one hour or less. The heaviest authenticated measurement is 0·33 in. in two minutes, which is equal to the hourly rate of 9·90 in. at Chepstow in March, 1888, and this is followed by 0·50 in. in four minutes, which is equivalent to 7·50 in. per hour, at Ilkley in June, 1906. A reported fall of 1·25 in. in five minutes at Preston in August, 1893, which gives a rate of 15 in. per hour, is accepted with caution. At Beddington, in May, 1903, a fall of 3·50 in. occurred in an hour. This table is of considerable value, as it affords means of comparison for such extraordinary rains as have recently occurred in Norfolk, where at Norwich, between noon and 1 p.m., September 26, the rainfall amounted to 1·15 in., and to 7·32 in. in twenty-four hours ending 4 a.m., September 27.

C. H.

[1] "British Rainfall, 1911." On the Distribution of Rain in Space and Time over the British Isles during the Year 1911, as recorded by more than [illegible] Observers in Great Britain and Ireland, and discussed with Articles upon various branches of Rainfall Work. THE EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

THE Congress of Applied Chemistry, which met this year in Washington and New York, is the eighth of a series of triennial gatherings held hitherto in centres of chemical activity in the Old World, the last three meetings having taken place in London, Rome and Berlin.

The onerous task of preparing for the reception of the eighth congress was commenced three years ago by an influential committee of American chemists, Prof. E. W. Morley and Dr. W. H. Nichols being nominated honorary president and president respectively, with Dr. Bernhard C. Hesse as secretary. The interesting programme drawn up by this committee attracted a large number of European chemists, chiefly from Germany, and about thirty nationalities were represented by official delegates. Among the eminent chemists attending the meeting were three past-presidents of former congresses—Prof. L. Lindet (Paris), Sir William Ramsay (London) and Prof. F. Strohmer (Vienna). Prof. P. Walden, president-elect of the next congress (St. Petersburg), was also present.

The scientific work of the congress was divided into twenty-four sections, and one very noteworthy feature, which distinguished this meeting from its predecessors, was the rapid printing of the proceedings in twenty-four volumes, containing nearly 600 accepted papers, these being ready for distribution to the members at the opening of the meeting on September 3. The discussions taking place in the various sections were recorded phonographically by a special phonograph devised for this purpose by Mr. Edison.

The congress was opened formally at Washington, in the Memorial Continental Hall, on September 4, and the delegates and members were welcomed by His Excellency President Taft, at the White House. Several Government institutions established at Washington were visited by the members, special attention being devoted to the laboratories of the Department of Agriculture, the Bureau of Standards, the Geophysical Laboratory and the U.S. Geological Survey. The scientific work of the sections was carried on in New York from September 6 till September 13, the meetings being held in the lecture-rooms placed at the disposal of the congress by the authorities of Columbia University, to whose generous hospitality the congress is indebted both for this suitable and compact group of rooms and also for the use of several residence-halls in which many members were housed during the congress meetings.

In the analytical section were presented several important papers and reports of committees on the standardisation of methods of sampling and analysis. The extraction of potash from felspars and other minerals was discussed in the section of inorganic chemistry, and joint meetings with the sections of metallurgy and mining were held to consider topics of interest in connection with new alloys, among which may be mentioned the combinations of boron with copper and other metals, demonstrated by E. Weintraub. The electric furnace and its applications was the subject of a joint session between the metallurgical and electrochemical sections. The production and properties of Portland cement were debated in the section of silicate industries. In the explosives section stability tests for these materials were discussed by several investigators, and tetranitroaniline was recommended by its discoverer, B. Flurscheim, as a safe explosive with a shattering power only second to that of nitroglycerin.

The section of organic chemistry received the greatest number of papers and was the scene of several animated discussions. The chemical structure of the azoimide nucleus present in organic and metallic azides was dealt with by M. O. Forster. The perennial topic of colour and constitution was discussed in joint session with the section of coal-tar colours, interesting papers on aniline black and quinonoid addition in dyestuff synthesis being contributed by A. G. Green. In the sugar section, reports were presented on uniform methods of sugar analysis by von Buchka, Prinsen-Geerlings, Saillard, Strohmer and Weichmann. A paper on the valuable plastic material "baekelite," the condensation product of phenol and formaldehyde, was read by its discoverer, L. H. Baekeland, before the section of indiarubber and other plastics. A report on the standardisation of methods of determining water in coal and in other fuels and in minerals, drawn up by G. T. Holloway, was presented by R. Lessing to the section on fuels.

Among the large number of important papers contributed to the section of agricultural chemistry may be mentioned a series of communications by G. Bertrand and his collaborators on the catalytic action in fertilisers of small quantities of manganese, boron, zinc and aluminium. The standardisation of disinfectants by the Rideal-Walker test was advocated by S. Rideal in the section of hygiene. The sterilisation of potable water by hypochlorites was the subject of several communications to the same section. An interesting paper on the chemical reactions of micro-organisms was read before the section of biochemistry by F. Ehrlich, and several investigators presented communications bearing on the relationship between chemical constitution and germicidal or physiological action.

The utilisation of American natural gas has led C. Baskerville to study the chlorination of this cheap source of methane, and his results were communicated to a joint meeting of the sections of inorganic chemistry, photochemistry and electrochemistry. To the last of these sections were presented several papers on the electric smelting of iron, zinc and other metals, and on the electrolytic processes of producing chlorine, alkali and hypochlorite.

In the section of political economy and conservation of natural resources reference was made to the conservation of forests and water supplies, and to the utilisation of peat and coal waste.

Another important feature of the work of this congress was the delivery of four lectures of general interest by eminent chemists representing France, Germany, Great Britain and Italy. The great hall of the college of the city of New York, having a seating capacity of 3000 persons, was available for this purpose and for the general meetings of the congress.

Prof. Gabriel Bertrand spoke on the part played in agriculture by the minor constituents of plants. It has been demonstrated that the element manganese, present only in minute quantities in plants, enters into the composition of laccase, an enzyme, first extracted from the lacquer tree, which is capable of bringing about an assimilation of atmospheric nitrogen. Small additions of manganese have been found to increase crops to a considerable extent, and similar effects have been produced with other of the less common elements. These results lead to a new class of fertilisers—the catalytic manures—which are capable of modifying favourably the fertility of the soil.

Dr. Carl Duisberg lectured on the latest achievements and problems of the chemical industry. The problem of the utilisation of peat has received a solution in Frank and Caro's process of producing peat gas for heating purposes with recovery of the nitrogen as ammonia. Great strides have been made in the manufacture of refined steels containing other elements besides iron and carbon. The nickel alloys are of great value; those containing 23 per cent. and upwards of this metal are non-magnetic, whilst the 45 per cent. alloy has a coefficient of expansion not greater than that of glass. Steels containing chromium and molybdenum are remarkably resistant to mineral acids; the alloy containing 60 and 3 per cent. of these metals respectively is not appreciably attacked by boiling aqua regia. Steels containing chromium, tungsten and vanadium have a high degree of hardness. Vanadium steel is employed in forging high-speed tools, and the firm of Krupp have patented a steel which can neither be drilled, nor disintegrated by explosives, nor cut by the oxyhydrogen or oxyacetylene flame. Electrolytic iron, which is now manufactured free from hydrogen by electrolysis in hot solutions, can be magnetised and demagnetised more readily than ordinary iron containing carbon and silicon. Electromotors in which this material is used are two-and-a-half times as efficient as those constituted of silicon iron. The lecturer reviewed the recent developments in colour synthesis, pharmaceutical chemistry and chemotherapy, the treatment of infectious disease with chemical compounds. The production of non-inflammable kinematograph films ("cellite") and non-inflammable celluloid ("cellon") from acetylcellulose are valuable improvements which must eventually promote greater security of life and property from fire.

A controversial topic was reached when the lecturer dealt with the problem of the manufacture of artificial rubber. He asserted that F. Hoffmann, of the Elberfeld factory, is to be regarded as the real discoverer of synthetic rubber, this investigator having polymerised isoprene to rubber in 1909, a discovery which has been followed by the production of certain homologues of natural rubber. This view of the synthesis of rubber was subsequently refuted by Prof. W. H. Perkin in a lecture on the polymerisation of butadiene and isoprene, when reference was made to Tilden's discovery of nearly thirty years ago that isoprene polymerised to a substance identical with natural rubber. Specimens of Tilden's preparations were exhibited, and the lecturer gave an account of recent successful experiments on rubber synthesis starting from amyl alcohol made by a group of English chemists in collaboration with the French bacteriologist Fernbach.

The third general lecture was delivered by Prof. Perkin, who described the experiments which led to the fireproofing of the very inflammable material flannelette with precipitated hydrated stannic oxide, a treatment which renders the fabric ("Non-flam") permanently fireproof without affecting the colour of the dyed cloth, while its strength is increased by 20 per cent.

The fourth general lecture was delivered by Prof. G. Ciamician, who spoke on the photochemistry of the future and advocated the utilisation of radiant solar energy either directly in promoting photochemical change or indirectly by the intensive cultivation of plants yielding industrially valuable products, the harvested plants being subsequently converted economically into gaseous fuel and their mineral ash and recovered nitrogen being restored to the soil.

Closely allied to the subject of intensive cultivation were two addresses dealing with the fixation of atmospheric nitrogen. In the first of these discourses Dr. S. Eyde, who referred to the oxidation of atmospheric nitrogen, described the remarkably rapid growth of the synthetic nitrate industry of Norway and the methods employed in utilising the water-power of that country. In the second address Dr. H. A. Bernthsen gave an outline of Haber's process for synthesising ammonia, now being developed on a manufacturing scale by the Badische Anilin und Soda-Fabrik.

By operating with purified hydrogen and nitrogen under high pressure (200 atmospheres) at 650–700° C. in the presence of a suitable catalyst (iron, manganese, molybdenum, tungsten, uranium carbide, &c.), about 8–10 per cent. of the gaseous mixture is converted into ammonia, which is either separated by liquefaction or dissolved out by water.

In addition to the general lectures and sectional meetings, the social side of the congress was fully developed, and a special entertainment programme was arranged for the ladies accompanying the members and delegates.

At the close of the congress nearly 300 of the members proceeded on one or other of two tours arranged by Drs. Rosengarten and Day and other members of the special transportation and factory inspection committees. Two special trains were provided, and at each stopping-place local committees had been organised, the representatives of which met the visitors and conducted them by rail or motor-car to factories, laboratories and other places of interest. The shorter of these tours took ten days, during which the party visited Philadelphia, Pittsburg, Niagara, Detroit, Chicago, Cleveland and Boston. The longer tour included a journey to the western and southern States, with visits to Salt Lake City, San Francisco, Los Angeles, Grand Canyon, Arizona, New Orleans, Atlanta and Washington.

The small band of British chemists who had the good fortune to attend this congress and take part in the excursions are unanimous in their praises of the splendid organisation and cordial generous hospitality experienced at every stage of their visit. American chemists are to be congratulated not only on a congress of great scientific interest and importance, but also on the unqualified success which invariably attended their praiseworthy efforts to entertain and instruct their guests.

G. T. Morgan.

PREHISTORIC MURAL DECORATIONS IN BACON'S HOLE, SOUTH WALES.

The cave of Paviland (Gower, South Wales), first investigated by Buckland so long ago as 1823, has lately acquired a fresh interest in the light of recent discoveries made in France.

Most of the objects found by Buckland are exhibited in the Oxford University Museum, where they fill the greater part of a case devoted to the Aurignacian age. Among them are cylindrical rods (like lead pencils in size and shape) carved out of mammoth ivory, an ivory lissoir (*i.e.*, smoother), and some other rudely shaped pieces of ivory. Prof. Breuil, the greatest authority on Aurignacian remains, being on a visit to Oxford, made an examination of these objects last week and unhesitatingly referred them all to the Aurignacian age. There are also some fragments of a beautifully worked ivory ring, about the size and shape of an Indian bangle, or a little smaller; these also were assigned with equal confidence to the Aurignacian, precisely similar rings having been found in deposits of this age in France.

As a consequence of these results, Profs. Breuil and Sollas decided to visit the caves of Gower in the hope of finding some painting on the walls. A halt was made on the way at Swansea, in order to examine the rich collection of flint implements from Paviland which are preserved in its museum. These proved unusually interesting, and were for the most part identified by Prof. Breuil as Upper Aurignacian, a few being Proto-Solutrian. A systematic search was then made of the caves, beginning with Paviland, on the west, and working towards Bacon's Hole, on the east; as cave after cave failed to yield any signs of painting, hope began to wane, but, on entering Bacon's Hole, colour was seen on the right-hand wall. Closer examination revealed the presence of ten bright red bands, approximately horizontal or slightly divergent, fan-like, arranged one above the other in a vertical series, about a yard long, each band being perhaps a foot in length and one to two inches in breadth, but no exact measurements were made. The stalactite which has tapestried the wall is very clean and has completely sealed up the red pigment (iron-ochre), so that it cannot be removed by rubbing.

It is of interest to note that similar bands, similarly arranged, but only eight in number, have been observed at the end of the great gallery in the Font de Gaume of Dordogne.

It is to be hoped that a general search will now be made in our English caves for other examples of mural decoration; they may be easily passed over by the casual visitor, and to be seen must be looked for.

NOTES.

As already announced in these columns, a meeting is to be held at the Mansion House at 2.30 p.m. on October 23 to take steps to raise a fund for the establishment of a memorial to the late Lord Lister. Among those who will address the meeting are the Prime Minister, the president of the Royal Society (Sir Archibald Geikie, K.C.B.), the president of the Royal College of Surgeons (Sir Rickman J. Godlee), Lord Avebury, F.R.S., and the Hon. W. F. D. Smith.

The Paris correspondent of *The Times* announces that the international conference on time reckoning was opened at the Observatory on October 15 by M. Guist'hau, Minister of Education; and M. Bigourdan, member of the Institute and of the Bureau des Longitudes, was elected president. The conference has been summoned mainly with the object of dealing with various practical uses of wireless telegraphy in the synchronisation of time signals throughout the world.

Sir George Darwin, who recently underwent an operation, continues to make such good progress toward recovery that no further bulletins will be issued.

The death is announced, at the age of fifty-eight, of Mr. F. H. Low, the honorary secretary of the Röntgen Society. Mr. Low was the medical officer to the X-ray department of the London Medical Graduates' College and Polyclinic.

It is announced, through Reuter's Agency, that the Nobel prize for medicine for 1912 has been awarded to Dr. Alexis Carrel, of the Rockefeller Institute for Medical Research in New York, for his works on the suture of vessels and the transplantation of organs. The prize this year is said to amount to about 7800*l*.

A course of six lectures on the properties and manufacture of concrete is to be given, by Mr. H. Kempton Dyson, secretary of the Concrete Institute, at the Concrete Institute, Denison House, Vauxhall Bridge Road, Westminster, at 5.30 p.m. on Tuesdays, beginning on November 12. The lectures are free, and tickets of admission may be obtained from the secretary of the institute.

A memorial service for the late Mr. H. O. Jones, F.R.S., fellow of Clare College, Cambridge, demonstrator to the Jacksonian professor of natural experimental philosophy, and Muriel Gwendolen Jones, his wife, who were killed in the Alps in August while on honeymoon, was held at the University Church of St. Mary the Great, Cambridge, on October 12. The service was attended by a large congregation, which included masters of several colleges, University professors, and many other members of the University. The Royal Society, the Alpine Club, and the Cambridge Alpine Club were also represented.

The council of the Institution of Civil Engineers has made the following further awards for papers read during the session 1911–12:—A Watt gold medal to Prof. W. H. Burr (New York), and the Crampton prize to Prof. R. J. Durley (Montreal). The following Telford premiums have also been awarded for papers published in the Proceedings without discussion during the same session:—To Messrs. Paul Seurot (New York), David Anderson, and Harry Cunningham (London), Dr. S. P. Smith (Birmingham), Mr. E. G. Rivers (Richmond), Mr. E. H. Morris (Manchester), and Prof. A. H. Gibson (Dundee). The Howard quinquennial prize for 1912 has been awarded to Mr. J. H. Darby (Sheffield), in recognition of improvements introduced by him in iron and steel production, and the Indian premium for 1912 to Mr. H. H. G. Mitchell (Madras).

The nineteenth report of the Museum and Art Gallery Committee to the Town Council of the borough of Leicester deals with the period from April 1, 1910, to March 31, 1912, and provides an interesting description of two years' excellent work and progress. In addition to the Saturday evening public lectures, which have long been a successful part of the committee's work, a commencement has been made in the matter of lectures to teachers. The movement among educational authorities in favour of a more enlightened use of museums calls for a knowledge on the part of teachers of the contents of these institutions. In Leicester the curator has arranged a series of lectures to local teachers, intended to show how the contents of the museum may be used to instruct and interest children in the subjects illustrated by the exhibits. The report also points out that a small vivarium has been commenced and has proved a great attraction to visitors. Various living examples of British reptiles, batrachians, and invertebrates are on show, as well as two or three exotic forms.

A recent number of *The Journal of Tropical Medicine and Hygiene* (vol. xv., No. 17) contains an account of the investigations on the etiology of pellagra carried on by Drs. Sambon and Chalmers, for which financial support was generously provided by Mr. Henry S. Wellcome. There are two opposed theories in the field with regard to the causation of this disease; according to the prevailing view, that of the "zëists," pellagra is the result of poisoning by unsound maize; Dr. Sambon, on the other hand, believes the disease to be due to infection by a parasitic organism, propagated by the agency of Simuliidæ, small biting flies which breed in running streams. As the result of epidemiological investigations carried on in many countries, Drs. Sambon and Chalmers have brought together a considerable body of facts and observations which tend to disprove, on one hand, any connection between pellagra and a maize diet, and to prove, on the other hand, that all areas in which the disease is endemic are situated in close proximity to streams in which Simuliidæ breed. It remains, however, for the parasitic theory of pellagra to receive definite proof by the discovery of the parasite (provisionally assumed to be "protozoal" in nature), and of its transmission and life-history.

The Museums Journal for September contains a notice, accompanied by a plan, of the proposed extensions of the Natural History and the Science Museums, based on "White Paper" Cd. 6221. It is pointed out that the housing of the Geological Survey and its collections in an extension of the eastern end of the Natural History Museum ought to prove advantageous on account of leading to greater facilities of cooperation between the palæontologists of the museum and the officers of the survey. On the other hand, the trustees of the British Museum are supported in their objection to the proposed removal and rebuilding of the spirit building at the Natural History Museum.

Under the heading of "The Insect's Homer," Mr. Maurice Maeterlinck directs attention in the September issue of *The Fortnightly Review* to a little-known work by J. H. Fabre, in ten volumes, entitled "Souvenirs entomologiques." Fabre, it appears, was a native of Provence, where his memory has recently been honoured by a special celebration. According to the author of the article, he was "one of the most profound and inventive scholars, and also one of the purest writers, and, I was going to add, one of the finest poets of the century that is just past." In these volumes, from which copious extracts are given, Fabre recorded the results of fifty years of observation, study, and experiment on a number of insects, including wasps and wild bees, certain gnats, flies, beetles, and caterpillars.

In the Bulletin of the American Museum of Natural History (vol. xxxi., p. 313) Mr. Abbott H. Thayer replies—and we venture to think very ably—to recent criticisms of his views with regard to cryptic and protective coloration in animals. After replying to objections that have been made against the protective nature of the "white-belly" type of coloration, the author directs attention to the extreme importance of the level from which the cryptically coloured animal is viewed. "An animal [such as a zebra] seen from a level above his own, has the dark earth for a background, while, at the very same moment, seen from two or three feet lower down [the lion's point of view] he has the bright sky instead, or is, at least, seen in the direction in which sky or glimpses of sky are to be expected. The moment this is understood, it becomes obvious that there is no such thing as a cryptic coloration *per se*, and that any amount of conspicuousness from all other view-points has nothing whatever to do with the question." The author illustrates this pictorially by means of a photograph of a "dummy" zebra and ass placed among thin scrub, and viewed from a lower level, when the former animal becomes practically invisible against the sky-line, while the latter stands out sharply silhouetted against the same.

The bright coloration of most Hemiptera is due to a fatty tissue known as pseudovitellus, and this tissue invades the developing egg at an early stage of maturation. Its significance has been variously interpreted, but only quite recently has its true function been discovered. Thanks to Sulc and Pierantoni, it is now known to be the habitat and to provide the food of multitudes of symbiotic organisms, probably yeasts. Every Aphis, every Psyllid, is a synthesis of two organisms, one the insect and the other the symbiont. Dr. Buchner, "Studien an intracellularen Symbionten" (part i., *Archiv f. Protistenkunde*, vol. xxvi., 1912), has taken up the detailed study of the range and nature of this form of symbiosis, and he gives a very interesting and well-illustrated account of his researches. Beginning with certain Coccidæ, in which the pseudovitellar cells may be present or absent (facultative mycetocytes), he proceeds to describe the definite organ (mycetom) which they form in Aphids and others. They may be infected by one kind of symbiont, by two kinds rigidly kept from commingling, or even (Psyllidæ) by three kinds. Similar symbiotic organisms are not limited to Hemiptera, and indications are given that they occur in cockroaches, beetles, Hymenoptera, and Lepidoptera. The organisms are carefully described, and the whole subject is one that deserves the fullest attention from botanists, and especially from mycologists. The relations between the insect and the symbionts are still in need of elucidation.

We have received from Messrs. Gallenkamp and Co., Ltd., Sun Street, Finsbury Square, E.C., a copy of their new catalogue of apparatus for botanical laboratories (List No. 61). This catalogue, in which every requisite for the study of plant physiology is listed, with numerous illustrations of special apparatus for physiological experiments as well as of general laboratory materials, is indispensable to teachers of botany. The chief feature of the catalogue is the listing of the apparatus described in standard text-books on plant physiology; the portion dealing with botanical material and slides contains a rather large number of misprints in the names of plants.

Mr. O. F. Cook has published an interesting note in the Journal of the Washington Academy of Sciences (vol ii., No. 9) on the morphology of the leaf in various members of the Prunus section of Rosaceæ, sometimes regarded as a separate family (Amygdalaceæ). The leaves of plum, peach, apricot, &c., have a joint at the base, just above the insertion of the stipules, as in many leguminous plants; the part below this joint does not fall off with the leaf-stalk, but remains alive and forms a supplementary bud-scale. This is regarded as a vegetative character which supports the view that the Amygdalaceæ are deserving of family rank, and also as strengthening the connection between the rosaceous and leguminous series. The fact that small leafy outgrowths sometimes replace the nectaries on the upper part of the leaf-stalk in various Amygdalaceæ suggests the view that the immediate ancestors of this family had compound leaves, these nectaries corresponding to the marginal glands of the leaf-blade and representing rudiments of divisions of compound leaves.

Mr. F. W. Clarke returns to the consideration of the average composition of various rocks in a paper on some geochemical statistics (Proc. Amer. Philosophical Soc., vol li., 1912, p. 214). His results give us an average igneous rock with a silica percentage of about 60, and the "surprising conclusion" (p. 227) that the volume of limestones in the crust is less than that of the salts dissolved in the ocean. The relation of these salts to the earth's age is again referred to.

Dr. Vaughan Cornish considers the origin of the Jamaica earthquake of January 14, 1907, in a short paper in *The Geographical Journal* for September. In his account of the earthquake published in the same journal for March, 1908, he shows that the destructive intensity of the earthquake was almost limited to a narrow zone crossing the island from near Kingston to Buff Bay on the north coast. The earthquake evidently originated in two foci, one near the mouth of the river Hope, a few miles east of Kingston, the other about ten miles to the north in the neighbourhood of the head-waters of the river at Hardware Gap. The earthquake could be assigned to no known fault, but, as shown by the small extent of the area of destruction, the depth of the foci must have been inconsiderable. Dr. Cornish therefore attributes the earthquake to the redistribution of stresses in the surface-crust through the action of river-denudation, the added load near the mouth of the Hope river causing a subsidence along a shallow-seated fracture, while the diminution of pressure among the mountains at Hardware Gap would, he thinks, result in elevation along another fracture.

The report of the Sonnblick Society directs attention to the fact that in September, 1911, the Sonnblick Meteorological Observatory, at an altitude of 3105 metres, completed the twenty-fifth year of its useful work. It is the highest in Europe which has a resident staff all the year round, and was established by the Austrian Meteorological Society at the instigation of Hofrath Dr. J. Hann. At the end of 1892 it was in danger of being relinquished owing to the want of funds, when the Sonnblick Society was formed and came to its rescue by obtaining subscriptions, which are still continued. Later on the permanency of the establishment was assured by a Government grant in aid. The following data are extracted from the published results for 1911:—

	January	July	Year
Mean temperature (C.)	−13·4°	2·2°	−5·9°
Absolute maximum	−4·4	10·1	10·1
,, minimum	−28·5	−5·6	−28·5

The melted snow and rain for the year amounted to 1398 mm., on 229 days. Rain was only measured on a few days from June to September. Fog occurred on 230 days.

In the Journal of the Meteorological Society of Japan (vol. xxxi., No. 7) Mr. G. Ishida describes some experiments carried out at Hamada with the view of improving the efficiency of storm warning signals at night. In the tests two kinds of oil lamps were used, provided respectively with circular and flat wicks.

Observers were stationed at various distances up to 5·4 kilometres from the signals, and naked-eye records were taken. There were three sets of experiments, to determine (1) the relative advantages of circular and flat-wick lamps; (2) the range of red and green lights; and (3) the distance at which two separate lights can be distinguished. The results showed (1) that the light from the flat wicks was considerably brighter at a distance than that from the round wicks, particularly when the line of vision formed a right angle with the sides of the wick, and (2) that the range of the red lights (flat wicks) was approximately double that of the green, the latter being scarcely visible at 3 kilometres, while the former were still bright at 5 kilometres. In the third set of experiments observations were taken at distances of 2 and 3 kilometres of pairs of lights separated by intervals of 2, 3, 4, and 5 metres. At 3 kilometres none of the pairs were distinguishable as separate lights when the space between them was less than 4 metres. With a separation of 2 metres red or green pairs were merged into one bright light. When red and green lights were shown simultaneously, the green light was eclipsed altogether by the red at 2 kilometres if the distance separating them was not more than 2 metres.

PART 15 of the *Verhandlungen* of the German Physical Society contains a description of a mechanical pump for high vacua recently devised by Dr. W. Gaede, which makes use of a principle not previously utilised in the construction of such apparatus. If a shaft revolving in a well-fitting bearing has a circular slot cut in it, the air in the slot will to a large extent be carried round with the shaft. If at one part the bearing projects into the slot so as to fill it completely, the gas in the slot will be carried round with the shaft from one side of the projection to the other, and the pressure will in consequence be less on one side than on the other. If two openings are made through the bearing, one on each side of the projection, air will be drawn in through one and delivered through the other. By making a number of slots in the shaft and connecting the openings into them in series, the action will be intensified. A pump constructed on these lines exhausts five or ten times as fast as one of Dr. Gaede's well-known mercury pumps taking the same power, and deals with the water vapour as well as the gas, so that no drying materials are necessary. As it works better at low than at high pressures it is run in conjunction with another pump, which reduces the pressure to a few centimetres of mercury.

IN a publication of the *R. Accad. delle Sci. dell' Inst. di Bologna*, which has recently come to hand, Prof. A. Righi describes some interesting experiments on the emission of ions in directions perpendicular to that in which the main discharge passes. Two wire electrodes are sealed into a cylindrical vacuum tube, perpendicular to the axis, with only their points exposed. When an impulsive discharge is passed between them it is found that ions are shot along the axis of the tube. The distance they penetrate and their relative numbers under different conditions are studied by collecting them in a suitably placed Faraday cylinder. By an ingenious arrangement of vanes, which rotate when the ions strike them, it is possible to follow the paths of the particles. This transverse emission of ions is most vigorous near the ends of the main discharge. When the tube is placed in a magnetic field parallel with its axis the neutral doublets, already investigated by Prof. Righi in earlier papers, are formed, and, as would be expected, the Faraday cylinder collects less charge. On the other hand, owing to the large mass of the doublets, the mechanical effects are increased.

AN article in *Engineering* for October 11 recalls the discussion of a few years ago on the distribution of shearing stresses on the horizontal layers of a dam. Messrs. Wilson and Gore showed experimentally in 1908 that the stresses did not follow a parabolic distribution, but were much more uniform. Prof. E. G. Coker has lately described experiments at the Royal Society on thin celluloid sheets under shearing stress, the conditions resembling that of the web plate of a plate girder. It has been contended that the shearing stresses in the girder web follow the parabolic law, but these experiments indicate that this law is only approached when the plate is shallow. Otherwise the shear curve had no maximum at the centre of the specimen, but showed two equal maxima, which are at points situated at a distance from the ends equal to rather less than the width of plate under test. Reducing the depth of the plate causes these two maxima to approach each other, and they finally coalesce when the depth of the specimen is about equal to its width.

A SECOND edition of Mr. T. H. Byrom's "Physics and Chemistry of Mining: an Elementary Class-book for the Use of Mining Students," has been published by Messrs. Crosby Lockwood and Son. In this edition the chapter on magnetism and electricity has been omitted, and additional matter has been introduced in both the physical and chemical sections. The price of the volume is 3*s*. 6*d*. net.

MESSRS. H. F. ANGUS AND CO., of Wigmore Street, London, have issued a new catalogue of second-hand scientific apparatus and accessories which are available for sale, exchange, or hire. We notice that all the instruments listed, unless otherwise stated, have been tested, adjusted where necessary, and are capable of work of equal precision as when new. Interesting particulars are given in the list of microscopes and accessories, as well as of various other optical instruments.

OUR ASTRONOMICAL COLUMN.

GALE'S COMET, 1912*a*.—London urban skies have remained comet-proof for some time now, but Mr. Franks, writing to *The Times* (October 15), reports that he saw Gale's comet very well, with a 6-inch refractor, during the week ending October 11, at East Grinstead. He states that it appeared to be brightening, for it was about fifth magnitude when he first saw it, and was nearer fourth on October 11. On this date it was a fine object, plainly seen in the finder, and, by sighting along the telescope, it could be seen by the naked eye as a misty spot about half a degree below α Serpentis. When seen on a dark sky it presented an extensive coma with a large bright nucleus and a tail at least half a degree in length. Mr. Franks also reports that it was nearly a degree north of its predicted position on October 11, and that the difference is increasing, but it seems probable that he was using the earlier ephemeris published by Dr. Ebell, and not the later one from which we gave an extract last week. The following is a continuation of the corrected ephemeris :—

1912	α (true)	δ (true)	1912	α (true)	δ (true)
	h. m.	° ′		h. m.	° ′
Oct. 18	...15 49·9	...+13 20·0	Oct. 22	...15 54·1	...+16 52·0
19	...15 51·0	...+14 14·6	23	...15 55·1	...+17 42·5
20	...15 52·1	...+15 8·2	24	...15 56·1	...+18 32·0
21	...15 53·1	...−16 0·6	25	...15 57·0	...+19 20·5

According to this ephemeris, the magnitude should now be 6·6, and decreasing slowly, but, as Mr. Franks remarks, the comet is exceeding expectations, and, with its indications of abnormal brightening, may well repay careful observation, especially in the form of a close series of photographs, by those who are favourably situated; on October 21 the comet will be about one-third of a degree east of γ Serpentis.

THE RECENT TOTAL ECLIPSE OF THE SUN.—It is with much regret that we learn from Greenwich that all attempts to make observations of the recent total eclipse of the sun were frustrated by the heavy rain which prevailed in the eclipse region of Brazil on eclipse day, October 10. The Greenwich observers, Messrs. Eddington and Davidson, were located at Alfenas, an elevated village some 185 miles north of Santos, where there were also eclipse parties from France, Germany, Brazil, and other countries. The Brazilian officials rendered all the assistance they could, and the Government voted a sum of 5000*l.* for the reception of the visiting astronomers at Rio. According to a characteristically interesting letter from Mr. J. J. Atkinson, which appeared in *The Morning Post* on October 8, the Greenwich equipment weighed about three tons, and had to be transported from Rio to the terminus of the State railway, a distance of about 150 miles towards the mountains; owing to the sharp incline the latter part of the track has to be worked on the cog system. Mr. Atkinson, who accompanied the Greenwich observers as a volunteer, also recites some interesting reminiscences of his previous eclipse experiences.

THE CONSTANT OF ABERRATION.—In No. 15, vol. xxvii., of *The Astronomical Journal*, Prof. C. L. Doolittle gives the result of twenty-two determinations of the aberration constant derived from thirty-two years' latitude work at the Sayre and Flower Observatories. The observations were made at two different places, with what are practically four different instruments, only the observer remaining the same, and the mean probable error is less than 0·01″. Taking the weighted mean of all the observations, Prof. Doolittle finds for the constant the value 20·525″ ± 0·0043″, and the corresponding value for the solar parallax is 8·780″.

THE AUTUMN MEETING OF THE INSTITUTE OF METALS.

THE papers presented at the autumn meeting of the Institute of Metals, which took place at the Institution of Electrical Engineers on September 25 and 26, may be divided into two groups according as their interest lies principally on the practical or on the scientific side.

Among the "practical" group two papers dealing with the joining of non-ferrous metals and alloys may be mentioned. In these Prof. Carnevali, of Turin, and A. E. Tucker, of Birmingham, discuss the question of autogenous welding, although the latter paper also deals in an interesting if somewhat scrappy manner with many other processes, such as soldering and brazing, &c. In view of the great extension of autogenous welding by means of oxygen and acetylene, the question how far the results of this process can be trusted is an important one. Tucker appears to regard a weld as satisfactory if it is found on testing it to destruction that the fracture occurs away from the weld itself. As a matter of fact, however, the weakest portion of a welded joint, as Carnevali points out, is not the weld itself, but the region of injured metal on either side of it. According to this author the strength of welds in copper and its principal alloys cannot be depended upon, and this conclusion agrees with the views on autogenous welds in iron and steel recently expressed by Fremont and others. In regard to pure aluminium, however, Carnevali finds the method to give satisfactory results, but the efficiency of a weld is much reduced as soon as it is applied to one of the stronger light alloys of aluminium. Broadly speaking, these papers lead one to view the rapid development of autogenous welding practice with some suspicion.

Still on the "practical" side were a number of papers dealing with impurities in copper and copper alloys. An interesting and suggestive paper by E. F. Law dealt with oxygen and oxides as deleterious impurities in alloys. This author took the view that progress in non-ferrous alloys was largely a question of the better elimination of oxides, and this view was strongly supported in the discussion by Rosenhain. The paper by Prof. Turner, however, emphasised the existing difficulties in the way of analytical determination of oxygen in brass, and an appeal was made to chemists to devise a satisfactory method for this purpose. F. Johnson dealt with the effect of impurities, chiefly antimony, on the properties of tough-pitch copper, and here again discussion centred round the part played by oxygen. The lenient view as to the deleterious effects of antimony put forward by the author was, however, strongly opposed by all those who have to deal with copper on the large scale. Other papers of a "practical" character dealt with high-temperature tensile tests on copper and its alloys, and with the annealing of coinage alloys, and both these papers were vigorously criticised in the discussion on the ground of the experimental methods employed by the authors.

The "scientific" papers were not so numerous, but of special interest. Prof. H. C. H. Carpenter contributed two papers dealing in further minute detail with the inversion which he has discovered in a certain range of copper-zinc alloys (brass) at a temperature of 470° C. In one of these papers the author deals with the effect of impurities on this inversion and finds that any addition of a third metal to these alloys tends to facilitate rather than to inhibit the transformation in question; since the change renders the metal weak and more brittle, it is evident that the use of the purest copper and zinc is desirable in the manufacture of those varieties of brass containing the constituent.

In a very short note Dr. G. T. Beilby, F.R.S., discusses the phenomena of the solidification of metals from the liquid state in reference to the "foam cell" theory of Quincke. In his May lecture to the institute, Dr. Bielby had suggested the importance of a full experimental investigation of the views put forward by Quincke, and the present note is intended to state more precisely the problem which Dr. Beilby desires to see investigated. The fundamental question, which goes beyond Quincke's hypothesis, is this, whether the liquid metal undergoes any changes or separations before actual solidification commences, and, if so, whether there is really any formation of foam cells or analogous structures governing the crystallisation of the metal. In his note Dr. Beilby quotes some lines of evidence from the manner in which a thin film of fused salt or other substance solidifies on a glass slip which appears to be strikingly contradictory to Quincke's views, and indeed the impression derived from reading Dr. Beilby's note is rather that he finds the "foam cell" theory less attractive after thus considering it more closely. A practical result is, however, likely to follow from Dr. Beilby's interest in the matter, in the shape of an exhaustive report on our present knowledge of the passage from the liquid to the solid state in metals, prepared under the auspices of a committee of the Institute of Metals, and this will certainly be very welcome.

Of purely theoretical interest is the paper presented by Dr. Rosenhain and Mr. Ewen, of the National Physical Laboratory, on the intercrystalline cohesion of metals. In this paper the authors advance the hypothesis that the crystals of a pure metal are held together by the action of a thin layer of metal in the amorphous condition forming a species of cement between the crystals. The conception of the existence of such a cement has already been put forward by Bengough and by Osmond, but the authors claim to have used it as a working hypothesis in their own laboratory before others had published their views. The paper begins with a detailed discussion of the general facts which lead in the first place to the idea that there should be some special condition at the boundary surfaces of crystals in solid metals; perhaps the most striking of these facts is the strength of these bounding surfaces, since it has been conclusively shown that pure metals normally undergo fracture through the crystals and not along the boundaries between them; the cohesion across these bounding surfaces is thus stronger than that across the cleavage planes of the crystals themselves.

The authors next suggest in general terms that when two growing crystals approach one another, a region is formed at their boundary in which the molecules are no longer able to assume the crystalline arrangement, and they further point out that if the unit or element of which the crystal is built up is large compared with the "liquid" molecule, then at the junction of two crystals gaps must remain which are too small to contain another complete crystal unit and that consequently such gaps would ultimately be filled by undercooled liquid metal which had been unable to crystallise. This undercooled liquid would then be identical with the "amorphous phase" of Beilby, and would possess similar properties. The paper points out that Beilby has shown that the amorphous phase is more soluble in acids and possesses greater chemical activity than the crystalline phase, and it would accordingly possess a higher vapour pressure under corresponding conditions of temperature. It follows that if two pieces of the same metal, one containing a small and the other a relatively large proportion of amorphous matter, were heated to the same high temperature in a high vacuum, the one containing the larger proportion of amorphous matter would lose weight more rapidly than the other.

This conclusion the authors have submitted to the test of experiment in the following manner. If an amorphous intercrystalline cement exists, then a specimen of metal consisting of a few large crystals would contain less of this amorphous material than a piece of the same metal which consists of a very large number of minute crystals, since the material of the cement is chemically identical with the bulk of the metal. Specimens possessing large and small crystals respectively were prepared by the authors in various ways, and these specimens were heated in high vacua (0·005 mm. and under) at temperatures sufficient to produce considerable volatilisation losses,

FIG. 1.—×100.

but still well below the melting points of the metals in question.

In the case of silver, zinc, and copper the authors found their expectations verified; the specimens possessing the minute crystal structure in every case losing weight at a greater rate than the coarsely crystalline specimens. The differences found were, in fact, considerably greater than the amount of amorphous cement which could reasonably be supposed to exist in the specimens, but although this point was

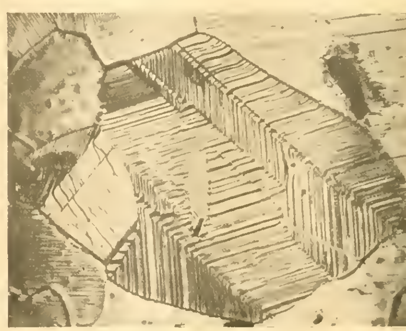

FIG. 2.—×200.

somewhat laboured in the discussion, the authors offer a fairly satisfactory explanation by showing that the formation of fissures due to the evaporation of the "cement" allows all the crystals in the fine-grained metal to undergo volatilisation from all their surfaces, so that after a time the effective evaporating surface of the fine-grained specimen is much larger than that of the coarse-grained.

This explanation is supported by microscopic evidence, since the widening by evaporation—of the intercrystalline boundaries is clearly visible on the specimens. An example of the channels formed in this way is shown in Fig. 1, reproduced from the paper. An interesting confirmation of the authors' views is further found in the fact that while the boundaries between adjacent crystals always exhibit this deep channel, the boundaries of twin-crystals do not show such a groove; since the crystal units on either side of a "twin" boundary fit into one another in a regular manner there is no room for amorphous matter in these boundaries, hence the absence of the groove. With the metals antimony, cadmium, and aluminium the authors obtained irregular losses of weight which neither confirmed nor refuted their views; they put these views forward merely as a suggestive working hypothesis, and do not claim to have furnished a valid proof of its truth.

Incidentally, the method of heating metals in high vacua furnishes an interesting means of developing their micro-structure, and this method has been used by the authors to study the conditions under which twinned crystals are developed in silver. One of their photomicrographs showing the structure of a twinned crystal of silver is reproduced in Fig. 2.

THE SURFACE-TENSION OF LIVING CELLS.[1]

PROF. CZAPEK'S pamphlet contains most important experimental work upon one of the fundamental physical attributes of the living protoplasmic cell, namely, the surface-tension of its external limiting layer. He makes it clear that the tension conditions obtaining in this layer, which intermediates between each metabolic unit and its environment, are of great significance for secretion and for absorption, and he has established that the surface-tension of the cells of the higher plants is maintained fairly constant at the value of about 0·685, the surface-tension of water in contact with air being taken as unity.

This very important conclusion is the outcome of a line of research which began at an apparently remote point, the successive stages of which may be briefly set out. The work started with the investigation of the curious precipitates that could be produced in the living cells of many plants by the action of dilute ammonia or 0·2 per cent. caffein, such as had been described as "aggregation" by Charles Darwin, in the tentacles of Drosera. Czapek first established that this "myelin-like" precipitate is a compound of caffein with the soluble tannin of the living cell, and is produced in all cells that contain tannin, the mesophyll of Echeveria and Sedum being the most suitable material. He then found that if such living cells are immersed in solutions of organic substances for some hours, the power of giving a precipitate with caffein may be entirely lost. This loss was traced to exosmosis of the tannin from the living cell, and it was further found that for each organic substance there was a particular limiting concentration below which no effect was produced and above which the exosmosis became very rapid. On comparing these limiting concentrations for the series of monovalent alcohols it was found that at each step in the homologous series the molecular concentration required diminished to one-third. Such a relation was, however, exactly what Traube had established for the surface-tension effect of the members of this series.

[1] "Ueber eine Methode zur direkten Bestimmung der Oberflächenspannung der Plasmahaut von Pflanzenzellen." By F. Czapek. Pp. iv+86. (Jena: Gustav Fischer, 1911). Price 2.60 marks.

Following up this clue, Czapek measured the surface-tension of a large number of solutions of organic substances, and compared their action in causing exosmosis from the cell with their activity in lowering the surface-tension of water. He thus was able to establish securely the unexpected generalisation that *on dissolving in water sufficient of any organic substance whatever to lower the surface-tension to about* 0·685, *a solution is obtained which just causes the exosmosis of the contents of living cells.* The critical concentration may require twelve to twenty-four hours to produce its effect, but stronger solutions with a lower surface-tension work very quickly and thoroughly, so that after a short time treatment of the cells with caffein gives no intra-vital precipitate at all.

The power of the protoplast to retain its dissolved contents is thus shown to be a matter of physical organisation, depending upon the surface-tension of the cell being below that of the medium in contact with its outer surface.

From true solutions Czapek passed to try the effect of emulsion-colloids of a lipoid nature (proteids and carbohydrates do not lower surface-tension enough to give the critical value of 0·685). The lipoid emulsions are, however, extremely active, and give exactly the same effects as true solutions.

The last step in the progress was an attempt at identification of the substance actually present in the plasmatic membrane which causes it to have normally so low a surface-tension as 0·685. Czapek finds that saturated emulsions of neutral fats lower the surface-tension just to this value and no further, so that it seems very probable that these are the effective substances in the living cell.

We have thus striking support for the view, widely adopted from the work of Overton and Meyer, that the plasmatic membrane is of a lipoid nature. Overton's later view was that lecithin and cholesterin rather than neutral fats were the particular lipoids present, but these give a lower surface-tension down to about 0·5. The present line of work indicates that these may be the effective substances in some cells, not those of the higher plants, for yeast and red-blood corpuscles require a medium of about this lower surface-tension to bring on exosmosis of invertase and hæmoglobin respectively.

Many supporters of the lipoid theory of the constitution of the plasmatic membrane have interpreted it to mean that there exists at the surface of the cell a continuous film of a lipoid nature, and this has raised difficulties in understanding the intake of typical nutrient substances which are freely soluble in water, but not in fat. Czapek points out that an emulsion containing only a small percentage of fat is all that is needed to endow the cell with the observed specific properties.

Willard Gibbs showed from thermodynamical considerations that substances in a solution which strongly reduce surface-tension must accumulate in the surface-layer until their return by local excess of osmotic pressure produces a state of equilibrium between the surface and the mass. With emulsified fat particles, however, the osmotic pressure is very slight, and very great accumulation in the surface-layer must result.

This piece of work may serve as a model of scientific method on account of the way in which the mysterious phenomenon of "aggregation," described by Charles Darwin, has been followed on and on until it has led to the evaluation of so fundamental a vital constant as the surface-tension of the living cell.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS BY PROF. JOHN ADAMS, M.A., B.Sc., LL.D., PRESIDENT OF THE SECTION.

An Objective Standard in Education.

Of those who deny to education a place among the sciences the name is legion, for they are many. The mere classification as a science is not perhaps of much consequence, but it is useful for the student of education to examine the popular view, and see how far it is justified. The following statement, the words of a former occupant of this chair, will be generally accepted as representing the prevailing opinion:—

"If we take science to mean, as commonly understood, organised knowledge, and if we are to test the claim of any body of facts and principles to be regarded as science by the ability to predict, which the knowledge of these facts and principles confers, can we say that there exists an organised and orderly arrangement of educational truth, or that we can logically, by any causative sequence, connect training and character either in the individual or in the nation? . . . It is very doubtful whether we can say that educational science is yet sufficiently advanced to satisfy these tests"

First, with regard to organised knowledge, there is certainly a great mass of matter available in the subject of education. It is true that there is nothing easier than to show that this matter is not at present well organised. It is only too easy to find examples of contradictions among those who make a study of education and venture to write or speak on the subject. We are told that there is scarcely any important statement made by a writer on education that cannot be met by a direct contradiction in the works of some other educational writer. It has to be admitted that writers on education in the past have been strangely opinionative and dogmatic in view of the very complex and delicate problems they have had to handle. Too frequently they assumed a simplicity in their subject-matter that was certainly not there. Even the massive common sense of Dr. Johnson was not able to keep him from regarding education as a study that had reached its limits long before his time. But between those who regard education as too simple to need any further examination, and those who treat it as so complex as to defy human analysis, there are those who take the view that education is a science like any other, though they admit that there may be room for wide difference of opinion regarding the stage of development it has reached.

At the present moment it is becoming increasingly evident that educational theory is consolidating: it can now be claimed that there exists a great body of educational doctrine that is of general acceptation. It need scarcely be said that there are many and deep differences among the various schools of educational writers. But if we compare any two schools we shall find that the points of agreement far outnumber the points of difference. This was true even in the older times of naïve theory, but is making itself very evident in these latter days. Anyone who has occasion to read all the books on the theory of education as they appear is impressed in spite of himself by the large body of doctrine that is common to them all. It is not that the books lack originality: each writer has his new point of view or his new interpretation of certain phenomena; yet each either baldly states or tacitly takes for granted a great body of truth that is held to be generally accepted. This body of recognised truth is gradually increasing as the result of collective thinking and the corrections involved in active criticism. Already critics are beginning to find fault with any writer who produces a book—not avowedly a text-book—that professes to deal with the whole range of education. He is reminded that what is now wanted is a special development along certain definite lines. The general principles of education are held to be established and accepted.

In confirmation of what has been said, it may be added that within the past year or two have appeared no fewer than five separate treatises each bearing the same title: "The Principles of Education." These books are mainly for the use of students, and contain what are regarded as the accepted results of educational investigation up to the present date. Their authors obviously recognise the existence of a certain body of truths on which all are agreed. In some of the professions it is customary to speak familiarly of "the books," meaning the standard works to which appeal is constantly being made. If among teachers we have not yet reached this stage, we are obviously far on the way towards it. The books are there, but the profession needs some time yet before, in its own deliberate way, it recognises their importance. By and by it will realise the fact that it has at its disposal material that will enable it to prophesy, and thus fulfil, the second condition imposed upon all who lay claim to scientific knowledge. It is true that in the past there was little diffidence about prophesying: it was the fulfilment that gave trouble. Wolfgang Ratke supplies, if not the first, at any rate the most dramatic application of a control test in the working of educational prophecy. He went to prison because the people of his time did not make allowance for the insufficiency of the body of knowledge on which he based his predictions. There was indeed nothing scientific about the procedure of Ratke. He was at the empirical stage, and could not rise above it. His modern fellows have not quite got beyond the empirical, but they are on their way.

No claim is here made that Education has yet justified her demand to be recognised as a fully developed science; but it may be fairly maintained that she has at least entered upon the stage of scientific method: she is seeking to free herself from mere empiricism. In such a struggle there are at least two possible lines of action.

The first requires some ingenuity, but is natural and pleasant. It consists in superimposing principles upon the facts of the case. The educational theorist invents or assumes certain broad general principles, then proceeds to fit in all the observed facts, and often shows great skill in the process. This method is of very general application. Sometimes it is worked consciously and deliberately, as in the case of Socrates' doctrine of Reminiscence. Here we have the whole scheme of teaching simplified by this superimposed generalisation. Quite frequently, however, the broad underlying principles are not brought to clear consciousness, and are, in fact, sometimes contradictory to each other. Examples may be found in Rousseau. For our present purpose this tendency towards what may be called rational pedagogy is best illustrated in the system of education elaborated by Herbart. Though the metaphysical basis on which he builds is generally regarded as false, it was deliberately adopted by him, and if it is once granted to him, all the rest of his system must be admitted to be built up on strictly scientific principles. It is true that while logically Herbart's pedagogy was built upon his psychology, in point of fact his pedagogical thinking preceded and dominated his psychological theory. While Pestalozzi sought to psychologise education, Herbart may be said rather to have educationalised psychology. In any case, he supplies us with a system that challenges recognition as scientific, whether the claim be admitted or not.

The other method by which a study may seek to escape from mere empiricism is by dealing with observed results so as to reach the underlying principles. In this method, instead of setting up principles and making the facts square with them, we examine the phenomena and seek to discover the underlying principles. Obviously this at once introduces the experimental method, since no satisfactory progress can be made by mere passive observation. This is the stage we have now reached in educational theory. We are passing from an appeal to experience to an appeal to experiment. Naturally, educational method has always had to stand or fall by its results, but in estimating results there has too frequently been a confusion between cause and effect. So soon as a conscientious analysis of educational problems is attempted, there comes the need of experiment. Certain questions have arisen demanding a definite answer, and the answers supplied must stand the test of practical application. Education is, in fact, called upon to prophesy, and to stand or fall by the results. Now the method of experiment is really a system of tentative prophecy, under rigidly determined conditions. We acquire skill in prophesying by a process of trial and error. We become prophets by prophesying. From all the knowledge at our disposal we calculate that a certain process will give a certain result. We apply the process, and then if the result is not what we expected, we examine all the conditions, seek out the cause of our error, and proceed to another tentative prophecy. By and by we acquire the power of prophesying with confidence within certain recognised limits, and within those limits we may claim to proceed scientifically.

But in the evaluating of results that is necessary in this process of training in prophecy there is need for some recognised standard. Unless this condition be fulfilled there can be no general agreement among investigators. Accordingly, the first step in raising a study to the scientific level is the establishment of such a standard. In the study of education in the past—and it must be admitted that the same is true to a large extent at the present—the standard adopted was in most cases a subjective one. There is a tendency to have everything determined by individual opinion. Certain educational processes are gone through; certain results follow in the lives of the educands. The casual relations involved are arranged by the individual observer to suit his own views. According to some, the battle of Waterloo was won on the playing-fields of Eton; according to others, the battle of Colenso was lost there. We have need of some standard that is independent of private opinion.

Obviously the whole question of the relativity of knowledge is here involved. The educator is too apt to apply to his own case the Protagorean view, and maintain that "man is the measure of all things; of things that are, that they are, and of things that are not, that they are not." Into this antique problem we need not here enter. There is a sense in which the epigram of Protagoras may be justified. Without doubt, for his own practical purposes, the individual is the measure of his universe of experience. But so far as his universe has to do with the universes of others, the individual needs some common standard, something outside of himself, something that others besides himself recognise—in short, an objective standard.

The matter may be illustrated by what took place in the development of certain of the sciences. The secondary qualities involved in the Lockean epistemology—such things as colours, tastes, smells, sounds—lend themselves to a subjective standard; but so long as we confine ourselves to a standard of this kind we cannot be said to treat such matters scientifically. The individual is the sole judge of how a particular sound or colour strikes him, and against his decision there is no appeal. But it seems as if we could not have a science of sounds or of colours based on this individual judgment. Each observer would rely upon his own sensations, and would interpret them in his own way. Fortunately, in the study of physics it was discovered that certain of the conditions of sensation are constant. When we get a knowledge of wave-lengths, and the laws of refraction and reflection, we have passed from the merely subjective sphere, we have an outside standard, we can compare, abstract, and analyse independently of the individual. "C natural" has a definite meaning to science, even if there were not a single ear that could hear the sound. It is true that, in the ultimate resort, we cannot eliminate the individual observer. He is too important in ordinary life, and a great deal of the work of science is done, after all, at his address. How *red* strikes an observer is as important to a man of science as is the exact wave-length that is necessary to produce *red*. The relation between a certain wave-length and a certain sensation is complicated by the individual peculiarities of the sense organs of the living being concerned. In certain respects the science of optics is self-contained, and has a definite objective standard. In certain other respects it depends for its data on individual experiences, and has to content itself with a subjective standard. No doubt it can call in the aid of physiology, a science that has an objective standard of its own, and in this way eliminate a certain amount of subjectivity. But in the last resort there is a corner of the field in which no objective standard can be obtained.

It is true that in pure mathematics we appear to get into a region where the subjective may be practically excluded altogether, but even here the science of space and time is limited by the fact that it can deal with its data only from the point of view of human limitations. And there are certain borderline studies that are mathematical in their essence, yet have a direct reference to our bodily organs. Linear perspective, for example, is usually regarded as a science, indeed, as an exact science. Yet when we look into the matter we find that linear perspective is nothing more than a conventionalised method of treating, in an exact way, the results of individual experience. The whole science is really an objective standard by which the ordinary processes of vision may be compared, analysed, and classified. Perspective tells us what we ought to see. It is not independent of our sense functions, it is only a mode in which the variable subjective is reduced to uniformity by the application of the objective standard. Indeed, in the teaching of art there sometimes arises a curious conflict between the subjective element and the objective. Students who have studied perspective before they are called upon to draw real objects set before them are very apt to draw according to the rules they have learned, instead of observing what is actually before them and reproducing that as it appears to their senses. In other words, they set up the objective standard as paramount. So markedly is this the case that sometimes the study of perspective is forbidden until familiarity with model drawing has been attained. When a teacher urges a pupil to draw what he sees, and not merely what he knows from the rules of perspective he ought to see, we have an appeal to the subjective standard. The teacher is turning from the science of perspective to the art of drawing.

This illustration is of particular advantage to us in our present work, because it not only exhibits the subjective standard working alongside of the objective, but it introduces the idea of an *exact* science in relation to our human organs. Astronomy is an exact science, and yet the problem of the "personal equation" shows that even here the subjective must be taken into account. The "personal equation" is, in fact, nothing but the elimination by quantitative methods of the disturbing subjective elements. It is by similar methods that we must seek to establish an objective standard in education. The difficulty in this subject is very great. Astronomy and physics touch the subjective only at what may be called the point of application the point at which they are brought into contact with human life. Their subject-matter is external, and lends itself to objective treatment. In education the subject-matter is human nature, which is so complex and involves such volatile elements that it is almost impossible to reduce its working to fixed laws. The same difficulty obviously applies in psychology. Itself a comparatively new subject, psychology has great difficulty in getting recognition as a science. For this there are two main reasons. To begin with, psychology began life as a branch of philosophy, and scientific men regard with suspicion anything that comes from that quarter. Besides, there was the less reason to make room for the new subject, since it had already a settled place in the hierarchy of studies. The second reason is that which interests us here—the difficulty of establishing an objective standard. The descriptive generalities of Dugald Stewart and Thomas Brown had to give way to something based upon laws that are generally accepted. The line of least resistance in seeking for an objective standard in psychology is to fall back upon a physiological basis. It is generally admitted that nerve action can be referred to an objective standard, and by correlating psychic and bodily phenomena psychologists are able to get a series of recognised principles on the physical side that may be easily interpreted in terms of spirit. Psychophysics has at least a plausible claim to rank among the sciences, and the unbridged gulf between mind and matter is conveniently ignored. As a matter of fact, such a generalisation as the Fechner-Weber law ranks parallel with the laws of linear perspective—that is, it is a law that states in an unjustifiably exact way what ordinarily takes place in the individual experience. While rejecting the materialistic alliance, Herbart, as a psychologist, deliberately set up a mechanical system of ideas as forces, and in this way established at once an objective standard by means of which all mental process may be understood and manipulated. So scientific is his system that he claims that the interaction of the ideas may be calculated in certain cases by a simple application of the rule of three. With Herbart, psychology has certainly been raised to the rank of a science; but unfortunately it has to be admitted that his objective standard has been illegitimately assumed.

Just as psychology utilises physiology in its effort to gain a standing as a science, so education is inclined to use psychology. Frequently we hear psychology described as a science, while education is relegated to a place among the arts. It is natural, therefore, for the educator who wishes to claim rank in science to appropriate the scientific status of his auxiliary science. As a matter of fact, education has captured psychology. This is only one of many cases in which a profession has taken possession of an abstract study, and in this way enabled the abstract study to make real progress. Theology as a study has gained greatly by the fact that it is a compulsory subject for those who are preparing for a great profession. Astronomy owes a great deal to the support it has received from its practical value to navigators. Physiology would not be what it is to-day had it not become an essential subject in the preparation for the practice of medicine. Physiologists sometimes complain that their subject is hampered by its professors having to waste time in teaching mere medical students; it is well to remember, however, that but for the demands of the medical profession physiology would have been left to the few private investigators who might be able at their own cost to carry on under adverse conditions the work that is now being done in thousands of well-equipped laboratories. In the same way it is greatly to the advantage of psychology that it has become an essential part of the professional training of teachers. The subject is now receiving an amount of attention that it would never have had but for the support of its connection with the profession of teaching. But after all a teacher is not a mere psychologist: education is more than applied psychology. If education is to rank as a science, it cannot be in virtue of its use of another study that itself has an insecure foothold among the sciences. It must establish for itself an objective standard.

Mere quantitative manipulation of the elements of a study, if only carried out on a sufficiently large scale, has a tendency to evolve an objective standard, apart from any deliberate search for such a standard. We may gather something from an examination of a standard of this kind that, unexpected and unsought, evolved itself in the ordinary course of educational administration. What Binet and his colleagues and followers have been trying to do of set purpose was, to some extent at least, accomplished automatically by the working of the system of individual examinations under the English and Scotch codes of elementary education. Binet has drawn up certain tables with the express purpose of testing the intelligence of children at various ages. But we are only at the threshold of investigation work of this kind, and the tests cannot be regarded as satisfactory, either in themselves or in their application. But they have been drawn up with the deliberate purpose of supplying a more or less objective standard of intelligence. Now in the British elementary school codes we have the examination requirements from the pupils of different ages set out in a series of tables each corresponding to one of the seven grades known technically as "standards." The purpose of these tables of requirements was not primarily to determine the intelligence of the pupils, but rather to indicate certain minimum amounts of information that had to be communicated in consideration of a certain money payment. Yet these tables bear a generic resemblance to those of Binet, and in actual practice the "standards" did win acceptance as a test of intelligence. The requirements were perhaps less scientifically determined than are those of Binet's tests, but their practical value was very much greater, because of the extremely wide range of their application.

When the codes had been in working order for a score of years it became evident to thoughtful observers that there had arisen a standard of comparison among pupils in elementary schools that was gradually being recognised all over the country. It was an objective standard as was shown by the fact that each of the standards began to have a meaning of its own, apart from the individual school in which a particular pupil happened to be found. No doubt there were differences in detail. A Standard III. boy in one school would be found to have greater knowledge and skill than a Standard III. boy in another. But the important point is that the phrase "a Standard III. boy" came to have a definite meaning apart from any particular school. It began to be used absolutely, and not merely relatively. Further, if a boy were found to be in a standard lower than his years warranted, people had no diffidence in drawing their own conclusions regarding his ability. It will be remembered that Binet tells us, somewhat vaguely, that if a boy is a year behind others of the same age who have had the same opportunities, it indicates that he is duller than the others, but not necessarily permanently so. If, however, the pupil is two years behind the normal test for his age there is a presumption in favour of his being inherently and permanently duller than his fellows. All this is very familiar and indeed commonplace to the elementary teachers who were brought up under the code examinations by standards. To tell the truth, M. Binet's tests are regarded with much suspicion by such elementary teachers as have been induced to give them attention. They have the feeling that here we have a university professor working out as something new a belated scheme that has had its day, and in that day done a great deal of damage. They are afraid that the prestige given to the intelligence tests may encourage the re-establishment of the rigid individual examination system from which they have escaped. All the same, experienced elementary teachers do not deny that the old system did at least have the effect of establishing a generally recognised standard. Their belief is that the standard was not worth what it cost.

It is left for Binet's successors to invent a better scheme than he was able to produce, and in this way to establish an objective standard, at least in respect of intelligence. Such a standard is needed in many connections, but there is one special department of educational administration where such a standard is at present urgently required. Nothing better illustrates the groping of education after a scientific basis than the present demand for some means of determining which children are "defective" and which merely dull. So imperative is the need for an objective standard here that it must be satisfied at any price, with the result that the decision is being more and more left to the doctors instead of to the teachers. The cause is not difficult to find. Physiology has already an objective standard, and the doctors are evidently expected to get their results by physical examination. No other explanation is admissible, since they are not only not superior to teachers in their knowledge of the mental reactions of the child, but obviously inferior. At present the argument moves backwards and forwards. Some say: Give the teachers a tincture of physiological knowledge, and then they will manifestly be the best persons to determine the defective stage. Others reply: Give the medical men some little experience of school conditions and the working of the immature mind, and they cannot but be the proper authorities on all questions of intelligence. The important point in this competition for power between the two professions is the implied recognition of the need for an objective standard, and the admission that, at present, such a standard does not exist. Much investigation, experimenting, and verification are necessary before the truth on this particular subject can be reached. But the recognition of the existence of the problem is in itself an indication of progress, and the need for scientific method in working it out is being more fully recognised. From our point of view it is important to note that we are here dealing with a problem that is distinctly educational, and the bringing in of men from another profession does not make it less so. If the doctor acquires the power of dealing with delicate questions of intelligence, it is because he has learnt to be an educationist if not an educator. Medical men who specialised in this matter would no doubt very soon attain to high skill, since their previous training gives them a very suitable preparation to begin the study of education. Doctors are consulted regarding "defectives" mainly for two reasons. First, these defective children are naturally classed in the popular mind with the mentally deranged, and these have always been regarded as peculiarly suitable subjects for the doctor. Further, there exists, without doubt, the implicit feeling in the public mind that the doctor has definite standards while the teacher has only general impressions. But it has to be noted that this invasion of the field of education by men from another realm of study does not in any way affect the claims of education to rank as a nascent science with needs and methods of its own. If the doctors can supply education with an objective standard, education should be very grateful, but need not abdicate in favour of medicine. Education may use the results of both psychology and physiology without in any way surrendering its claims to be an independent science. We must not, of course, make too much of the distinctions among the sciences. Nothing but error can result from seeking to make each of them rigidly self-contained. So far as education is concerned, what we have to seek is that objective standard that we have conceded to be essential to the recognition of a study as a possible science, and this without falling back on the standards of either pure psychology or pure physiology.

We may learn something from what we have found out about the results of the individual examination system. The general tendency of quantitative methods is to eliminate the subjective element. Even in the case of marking examination papers experience shows that the use of numerical marks tends to objectify results, and to get rid of some at least of the difficulty involved in the personal equation of the examiners. Marking by general impression of a whole paper is much less free from subjective variation. Every individual number set down as a mark implies a fresh exercise of the critical power, and when there are many questions there is a compensating principle at work, inasmuch as each impression is recorded as it is made and the addition of the marks produces a balancing in which the latest impression has not the determining influence it too frequently has when a paper is marked as a whole. If an examination includes many subjects, many examiners, and a great body of examinees, the subjective element in the marking is, to a large extent, eliminated, and we can deal with the results in accordance with what is practically an objective standard. We must not, of course, neglect the fact that after all the whole basis of the results is the judgment of the individual examiner on the material submitted to him. This corresponds to the application to real life of any of the physical sciences. Here, as in many of the other sciences, we have a surd of subjectivity that can never be got rid of entirely. But its disturbing influence can be minimised by the counteracting influences of other forces in the quantitative manipulation of the data.

Of late the quantitative method of dealing with educational problems has been greatly developed. Karl Pearson's product-moment formula has enabled us to make an accurate arithmetical statement of the amount of correlation that exists between series of quantitative data. By the application of this formula, and the simpler formulæ of Professor Spearman, it is now possible to correlate a great many facts that were formerly treated as having only a problematic connection with each other. If these formulæ produce really trustworthy results, we have at our command a means of answering definitely and definitively a great number of questions that have hitherto been regarded as the more or less legitimate matter for the professional controversialist. The vexed question of "formal training," for example, may be set at rest once and for all by a sufficiently extended series of correlations of the results of pupils' progress in certain subjects. The peculiarity of this method of dealing with correlations is that once we have handed over our facts to the formulæ, the process passes out of our hands altogether. We have only to work out our equations and the results make their appearance. Here we certainly seem to have reached an objective standard.

Such results, however, are not unnaturally regarded with some suspicion. Once the formulæ have been established by mathematical proof they must, of course, be accepted as irrefutable on that side; but their application to educational problems is so mechanical and indeed inhuman that many are unwilling to accept and use them. Some people are doubtful whether, in dealing with human beings, it is desirable, even if it were possible, to have an objective standard that eliminates humanity from all human problems. It has to be pointed out to such critics that all human problems must begin with the individual and end with the individual. All the intermediate process may be carried on in the pure objectivity of quantity, without dehumanising the application of its results. This will be kept in view when we deal with the average.

Apart from the danger of dehumanising our subject, there are two real possibilities of error in the application of the formulæ. First, there is the danger that the investigator may be satisfied with an application to an insufficient number of cases. The second danger is that the subjective element may cause error in the preparation of the data. If the first possible source of error be minimised, the second will be practically removed. Granted a really wide investigation, there is little room for serious error. If a sufficiently large number of cases be examined, and these cases selected under sufficiently varied conditions, the subjective variations will neutralise each other, and a trustworthy result will be produced. It must never be forgotten that the Pearson and other formulæ are merely means of dealing with material already acquired. It is only to this extent that they supply an objective standard. Many of the recognised sciences are in no better case.

The hope of the evolution of education as a science lies in the proper manipulation of the method of experiment. Students of education have always been in the habit of asking questions, but they have not always waited for an answer. Nor have they usually taken sufficient care in making their questions precise. They have not laid down with the necessary detail the conditions implied in the question, and when they have reached some answer they have been too often content either to accept it without any verification at all, or with the support of nothing but a few general considerations that seemed to confirm it. In the newer educational investigations questions are set out in great detail. They are usually limited to one point, and all the relevant conditions are carefully laid down. Various control tests are applied during the progress of the investigation, and every precaution taken against the introduction of interfering forces. Then when a result has been obtained various confirmatory tests are applied. Even when all has gone well so far the result is not regarded as authoritative until the experiment has been repeated with the same results by different experimenters working under different general conditions, though, of course, all the detailed conditions must be precisely the same as in the original experiment.

The questions asked are often of a very practical character. In the current number of *Child-Study*, Mr. W. H. Winch gives an example. The question is whether one gets better results in working "problems" in arithmetic by (*a*) direct teaching for a certain period in how to work such problems; or (*b*) spending the same period in giving the pupils practice in working such problems. Mr. Winch gives a very instructive account of all the conditions under which his experiment was carried out, including all the necessary precautions. The result is that those who had had the teaching scored an average of 11·1 in the final test, while those who had had the practice scored only 9·2: the group that was taught improving on its preliminary record to the extent of 34 per cent., while the group that had been confined to practice improved by only 11 per cent. It is thus demonstrated, at present, that teaching counts for more than practice in the preparation of pupils to do problems in arithmetic. But the fact cannot be regarded as a part of the permanent possessions of the teacher till it is verified by many more experiments in this country and abroad.

We have seen that even at our present stage of advancement there is quite a respectable collection of recognised facts in connection with teaching and education, and that these are in process of organisation. We shall soon have such a volume of well-arranged knowledge as shall meet the first requirement for recognition as a science. But while organisation is imperatively needed and must go on, there is an equally urgent need for new knowledge. There are hundreds of definite practical questions that are being asked by teachers every day, and unfortunately answered according to individual experience, if not indeed according to individual caprice. Some few questions about the memory are now definitely answered, and practical educators have the benefit of the results of experiments; but there are scores of points with regard to memory on which there is still doubt, and yet these are points on which the practical educator must adopt a definite line in his daily work. He cannot postpone his decision: he must do one thing or another, and in the meantime he has no standard. Such investigations as are being undertaken by the committees of this section are helping to increase the total body of knowledge at present available. It is true that hitherto these investigations have been mainly concerned with psychological matters, and certainly our store of psychological knowledge is not so great as to warrant any complaint at the concentration on this aspect. But it is pleasant to note that this year we are having a report on more distinctively pedagogic matters. There could be no more useful subject of inquiry suggested than an investigation into the questions that are most urgently demanding answers at this time among the practical educators of the country. To discover and classify these, and then to correlate them with the various investigations that are being made throughout the world, would be to render a very practical service to the study of education. The truths thus acquired and recorded could be fitted in to the mass already at our disposal, and the result would be a great strengthening of that objective standard that is so essential to the independent progress of our study.

Education ranks with a group of studies that deal with humanity in its various aspects. Psychology naturally is the science that underlies them all, since it is the abstract study of human nature which is their raw material. But politics, economics, sociology, eugenics, all claim to be sciences, and if we probe into their standards we find that they are largely statistical. It is quite possible by careful investigation among the subject-matter of these sciences to organise a system of general principles based upon averages obtained from a very wide field of investigation. These principles are of very general application, though they may not enable us to prophesy in individual cases. This, indeed, is at the root of a great deal of the criticism levelled at the claims of education to rank as a science. A parent or an education authority presents a boy to an educator and calls for a prophecy. The educator must decline, since he cannot honestly prophesy in an individual case, though he may be prepared to venture on a reasoned statement of what is likely to occur in the boy's educational career. The educator is, in fact, in precisely the same position as a medical man called in to a case. He can prophesy, but only in general terms. In both cases it is the application of general principles to a particular case.

This raises the whole question of the value of the average in matters of education. Psychologists, in addressing teachers, are beginning to warn them that the average is only an abstraction, and really does not exist. We are told that what the teacher has to concern himself with is "the living child here and now before him," and he is accordingly warned against the insubstantiality of the elusive abstract. But this is to confound two distinct things. It is true that the teacher must always deal with a living pupil here and now before him. But in his dealing with that living pupil he has to apply a paid-up capital of knowledge of men and of boys in general. He must seek to understand the living boy by the aid of knowledge previously acquired, and this knowledge is represented by the average. The master may be unable to prophesy with certainty how Jones minor will act under certain specified conditions. But from a knowledge of third form boys in general he can make a guess that is very likely to hit the mark. The teacher who applies his knowledge of the average third form boy to the minor Jones, without modification to suit Jones's case, acts unintelligently; but the possibility of blunders by a dull master does not reduce the value of the knowledge of the average in the hands of one who is capable. The concept of the average boy as it is developed by experience and study in the mind of the master forms a standard by which other boys may be estimated. This standard is partly subjective, partly objective. In so far as the standard is acquired by the personal experience of the master it is subjective. The unreasoned but very effective knowledge of boy nature that enables an efficient master who is guiltless of any acquaintance with educational theory to know how a boy is likely to act in given circumstances results from the training of experience, and is peculiar to its possessor. On the other hand, the knowledge of boy nature that has been acquired by deliberate study and by experiment is something that has an existence independent of the individual. It is objective, or at any rate has an objective bias.

We must distinguish in practice between the average and the type. The average boy may have no existence in reality, he may be a pure abstraction; but the type is concrete, and may be regarded as the embodiment of all the essentials that go to make up the average, with the addition of certain qualities that must be present in some form or other, though the particular form is immaterial. The average is to the type as the concept is to the generalised image. The type may form a very useful standard for masters whose tendency is strongly towards the concrete; but the average has a special and a different value, and in capable hands is more effectively applied because it is of a wider range. To consider a class as made up of types tends to break up the class feeling, and make the master think of his pupils as a mere group of separate individuals. Undoubtedly the master must in certain connections think of his pupils as individuals, but in other connections he must deal with his class as a whole, as a psychological unit.

This introduces one of the most striking developments of modern educational theory. The older psychologists treated their subject as limited to the study of the mature human individual. The introduction of the idea of development led to the founding of a genetic psychology with its consideration of the individual at his various stages. A further advance is marked by the appearance of collective psychology, which carries the study of the individual into his relations with other individuals. Naturally, both changes were of the greatest advantage to education. The first gave scientific guidance to the popular movement known as Child-Study, the second suggested the scientific study of the class as a collective organism. It is true that this collective psychology is at present in its infancy. But while we owe much to the French psychologists with their dazzling exposition, we are glad to turn to our more solid McDougall for the best scientific basis available for a sound collective psychology. The material he has supplied is waiting to be worked up from the educational side. His statement of the relation between the instincts and the emotions and his manipulation of Mr. Shand's theory of the sentiments provide tempting material for the establishment of an objective standard in connection with the training of the individual character and the interaction of individual characters in groups. Naturally, the results must be expressed in averages, and equally naturally there will be a complaint from certain practical educators. What is the use, it will be asked, of information about how classes in general act? What we want to know is how this particular class before which I stand is going to act. But this is to confound the practice of a science with the science itself. There must always be an intelligent intermediary between the principles of a science and their application to the affairs of life. In this respect the nascent science of education differs in no way from those that are more fully developed. The educator who prides himself on being specially practical is frequently very unreasonable in his demands from educational theory. He is rather apt to complain that it does not supply him with sufficiently detailed instructions. What he wants is a series of recipes which, if scrupulously followed, will inevitably produce certain specified results. But such men take a very humiliating view of their profession. So far from seeking this spoon-feeding, they should rejoice that their work demands the exercise of intelligent initiative. Herein consists, in fact, the dignity of the educator's office. He must be master of the organised knowledge that education has acquired, and must have the power of making the appropriate application of that knowledge to every case as it arises. To assist him in avoiding error he is entitled to look for an objective standard at the hands of those who make education their special study, but for the use of that standard he must himself accept the full responsibility.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE proceedings of the Geological Section at Dundee were of exceptional interest, and the attendances were large up to the end of the meeting. The success of the section was due to two or three special features. Many of the papers dealt with the problems of the Highlands and of the Highland border, questions which are full of knotty points, and the men who are engaged in solving these problems were able to assemble in the meeting-room and there state their views and face discussion, which was often very lively and always full of vigorous earnestness. Then we had a commodious and quiet meeting-room, and the President (Dr. B. N. Peach) was a host in himself. As Dr. Heim said, in seconding a vote of thanks to him: "When I look in front I always see the sun," and the vivacious countenance and stirring enthusiasm of Dr. Peach were an incentive to all present to rise to their best.

After the delivery of the President's address on "The Relation between the Cambrian Faunas of Scotland and North America," which was a timely and most valuable deliverance giving the evidence for the land connection between North America and North-west Europe in Cambrian times, a lecture was delivered by Dr. T. J. Jehu on the local geology. After a brief reference to the exposures of the Highland Boundary series in Forfar and Kincardine, and to the recent discoveries of rocks of Downtonian age near Stonehaven, the lecturer dealt with the groups of rocks found in the area:—(1) The Highland metamorphic rocks; (2) the Old Red Standstone; (3) the Carboniferous system of Fife.

(1) The prominent series of metamorphic rocks comprises the Dunkeld slates, schistose slates and micaceous grits included in the Ben Ledi group. With the schists are associated the "Green Beds" of the Geological Survey and certain basic intrusions mapped as hornblende schists.

(2) Two divisions of the Old Red Sandstone are represented, Lower and Upper, separated by a marked unconformity. They consist of two sedimentary groups separated by the great volcanic series of the Sidlaws and the Ochils. The distribution and characteristics of the volcanic beds were described, and the probable positions of the vents from which the materials were ejected were indicated. The Lower Old Red Sandstone rocks were folded and denuded before the deposition of the Upper Beds, which pass conformably up into the Carboniferous System in Fife.

(3) The Carboniferous rocks of Fife consist of the Calciferous Sandstones at the base, overlaid by the Carboniferous Limestone series, which are overlaid by Millstone Grit and Coal Measures. Special attention was directed to the splendid development of workable coal-seams in the middle group of the Carboniferous Limestone series, as well as in the Lower Coal Measures of the district. The remarkable diversity of igneous rocks and the great development of volcanic rocks on the coast of Fife were described, and were subsequently displayed to the members by a field-excursion to Elie.

During the meeting various problems connected with the Pre-Cambrian rocks of the Highlands and the Highland border were thoroughly expounded and discussed.

Mr. E. B. Bailey described the occurrence in eastern Mull of a great breccia-formation with intercalated rhyolitic lavas. The breccia consists of an unbedded assemblage of blunted rocks and fragments of gneiss, granophyre, gabbro and basalt, often associated with rhyolitic *débris* of volcanic origin. The basalt lavas of Mull have been violently folded into a series of anticlines and synclines, and it is in one of these synclines that the main outcrop of the breccia is preserved. It appears that the breccia is a thick layer overlying the basalts and folded with them. Though some parts of the breccia may be of volcanic origin, Mr. Bailey suggests that the greater part has resulted from erosion, which operated during the period of upheaval of the ridges.

Dr. J. S. Flett opened a discussion on the sequence of volcanic rocks in Scotland in relation to the Atlantic-Pacific classification of Suess. He pointed out that the recognition of two great families of igneous rocks, the Atlantic and the Pacific, and their relation to certain types of earth-movement, which we owe to Mr. Harker, constituted one of the greatest advances in rational petrology. In Scotland the Carboniferous volcanic rocks are typical Atlantic types, associated with collapse and great faults, and the rocks of Lower Old Sandstone age are characteristic of the Pacific group (great crumbling). To the Atlantic group could be added the Permian or late-Carboniferous rocks of Ayrshire and East Fife, and the nepheline-basalts (presumably Tertiary) of Caithness with their associated camptonites and monchequites. The Tertiary volcanic rocks of the Hebrides and the abundant north-west dykes were also ascribed to movements of Atlantic type. The remaining rocks of Scotland Dr. Flett desired to assign to an independent, intermediate group. They are characterised by pillow-lavas and are not connected with movements either of the Pacific or the Atlantic kind, and may thus be placed in a special family.

Dr. Flett's address was followed by a vigorous discussion, in which considerable criticism was expressed of the terms Atlantic and Pacific, and especially of their application to types of rocks in Scotland; but Dr. Flett pointed out that some terms must be used, and these were convenient, but he was not pledged to them in any way. Dr. J. W. Evans (London) thought that Dr. Flett had made out a *primâ facie* case, so far as the Scotch volcanic rocks were concerned. He believed that the first differentiation of igneous rocks was a result of the separation of the original magma, on cooling, into two fluids, one consisting mainly of water, silica, alumina and alkalies, the other made up chiefly of magnesia and ferrous oxide with sufficient alumina and silica to form anorthite and the ferric minerals. Subsequent differentiation was principally due to crystallisation. In folded areas the segregation took place at a considerable depth, while the magma still retained its original aqueous contents. The primary differentiation was therefore comparatively complete, and the normal or "Pacific" series of rocks was ultimately formed. In districts of plateau faulting, on the other hand, the differentiation occurred nearer the surface and under conditions which facilitated the loss of water, so that the separation was imperfect, the basic portion retaining more silica and a considerable amount of alkalies, and subsequent segregation by crystallisation gave rise to the alkali or "Atlantic" series. He also suggested that the occurrence of sodium with the basic rocks might be due to the presence of an unusual amount of chlorine, which separated out with the basic constituents and brought the sodium with it.

Dr. Tempest Anderson did not agree with the suggestion that pillow-lavas had been formed in deep water, and gave instances which he had seen of their formation by lavas flowing into shallow waters, and apparently due to sudden cooling by the waves. Mr. G. W. Tyrrell (Glasgow) much preferred the terms "alkalic" and "calcic" for Dr. Flett's main divisions. The differences were mainly chemical and mineralogical, not geographical. Many group names cover a wide diversity of types, and we appreciate the great value of Dr. Flett's recognition of mono- and poly-phyletic rocks, that is, types highly characteristic of one group only and types to be found in all the main divisions of igneous rocks. Dr. Hatch pointed out the advantage of a division which recognises a well-defined suite of rocks in which the alkali and calc-alkali felspars are developed in equal proportions, a series to which Brögger has given the name Monzonite series, and hoped that such a classification would be generally adopted.

Mr. G. Barrow gave a valuable paper on the older granite in Lower Dee Side, in which he showed that in place of forming large coherent masses, it was distinguished by *lit-par-lit* intrusions. The granite material in these cases formed minute sills parallel to the foliation of the associated gneiss into which it had been intruded. The granite rises as a dyke and the sills diminish in thickness and extent as they near the surface. In the interior parts the granite is usually grey and contains more biotite than muscovite, and oligoclase is usually abundant. The oligoclase and biotite are found to diminish steadily as the rock is traced towards the taper end of the sills. At this point there is little oligoclase and often no biotite; muscovite is fairly common and the bulk of the felspar is of alkaline composition. It would appear that the fissures in which the dykes occur were filled with igneous material, and that under great pressure the walls were burst open and the still liquid material forced out, and thus separated from that which had already become segregated. This phenomenon may be described as magmatic differentiation intensified by dynamic action. Mr. Barrow also read a paper on buckled folding. Descriptions have been published of areas of regional crystalline metamorphism in which the dip of the bedding is described as at a low angle over a considerable area. Experience is gradually proving that these altered sediments are always intensely folded, and the low dips really represent the most complicated structure, for which the name "Buckled Folding" is suggested. This structure is best seen in the Moine Gneisses, and its development can be studied in the cliff sections between Stonehaven and Muchalls. The grits and shales on the limb of the folds, near Stonehaven, ascend the cliffs in an unbroken course from bottom to top, being isoclinal and unbent. But as we proceed northwards the course of the grit bands up the cliff face is no longer straight, but a small overfold, or "buckle," is developed in it. At first only one is seen in the whole height of the cliff, then two, then three, and so on, until they are so close together that the still straight portion of the fold is no longer than the "buckled" or overfolded portion. If the upward course of each grit band be followed, it will be found that this structure does not alter the dip of the band as a whole. It still descends at much the same angle, but by a zigzag course. The overfolds all face in the same direction right up to Muchalls, and must have been produced after the isoclinal folding was completed. There is no justification for separating the buckled beds from those in which buckling does not occur. A key to the connection is found in the area about Shiehallion, where the quartzose beds forming the margin of the quartzite and containing the boulder bed and the limestone show isoclinal folding; whereas further north the same group comes on again, but this time with buckled folding, or Moine gneiss.

Dr. B. N. Peach and Dr. J. Horne described some interesting investigations which they had recently made on the Archæan rocks of Lewis, in which they showed how closely these beds corresponded to the rocks of the adjoining mainland, without the great series of acid intrusions. The structure is coarsely granulitic, and there is a marked absence of the pyroxene-gneisses with blue quartz, of pyroxene-granulites, and other basic forms, which are so characteristic of the mainland. The remarkable series of basic dykes in the west of Sutherland had not been detected in Lewis. The north-west and south-east strike, referred to by Murchison, was not characteristic of the gneisses of Lewis. The dominant strike is almost north and south, but north-east to south-west or east to west in other areas. The flaggy granulitic gneisses of the Butt of Lewis, which appear to run southwards along the belt of high ground between Stornoway and Barvas, resemble closely the Moine gneisses east of the Moine thrust-plane, but they differ petrologically from the rocks of sedimentary origin which form the Moine series. The system of overfolding and the direction of the axial planes of the folds approximate to those found in the Moine rocks on the mainland. The platy rocks, or mylonites, occur along definite lines of movement approximately north to south, and thrust-planes have been detected which point to displacement in a westerly direction. Various stages in the development of mylonites from the acid and basic gneisses are represented. In the discussion which followed the value of these investigations was emphasised by Dr. Flett and others.

Important discoveries of fossils in old rocks were announced by Dr. R. Campbell (Edinburgh) and Prof. T. J. Jehu (St. Andrew's). Dr. Campbell described fossil remains found in the Jasper and Green Schist series of the Highland border, at Craigeven Bay, Stonehaven. Crushed spilitic lavas with intercalated black shales, jaspers, and cherts, which in their lithological characters resemble closely the green igneous rocks and associated sediments along the line of the Highland fault, appear on the old Geological Survey maps as of (?) Arenig age. In 1909, in company with Dr. Peach and Dr. W. T. Gordon, the author found several fossils in the black shales. Detailed search by Mr. D. Tait revealed fossils of the forms Lingulella, Obolella, Acrotreta, Linnarssonia, and Siphonotreta; a bivalve phyllocarid allied to Caryocaris and Lingulocaris; and cases of a tubuloid worm. The above genera are most commonly found in the Ordovician beds and in the Upper Cambrian, but, owing to the absence of graptolites, Dr. Peach suggested that Upper Cambrian was the most probable age. Whatever may be the ultimate decision as to their stratigraphical horizon, the discovery of these fossils leaves very little doubt that the boundary fault series is *not* pre-Cambrian.

Dr. Jehu followed this paper by one on the discovery of fossils in the boundary-fault series, near Aberfoyle. This series is well exposed between Loch Lomond and Callendar, forming a narrow belt separated by a reversed fault from the Lower Old Red Sandstone on the south-east, and probably by a line of thrust from the Leny Grits on the north-west. It consists of black and grey shales, cherts, grits, and calcareous beds. Remains of Radiolaria were discovered by Dr. Peach some years ago in cherts near Gualann. Recently a number of fossils have been found in pale-grey chert bands near Arndrum. These fossils occur in muddy films in the chert belt. They are almost all hingeless brachiopods, and the following forms have been determined by Dr. Peach:—Acrotreta, Lingulella, Obolus, Obolella; also the flattened chætæ of polychæte worms. These fossils were regarded as indicating an Upper Cambrian age. Dr. Horne, in the discussion, regarded the collection of fossils from the chert and green-schist series at Stonehaven and Aberfoyle as the most important palæontological "find" affecting Highland geology since the discovery of Olenellus in the west of Ross-shire. The strata containing these fossils, which had been provisionally referred to the Upper Cambrian by Dr. Peach and Dr. Walcott, could no longer be considered as of pre-Cambrian age, like those of similar rocks in Anglesey. At a subsequent meeting Dr. Horne read a letter from Dr. Ami (Toronto), who had examined Dr. Jehu's collection of fossils from Aberfoyle, and found them closely resembling those obtained from Upper Cambrian beds belonging to the Quebec group. His opinion was based partly on the brachiopods and partly on the occurrence of an obscurely preserved graptolite resembling *Retiolites ensiformis*, Hall—a type eminently characteristic of the Sillery Sandstones of the Quebec group of Upper Cambrian age. Dr. Horne further stated that this form had been shown to Miss Ellis (Cambridge), who recognised it as a graptolite with Ordovician affinities.

Dr. A. W. Gibb (Aberdeen) read a paper on an actinolite-bearing rock allied to serpentine associated with the basic intrusion of Belhelvie. Towards the northern end of this mass, which consists of troctolites, serpentines, and allied types, there is a rock which shows a large number of dark-green rounded spots, set in a fine felt of paler green colour, full of glancing needles. Under the microscope the spots are seen to represent olivine, partly unaltered, partly serpentinised, as well as granulitised and drawn out. The rest of the rock is largely made up of actinolite in small crystal flakes, and green spinel and abundant magnetite are present. The exposure has recently been blasted away.

Dr. Wm. Mackie described the volcanic rocks round the Ord Hill of Rhynie, Aberdeenshire. The group embraces at least three lava flows, with associated tuffs and interbedded and overlying sedimentary rocks. Flow brecciation is frequent, and the tuffs are rhyolitic. The sedimentary rocks of the group consist of hard siliceous grits, which, under the microscope, show volcanic fragments. The whole of the group is characterised by fine, secondary quartz infiltration veins. They overlie the basic rocks of the younger Grampian granite series, but are probably considerably older than the oldest Old Red beds of the adjoining area. The lavas, being of an acid type, cannot be correlated with the interbedded andesites of the Old Red Sandstone.

Mr. G. W. Tyrrell (Glasgow) described the alkaline igneous rocks of Ayrshire. Recent work of the Scottish petrologists shows that one of the greatest developments of rocks characterised by primary analcite is contained in the midland valley of Scotland, one centre being in Ayrshire, the other in the area surrounding the Firth of Forth. Geologically these analcite rocks are Carboniferous in age, having a time-range from Carboniferous Limestone to Early Permian. They occur in the form of stratiform sills, lenticular intrusive masses, volcanic plugs, and as a series of lava flows. No masses of true plutonic habit are known.

Passing to Wales, a paper was read by Mr. Edward Greenly on the origin of some of the mica-schists of Anglesey. The mica-schists of southern and central Anglesey are holocrystalline rocks with strong parallel structure, and composed essentially of quartz, alkali-felspars, and white mica. Dr. Teall regards them as broken-down and partially reconstructed porphyritic felsites. Twenty-five years ago Dr. Callaway recognised their felsitic origin, which the present investigations confirm. These schists, therefore, may be looked upon in general as derived from acid igneous rocks. In some areas mica schists in continuity with them are found in intimate relations to schists of sedimentary origin, so that, probably, pyroclastic material was present in the original igneous series.

Dr. Robert Campbell (Edinburgh) gave a valuable *résumé* of his recent investigations on the Lower Old Red beds of Kincardineshire, showing that a thickness of 3000 ft. ought now to be transferred to the Downtonian, the uppermost group of the Silurian system. At the base of the series near Stonehaven there is 200 ft. of breccias interbedded with fine red mudstones made up mainly of fragments of the underlying (?) Upper Cambrian rocks, and resting unconformably on them. Near Cowie Harbour there occurs a thick belt of grey and greenish mudstones which yield Dictyocaris in abundance. Ceratiocaris, Archidesmus, Eurypterus, and other forms have been obtained from the same horizon, and in another bed numerous plates of a new Cyathaspis have been found. These interesting fossil finds, which in other areas do not occur in rocks younger than the Upper Silurian, and the lithological characters recall the typical Downtonian of the south of Scotland. These beds pass upwards into the micaceous sandstone and conglomerates of Stonehaven Harbour, which may be considered as the base of the Lower Old Red Sandstone. The fish remains were examined by Dr. R. H. Traquair, who reported that the small scutes were referable to the category of Cephalaspidian scutes, that the species to which they belong is pretty certain, but additional material is required before proceeding further with identification. He described several specimens of a beautiful new Cyathaspis, which he dedicated to Dr. Campbell.

Mr. C. J. Gardiner gave an account of the Silurian inlier of Usk. It is an oval area, eight miles by four, crossed by an important east and west fault. The southern half is composed of two anticlines separated by a fault. The axes of these folds run north and south, and dip southwards. The western anticline is the larger of the two, and shows Wenlock Shales and Limestone and Ludlow beds. The northern half of the inlier is far less simple than the southern in its structure, and is more concealed by drift. The Wenlock Limestone is not met with in this half. The simplest explanation is that the Wenlock Shale is faulted against the Ludlow beds on both sides. As the Aymestry Limestone is absent from the area, it is impossible to separate the Ludlow beds into an upper and lower division. The main boundary faults are crossed at several spots by minor east and west faults which cause small lateral displacements.

There were three important contributions from the palæobotanical side. Dr. Marie C. Stopes gave an outline of a controversy in New Brunswick between the palæobotanists and the stratigraphers. In the "Fern Ledges" of St. John there is a rich fossil flora, but no animal remains. Sir W. Dawson described the plants as Devonian. Recent attempts have been made to include the beds in the Silurian for stratigraphic reasons. The author's work in the field indicated considerable overthrust. The unique series had recently been redetermined. Type specimens had been lent by the Canadian museums and brought to London and Paris for comparison, resulting in the identification of a large proportion of well-known European types in the "Fern Ledges" flora as Carboniferous and mostly typical of the Westphalian division of the Coal Measures.

Dr. W. T. Gordon read a paper on the fossil flora of the Pettycur Limestone in relation to botanical evolution. The flora of the Pettycur Limestone (Lower Carboniferous) has a double interest. These forms constitute fragments of the oldest known flora, as Lower Carboniferous plants do not differ markedly from the Upper Devonian forms. Although the Devonian flora is distinct from that of the Permo-Carboniferous epoch, yet the organisation does not indicate that the plants were primitive. The result of Dr. Gordon's investigations was that the flora represented in the Pettycur Limestone appears, on the whole, to contain more generalised and simpler types than occur in the Coal Measures and later strata, and these types may be arranged in order so as to suggest certain possible lines of evolution.

Mr. W. R. Don (Dundee) read a paper on the nature of *Parka decipiens*. This fossil is the only common and quite the most characteristic fossil of the Lower Old Red Sandstone of the Kincardine-Forfar-Perth area. A re-investigation, chiefly microscopical, has been attempted with the aid of Schultz's solution (strong nitric acid and potassium chlorate). Most previous investigators had pronounced it to be vegetable, though Mantell, Lyell, and others considered it as an egg-packet of Pterygotus. The conclusions of the author were confirmatory of those of Sir W. Dawson and Prof. Penhallow that it was vegetable, and after boiling in nitric acid, the presence of spores within the carbonised tissue was demonstrated. In attempting to form some conception of the original structure and shape of Parka, the author concluded that the original spore-containing tissue was almost flat, not spherical, and unlike any known sporangia of to-day. There was, certainly, intimately connected with it a so-called "indusium." In the discussion, Dr. G. Hickling stated that his independent observations on Parka were in very close agreement with those of Mr. Don. He questioned, however, the nature of the cells, hitherto regarded as spores, and preferred to consider them as constituting simply a parenchymatous mass. These masses possibly served as reproductive buds analogous to the gemmæ of the Hepaticæ. Dr. Newell Arber (Cambridge) remarked on the extreme interest of Mr. Don's careful work on Parka, and was quite prepared to allow that the organs termed spores were undoubtedly of that nature. He differed from Dr. Hickling's criticisms, and pointed out that if these bodies were not spores, but parenchymatous cells, they certainly could not have survived the extremely severe chemical treatment to which they had been subjected. Dr. Hickling appeared to have examined chiefly spore sacs in which the spores were not yet mature, a condition also commonly noticed in some of Mr. Don's specimens, and this appeared to have been the chief basis of his criticism. Dr. Arber agreed with Mr. Don that Parka was undoubtedly a member of the Thallophytæ, and very possibly an alga.

The first results of investigations on the contents of the Millstone Grit of Yorkshire were communicated by Mr. Albert Gilligan (Leeds). Following up the work of Dr. Sorby, the late Mr. A. Longbottom had collected some very large pebbles from the Middle Grits of Silsden. These had been examined by the author, who had extended his researches to other beds of the series in Yorkshire. Some of the pebbles were of considerable size and showed a remarkable assemblage of rocks. By far the most common were acid igneous rocks. Only one specimen of a basic igneous rock had been found. The metamorphic rocks were quartz-schist and mica-schist, with a few fragments of gneiss. Numerous pebbles were found to be perfectly fresh microcline. Pieces of pegmatite were common. Some fragments obtained from the Plompton Grit proved to be a peculiar silicified oolitic rock. A few pebbles showed traces of organisms such as sponge spicules. The heavy minerals of the grits were not numerous, zircon and garnet being the most plentiful. The felspars in the grit were quite fresh, and this suggests either disintegration of the parent rock by differences of temperature and rapid transportation, or comparative absence of carbonic dioxide in the atmosphere. The author had been much impressed by the many points of similarity between the Millstone Grit and the Torridon Sandstone, and was disposed to think that areas of similar rock types were laid under contribution for each.

Mr. T. O. Bosworth gave an account of some investigations into the heavy mineral grains in the sands of the Scottish Carboniferous. The chief heavy minerals found were garnet, zircon, magnetite, tourmaline, rutile, staurolite, anatase, barytes. The sands containing an extraordinary amount of angular garnet were probably derived from the Highland schists of the north and north-west. The sands devoid of garnet probably came from the north-east, east, or south.

Mr. J. S. Owens communicated the results of some experiments on the settlement and transport of sand in water. It was shown that there is a definite relation between the rate of settlement and the temperature of the water. The curves show that velocity of fall varies almost with the water temperature, the rate being always increased by rise of temperature, but that as the diameter of the grains increases the temperature effect becomes less, until for grains more than one-tenth inch in diameter the effect is practically negligible.

Mr. Edward Greenly contributed a theory of the Menai Strait, in which he accepted Ramsay's view of the Strait as a glacial furrow, but the middle of the Strait cannot be explained in that way. Evidence was adduced to show that this reach was excavated by glacial waters during the recession of the ice at a time when the mutual relations of the ice of the mountain land and of the sea-basin admitted of the accumulation of a temporary lake. Post-glacial erosion and subsequent changes of level have completed the bed of the Strait as it now exists.

The origin of kopjes and inselberge was dealt with by Dr. J. D. Falconer. It had been suggested that a landscape with inselberge was of desert origin, but the various phenomena could be explained more readily as the result of weathering and erosion during successive small oscillatory movements of a regional character in the neighbourhood of base-level.

Mr. G. W. Grabham gave notes of an exploration of the country north of Lake Albert. This area extends west from Rejaf to the watershed and southwards as far as the lake. It is entirely composed of gneisses, which are for the most part affected by a north-south foliation. The only member of apparently sedimentary origin consists of a band of quartzite which is traceable for some distance. Among the gneisses, a group characterised by graphitic pegmatite was recognised. Some intrusions occur among these gneisses, and form the only intervening link in time between them and the surface deposits. In the country north of Lake Albert extensive deposits belonging to an extinct lake were found. Lake Ismail, as it is proposed to call this lake, stood about 600 ft. above the present river-level, and its site is marked by gravels and beds of clay. Its limits are uncertain, but it did not extend into the area now occupied by Lake Albert. In later times the crust fractures of the Rift Valley occurred, and the present lake and river system was initiated. In more recent times still the river has again been modified by crustal movements.

The usual grants were recommended for the continuance of committees of research, and a new committee was formed to investigate the fish beds of Dura Glen. The meeting was attended by a large number of foreign geologists, who took an active interest in the discussions of the section. Among them were Prof. C. Barrois (Lille), Dr. Tschernyschew (St. Petersburg), Prof. A. Heim (Zurich), Dr. H. Reusch (Christiania), Prof. J. Welsh (Poitiers), Prof. E. Trietze (Vienna), Dr. Pirrson (Yale), Dr. Leith (Wisconsin), Dr. Ami (Toronto). The annual geological dinner was held at the Royal Hotel on Friday evening (September 6). Dr. Peach made a most genial chairman, and delighted the audience by rendering the "Song of the Seraphim," specially written for the Red Lion Club dinner held during the Dundee meeting in 1867, and then sung by the author, Dr. Henry Woodward, to the tune of "Bonnie Dundee." The menu card was graced by a photographic copy of the picture of Sir Charles Lyell painted in 1870 by Lowes Dickenson, when Sir Charles was seventy-three years of age. The picture was on view in the loan collection. Dr. Jehu and his assistants arranged three enjoyable excursions for the afternoons, and a whole day to see the wonderful coast sections of Carboniferous puy eruptions near Elie. At the close of the meeting two extended field excursions were arranged, one to Loch Assynt, under the leadership of Dr. Peach and Dr. Horne, and another to the country between Aberdeen and Arbroath, under the leadership of Mr. Barrow, Dr. Campbell, and Dr. Hickling. These were very enjoyable and instructive, and proved great attractions to the foreign geologists and a large number of their British *confrères*.

W. LOWER CARTER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The John Winbolt prize has been awarded to R. V. Southwell, of Trinity College, for an essay on "The Failure of Thin Tubes by Instability or Secondary Flexure."

BIRMINGHAM.—During the winter and spring terms two courses of lectures on "Civic Design and Town Planning" are to be given, by Mr. Raymond Unwin, in the department of civil engineering.

The following appointments have been made:—Mr. C. Walker as lecturer in physiology; Mr. Laurence Ball as assistant lecturer in pathology and bacteriology; Mr. P. M. Chadwick, assistant lecturer and demonstrator in civil engineering; Mr. A. Clubb, demonstrator in mining (as successor to Mr. C. D. Mottram); Mr. H. I. Coe, assistant lecturer and demonstrator in metallurgy. Mr. Percy May has resigned his post as assistant lecturer and demonstrator in chemistry, and Mr. Frederick Challenger has been nominated to the vacancy.

A COURSE of free lectures to teachers on "The Past Around Us," a series of brief studies introductory to the folk-culture of Britain, is being given by Mr. Walter W. Skeat, at the Horniman Museum, Forest Hill, S.E., on Saturday mornings, from October 12 to December 14. Admission is by ticket only, to be obtained from the Clerk of the London County Council.

LECTURES on volcanic action, earth movements, the geological action of water, and the evolution of scenery and life on the globe are to be delivered by Dr. Werner Marchand on October 17, 24, and 31, in the meeting rooms of the British Esperanto Association, 133 High Holborn (Museum Station Buildings), W.C. They will commence at 7.30 p.m., and will be delivered in Esperanto.

THE winter meetings of the Child Study Society begin this evening at the Royal Sanitary Institute, when Dr. T. P. Nunn will lecture on the psychological development of the school subjects. The list of lectures and discussions to be held this year provides many subjects of interest to students and teachers concerned with the education of children. Particulars as to membership may be obtained from the honorary secretary of the society, Mr. W. J. Durrie Mulford, 90 Buckingham Palace Road, London, S.W.

THE University College (London) Committee will shortly proceed to fill the vacancy in the Quain studentship in biology which has been created by the resignation of Mr. E. J. Salisbury, on his appointment as lecturer in botany at the East London College. Any student of the college is eligible for the studentship who has for at least three terms attended one or more classes in the special study in respect of which the studentship is awarded. Applications should be received on or before Saturday, October 26.

FOR some time articles have been appearing at regular intervals in the Journal of the Department of Agriculture and Technical Instruction for Ireland describing recently established Irish technical schools. These articles have been published afterwards as separate pamphlets for distribution by the department. The twelfth and thirteenth contributions to the series have been received in booklet form. The former is called "Technical Instruction in Limerick," and has been written by Mr. J. Comerton, the principal of the Limerick Technical Institute; the other deals similarly with Cork, and is by Dr. John H. Grindley, principal of the Crawford Municipal Technical Institute, Cork. The accounts of the work done in technical education in these important Irish industrial centres provide excellent evidence of the success which is attending the department's efforts to meet the educational needs in different parts of Ireland.

THE distinguishing characteristic of the calendar for the present session of the City of Bradford Technical College is the excellent series of thirty plates, which chiefly illustrate the very complete arrangements made for the practical study of the branches of technology on which the industries of the district depend. This college awards certificates, diplomas, and an associateship. The diploma of the college is awarded to each day student who has been in attendance for three complete sessions, subsequent to passing an entrance examination, and has passed the college examinations in all subjects of the diploma course taken. The diploma is awarded to evening students under the same regulations as to day students, except that an evening student who has been at least three years in attendance, and has obtained the ordinary certificate, is exempt from the first-year diploma course. To become an associate a candidate must be twenty-one years of age and have had at least one year's practical experience with a firm engaged in his trade or profession, subsequent to obtaining the diploma. Some of the subjects in which diplomas may be obtained are: preparing, combing and spinning, weaving and cloth structure, chemistry and dyeing, and power production and transmission.

ON Wednesday, October 9, at Bradfield College, Berks, a new block of science rooms was opened by Sir William Osler, F.R.S. A large proportion of the boys at the college have studied science during the last twenty years, and some fifty to seventy pupils work in the mechanical shops added in 1898. The new science schools have this year been added to deal more effectively with the growing demand, and mainly through the efforts of the present headmaster, the Rev. H. Costley White. Among the assembly present at the ceremony were the warden (Mr. Edward Armstrong), the Right Hon. G. W. Palmer, Mr. R. Dyke Acland, K.C., Sir Arthur Rücker, F.R.S., and Mr. J. H. Benyon. Sir William Osler, in a speech after the ceremony, dwelt on what he considered to be an ideal education for those suited to and seeking scientific pursuits in after life. He would have a thorough knowledge of Latin and Greek; he believed in the optimistic Greek outlook on life for boys; during his last two years the boy should specialise in science, which should occupy most of his school hours. The speaker objected very strongly to the use of the term "stinks" as applied to science study. He said that that one word had done more harm in implying discredit to, and in keeping back pupils from the study of, the subject than any other factor. The new science block is detached from the rest of the school buildings, and has an attractive exterior. The entrance lobby leads into two chemical laboratories on the right and two physics rooms on the left, each easily accommodating twenty boys. In the chemical laboratories each room is adequately fitted with fume cupboards, balance slabs, and store cupboards, and has a raised demonstration bench at one end of the room. The two physics rooms are each supplied with three central tables and side benches round the walls, balance slabs, and large sinks. Behind the entrance lobby is a lecture-room with raised tiers to accommodate fifty boys, with a demonstration bench, fume cupboard, and lantern screen. The architects are Messrs. Steward Smith and Hutt, of Reading, the builders Messrs. Hughes, of Wokingham, and the furniture has been supplied by Messrs. Baird and Tatlock.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 7.—M. Lippmann in the chair.—Maurice **Hamy**: An arrangement of the arc with iron electrodes working with alternating currents. The spark spectrum of iron, used as a comparison spectrum, presents difficulties owing to the variations caused by slight changes in the experimental conditions. The arrangement of the arc between iron electrodes described in the present paper was designed to replace the spark as a source of the iron spectrum.—Gustave **Sannia**: The simple characteristics of partial differential equations with two variables.—N. **Saltykow**: The theory of partial equations.—U. **Cisotti**: The movement of a solid in viscous liquid.—E. **Mérigeault**: The influence of the velocity of combustion on the efficiency of a gas motor.—V. **Auger**: A new volumetric method for the estimation of uranium. The solution is reduced with metallic zinc and titrated with a standard solution of a ferric salt, using ammonium thiocyanate as indicator.—Paul **Gaubert**: The polychroism of crystals of potassium sulphate artificially coloured.—Marcel **Mirande**: The presence of hydrocyanic acid in *Trifolium repens*. The presence of hydrocyanic acid, or of a substance giving rise to it under the action of an enzyme, was proved in the stems and leaves of this plant. None was found in the roots.—C. **Dhéré** and W. de **Rogowski**: The absorption of the ultra-violet rays by α- and β-chlorophyll and by crystallised chlorophyll. Pure chlorophylls are remarkably transparent for the ultra-violet rays.—Léopold Le **Moult**: The destruction of certain Hemiptera by vegetable parasites.—M. and Mme. Pierre **Delanoë**: The relations between the cysts of Carini of the lung of the rat and *Trypanosoma lewisi*. The authors conclude that the pneumocysts of Carini represent a new parasite of the rat; they are not connected with *Trypanosoma lewisi*.—E. **Foëx**: The "Fibrinkörper" of Zopf, and their relations with the metachromatic corpuscles.

NEW SOUTH WALES.

Linnean Society, August 28.—Mr. W. W. Froggatt, president, in the chair.—G. I. **Playfair**: The plankton of the Sydney water-supply. The Sydney water-supply is the water of the Nepean and Cataract Rivers, which is impounded in the Cataract Reservoir, and thence brought down, by many miles of canal, through the Prospect Reservoir to Guildford and Pott's Hill, where it is filtered by being passed through a double series of wire screens. These screens being periodically raised and washed with a hose, the effluent from this operation has been the principal source of the material studied.—Allan R. **McCulloch**: Descriptions and figures of three young specimens of sunfish (Molacanthus) from the Central Pacific Ocean. The specimens described were received by the trustees of the Australian Museum from Dr. Thomas D. Liddle, R.N. They are only 9·5-13 mm. long, and were taken from the stomach of a kingfish caught swimming near the surface during the passage of H.M.S. *Torch* between the Ellice and Union Islands, Central Pacific, in 1911.—H. J. **Carter**: Notes on Stigmodera, with descriptions of new species and of other Buprestidæ. Eleven species of Stigmodera are proposed as new, comprising five from West Australia, four from Queensland, one from New South Wales, and one from Victoria. Two species of Neocuris and one of Curis, all from Queensland, are also described.

CALCUTTA.

Asiatic Society of Bengal, September 4.—L. L. **Fermor**: Preliminary note on the origin of meteorites. As the result of investigations into the conditions of formation of garnets, especially with respect to pressure, the author has been led to postulate the existence, below the plutonic rocks of the earth's crust, of a zone of rocks characterised by the abundant presence of *garnets*, the garnets being the result of the high pressures (and temperatures) existing in this zone. For this zone the author proposes the term *infraplutonic*. Armed with the conclusions thus obtained with reference to terrestrial rocks, the author proceeds to the consideration of meteorites, in particular of the stony forms known as aerolites; he is able to offer an explanation of the round bodies known as *chondrules*, so characteristic of many stony meteorites; he shows that each chondrule was once a garnet, and that the rock now represented by the chondritic meteorite must have been a garnetiferous eclogite situated at a considerable depth below the surface of some primeval stellar body. The disruption of this body was accompanied by a sudden reduction in pressure, which caused the garnets to liquefy with increase of volume. The rapidly decreasing temperature after this disruption caused the rapid crystallisation of these liquid drops with formation of the radiate and other crystalline aggregates of enstatite and olivine (sometimes with glass) so characteristic of chondrules. Starting from this interpretation of the chondritic meteorites the author is able to refer each of the great groups of meteorites to their respective positions in the primitive stellar body before disruption.—Anukul Chandra **Sircar**: A possible chemical method of distinguishing between seasoned and unseasoned teak wood. The work of R. Romanis on "Certain Products from Teak" has been extended with a view to determine whether the composition of the resinous extracts might be used as a criterion for the extent of seasoning of teak wood. The results obtained by this method were not encouraging, but another is indicated wherein the percentage of a white, crystalline body obtained from the wood by steam distillation is used as an index of the amount of seasoning.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts 5 and 6 for 1912, contain the following memoirs communicated to the society:—

October 28, 1911.—F. **Klein** and M. **Brendel**: Materials for a scientific biography of Gauss. ii., Fragments on the theory of the arithmetico-geometric mean from the years 1797–99, explained by L. Schlesinger.

December 23, 1911.—Th. von **Kármán**: The mechanism of the resistance experienced by a body moving in a fluid.

January 13, 1912.—L. E. J. **Brouwer**: The topological difficulties in proving the continuity of the existence-theorem for one-valued reversible polymorphous functions on Riemann's surfaces.

February 18.—L. **Geiger** and B. **Gutenberg**: Seismic waves. vi., Constitution of the interior of the earth, derived from the intensity of longitudinal and transversal seismic waves, with some observations on prodromals.

March 2.—G. **Tammann**: The dependence of crystalline form upon temperature, and on re-crystallisation in conglomerates.—L. **Bieberbach**: $\Delta u = e^u$ and the automorphous functions.

BOOKS RECEIVED.

Memoirs of the Geological Survey, Scotland. The Geology of the Districts of Braemar, Ballater, and Glen Clova. By G. Barrow and E. H. C. Craig, with contributions by L. W. Hinxman. Pp. vi+138. (London: H.M. Stationery Office.) 2*s.* 6*d.*

Transport de Force. By C. Le Roy. Première Partie. Pp. ii+172. (Paris: A Hermann et Fils.) 6 francs.

" To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

INDEX NUMBER.

No. 2243, Vol. 90] THURSDAY, OCTOBER 24, 1912 [Price One Shilling

Registered as a Newspaper at the General Post Office.]

THURSDAY, OCTOBER 24, 1912.

THE DAWN OF LAND VERTEBRATES.

American Permian Vertebrates. By Prof. S. W. Williston. Pp. v+145+38 plates. (Chicago, Ill.: The University of Chicago Press; Cambridge [Eng.]: University Press, n.d.) Price 10s. net.

IT is now evident that not only amphibians, but also reptiles with considerable diversity of habits and structure, arose in several parts of the world before the close of the Carboniferous period. It is thus becoming more and more difficult to interpret the relationships of the numerous genera—even those known by complete skeletons—which have already been described from the Permian rocks of Europe, North America, Brazil, and South Africa.

Some years ago, when only a few types were known, the direct passage from amphibians to reptiles, and that from these early groups to mammals, seemed to be almost discovered; but later researches have complicated rather than simplified the problem, and at present no satisfactory classification is possible. Realising this position, Prof. Williston and his colleagues are devoting themselves to a precise description of the numerous important skeletons and skeletal fragments which they have obtained from the Permian of Texas and New Mexico, and the small, well-illustrated volume now before us is one of the results. As Prof. Williston truly remarks, "the chief need in the palæontology of the early vertebrates is more facts," and students will gratefully accept the rich collection offered to them in his new work.

Photographs of restored skeletons of the theromorph reptiles Varanosaurus and Casea are given to show how astonishingly similar is their general aspect to that of the contemporaneous amphibian Eryops. Other figures and descriptions suffice to indicate that there is no longer any single skeletal character by which an early reptile can be distinguished from an early amphibian; but Prof. Williston thinks that when the sum-total of characters of a skeleton is considered, there is still no difficulty in assigning the specimen to its true place in one or other of the two classes.

In some groups the various modifications of the skull seem likely to prove as numerous as those observable among modern lizards, so that caution is necessary in dealing with fragments. These and other difficulties, however, can only be recognised and overcome through the progress of such technical and detailed descriptive work as that which we welcome from the professor of palæontology in the University of Chicago.

A. S. W.

SCIENCE OF THE SOIL.

Soil Conditions and Plant Growth. By Dr. Edward J. Russell. Pp. viii+168; with diagrams. (London: Longmans, Green and Co., 1912.) Price 5s. net.

"HOW the chemist can help the farmer. He can analyse the soil and the crop, and by comparing the results of his analyses, can tell the farmer how to manure his land so as to grow profitable crops." The above is a quotation, as nearly as the writer can remember, which formed the preface to a syllabus on which he was asked to give a course of local lectures about twenty years ago, when local lectures were in full swing under the newly-constituted technical education committees of the county councils.

At that time there was some excuse for such misconceptions, for the literature of the somewhat hybrid subject known as agricultural chemistry was scattered through numerous periodicals, mostly in foreign languages, and by no means easily accessible to the budding lecturer. Since then many excellent text-books have been written, and are now in the hands of both teachers and students. None of them, however, go to the root of the matter, and give the substance of the classical researches which should form the foundations of the faith of the agricultural chemist, as does Dr. Russell's excellent monograph.

Dr. Russell has made a comprehensive survey of the literature of the subject so far as it deals with the relations between the soil and the plant. He has succeeded in giving the gist of the more important and fundamental contributions to the knowledge of the subject, and in pointing out with true critical spirit what is really proved to demonstration and in what directions further investigation is necessary.

His book will be of the greatest use both to the teacher of agricultural chemistry and to the investigator—to the latter especially, as it will put him in touch with the literature of the subject. It can scarcely fail to stimulate in this country the output of definite experimental work on the various problems connected with plant-growth. The chapter on soil analysis and its interpretation will be particularly welcome to the staffs of the several colleges who are engaged on soil surveys of their own districts, or are contemplating such surveys. It should do much towards guiding their work on to really useful lines.

The book is printed and issued in the same style as the other well-known "Monographs on Biochemistry." It is singularly free from errors of all kinds, but there is a slip on p. 91, where the formula of potassium phosphate is written K_2PO_4.

T. B. W.

PHILOSOPHY AND PSYCHOLOGY.

(1) *Outdoor Philosophy: The Meditations of a Naturalist.* By Stanton Davis Kirkham. Pp. xii+214. (New York and London: G. P. Putnam's Sons, 1912.) Price 5s. net.

(2) *An Introduction to Psychology.* By Prof. Wilhelm Wundt. Translated from the second German edition by Dr. Rudolf Pintner. Pp. xi+198. (London: George Allen and Co., Ltd., 1912.) Price 3s. 6d.

(3) *The Composition of Matter and the Evolution of Mind. Immortality a Scientific Certainty.* By Duncan Taylor. Pp. 176. (London and Felling-on-Tyne: The Walter Scott Publishing Co., Ltd., 1912.) Price 3s. 6d.

(4) *The Triuneverse: A Scientific Romance.* By the author of "Space and Spirit." Pp. xiv+221. (London: Charles Knight and Co., Ltd., 1962!) Price 5s. net.

(1) THIS book is a pleasure and a refreshment to read. It is not exactly science, or philosophy, or religion, but it partakes of all three, and each is at its best in Mr. Kirkham's pages. Further, the literary quality, apart from the matter, is excellent. It is not too much to say that the reader is continually reminded of Emerson and Thoreau, by whom, indeed, the author has been influenced and inspired; yet there is no plagiarism—we feel the originality of his nature-impressions. "Something in me, deaf to all preaching, responds to that bluebird's note." "And there is the sky—the unimproved sky—the only dome that gives room for thought, the only roof that does not sometimes seem too near." Our life is sick and artificial: the birds and beasts and trees are sounder and saner than we, though they know nothing of soundness and sanity. With our book-learning and our words, words, words, we confuse ourselves until we forget to learn from Nature at first hand. Let us go to the woods and listen, the sweet wind washing us clean of morbid artificialities, and refreshing us after our contact with a "too garrulous and gregarious world."

An admirable book. May it be widely read!

(2) This is a popular introduction to the Wundtian psychology. It is translated from the second edition of the work which has had such a remarkable success in Germany. The author begins with metronome-experiments, showing the scope of consciousness and its "rhythmical" nature, with the difference between apprehension and apperception. He then proceeds to differentiate sensation and idea (simple and complex awarenesses), giving his own and rather unusual meaning to the latter word, which with most writers means a complex that does not arise from direct outward impressions. There is much to be said in favour of the Wundtian use. From this we go on to association and feeling, and the growth of abstract concepts from concrete ones perceptions. The last chapter deals with the "laws of psychic life," holding close to psychophysical parallelism (which truly needs emphasising, in view of Bergson's ably urged heresies in "Matière et Mémoire"), and admonishing metaphysics to base itself on facts and to beware of abstractions.

Prof. Wundt and his translators are to be thanked. In this volume they give us the best elementary book of its size and kind that exists in English.

(3) The sub-title will probably have an effect contrary to the expectations of the author. Thoughtful readers—still more men of scientific training—are rendered at once suspicious by "certainties," and are apt to avoid books which make great claims. And, indeed, in this case they would be justified. The book is a queer collection of incoherent paragraphs, and, so far as the present reviewer can see, does not prove anything. Such paragraphs as are comprehensible often contain the most reckless statements, as, *e.g.*, "we know that the solar system itself, with its full-orbed, glorious centre, is circling round a greater centre" (pp. 12, 13). Similarly, the planetary structure of the atom is too stiffly put. These things may be true, but at present they are not more than provisional hypotheses or even (as in the astronomical sentence) wild guesses. We sympathise with the author's aims and feelings in certain points, but he should have made his book more carefully accurate and more coherent. He jumps about too much from physics to metaphysics—Christ and gravitation, God and æther, omniscence and mass. If we may be permitted the phrase, we might say that he seems to have got intoxicated on M. le Bon.

(4) One gets rather tired of these "Looking Backward" books, which usually follow Mr. H. G. Wells, *longo intervallo.* The one under review begins at 1950 A.D., and opens with a description

of some astronomers watching Mars split into two, then into four, and finally into about 500 bits. This cluster then proceeds to swallow Jupiter and Saturn; the sun blows up, and the earth starts off somewhere on a wild career, with a piece of sun just big enough to keep it fairly warm. Then two of our astronomers suffer a magical shrinkage in size, entering the infratonic (less than electronic) world. And here we may as well leave them, for NATURE is a scientific journal, and this book, though a romance of science, is more of the former than the latter.

(8) *Chemical Theory and Calculations.* An Elementary Text-book. By Dr. F. J. Wilson and Dr. I. M. Heilbron. Pp. iv+138 (London: Constable and Co., Ltd., 1912.) Price 2*s.* 6*d.* net.

(1) DR. PRICE'S monograph on the per-acids and their salts is the second volume of a series of monographs on inorganic and physical chemistry, the previous volume (Mr. Soddy's book on the chemistry of the radio-elements) having been reviewed recently in these columns. One half of the book is occupied with an account of the persulphuric acids and persulphates, the remainder of the volume dealing with perborates, percarbonates, pernitric and perphosphoric acids; pertitanates, perzirconates and perstannates; pervanadates, percolumbates, and pertantalates; perchromates; permolybdates, pertungstates and peruranates. The new volume will go far to establish the reputation of the series for thoroughness and utility. More than three hundred references are given to the literature of a subject which would scarcely have been credited by the ordinary readers with having provided material for one-half this number of papers.

A word of comment may be added in reference to the author's criticism of the view that in presence of concentrated sulphuric acid, the peroxidised material consists mainly of pertetrasulphuric acid, $H_2S_4O_{14}$. Such solutions on dilution undoubtedly yield an oxidised acid of the formula H_2SO_5. But the appearance of this acid is quite compatible with its formation by hydrolysis on the dilution of a solution containing the higher acid, as shown by the equation

$$H_2S_4O_{14}+3H_2O=3H_2SO_4+H_2SO_6;$$

such a hydrolysis would not disturb the ratios of "persulphuric oxygen" to "peroxide oxygen," on which the formula $H_2S_4O_{14}$ was based. The hydrolysis of Marshall's acid to Caro's acid, as shown by the equation

$$H_2S_2O_8+H_2O=H_2SO_5+H_2SO_4,$$

by dissolving it in concentrated sulphuric acid and then diluting, presents some analogy to the conversion of ethylene into alcohol by a similar process; in each case the initial process may very well be a condensation of the hydrolyte with the acid to form a more complex substance, which is then easily hydrolysed on dilution.

(2) The third volume of Messrs. Cross and Bevan's "Researches on Cellulose" covers the five years from 1905 to 1910, but has been delayed to include research work published in 1911. Special interest attaches to the final chapter on technical developments, in which a brief account is given of some important modern cellulose industries. It is noted that in the artificial silk industry the last five years have been marked by rapid developments, accompanied by a rapid gravitation to the level of competitive prices. This has arrested the development of the collodion processes, and has accentuated the struggle between the cuprammonium and viscose processes, in reference both to relative costs and to the textile qualities of the products. A remarkable development consists in the production of transparent films of viscose in lengths of 1000 to 10,000 metres at an average width of a metre, and at a thickness of 0·25 down to 0·01 mm. In view of the fact that the process involves (1) coagulation, (2) purification from sulphur, (3) bleaching and purification by special washings,

and (4) drying, and, moreover, that the shrinkage in width may amount to 30 to 40 per cent., this accomplishment is little short of marvellous. It is accomplished by a single machine, but this has a length of 50 to 60 metres. The material can be coloured and embossed in a very effective way, as is shown by a series of seven samples enclosed with the volume. Experiments are also described on cellulose acetate, which serves, amongst other purposes, as an excellent material for insulating the wire of galvanometers and other instruments in which its extreme thinness gives it a marked advantage.

(3) Mr. Pope's book on modern research in organic chemistry is one of those useful summaries of research work that have formed a conspicuous feature of recent publications. The subjects selected are the polymethylenes, terpenes and camphors, the uric acid group, the alkaloids, colour and constitution, salt-formation, pseudo-acids and bases, the pyrones, ketenes, ozonides and triphenylmethyl and the Grignard reaction. The work has been well and thoroughly done, and full bibliographies are given. The book will therefore be of considerable service both to honours students and to teachers who are not able to acquire complete series of the journals in which original papers are published, but will be glad to place this book upon their shelves.

(4) The "Second Year Course of Organic Chemistry" deals with the carbocyclic compounds, and does not differ very widely in its treatment from other books of a similar type. Some of its most valuable features are found in the appendices, which contain a scheme for qualitative organic analysis and tables of physical constants, suitable for use in identifying organic compounds.

(5) This little book covers a course of elementary chemistry which should be completed in two years by a class working two hours a week. It is based upon the report presented at the Newcastle-upon-Tyne meeting of the British Association by the committee formed to investigate the methods of teaching chemistry. The author claims to have been one of the first to put the suggestions of that committee to a complete practical test in the laboratory. He has found it advantageous to short-circuit the heuristic method in its strictly historical form, and thus finds a proof of the presence of oxygen in lime by direct combustion of metallic calcium. In one respect he has broken away from a hoary tradition, and in reconstructing Lavoisier's decomposition of the oxide of mercury has provided a spirit-lamp as a source of heat in place of the Bunsen burner usually introduced into the picture. It is unfortunate that he should have introduced the terms monoxide and dioxide before the significance of these terms can be explained; as a matter of historical treatment the anachronism may be pardoned in a book that does not profess to teach history, but there would be a great logical advantage in using in place of "carbon dioxide" one of the earlier names, "fixed air," "carbonic acid gas," or "carbonic anhydride."

(6) The "First Year's Course of Chemistry" is arranged in such a way that the experimental work of each lesson occupies the earlier part of each chapter, and is followed by a discussion of the results of the experiments. This system, which has been adopted in at least one other class-book of chemistry, possesses obvious advantages in actual practice, as it agrees with the system followed in the laboratory. The course is intended to occupy a single session, with an allowance of three or four hours per week on the time-table, and covers much the same ground as the volume noted in the preceding paragraph, the direct combustion of calcium being used here also to prove the nature of lime.

(7) The Tutorial "Elementary Quantitative Analysis" describes the simplest forms of gravimetric and volumetric analysis. A conspicuous feature of the book is the introduction of a large number of problems as variants on the usual direct analyses. These resemble closely the problems set in recent examinations, and will doubtless serve to brace the student to face the ordeal of a practical test in quantitative analysis.

(8) The text-book on chemical theory and calculations is primarily intended to provide a series of numerical examples of the different types of calculations that are likely to occur in a course of chemistry. The text is confined almost entirely to stating the theories and describing the apparatus involved in the problems, but some half-dozen chapters have been included which deal with subjects, such as the periodic classification of the elements, which do not lend themselves to numerical exercises. T. M. L.

OUR BOOKSHELF.

Handbook of the Technique of the Teat and Capillary Glass Tube, and its Applications in Medicine and Bacteriology. By Sir A. E. Wright, F.R.S. Pp. xvi+202. (London: Constable and Co., Ltd., 1912.) Price 10s. 6d. net.

In this book Sir Almroth Wright gives a full account of the ingenious apparatus and methods which he and his co-workers have evolved for making quantitative estimations, principally in connection with the blood and other body fluids. It is generally not possible in this kind of work to deal with quantities greater than a small fraction of a cubic centimetre, and therefore ordinary graduated pipettes and measures are not applicable. It is true that graduated pipettes to deal with such small quantities are obtainable, but they are costly, and it would be out of the question to employ them in the numbers and in the manner required, for instance, for opsonic determinations. As the author says, "it is a technique for conducting quantitative tests in uncalibrated capillary tubes with minimal quantities of reagents."

Briefly, the method consists in the use of glass pipettes, formed by drawing out a piece of glass tubing in the blow-pipe flame into a fine stem. By adapting a suction apparatus in the form of a rubber teat to the undrawn-out portion, and making a mark somewhere on the drawn-out stem, we have the means of taking up any number of minute similar volumes of a fluid and of making any mixtures of fluids and dilutions thereof required with considerable accuracy.

By an adaptation of these principles, Sir A. Wright has devised methods for estimating the bactericidal, agglutinative, and opsonic powers of the blood, for measuring the coagulation time of the blood, and for estimating quantitatively its alkalinity, content of magnesium and calcium salts, and anti-tryptic power. The making of blood-films and preparation and standardisation of therapeutic vaccines are also dealt with.

Full details are given for the manipulation of the glass in the blow-pipe, the making of the apparatus required, and the carrying out of the various procedures. The descriptions are supplemented by a profusion of illustrations in the text and five plates, four of which are coloured. Truly no bacteriological or pathological laboratory can afford to omit this book from its working library, and we fancy that the chemist and physicist might gather some hints of value from it.

R. T. Hewlett.

Lines in the Arc Spectra of Elements. By F. Stanley. Pp. 140. (London: Adam Hilger, Ltd.) Price: cloth, 12*s.* 6*d.*; half-morocco, 15*s.* 6*d.*

In this publication the wave-lengths of the chief lines in the arc spectra of fifty-five elements are given. These are arranged in one long table in the order of the wave-length numbers. The intensities of the lines in the spectrum of the undiluted element are also given on a scale of 1 to 10, the latter denoting the brightest lines. In a separate column and on the same horizon as any particular line will be found the wave-length of the next prominent line belonging to the corresponding element. This is very useful in determining whether any element is present in a substance under investigation. The most persistent lines of any given element—that is, the lines which last longest as the proportion of the element in question is gradually decreased—are specially denoted. The wave-lengths, which extend from λ 7900 to λ 2200, are given to the nearest tenth of an Angström unit, and have been taken from the most recent and trustworthy measures available. The pages opposite the wave-length tables are left blank for the insertion of notes. To practical workers in elementary spectroscopic analysis the compilation will be decidedly useful.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

X-rays and Crystals.

Messrs. Friedrich, Knipping and Laue have recently published (*K. Bayer. Akad. der Wiss.*, 1912, p. 303) some remarkable effects obtained by passing a fine stream of X-rays through a crystal before incidence upon a photographic plate. A curious arrangement of spots is found upon the plate, some of them so far removed from the central spot that they must be ascribed to rays which make large angles with the original pencil.

The positions of these spots seem to depend on simple numerical relations, and on the mode in which the crystal presents itself to the incident stream. I find that when the crystal (zincblende) is placed so that the incident rays are parallel to an edge of the cube in the crystal the positions of the spots are to be found by the following simple rule. The atoms being assumed to be arranged in rectangular fashion, any direction which joins an atom to a neighbour at a distance na from it, where a is the distance from the atom to the nearest neighbours and n is a whole number, is a direction which a deflected (or secondary) pencil will take, and it will in doing so form one of the spots. In other words, we have to seek for all the cases in which the sum of three squares is also a square, and we then recover the positions of all the spots on the diagram. For example, secondary pencils take the directions (2, 3, 6) (4, 1, 8), and so on. In a few cases the sum of the squares is one short of a perfect square, *e.g.* (5, 7, 11), but in no case is it on the greater side; and there is at least one direction (2, 5, 14) which ought by the rule to be on the diagram and is not. Otherwise the rule is quite successful.

Until further experimental results are available, it is difficult to distinguish between various explanations which suggest themselves. It is clear, however, that the diagram is an illustration of the arrangement of the atoms in the crystal.

The rule has suggested itself to me as a consequence of an attempt to combine Dr. Laue's theory with a fact which my son pointed out to me, viz. that all the directions of the secondary pencils in this position of the crystal are "avenues" between the crystal atoms.

Leeds, October 18.

Glaciation and Striation.

In your issue of September 26, Dr. A. Irving asks whether in my plate 17 (Phil. Trans., Ser. B., vol. ccii) I have not overlooked the fact that the striations are on the original cortex of the flint nodule. My answer is that I have not done so; the striations are *not* on the original cortex of the flint nodule—as is clear both from my description of the specimen and from the carefully drawn figure.

Dr. Irving also asks whether I have overlooked the probability that the markings shown in Fig. 2 are the etched-out skeletons of some spongoid fossil. My reply is that no such probability exists, and that, in consequence, I have not overlooked it.

Your correspondent appears to be under some misapprehension. He has never seen the specimen referred to. Moreover, he is mistaken in supposing that I am not acquainted with the facts and theories as to the structure and history of flint in its various conditions. As a matter of fact, this subject has occupied my attention during the greater part of a lifetime.

The specimens of "worked" flints from the sub-Crag detritus-bed—dealt with in my recent paper in the Phil. Trans.—have now been presented to the Department of Ethnology of the British Museum (Bloomsbury), and it is now possible, for those who wish to do so, to study the actual material upon which my statements are based, and to discuss them with the needful preliminary knowledge of the things under discussion. E. RAY LANKESTER.

29 Thurloe Place, South Kensington.

Nautilus Pearls.

THE letter from Mr. H. Lyster Jameson in the last number of NATURE reminds me that I have in my possession a small pearl that is alleged to have been found in a Nautilus. It was given to me by a Dutch magistrate in North Celebes, who had in turn received it from a native. It is irregularly pear-shaped, and weighs 2·75 grains.

As there is so little substantial evidence that this or any other pearl or stone has really been formed within the body of a pearly Nautilus, I have never felt disposed to assert that I possess a Nautilus pearl. However, there can be no doubt whatever that there is a widespread belief among the natives of the Malay Archipelago and Polynesia that such pearls are occasionally found, and although in the Sulu Archipelago, according to Mr. Haynes's account, they are regarded as unlucky, in Celebes they are treasured as charm stones that bring good fortune.

Rumphius, in his "D'Amboinsche Rariteitskamer," published in 1702, gives a description of such a stone found in a Nautilus, and relates an interesting story connected with it. He says that the stone belonged to a Chinese woman in Boero, who had kept it in a little box and treasured it as a charm. One day she discovered that it had given birth to another small pearl, and later on two other small pearls were born in a similar manner. This statement reminded him of the story told by Pliny in Lib. 37 of the reproductive stones called Peantides and Gemonides.

SYDNEY J. HICKSON.

The University, Manchester, October 18.

Sailing Flight of Birds.

THERE can scarcely be a doubt that Prof. E. H. Hall has given, in NATURE of October 10, the true explanation of the sailing flight of gulls when they follow a ship without any movement of their wings. When there is a fairly strong head-wind or a wind which, without being strictly a head-wind, makes a small angle with the line of the ship's course, the gull has an up-current of air provided for him which will not only support him, but which, if he inclines his body (and supporting surfaces generally) slightly downward, will enable him to make headway.

Sometimes the gull will hang directly over the stern, at others slightly to windward, at others, but I think not so often, slightly to leeward. Some experiments which I once made with a vane that worked vertically showed that when the wind strikes a bank six feet high at right angles, there is a steady up-current four yards to windward. Five yards to leeward there was a down draught, and some ten yards to leeward irregular up-and-down draughts. Recently in Texel I frequently saw gulls hovering with motionless wings a few yards to windward of embankments some twenty feet high. F. W. HEADLEY.

Haileybury (Hertford), October 13.

The Zodiacal Light.

As of possible interest to some of your readers I beg to report to you a phenomenon which I have observed here during the last ten days. It may be described as follows: every evening after sunset when twilight has completely died out of the western sky there is observable an illumination, starting due west and extending upwards to a height of about 40° above the horizon, fading away towards the top; in character it is much like the Milky Way, a little broader at its base, slightly less brilliant but more uniform. It extended this evening (August 10) from a point due west at 7.30 p.m., Gallegos mean solar time, upwards to a height of about 35° from the horizon, in the direction of the planet Jupiter, inclining towards the north at an angle with the horizon of about 60°. A curious fact I noticed in connection with this phenomenon was that it was best observed when the rays from it were allowed to fall on the periphery of the retina, as when the eyes were fixed on a point about 20° distant. It could be observed for about two and a half hours after sunset, gradually setting in the west. I presume this is the zodiacal light, but as I never noticed the same phenomenon in these latitudes (51° south) before, I thought it worth while mentioning the fact. E. G. FENTON.

Rio Gallegos, Patagonia, Argentine Republic, August 10.

Colours of Plasmodia of Some Mycetozoa.

To my communication under this heading that appeared in NATURE of June 23, 1910, p. 489, allow me to make the following additions:—

Species of Mycetozoa.	Colours of Plasmodia.
Physarum variabile, Rex, var. *sessile*, Lister	Orange yellow.
Colloderma oculatum, G. Lister	Dingy watery-white with greenish or olivaceous tinge, then ochraceous, ultimately ferruginous and dirty throughout.
Cribraria intricata, Schrad.	Pitch-black when the plasmodium is thick, and oil-brown when it is thin; in either shade it closely simulates the solution of asphalt in oil of turpentine.
Perichaena chrysosperma, Lister.	Stated to be pale brown in Lister's "Monograph," second edition, 1911, p. 248, but I found it to be pallid pink.
Craterium concinnum, Rex.	Said to be yolk-coloured in the same work, p. 95, but I found it milky, then cream-coloured.

Since my letter above mentioned was published, I have gathered nineteen species new to Japan, which make the native Mycetozoa taken altogether amount to 105 species, of which three are new to science, viz. *Arcyria glauca*, Lister, *Hemitrichia minor*, G. Lister, and *Diachaea robusta*, G. Lister.

KUMAGUSU MINAKATA.

Tanabe, Kii, Japan, September 17.

THE "MICHAEL SARS" IN THE ATLANTIC.[1]

THE cruise of the *Michael Sars* in the North Atlantic in 1910 has shown what a great deal of excellent work in investigating the deep waters of the ocean can be done by a comparatively small vessel, when the best possible equipment is provided, and men of exceptional competence and experience are in charge. Sir John Murray's judgment was sound when, instead of fitting out *de novo* a larger vessel for the investigations he wished to carry out in the Atlantic, he arranged with the Norwegian Government for the use of its fishery research steamer, a vessel only 125 feet long and of 226 gross tonnage, together with her scientific staff and crew. The immense advantage of proved men, accustomed to work together, and each thoroughly competent in his own particular line, for the successful execution of investigations of the very difficult kind which were undertaken by this expedition cannot be overestimated.

The work of the expedition was not only well done, but the results are being well presented both to the scientific and to the lay public. The detailed scientific reports are to be published in a series of volumes issued by the Bergen Museum, and will without doubt constitute a valuable and permanent addition to our knowledge of the physical and biological conditions of the Atlantic. The book now under review is designed to appeal to a wider public, and from the interesting way in which the facts are presented and the large number of excellent illustrations which it contains, it can scarcely fail to achieve its purpose. Although the book is chiefly devoted to an account of one particular expedition, Sir John Murray and Dr. Hjort have taken the opportunity, as the sub-title indicates, of placing before the public "a general account of the modern science of oceanography." The success with which the authors, and those who have collaborated with them, have carried out their task makes "The Depths of the Ocean" by far the best English book from which the general reader can gain a trustworthy knowledge of the aims and progress of the modern science of the sea.

Within the limits of a single article it would be quite impossible to give any adequate account of the wealth of interesting matter which this large volume contains. It will only be possible, therefore, whilst noting the general contents of the several chapters, to direct special attention to some of the questions upon which the results of the *Michael Sars* expedition have thrown new light.

The first chapter, on the history of oceanographical research, is written by Sir John Murray. It condenses and brings up to date the well-known historical account of the subject which Sir John wrote for the "Summary" volume of the *Challenger* reports. If a word of criticism may be allowed, it seems a pity that the more recent work around the coasts of north Europe, more particularly that done in connection with the international investigations, receives such slight reference. We should have been glad to see some more detailed notice of the brilliant achievements of the Danish workers in the North Atlantic, and one would have expected a good Scotsman like Sir John Murray to have at least mentioned the important work done by the Scottish Fishery Board, even though he did not consider that carried out by England and by Ireland as worthy of a place.

FIG. 1.—S.S. *Michael Sars* in Plymouth Harbour. From "The Depths of the Ocean."

In the second and third chapters Dr. Hjort gives a narrative of the cruise, with many details of the equipment of the ship and the methods of work. The feature of most interest to the working naturalist is perhaps the account of the number of different pieces of apparatus for capturing pelagic animals which it was found possible to work at one and the same time. As many as nine or ten nets, including two or three Petersen young-fish trawls and some very large tow-nets, were towed together at different depths, and appear to have worked well.

[1] "The Depths of the Ocean." A General Account of the Modern Science of Oceanography based largely on the Scientific Researches of the Norwegian Steamer *Michael Sars* in the North Atlantic. By Sir John Murray, K.C.B., F.R.S., and Dr. Johan Hjort. Pp. xx+821. (London: Macmillan and Co., Ltd., 1912.) Price 28s net.

Sir John Murray's principal contribution, which is on the depths and deposits of the ocean, constitutes chapter iv. The chapter is mainly devoted to a general account of these subjects. Written as it is by the greatest living authority, in a style as interesting as it is scientifically accurate, it cannot fail to be welcome to all who wish to learn the present position of our knowledge of the configuration of the ocean basins and the nature of the deposits which lie upon their floors. The section dealing with the mineral collections obtained during the cruise of the *Michel Sars* is by Drs. Peach and Horne, who examined the specimens. The most interesting fact recorded by them is the discovery of glaciated stones, some of which are illustrated, at a depth of a little more than a mile, at a point 230 miles south-west of Mizen Head, Ireland.

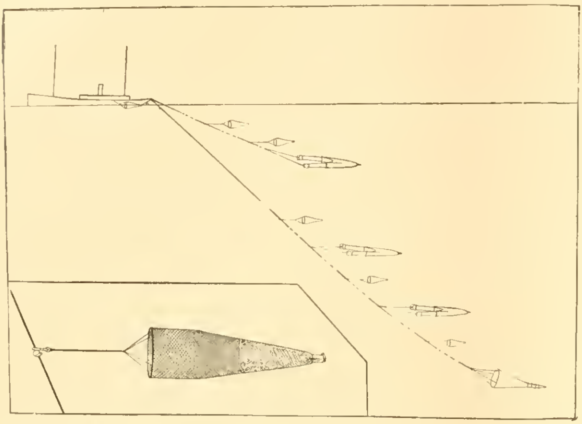

Fig. 2.—The *Michael Sars* towing ten nets and pelagic trawls (surface net not shown). From "The Depths of the Ocean."

Dr. Helland-Hansen's chapter on physical oceanography is certainly the best summary of the modern aspects of this subject which has yet appeared in English. Of the work of the expedition itself the striking features are the direct measurements of the currents entering and leaving the Mediterranean through the Straits of Gibraltar, the determination of the depths to which an amount of light penetrated sufficient to produce an effect on photographic plates, and the very close agreement which was found in the deep-water temperatures taken by the best modern instruments with those taken at the same stations by the *Challenger* expedition more than thirty years before.

Dr. Helland-Hansen is followed by Prof. Gran, with an account of the pelagic plant life, one of the most interesting chapters of the whole book. The general subject is treated in a masterly way, and the importance of these minute vegetable organisms, forming as they do the fundamental food supply of the ocean, cannot be overrated. The special contribution of the expedition to the advancement of this subject is the discovery, by means of a large centrifuge worked by the steam-winch of the vessel, of the extraordinary abundance of the most minute plankton forms, especially in the warmer seas. These forms are so small that they pass through the meshes of the finest silk nets, yet they occur in such vast quantities that they constitute in these waters perhaps the most important part of the pelagic plant life.

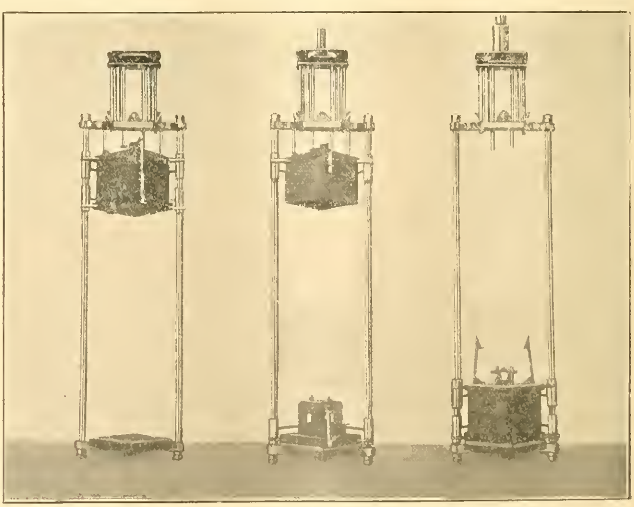

Fig. 3. Helland-Hansen's photometer. On the left, as it is sent down; in the middle, open for exposure; on the right, closed and ready for hauling up. From "The Depths of the Ocean."

Sections dealing with the bottom fauna are contributed by Dr. Hjort and Dr. Appellöf in chapters vii. and viii., the former writing on the fishes, the latter on the invertebrates. It is a task of no little difficulty to treat such extensive subjects in a concise and yet comprehensive way. With the help of a large series of figures illustrating the numerous species mentioned, both authors have succeeded well, and it is to be hoped that their efforts may result in reviving popular as well as general scientific interest in these branches of marine biology, which, fascinating as they are, have rather tended to become of late years entirely relegated to specialists on particular groups.

Following these, chapter ix., on pelagic animal life, by Dr. Hjort, contains perhaps the largest proportion of original matter to be found in the book. This is due to the fact that the collecting gear chiefly used by the expedition consisted of townets and large pelagic nets of various patterns, all of them of very much greater fishing capacity than the nets which have previously been used in ocean work. From the nature of the results already reached—and the material has as yet been only partially worked out—it seems clear, as Dr. Hjort maintains, that the qualitative results obtained by the use of these large nets towed for long periods give a more correct and comprehensive picture of the free-swimming life of the Atlantic than was obtained with the relatively small nets used by the German plankton expedition, the material from which Prof. Hensen and his helpers have attempted to work out quantitatively at the cost of such vast labour.

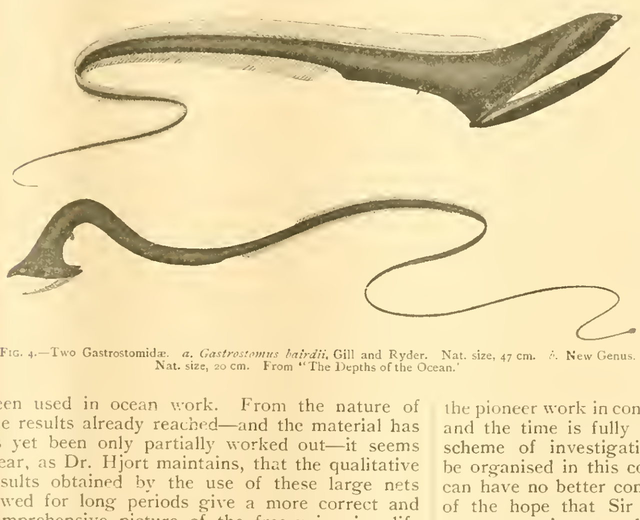

FIG. 4.—Two Gastrostomidæ. *a. Gastrostomus bairdii*, Gill and Ryder. Nat. size, 47 cm. *b*. New Genus. Nat. size, 20 cm. From "The Depths of the Ocean."

The final chapter, entitled "General Biology," is also written by Dr. Hjort. It deals with innumerable problems of scientific importance in a most suggestive and stimulating way, and maintains the high standard of the whole book to the end. Among the numerous questions dealt with are the colours of marine animals and their relation to the conditions in which these animals live, phosphorescence and luminous organs, the eyes of deep-sea fishes and the meaning of the great variations in their size in different species, the factors which influence the floating of pelagic organisms, and the organs which are special adaptations for floating.

One other subject in this final chapter must not be passed without notice—namely, the valuable contribution made by the *Michael Sars* expedition to the wonderful story of the life-history of the fresh-water eel. The expedition secured numerous eel larvæ of stages much younger than any previously found, and from the distribution of these larvæ the conclusion seems justified that the eel spawns south of the latitude of the Azores, and the larvæ are later carried into the northern North Atlantic and towards the coasts of northern Europe by the Gulf Stream.

Nothing could be more calculated than this book to awaken fresh interest in the importance of the thorough and complete investigation of the problems of the great oceans. A knowledge of the changes which take place from season to season and from year to year in the Atlantic would be of incalculable value to every country in Europe, for there can now be scarcely a doubt that it is upon these changes that the variations in the yield of the harvests both of the land and of the sea are mainly dependent. These changes can never be ascertained by single cruises such as that of the *Michael Sars*, brilliantly though that cruise was carried out. What we now want is systematic and sustained researches extending over a period of years. Great Britain did the pioneer work in connection with ocean research, and the time is fully ripe when a comprehensive scheme of investigation in the Atlantic should be organised in this country. The present notice can have no better conclusion than the expression of the hope that Sir John Murray will use his great experience and commanding position in trying to ensure that the British Government should make the necessary provision for such an investigation.

E. J. ALLEN.

THE SWISS SOCIETY OF NATURAL SCIENCES.

THE Société Helvétique des Sciences naturelles, which, in Switzerland, takes the place of a scientific academy, and is the centre of all concerted action in the scientific life of that country, held its annual reunion at Altdorf, in the canton of Uri, on September 8–10.

The first day was devoted to a general assembly, at which various matters were discussed, and some general addresses also delivered. Profs. Kovalski, Wiechert, and Weiss reviewed recent work on radiations, atmospheric electricity, and the *rôle* of magnetic phenomena in the study of molecular and atomic conceptions. The second day was devoted to meetings of sections, at which a great number of communications were presented on mathematics, physics, chemistry, geology and mineralogy, botany, and zoology. Finally, on the concluding day another general assembly was held, again devoted to administrative matters and general addresses, among which may be specially mentioned that by Prof. Chodat, on vegetable pigment, and that by Dr. Paul Sarasin, on the Swiss National Park.

The Société Helvétique des Sciences naturelles, founded at Geneva in 1815, has been the moving spirit in many important scientific undertakings in Switzerland. It has successfully created, or, at least, been the means of creating, the fine topographical map of Switzerland, the geological, geodetical, and meteorological services, the investigations of earthquakes, glaciers, rivers, lakes and marshes. The various branches of work are directed by special commissions or committees, selected from the Society's ranks, which send in reports annually; they receive grants from the Swiss Government totalling annually about 80,000 francs (3200*l*). As each branch expands in course of time, and grows in importance, it is usually taken over by the Swiss Government and given an independent organisation. It is in this way that the Swiss Federal Services of Topography and Meteorology have originated, and the seismological service started and organised by the Society is now passing into the hands of the Federal Government in like fashion. By way of counterpoise, the creation of a new commission was decided at the Altdorf meeting, to be charged with organising studies and regular observations of atmospheric electricity.

But of all the recent activities of the Society, the most interesting for its importance and bearing is the work of the Commission for the Protection of Natural Sites, organised in 1906, which has culminated in the creation of a magnificent national park, situated in the lower valley of the Inn (Grisons), one of the wildest parts of the Swiss Alps. In accordance with contracts made with the commune of Zernez and various neighbouring communes, an uninterrupted stretch of territory of about 100 square kilometres area, which it is hoped soon to extend to 200 square kilometres, will be almost completely withdrawn from the interference of man. The flora and fauna, which are here relatively very rich—the region is still frequented by chamois, and a few bears are still met with—will be able to develop freely in accordance with natural laws of evolution. The only exception will be a few roads or paths to give access to the reservation, and some blockhouses constructed for the purposes of repressing poaching, enforcing the prohibition of hunting, and organising a service of regular observations. It will thus be possible to study the formation of a natural "biocénose" on a somewhat magnificent scale—a true "biological refuge" of a most interesting kind.

Part of the territory leased by the Society for the National Park of the Grisons has been taken for twenty-five years, the rest for ninety-nine years. The costs of rent, surveillance, and observations will be defrayed out of funds furnished by a popular league, the "Ligue suisse pour la protection de la nature" (founded under the auspices of the Société Helvétique des Sciences naturelles), the ordinary members of which pay an annual contribution of at least a franc, and the life members a lump sum of at least twenty francs. The Federal Government also has announced its intention of applying to the Chambers for regular annual grants.

The above details, taken from the bulky report of the Central Committee, and from the interesting address of Dr. Paul Sarasin, President of the Commission for the Protection of Natural Sites, prove that Swiss naturalists have made a great achievement. The "Territoire Réservé" of the Grisons is not only the most important in Europe, on account of its extent, but in some respects excels the celebrated American Reservations, which are only partially reserved, and do not form one unbroken block.

THE UNIVERSITY OF BRISTOL.

INSTALLATION OF LORD HALDANE AS CHANCELLOR.

THE installation of Lord Haldane as Chancellor of the University of Bristol on Thursday last, October 17, in succession to the late Mr. H. O. Wills, was made the occasion of a brilliant and memorable ceremony. Bristol, the ancient city of the west, is the youngest of the new universities; and it is peculiarly fortunate in having secured for its chancellor one who represents the modern spirit of organisation and progress. In presenting the deed to the chancellor, Mr. Lewis Fry expressed the profound satisfaction of the University that he had been able to accept the unanimous invitation to become its head. Lord Haldane, in the course of reply, remarked that he had spent a considerable part of his life and such energy as he possessed in endeavouring to forward the cause of the new civic university, and he hoped to be permitted to mould and fashion the operations of this great conception still further in the future.

In honour of the occasion, a large number of honorary degrees were conferred upon men and women distinguished in letters, art, science and public services. Lord Haldane himself received the patent of the honorary degree of LL.D., and among the other recipients of degrees were the following, who were presented in the order given.

M.Sc. (Engineering).—John Munro, professor of mechanical and mining engineering in the University.

M.D.S.—W. R. Ackland, lecturer in dental surgery in the University.

M.Ch.—N. C. Dobson, emeritus professor of surgery in the late University College, Bristol; J. P.

Bush, C.M.G., lecturer in operative surgery in the University.

M.Sc.—Herbert Bolton, director of the Bristol Museum and Art Gallery, and reader in palæontology in the University.

D.Sc. (*Engineering*).—W. Wilson, secretary for higher education to the County Palatine of Lancaster, formerly professor of electrical engineering in the Merchant Venturers' Technical College; H. S. Hele-Shaw, professor of engineering in University College, Bristol; J. Ryan, formerly professor of engineering in University College, Bristol; W. Ripper, dean of the faculty of engineering in the University of Sheffield.

M.D.—R. Shingleton Smith, emeritus professor of medicine in the late University College, Bristol; G. Munro Smith, formerly professor of physiology in University College, Bristol.

D.Sc.—Sydney Young, F.R.S., professor of chemistry in Trinity College, Dublin, formerly professor of chemistry in University College, Bristol; Silvanus P. Thompson, F.R.S., principal of the City and Guilds Technical College, Finsbury, formerly professor of physics in University College, Bristol; W. J. Sollas, F.R.S., professor of geology and palæontology in the University of Oxford, formerly professor of geology in University College, Bristol; Alderman Ernest H. Cook, chairman of the Education Committee of the City of Bristol; Sir Donald MacAlister, K.C.B., Vice-Chancellor of the University of Glasgow, president of the General Medical Council.

D.Litt.—T. H. Warren, president of Magdalen College in the University of Oxford, and professor of poetry in the same University.

LL.D.—D. S. Davies, medical officer of health for the city, county and port of Bristol, lecturer on public health in the University; F. Richardson Cross, special lecturer in ophthalmology in the University; Sir William Henry White, K.C.B., F.R.S., formerly Director of Naval Construction and Assistant Controller of the Royal Navy; Prof. J. Michell Clarke, pro-Vice-Chancellor of the University; Rev. T. Hamilton, Vice-Chancellor of the University of Belfast; Sir Henry R. Reichel, Vice-Chancellor of the University of Wales; Sir Alfred W. W. Dale, Vice-Chancellor of the University of Liverpool; Sir Alfred Hopkinson, Vice-Chancellor of the University of Manchester; the Right Hon. Sir William Mather, P.C.; the Right Hon. Sir Edward Fry, P.C., G.C.B., F.R.S.; the Right Hon. A. H. D. Acland, P.C., sometime vice-president of the Committee of Council on Education.

The following degrees were conferred *in absentia*, the recipients having been unavoidably prevented from attending the ceremony:—

LL.D.—The Prime Minister; the Right Hon. Arthur J. Balfour, P.C., F.R.S.

D.Sc.—Morris W. Travers, formerly professor of chemistry in University College, Bristol.

M.D.—R. Fletcher, librarian of the Surgeon-General's Library, Washington, editor of the "Index Medicus."

It was befitting that, in the presence of a chancellor who has, in more than one capacity, shown high skill in organisation, the proceedings should have been carried out with perfect precision from start to finish, thanks chiefly to the vice-chancellor (Sir Isambard Owen) and the registrar (Mr. James Rafter).

In the evening, Lord Haldane delivered his official address as Chancellor of the University before a large audience, taking as his subject "The Civic University." We give a few extracts from this address.

There was a time when men of business, accustomed to see closely to profit and loss, used to think that the work of a university was worth effort and expenditure only in so far as it produced aptitude for industrial and commercial production. Traces of this view are still apparent in the foundation deeds of some of the older university colleges of our municipalities. But this idea is now discredited, and the part played by science and by general learning in the production alike of the captain of industry and of the extension of invention is far greater than was the case even a few years ago. Applied science is in its best form only possible on a wide foundation of general science. And the fruitful scientific spirit is developed to-day on a basis of high intellectual training, the training which only the atmosphere of the fully-developed university can completely provide.

What is true of science in the narrower sense is also true of learning generally. It is only by the possession of a trained and developed mind that the fullest capacity can, as a general rule, be obtained. There are, of course, exceptional individuals with rare natural gifts which make up for deficiencies. But such gifts are indeed rare. We are coming more and more to recognise that the best specialist can be produced only after a long training in general learning. The grasp of principles which makes detail easy can only come when innate capacity has been evoked and moulded by high training. Our engineers, our lawyers, our doctors, our administrators, our inventors, cannot without it keep in front in the race. The competition is not merely with their fellow-countrymen; it is with the trained minds of other countries. These other countries are some of them advancing at least as rapidly as we are. An enlightened policy in education is the order of the day over most of the civilised world, and if we are to hold our own, even in the making of money, we are not to fall behind or lag in the endeavour to increase our efforts. We have more than ever before to see to it that we keep at least abreast in science, and science means far more now than technical training or the mere application of special knowledge to industry. It rests on a foundation of general culture which is vital to the maintenance of its standards, and it can develop only if the population has the fullest chance of an intellectual and moral training which goes deeper than mere science strictly so-called. It is the power of the highly trained mind that is required, and the full development of this trained mind can only be given by the highly organised universities.

A university to be a true university must be a place where the spirit is more important than the letter. The spirit of the university is the cooperation of professor and student in a common endeavour to learn. A university is a place where the most valuable advantage the student has is contact with an inspiring personality. That is why nothing short of the best level among the professors is enough for success. The professor must inspire. His labour must be one of love if he is to succeed. And if he is a great teacher he will have moulded the lives and tastes of the best of his students for the rest of their existence.

In Germany the technical colleges have been sharply divided from the university and given a separate existence. This is partly due to the division and separation in character of the great secondary schools in Germany. The resulting separation of the technical college from the university has been deplored by some of the most distinguished authorities on German education, notably by the late Prof. Paulsen. If this be a thing to be avoided we have avoided it. We have made our start by treating education as a single and indivisible whole—and by trying to keep the different kinds of students in one organisation. How powerful this tendency is we may see by the example of Cambridge. We have done even more, for we have developed in connection with our new universities a system of evening teaching for a separate class of student. That the tendency to recognise this kind of instruction as legitimate for the British university is increasing appears when we look at such cases as those of Glasgow and Manchester, where the great technical colleges of these cities are being brought into the closest relation with their universities. I believe this to be entirely right, and I am glad that you in Bristol took the same course at the beginning when you brought the Merchant Venturers' College, with its evening teaching, into your new University organisation.

Specialisation in each city university there will be and ought to be. *Non omnia possumus omnes.* In one place the distinctive strength will be in chemistry—general and applied—for exist without each other they cannot. In another, as in Sheffield, it will be the metallurgy of iron and steel; and it is not unimportant in this connection that Sheffield is the chief centre for the manufacture of the national guns and steel plates, an industry in which we dare not dispense with high science. In another place, as in the case of the Imperial College in London, we should have the great training place in the metallurgy of the precious metals for the students of a people which leads the world in their production. Some universities will be strong in engineering, civil and mechanical, or, it may be, marine. But the one thing requisite is that the broad foundations of the highest general knowledge should be there in each university, and that all specialisation should rest on these foundations. You cannot, without danger of partial starvation, separate science from literature and philosophy. Each grows best in the presence of the others. Another essential feature is adequate provision for the postgraduate student that is, the student who, having taken his degree, has in him the passion for excellence sufficiently strong to desire to continue in the university as a place of research and of the still higher learning which is inseparable from research. Such students may not be numerous, but when they are present they leaven the whole lump, and by their presence give a distinction to the university and to the professors under whom they work which could not be possible in their absence.

WILLIAM BOTTOMLEY.

THE death of William Bottomley at Glasgow on October 19, at sixty-three years of age, removes one who, throughout the greater part of his life, did genuine, unobtrusive service to the cause of applied science by the assistance he gave to his uncle, Lord Kelvin. A son of the late Mr. William Bottomley, of Fortbreda, County Down, and of Anna Thomson, the second of Lord Kelvin's sisters, Bottomley was trained as a civil engineer. In 1872, Sir William Thomson and Fleeming Jenkin undertook to act in partnership as engineers for the manufacture and laying of telegraph cables which were to connect the cities of the Brazilian coast, from the Amazon to the River Plate. Bottomley was put in charge of a staff of young assistants at the works of the Hooper Company at Millwall Docks where the cable was being made.

In those days there were no college laboratories which could compare with the testing-room of a cable factory as a scientific training ground for the practical electrician. The writer, who was a very junior member of the staff, well remembers Bottomley's cheery kindness, his capacity for management, and the ardour with which he threw himself into what was then a novel task. The art of cable testing, the necessities of which had been a chief factor in bringing into existence the scientific system of electrical units, was still undergoing evolution: new methods had to be devised, tested, and licked into shape for everyday use.

In 1873, Bottomley, along with his colleague W. F. King, accompanied Thomson and Jenkin in the maiden voyage of the cable ship *Hooper*, when the first section, from Para to Pernambuco, was laid. The sections from Pernambuco southward were laid in subsequent expeditions under their supervision, and in the absence of the chiefs.

Probably there are few parts of the later work of Kelvin in applied science with which William Bottomley was not in some degree concerned. With the Kelvin compass he had an early and intimate association. When the long struggle was over which preceded its general acceptance in the Navy and the mercantile marine, the task of looking after it as an article of manufacture and an object of business enterprise fell mainly on his shoulders. He had to train and superintend the skilled compass adjusters whose services were essential to its success. His own energy, his tact and judgment, and his appreciation of the scientific points at issue were in constant exercise for many years with the happiest results. The Kelvin compass came into universal use primarily, of course, because of its intrinsic merits; but these had to be demonstrated, defects had to be corrected, and prejudices to be overcome. In this work Bottomley's unfailing geniality, his simplicity and directness, and the warmth of his enthusiasm were valuable adjuncts to his technical knowledge: they were qualities, too, that endeared him to his friends.

J. A. E.

PROF. LEWIS BOSS.

IT is with deep regret that we have to record the death of Prof. Lewis Boss on October 5. While working as an assistant astronomer on the U.S. Northern Boundary Commission in 1877, Prof. Boss was greatly impressed by the urgent necessity for greater accuracy in star catalogues, and forthwith made the remedying of the defect his life-work; the immediate outcome was the extremely valuable "Boss's Declinations," in which, after discussing some hundred catalogues, he gave the declinations and proper motions of 500 stars for the epoch 1875. In 1878 he was appointed director of the Dudley Observatory, Albany, N.Y., a position which he held until his death, and after observing the corona at the solar eclipse of that year, he settled down to the solution of the many problems involved in the rigid determination of stellar positions. Generous friends showed their appreciation of Prof. Boss's labours by providing him with a new observatory in 1893, and later the Carnegie Institution of Washington showed practical sympathy with his work, also making him director of the Meridian Astrometry Department of the Institution.

Prof. Boss's publications are too many to refer to in detail here, but they dealt with many subjects such as the instrumental and magnitude errors in meridian work, the observation of comets, for which he published many ephemerides, and the determination of the sun's motion. In 1903 he published a standard catalogue of 627 stars distributed over both hemispheres, and in 1910 a preliminary general catalogue, in which he gave positions and proper motions of 6188 stars, of which about 4000 are brighter than the sixth magnitude.

The value of these researches is inestimable, but already many important results have accrued, such as the discovery of the Taurus stream of stars, and the value will rapidly advance as time passes. In 1905 the Royal Astronomical Society recognised Prof. Boss's work by presenting him with its gold medal, and in England, as elsewhere, the loss of a great and original investigator, and a personal friend, will be sorely felt. Prof. Boss was born at Providence, R.I., in 1846.

NOTES.

The Huxley lecture at the University of Birmingham is to be delivered on October 30 by Prof. John Joly, F.R.S., who has chosen as his subject "Pleochroic Halos."

The annual Huxley memorial lecture of the Royal Anthropological Institute will be held on Tuesday, November 19, at 8.30 p.m., at the theatre of the Civil Service Commission, Burlington Gardens, London, W., when Prof. W. Gowland, F.R.S., will deliver an address on "The Metals in Antiquity." Dr. Alfred P. Maudsley, president, will take the chair.

The Institute of Chemistry announces that Mr. E. White will deliver a lecture on thorium and its compounds on Friday, November 1, at 8 p.m., in the Chemical Lecture Theatre of Finsbury Technical College, London, E.C. Prof. R. Meldola, F.R.S., president of the Institute, will occupy the chair.

Prof. E. Metchnikoff, of the Pasteur Institute, Paris, will deliver a lecture on "The Warfare against Tubercle" in London on Friday, November 29, at 4.30, at the Royal Society of Medicine, Wimpole Street, Cavendish Square. The lecture is the Lady Priestley memorial lecture for 1912.

Much interest was aroused last March by the discovery of typical Upper Old Red Sandstone with fish remains beneath the neighbourhood of London. Mr. E. Procter, of the Imperial College of Science, exhibited to the Geological Society characteristic fragments of Holoptychius and Bothriolepis, which he had obtained from a depth of between 1100 and 1200 feet in a boring at Southall. He has lately presented these specimens to the British Museum (Natural History), where they are now to be seen among the fossil fishes.

Peabody Museum, Yale University, has received from the assistant professor of archæology, Dr. G. G. MacCurdy, the anthropological collections made by him during his summer visit to Europe. It has also acquired 2000 geological specimens gathered by Prof. C. Schuchert in Nova Scotia and the Lake Huron region, a collection made at Abydos in connection with the Egyptian exploration fund, and remains of a fossil three-toed horse found in Texas by Prof. R. S. Lull.

The death is reported, within a few days of his seventieth birthday, of Mr. Bradford Torrey, well known in America as a naturalist. He was a frequent contributor to *The Atlantic Monthly*, and was for several years one of the editors of *The Youth's Companion*. He had edited Thoreau's Journal, and was himself the author of "Birds in the Bush," "A Rambler's Lease," "The Foot-path Way," "A Florida Sketch-book," "Spring Notes from Tennessee," "A World of Green Hills," "Footing it in Franconia," "The Clerk of the Woods," "Nature's Invitation," and "Friends on the Shelf."

Dr. Morris Loeb, for several years professor of chemistry at New York University, died recently in his fiftieth year. He was a member of the executive committee of the International Congress of Applied Chemistry, which met a few weeks ago in America. His own research work was done chiefly in complex inorganic salts. Last year Dr. Loeb presented 10,000*l.* to the Walcott Gibbs Chemical Library at Harvard, of which university he was a graduate, and he was a generous benefactor of various scientific societies and Hebrew charities. He had been president of the Hebrew Technical Institute and of the Chemists' Club, and was a member of the New York Board of Education.

The death is announced, at sixty-eight years of age, of Mr. Robert Brown, fellow of the Society of Antiquaries, and distinguished by his works on comparative mythology. He was (says *The Times*) a student of Chaldæan myths, agreeing with Prof. Max Müller in tracing their origin to the movements of sun, moon, and stars, and the ebb and flow of natural phenomena, and opposing strongly the rival theory of totemism. His chief work, "The Great Dionysiak Myth" (two vols.), appeared in 1877–8, and he also published "The Myth of Kirke," "Aratus," "Researches into the Origin of the Primitive Constellations of Greeks, Phœnicians, and Babylonians," (two vols.), and "Semitic Influence in Hellenic Mythology."

We regret to learn from *The Times* that Prof. Otto Krümmel, who held the professorship of geography for many years at Kiel, and latterly at Marburg, and was recognised as the leading German oceanographer, died suddenly on October 12, at fifty-eight years of age. In 1911 he completed the publication of a standard treatise on oceanography, and he was joint author of the article, "Ocean and Oceanography," in the 11th edition of the "Encyclopædia Britannica."

As a member of the International Council for the Study of the Sea and of the Prince of Monaco's committee for the preparation of a chart of the depths of the ocean, Prof. Krümmel took a large share in promoting the recent advances in our knowledge of the ocean by international cooperation.

THE death is announced of Mr. James Parker, of Oxford, at seventy-nine years of age. Although best known as an antiquarian, Mr. Parker was an industrious student of geology, and made a remarkable collection of fossils from the neighbourhood of Oxford, including Teleosaurian skulls and a Megalosaurian skeleton described by Phillips in his "Geology of Oxford." For fifty years he was an active member of the Geologists' Association, and in 1876 he contributed to their Proceedings a paper on the valley of the Somme, France. In 1880, for the use of one of their excursions, he also published a map and sections of the strata south of Oxford. Earlier in life he was associated with Prof. Boyd Dawkins and the late Mr. Ayshford Sanford in the exploration of caves in Somersetshire, and he devised a raft for the navigation of underground waters.

ON Wednesday, October 16, a new gallery, which is to be entirely devoted to the illustration of local mammals, was opened at the Municipal Museum, Hull. The specimens include several historical examples from the collection of the late Sir Henry Boynton and other sources, and a number of them are the last records of the kind for the district. The collection is arranged in specially made cases, in which the animals are shown in their natural surroundings, in addition to which there are several large groups showing male, female, and their young, &c. The groups consist of otters, badgers, hedgehogs, deer, foxes, &c. On the occasion the curator, Mr. T. Sheppard, gave an address on the mammals of the East Riding of Yorkshire.

WE are informed that a new society, which has assumed the title of the South African Association of Analytical Chemists, has recently been formed, with headquarters in Johannesburg. The main objects of the association are to uphold the status and the interests of the profession of technical chemistry and to secure a high standard of professional conduct amongst analysts in South Africa. In its constitution the new association has made provision for undertaking any procedure which will encourage the study or extend the knowledge of analytical and technical chemistry. The first council of the association is:—*President*, Dr. J. McCrae; *Vice-President*, G. H. Stanley; *Honorary Treasurer*, A. Whitby; *Members*, Dr. R. B. Denison, J. Sprunt Jamieson, Dr. C. F. Juritz, Dr. R. Marloth, Dr. J. Moir; *Honorary Secretary*, Jas. Gray, P.O. Box 5254, Johannesburg.

THERE has recently been added to the exhibits in the Shell Gallery of the Natural History Museum a working model illustrating the phenomenon of "torsion" in Gastropod Mollusca. The model can be easily operated by the public, and exhibits the process of "torsion" in two stages. Two diagrammatic models of shells in skeleton outline, containing intestine and visceral commissure of the nervous system, are rotated successively by handles. The first model thus operated illustrates the production of the U-shaped flexure of the intestine by the approximation of the mouth and anus. The second shows the actual "torsion" of the intestine and visceral commissure. The model is diagrammatic and generalised, and does not attempt to suggest a cause for this phenomenon.

AT the annual meeting of the Royal Society of South Africa, held at Cape Town on September 18, the president, Dr. L. Peringuey, announced that the council had awarded the following grants-in-aid of research:—To Mr. E. J. Hamlin, of Cape Town, 90*l*., to carry on research on commutation in electrical machinery; to Mr. A. Young, of Cape Town, 20*l*., to continue investigations on a fluctuating well in the Karoo; to Mr. P. A. Methuen, of Pretoria, 50*l*., for a journey to the Great Karasberg Range for the study of the taxonomy and distribution of the lower vertebrates and several groups of the invertebrates of Great Namaqualand; to Mr. G. Rattray, of East London, 50*l*., for travelling expenses in connection with the continuation of the investigation of the taxonomy and distribution of South African Cycads; to Miss E. L. Stephens, of Cape Town, 15*l*., for (*a*) determination of South African fresh-water Algæ, (*b*) periodic change in fauna and flora of certain South African vleis; to Miss A. W. Tucker, of Johannesburg, 50*l*., for an ethnological survey of the Topnaar tribe of Hottentots.

AMERICAN naturalists are delighted by the announcement that Mrs. Russell Sage, widow of the late well-known Wall Street financier, has purchased Marsh Island, off the coast of Louisiana, in order to make it a perpetual bird sanctuary. "With one penful of ink," says Mr. W. T. Hornaday, in an enthusiastic letter to the American Press, "Mrs. Russell Sage has taken the greatest bird-slaughtering ground of the Gulf Coast away from the market gunners of Louisiana and dedicated it for ever to the opposite cause—the preservation of the birds of North America." The island in question is about 75,000 acres in extent. It is a sylvan labyrinth affording shelter and food to hundreds of thousands of wild birds which resort to it in winter when the northern lakes and streams are locked fast under ice. For this reason it has been the great killing ground for the markets of New Orleans, St. Louis, Cincinnati, and Chicago, no fewer than seventy market gunners being regularly employed there every winter. The price paid by Mrs. Sage for the island is 30,000*l*. This is said to be the second largest gift ever made for the protection of wild life in America, the largest being the bequest of 62,400*l*. by Mr. David Wilcox to the National Association of Audubon Societies.

THE Harveian Oration before the Royal College of Physicians was delivered on October 18 by Sir James Goodhart, who took for his subject "The Passing of Morbid Anatomy." Are physicians, he asked, sufficiently alive to the fact that pathology is no series of stationary phenomena, but constantly on the move, like all else in nature? What alterations have not been seen in forty years? Pyæmia may be said to be wiped out; typhus is well-nigh forgotten; typhoid fever has altered; diphtheria seldom attains the initial severity that so often characterised it of yore and is much more amenable to attack; scarlatina is of a much milder type; erysipelas is more of a rarity; malaria and Malta fever have been run to earth; the late results of syphilis seem to be far less often in evidence; lardaceous disease, so very common in earlier days, is now seen but seldom; and doctors have come at grips with acute rheumatism and, it is to be hoped, with tuberculosis. Probably as much might be said of other diseases, and good old age is both more prevalent and more enjoyable. Dealing with the future of pathology, Sir James Goodhart went on to say fatigue is a disease nowadays. All know the machine that will not spark aright. There is nothing to be called structural change, and even rest furnishes no remedy. It is clear that what is required is a fresh stock of some form of energy for charging up the machine that doctors are as yet not able to supply—so far away, and yet perhaps so nigh.

The new medical school attached to the Royal Hospital for Diseases of the Chest, City Road, London, was formally opened on October 17, when Prof. Nietner, of Berlin, delivered the inaugural address. He pointed out that the researches of the last ten years have brought to light facts that indicate that in a large majority of cases tuberculosis infection occurs during childhood, in the first years of life. Hamburger has declared that 90 per cent. of all children up to the completed twelfth year are infected. Schlossmann has gone so far as to say that tuberculosis is a true children's disease, is acquired during childhood, and must be prevented, treated, and healed during childhood. It is a fact that in by far the greater number of cases the source of infection can be traced to the human subject's suffering from "open" tuberculosis, and that infection is acquired through the close intercourse resulting from family life. Only those preventive measures can hope for success which take this fact consistently into account. But to prevent the child from becoming infected in his own home environment without weakening family ties and responsibilities offers a social problem of the utmost complexity. Tuberculosis is not a "school disease," and the school cannot justly be held responsible for the spread of infection. Finally, the lecturer said he attaches great value to the use of tuberculin in the treatment of tuberculous children, and claimed good results from it if properly administered.

Mr. H. Ling Roth, honorary curator of the Bankfield Museum, Halifax, has republished as No. 1 of the second series of "Museum Notes," his paper on Oriental steelyards and bismars, reprinted from vol. xlii. of the Proceedings of the Royal Anthropological Institute. The original centres of distribution of these instruments seem to be China and Japan, whence they spread to the ports of the Malay Peninsula and India, and thence to Europe. Neither the Babylonians nor the Egyptians, until Roman times, seem to have possessed them, and an English specimen of the seventeenth century, now in the Horniman Museum, preserves the characteristic Chinese turnover arrangement. The paper, with its abundant illustrations and careful description of the different varieties, forms an interesting chapter in the transmission of culture.

The September issue of *The National Geographic Magazine* is entirely devoted to an elaborate account, illustrated by an excellent series of photographs, of the head hunters of northern Luzon, by Mr. Dean C. Worcester, Secretary of the Interior of the Philippine Islands, who has already done much to elucidate the ethnology of the islands. Hitherto it has been supposed that the custom of head-hunting did not prevail among the Negrito tribes; but Mr. Worcester's exploration of their last important stronghold proves that this is a mistake. The difficulty of social intercourse with them is increased by the barrier reef which guards their coast. Besides the Negritos, this article contains an interesting account of the Ilongot, Kalinga, Ifugao, Bontoc, and Tingian tribes, who, in spite of various savage customs, have in certain directions attained a fairly high degree of culture. This valuable monograph on a little-known people deserves the attention of anthropologists.

The report of the Committee on Ancient Earthworks and Fortified Enclosures, prepared for presentation to the Congress of Archæological Societies, indicates that there were during last year more cases than usual of damage, or destruction, actual or threatened, to the structures under their care. Unfortunately, most of the damage has occurred during the construction of golf links, and the committees of such clubs have been urged to use their influence for the protection of prehistoric remains. It is also unpleasant to learn that Irish tenants who have acquired ownership of their farms under the Land Purchase Acts frequently destroy ancient earthworks, and that workmen, who some years ago, through fear of the fairies, would not touch such remains, are losing their superstitious belief. On the other hand, among the more intelligent members of the community in both islands there is an increasing desire for protection, and the Royal Commission on Ancient and Historical Monuments in England and Wales is collecting much valuable information, and is exciting public opinion towards their conservation.

In *The Victorian Naturalist* for September, Miss J. W. Raff describes the female of *Phreatoicopsis terricola*, a genus and species of isopod crustaceans previously known only by the male. It is remarkable that the species occurs in two isolated mountain areas —the Grampians and the Otways—which are about one hundred miles apart, and separated by a broad, dry valley, entirely unsuited to the habits of this isopod, which is restricted to forest.

In an article of sixty pages on Japanese cephalopods (in which all the known species are enumerated), published in the Proceedings of the Philadelphia Academy for July, 1912, Mr. S. S. Berry emphasises the remarkable resemblance between this fauna and the cephalopod fauna of the Mediterranean, although in its general character the former is nevertheless distinctly Indo-Malay. Apart from Loligo and Sepia, which are extraordinarily rich in peculiar forms, there are, indeed, remarkably few exclusively Japanese species. The presence of the group of species allied to *Polypus*, or *Octopus*, *honkongensis* suggests an invasion from the Aleutian-Californian province, although this is by no means certain.

IN an article on the cultivated and wild forms of cochineal insects, published in the September issue of *The Journal of Economic Biology*, Mr. E. E. Green protests against the transference of the name Coccus from these insects to another genus, and the substitution of Dactylopius. In retaining *Coccus cacti* for the typical cochineal insect, he will gain the approval of those naturalists who consider that familiar zoological names, which give an obvious clue to the animals they represent, ought not to be displaced. It is pointed out that the Indian cochineal insect, for which the author proposed the name *C. indicus* in 1908, was originally imported from Brazil in 1795, other importations being made subsequently. Nevertheless, it cannot apparently be identified with any American form, and therefore seems to indicate the development, within a century, of a new species, as the result of changed environment.

THE September number of *The Quarterly Journal of Microscopical Science* (vol. lviii., part 1) contains an important paper by Prof. G. E. Nicholls on the structure and development of Reissner's fibre and the subcommissural organ. Prof. Nicholls gives a very useful historical review of our knowledge of these remarkable structures, and severely criticises Sargent's work on the subject. He then passes on to a detailed account of Reissner's fibre and the subcommissural organ in the Petromyzontidæ and Myxinoidei, illustrated by a number of diagrams and some very remarkable photomicrographs. In the same number Mr. Geoffrey Smith publishes the ninth part of his "Studies in the Experimental Analysis of Sex." He finds that in hybrid pigeons, of which only males were obtained, the ripe spermatozoa are of about twice the normal size. This is explained by abnormalities in the process of spermatogenesis. In the first maturation division, the chromosomes, instead of forming the normal eight synaptic pairs, are irregularly distributed on the nuclear spindle, while the second maturation division is suppressed. Mr. Smith thus confirms the previous observations of Guyer, and adopts his view that the sterility of such hybrids is due to the inability of the chromosomes derived from specifically different parents to form the normal synapses.

WE have received a revised and enlarged edition of a neo-vitalistic essay by Prof. Moriz Benedikt, of Vienna. It is entitled "Biomechanik und Biogenesis" (Fischer, Jena, pp. 88), and deals in a somewhat esoteric, not to say eccentric, fashion with the problems of vitality. The author has devoted special attention to "action at a distance" in the life of organisms, to a monistic interpretation of psychical activity, and to the origin of living substance. As to the last, it probably occurred for the first time in the meshes of colloidal sea-sand, and the composition of our blood-serum is a hereditary reminiscence of the primeval cradle of life. But living matter has undoubtedly continued to be formed, else the organic world would long since have eaten itself up. Whether the results of present-day natural synthesis (which eludes our observation) attain to the level of the very simplest organisms we know, is questionable. But it is difficult to be quite sure when the genial author is not poking fun at us. "Biomechanik" is another word for "neo-vitalism," and Prof. Benedikt's general position is that the ordinary physical, mechanical, and chemical laws hold good for vital processes, but (to use his phraseology) do not completely dominate them. Laws "of a higher order" hold good in the realm of life—laws which cannot be deduced from those of the inanimate world. The movements of corpuscles in living matter are much more intricate than those in not living matter, and the author is especially concerned with the structural configurations that have made vital activities possible.

THE Pliocene deposits contain the key to many problems of modern animal distribution, including the centres from which man spread across the earth. Workers in European natural history will especially welcome Dr. J. P. Tesch's handsomely printed memoir, "Beiträge zur Kenntnis der marinen Mollusken im west-europäischen Pliocänbecken" (*Med. van de Rijksopsporing van Delfstoffen*, No. 4, The Hague, 1912, and Craz and Gerlach, Frieberg in Sachsen, price 6 marks). A list and commentary on the distribution of the known molluscan species of the area occupy the greater part of the paper, and considerable use is made of information obtained from borings in Holland.

THE new phenomenon Prof. Righi brought before the Academy of Science of Bologna in January, to which he gave the name of ionomagnetic rotation, is described in detail in the Memoirs of the academy and in the *Physikalische Zeitschrift* for August. If a spark from a condenser of considerable capacity is sent horizontally through a gas and two small vertical vanes of mica in the form of a cross are suspended in the middle of the discharge by a fine fibre attached to the centre of the cross, the spark produces no rotation of the cross. If, however, a vertical magnetic field is established in the gas the cross rotates through a considerable angle if the gas is air, and over a small angle in other gases. Prof. Righi ascribes this rotation to the bending of the paths of the ions or electrons and to the additional protection which the vanes afford each other against impacts from one side rather than from the other in these circumstances. The observed rotations indicate that the effects of the positive ions are in general greater than those of the negative.

A GENERAL lecture, delivered by Prof. G. Ciamician before the International Congress of Applied Chemistry in New York, is reprinted in *Science* for September 27, under the title, "The Photochemistry of the Future." At the outset some interesting suggestions are advanced as regards the utilisation of the solar energy in the days when our coal deposits shall be exhausted, and then the author describes briefly some of the principal results obtained by himself jointly with Profs. Silber and Ravenna, at the University of Bologna, in the study of photochemical action. In a series of recent experiments made to determine the physiological function of the glucosides, it was found possible to force maize, a plant which is normally free from the substance, to synthesise salicin, whilst the production of nicotine by the tobacco plant can be controlled so as to obtain a large increase or decrease in the quantity of this alkaloid. The possibility is suggested by these experiments of greatly increasing the proportion of the useful constituents of plants by a suitable treatment during the period of their growth.

Under the title "Une Loi Universelle," Prof. Wilden D. Bancroft publishes an interesting article in the *Revue Scientifique* for September 28, on the well-known theorem of Le Chatelier, for which he claims a wider application than it is generally credited with. He considers that this law, which in physics becomes the principle of least action, in biology becomes the law of the survival of the fittest, and in economics the law of supply and demand. In its most general form the law is stated by Prof. Bancroft in the following terms: The changes which affect a system are such that they tend to render minimum the disturbance of external origin. A number of cases are cited in which the principle is extended to vital phenomena, more particularly as regards the adaptation of plants and animals to temperature, light, humidity, and climate, and in exnlanation of the origin of variations. The position taken up is that no variation is spontaneous, but that if we go far enough back all variations are the result of changes in external conditions. The real problem in such cases is to show, for any given organism and any given variation, what part has been played by external conditions on the preceding generation, and the part played by conditions on the generations which preceded that one.

In the annual report of the Minister of Mines of British Columbia, just published, the reported discovery of metals of the platinum group in certain dykes near Nelson in that province is discredited. As a result of numerous analyses carried out, at the request of the Minister by various experts in America and Europe, on samples carefully taken from the portions of the dyke in which the presence of platinum metals had been reported, the complete absence of these metals was established. In none of the samples was any trace found either of any of the platinum metals or of anything corresponding with the supposed new metal, "canadium," the reported discovery of which was announced in these columns about a year ago.

The issue of *The Philippine Journal of Science* for July last takes the form of a memorial number to the late Dr. Paul Caspar Freer, who was director of the Bureau of Science of the Government of the Philippine Islands, dean of the college of medicine, and professor of chemistry of the University of the Philippines. Dr. Freer was also the founder and editor of *The Journal of Science*. This issue of the magazine contains eight appreciations of Dr. Freer's life and work. Mr. Martin Egan, editor of *The Manila Times*, writes of his life and career; Bishop Brent of his influence upon other men; Mr. R. P. Strong, chief of the biological laboratory in the Bureau of Science, describes his general influence upon scientific work in the Philippine Islands; Mr. Dean C. Worcester, secretary of the Interior of the Government of the Islands, gives an account of his work for the Bureau of Science; Mr. W. E. Musgrave, of the General Hospital, of his work for the university; Mr. Murray Bartlett writes of him as an organiser and administrator; Prof Calderon as a friend of the Filipinos; and Prof. H. D. Gibbs as a chemist.

A revised edition of Dr. J. G. Bartholomew's "School Economic Atlas," to which Prof. L. W. Lyde contributes an introduction, has been published by the Oxford University Press. The price of the atlas is 2*s*. 6*d*. net.

In the note on the first report of the Meteorological Observatory at Montserrat (Nature, September 12, p. 59), it should have been added that the daily maxima and minima of temperature were given in separate tables on other pages in conjunction with the values of humidity.

The presidential address delivered last September to the British Association, at its meeting at Dundee, entitled "Life: its Nature, Origin, and Maintenance," has been published in pamphlet form by Messrs. Longmans, Green and Co. at the price of 1*s*. net.

The most recent issue of the botanical catalogue of Messrs. John Wheldon and Co., of 38 Great Queen Street, Kingsway, London, gives particulars of some 1700 books and papers on various branches of botany. Many recent purchases and selections from several important libraries are included.

A fourth edition of the late Prof. Thomas Preston's "Theory of Light" has been published by Messrs. Macmillan and Co., Ltd. It has been edited by Prof. W. E. Thrift, and its price is 15*s*. net. The developments that have taken place since the publication of the third edition, in 1901, have led Prof. Thrift to make additions, which are suitably indicated. A fuller treatment of dispersion is given, an account of radiation phenomena in a magnetic field, and a more complete presentation of the electro-magnetic theory, which is dealt with from the electron point of view of Lorentz and Drude.

OUR ASTRONOMICAL COLUMN.

The Discovery of a Comet, 1912*b*.—A telegram from the Kiel Centralstelle announces the discovery of a comet by M. Schaumasse, at Nice, on October 18. The position of the object at 17h. 5m. (Nice M.T.) on that date was:—

$$\text{R.A.} = 9\text{h. } 57{\cdot}6\text{m., decl.} = +1^\circ\ 36',$$

and the motion was easterly. The magnitude was 11·5, and the position given lies in Sextantis, about 11° south of Regulus, thus rising about 2.30 a.m.

A second telegram from the Centralstelle states that

MM. Fayet and Schaumasse find the elements of the orbit of this object to be almost identical with those of Tuttle's comet.

COMET 1912*a* (GALE).—The following set of elements for the orbit of comet 1912*a*, from which he derived the corrected ephemeris we gave last week, is published by Dr. Ebell in No. 4604 of the *Astronomische Nachrichten*; it is based on observations made on September 8, 17, and 26:—

$$T = 1912 \text{ October } 4{\cdot}95917 \text{ M.T. Berlin.}$$
$$\left.\begin{aligned} \omega &= 25^\circ\ 33'\ 37{\cdot}9'' \\ \Omega &= 297\ \ \ 2\ \ \ 53{\cdot}3 \\ i &= 79\ \ \ 51\ \ \ 10{\cdot}2 \end{aligned}\right\} 1912{\cdot}0$$
$$\log q = 9{\cdot}854958$$

A further extract from the ephemeris is given below:—

Ephemeris 12h. M.T. Berlin.

1912	α (true) h. m.	δ (true)	1912	α (true) h. m.	δ (true)
Oct. 25	15 57·0	+19 20·5	Oct. 29	16 0·5	+22 26·5
26	15 57·9	+20 8·1	30	10 1·3	+23 11·1
27	15 58·8	+20 55·0	31	16 2·1	+23 55·2
28	15 59·6	+21 41·1	Nov. 1	16 3·0	+24 38·7

During the period covered by this ephemeris the calculated decrease in magnitude is 0·5.

MEASURING THE ANGULAR DIAMETERS OF STARS.—In No. 2, vol. xxxvi., of *The Astrophysical Journal*, Dr. Pokrowsky suggests a method whereby it should become possible to measure the angular diameters of stellar objects, a result which, if obtained directly, would greatly widen our knowledge of stellar physics. The method is too technical in detail to be given here, but it depends upon the consideration that if two rays emanate from different points on the surface of a distant light-source, such as a star, there will be a difference of phase depending upon the distance between the two points. These two systems of rays after polarisation form two images of different intensities in the focus of a telescope, and Dr. Pokrowsky shows that by measuring the difference of intensity the angular diameter of the star may be derived; thus the problem is reduced to one of stellar photometry, and it is calculated that for bright stars, such as Arcturus, Canopus, Capella (average magnitude, say, =0·0), angular diameters of 0·0031″ might be discovered. As the method would be very sensitive, atmospheric conditions would greatly interfere, and the apparatus could only produce positive results at a mountain observatory.

THE PERSEIDS OF AUGUST 12, 1912.—Some interesting data concerning the meteor shower of August last are given by Prof. Zammarchi, in No. 10, vol. i. (2nd series), of the *Memorie della Società degli Spettroscopisti Italiani*. The observations were made at the meteorological observatory attached to the seminary at Brescia, and in a total of 13·6 hours, spread over the nights of August 10, 11, 13, and 14, six observers recorded 170 meteors. The greatest horary rate occurred on August 11, when 93 meteors were seen in four hours; on August 12 the sky was covered and observations impossible. For each meteor the time, the magnitude, and the appearance are given, and in many cases the position of the beginning and end of the path.

THE PHYSICAL CAUSE OF THE z-TERM IN LATITUDE VARIATION.—A possible cause producing the z-term in latitude variation is suggested by Mr. S. Shinjo in a paper of which we have received a reprint from the *Tôkyô Sûgaku-Buturigakkwai Kizi* (second series, vol. vi., No. 16), published by the Tokio Mathematico-Physical Society. Putting on one side, as unlikely, the possibility of its being due to systematic error in the observations and the suggestion that it is due to real changes in the earth, Mr. Shinjo reverts to the probability that the z-term is introduced by the action of anomalous refraction. But no such inclination of the atmospheric strata as is necessary to produce the anomalous refraction has been observed over any large area. Mr. Shinjo, however, inquires into the purely local conditions appertaining to and immediately surrounding the observing station, and suggests that in these very localised areas the atmospheric gradient is frequently sufficiently sharp; for example, the difference in temperature between the sun side and the shade side of the observing hut might produce a pressure-gradient sufficient to produce the z-term. He concludes that the greater part of the term is probably produced by this cause, about one-fourth as a consequence of the daily variation of the pole, as remarked by Sitter, and a small part may possibly be due to real change in the earth.

THE BECQUEREL MEMORIAL LECTURE OF THE CHEMICAL SOCIETY.

AN extra meeting of the Chemical Society was held on Thursday, October 17, when Sir Oliver Lodge, F.R.S., delivered a memorial lecture in honour of Antoine Henri Becquerel, late honorary and foreign member of the Chemical Society. Prof. Percy F. Frankland, F.R.S., president of the society, occupied the chair.

Sir Oliver Lodge referred to the changes that of recent years have come over physical science. Not many years back its progress appeared to be placid, along well-worn channels, and based upon the substantial knowledge of the past. To-day it is characterised by intense speculative activity on the one hand, and, on the other, by exceptional scepticism.

Discoveries are of two chief kinds: the discovery of law and the discovery of fact. The discovery of law often leads to the discovery of new facts, and the discovery of new facts to either the formulation of new laws or new modes of statement, or to the resuscitation of discarded ones. As examples of the discovery of law may be instanced Newton's gravitational theory of astronomy, Maxwell's electro-magnetic theory of light, the atomic theory of chemistry, and the conservation of energy. As examples of the discovery of fact may be quoted the prehistoric discovery of flame, the discovery of static electrification, of the electric current, of magneto-electricity, of the electron, and of spontaneous radio-activity.

Of the scientific discoveries made during the past fifty years, that of the Röntgen X-rays perhaps created the most widespread interest; but even more striking and revolutionary was Becquerel's discovery of the spontaneous radio-activity of matter, for the spontaneous splitting up of atoms and the consequent expulsion of constituent fragments was not provided for on any theory.

A discovery of essential novelty cannot be made by following up a train of prediction. It is often made during the process of following a clue, but the clue does not logically lead to it. A really new fact comes as a side issue something unexpected and that might have been overlooked. The discovery which has been pointed to by theory is of great value, but it is usually the outcome of a long and fruitful period; whereas the discovery which comes as a surprise generally marks a fresh epoch, and opens a new chapter in science.

So with the discovery of spontaneous radio-activity. Becquerel was looking for the possible emission of Röntgen rays by a fluorescent substance. It was a reasonable thing to look for, and had it been found would have made an interesting extension of our knowledge; but, when critically examined, the kind of radiation turned out to be for the most part not Röntgen rays, but corpuscular, and to have nothing to do with fluorescence.

Becquerel set himself carefully to examine the kind of penetrating radiation which fluorescent substances exposed to light might be found to emit. Though not finding that for which he sought, he made a discovery of far greater importance.

After giving an account of the recent discoveries in radio-activity, the lecturer dwelt on the present trend of scientific thought; of the tendency to return to discarded hypotheses such as spontaneous generation and the corpuscular theory of light. Our attitude amongst so many conflicting hypotheses should be to admit that any law applicable to concrete objects and established by induction on a basis of experience must be of the nature of a postulate; that we should hold some of the postulates as so well-established that arguments necessitating their overhauling should, *ipso facto*, to that extent be discredited, and should not receive our encouragement unless supported by new facts. Our endeavours should be to harmonise new facts with the firmly established laws of physics until compelled to look for some higher generalisation.

Reference was then made to some of the well-established laws, and to the attempts to construct living matter from artificially combined materials. Life demands energy for its manifestations, and radio-activity may be suggested as a possible source of such energy. It is known that atoms give off energy as they disintegrate; that organic compounds likewise disintegrate and evolve energy, finally becoming inorganic. A decaying heap of refuse represents a close chemical analogy to the physical activity of uranium—one is an affair of atoms, the other of molecules. This stock of energy running to waste seems eligible for guidance. Life has to control this spontaneous disintegration of protoplasmic cells, to regulate the activity of the ganglia in the brain, for instance, or to suspend the disintegration of organic material until some appointed time, and then to direct it along some determined channel. We have yet to discover how life achieves this control. Those who say that life cannot guide material processes unless it is itself a form of energy, and those holding that life cannot act at all unless energy is at its disposal, forget the spontaneous activity of complex organised molecules and the atomic disintegration manifested by radio-activity.

There is a great difference between matter potentially living and actually alive. In the physical universe our power is limited to the movement of matter; after that, all that happens is due to the properties of matter and its ethereal environment. If potentially living matter is ever artificially made by placing things in juxtaposition and bringing physical resources to bear upon the assemblage, then it may become alive. If this last step be taken, it will be because something beyond matter, something outside the region of physics and chemistry, has stepped in and utilised the material aggregate provided. Only in this sense did the lecturer consider that the artificial incarnation of life would be possible. Some day life may appear under observation, but it will not be manufactured, any more than radium or radio-activity has been manufactured.

Sir Oliver Lodge spoke of the tendency of present-day science to materialise the invisible, quoting, among other examples of this, the fact that plague, which in olden times was attributed to such mysterious causes as a conjunction of the planets, the iniquities of the Jews, &c., is now known to be due to a minute vegetable parasite living on the fleas of rats.

The scientific life and work of Antoine Henri Becquerel were then dealt with, and an account given of his chief discoveries. A vote of thanks to Sir Oliver Lodge, proposed by Sir William Crookes, O.M., F.R.S., seconded by Prof. Henry E. Armstrong, F.R.S., and supported by the president, was briefly acknowledged by the lecturer.

THE RELATIONS BETWEEN VARIOUS SOLAR PHENOMENA.

TWO papers recently published in the *Comptes rendus* (No. 10, September 2, and No. 12, September 16), by Prof. Riccò and M. Deslandres respectively, contain several very important statements, concerning the interrelations of such solar phenomena as *filaments, alignements*, prominences, spots, &c., which no student of solar physics can afford to neglect, and which we briefly summarise below.

Prof. Riccò, having studied his valuable records of limb prominences and also those published by Wolfer, finds that the prominences frequently appear in the same position on the sun's limb for several consecutive days, and so must form files of prominence activity across the disc, strongly resembling M. Deslandres's filaments and alignments; he also finds limb prominences recorded at the time and in the positions indicated by M. Deslandres's filaments and alignments. He concludes that there is an indisputable connection between the two sets of phenomena. With sun-spots, however, he finds no connection with the filaments and alignments. But in his paper M. Deslandres considerably modifies this latter conclusion of Prof. Riccò's, and states that there is a general connection, the several phenomena obviously belonging to one system and reacting on each other.

M. Deslandres, in order to make the investigation more precise, gives further important results concerning the filaments and alignments shown on his wonderful series of photographs. He agrees that a prominence on the limb generally means a filament or alignment joining the limb at that point. The relation between the two sets of phenomena is confirmed. Further, he differentiates more clearly between filaments and alignments, the former being a special case of the latter, which cover much greater lengths. Alignments vary in intensity from feebly bright to very dark, and then merge into filaments which are exceptionally black and well defined. The alignments are frequently bordered, diffusely, with parallel bright lines, whereas the filaments are clearly-cut lines. Filaments are found on both the "hydrogen" and the "calcium" photographs, most strongly marked on the former, whereas alignments are, in general, only found on the "calcium" photographs. The brightest prominences occur at the ends of these bright companions of the alignments, and are, therefore, as Prof. Riccò also points out, not symmetrically placed with regard to the central dark alignment. Prof. Riccò suggests that this asymmetry is due to the fact that while the prominences are emission, the alignments are absorption, phenomena, and thus the two things probably represent activity in different layers of the solar atmosphere.

M. Deslandres suggests that the restriction of alignments to the "calcium" photographs, whereas the filaments are better shown on the "hydrogen" plates, may be due to the fact that the filaments probably exist at higher levels, not so readily reached by the calcium vapours. He also suggests that those eruptive prominences not connected with spots are intimately connected with filaments, and in his radial-velocity researches has found that these two phenomena are alike in showing an ascensional radial velocity.

The importance of these researches is obvious, and the results likely to accrue from the simultaneous study of the forms and velocities of the various features most valuable, but, as M. Deslandres points out, it will only be possible to state general and definite laws when continuous and complete observations have extended over at least one undecennial period of solar activity.

THE SIGNIFICANCE OF LIFE TO THE OMAHA.[1]

FOR twenty-nine years Miss Alice Fletcher has been studying the Omaha, and her monograph of the tribe is now published in the twenty-seventh Annual Report of the Bureau of American Ethnology. Her collaborator for most of this time was Mr. Francis La Flesche (the son of Joseph La Flesche, former principal chief of the tribe), who in his boyhood witnessed some of the ceremonies described in the memoir, which were later explained to him by his father and by the old men who were the keepers of these ancient rites and rituals. When Miss Fletcher first went to live among the Omaha, the tribe had recently been forced to abandon hunting owing to the sudden extinction of the herds of bison. All the men and women had participated in the old life, many of the ancient customs were practised, and much of the aboriginal life still lingered. The environment was changing quickly; all that they formerly had relied on as stable had been swept away; the bison, which they had been taught was given them as an inexhaustible food supply, had been destroyed by agencies new and strange; even the wild grasses that had covered the prairies were changing. Great unrest and anxiety had come to the people through the Government's dealings with their kindred, the Ponca tribe, and fear haunted every Omaha fireside lest they, too, be driven from their homes and the graves of their fathers. The future was a dread to old and young. Thanks to the strenuous efforts of Miss Fletcher on their behalf, a law was enacted in 1882 granting lands in severalty, and prospective citizenship. In 1802 the Omaha were reduced to about 300 by smallpox; twenty-seven years later they were said to number 1900; in 1906 the population of the tribe was 1228. The past is overlaid by a thriving present. The old Omaha men and women sleep peacefully in the hills while their grandchildren farm beside their white neighbours, send their children to school, speak English, and keep bank accounts.

"In the account here offered," Miss Fletcher says, "nothing has been borrowed from other observers; only original material gathered directly from the native people has been used, and the writer has striven to make, so far as possible, the Omaha his own interpreter." The most important previous accounts of the tribe are the Rev. J. Owen Dorsey's "Omaha Sociology," published in the third Annual Report of the Bureau in 1884, which ever since has been largely quoted, and his paper on "Omaha Dwellings, Furniture and Implements" (the thirteenth Report, 1896). It will be found that there are many discrepancies between Dorsey's and Miss Fletcher's statements. For example, Dorsey says that the Black Shoulder clan were originally bisons ("buffaloes") and dwelt under the surface of the water, but Miss Fletcher writes, "no Omaha believes that his ancestors ever were elk, or buffalo, or deer, or turtle, any more than that they were the wind, the thunder, or the sky" (p. 601).

As has just been stated, Miss Fletcher gives us only first-hand matter, which she has carefully sifted and verified so far as possible. She evidently did not like to criticise or correct Dorsey's statements; there can, however, be little hesitation by students which account they should follow when discrepancies occur. On account of the great changes that have taken place in the material, social, and religious life of the Omaha it is improbable that anything of importance can be gleaned by future workers, and much that Miss Fletcher describes will then be unobtainable. Her monograph, the result of arduous and protracted toil, is the record by a field worker of wide sympathy and insight of investigations which were begun at the critical time of incipient disintegration and while the old knowledge was still fresh in the minds of the people. Some American ethnologists even go so far as to say that she reads into the native mind ideas that it does not contain, but the more we learn about the North American Indian the more apparent it is that he is imbued with a rare spirituality, and it is a common experience that one field observer will discern what another cannot see, as an old writer has said, "The natural man receiveth not the things of the Spirit of God: for they are foolishness unto him: neither can be know them, because they are spiritually discerned." Doubtless Miss Fletcher is content to leave this matter to the arbitration of the intensive study of the religion of allied tribes.

The legendary home of the Omaha and cognate tribes was in the east, "near a great body of water," and the legend gives an interesting account of cultural evolution, due partly to invention and partly to borrowing from other tribes. All children passed through a ceremony of turning, which was directly related to the wind, earth, and fire, whereby it was introduced to the tribe. Later a lock of the boy's hair was cut off and given to Thunder; thereby the life of the child was given into the keeping of the god that controlled the life and death of the warrior. The next stage in the life of an Omaha youth was marked by the rite introducing him to individual life and to the supernatural. Four days and nights the youth was to fast and pray, then in a trance he saw an object which was his personal connection with the universe, by which he could strengthen his spirit and his physical powers. There were societies the membership of which was made up of men who had had visions of the same object. The sequence of rites began at birth, with the announcement to all created things that a new life had come into their midst; when the child had acquired ability to move about of its own volition, its feet were set in the path of life, and it entered into membership of the tribe; the entrance into manhood required voluntary effort, and by prayer and fasting the man came into direct and personal relations with the supernatural.

Miss Fletcher states that "the tribal organisation was based on certain fundamental religious ideas, cosmic in significance." The real division of the tribe was based on the dual division in nature; each contained several "gentes," which in their turn were divided into "subgentes. . . . The Omaha gens was a group of exogamous kindred who practised a particular rite, the child's birthright to which descended solely through the father; and the symbol characteristic of that rite became the symbol, crest, or 'totem' of the gens." A noticeable feature in the book is the large number of prayers and songs, which are given in the native language, with a literal and free translation, and with the musical notation. A considerable space is given to an account of the social and secret societies; the

[1] Twenty-seventh Annual Report of the Bureau of American Ethnology to the Secretary of the Smithsonian Institution, 1905–6. Pp. 672. (Washington: Government Printing Office, 1911.)

latter dealt with mysteries, and membership was generally attained by virtue of a dream vision. The Omaha were a thoughtful and practical people. The idea of personality is dominant in the language and in the religious beliefs and practices. The force within this personality was recognised as that of the will, and "the Sacred Legend, which preserved the experiences of the years, emphasised the vital fact that better conditions are always attained by the exercise of thought, not by magical interferences." Enough has been said to show that Miss Fletcher has given us a monograph that deserves the careful study of all ethnologists, and will still further increase their indebtedness to the Bureau of American Ethnology.

A. C. Haddon.

THE ROYAL MICROSCOPICAL SOCIETY.

On Wednesday, October 16, a conversazione was held in the Great Hall of King's College, about four hundred fellows and guests being received by the president, Mr. H. G. Plimmer, F.R.S., and Mrs. Plimmer. The object in view was, so far as practicable, to gather together a series of exhibits which would indicate the many uses, both in science and commerce, to which the microscope is put at the present time. In addition, the conversazione afforded an opportunity for those engaged in microscopic work to show objects of interest or to demonstrate the use of apparatus or appliances for special purposes.

The centre of the hall was occupied with pond life exhibits, about forty microscopes having been arranged on the tables under the direction of D. J. Scourfield, and these were a centre of interest to a considerable number of observers throughout the evening. Other interesting exhibits were some very beautiful botanical slides showing mitosis, by H. F. Angus and E. J. Sheppard; a Siedentopf ultra-microscope and cardioid condenser system for the observation of ultra-microscopic particles, by J. E. Barnard; an Abbe diffraction microscope illuminated by means of a quartz mercury-vapour lamp, by J. E. Barnard and Powell Swift; an instantaneous reflex photomicrographic camera, by F. W. Watson Baker; some preparations exhibiting Brownian movement, by G. P. Bate; a complete optical bench and an apparatus for polishing metal surfaces, by Conrad Beck; an extensive series of saccharomycetes, by A. Chaston Chapman; a very interesting old microscope and accessory apparatus, by Prof. A. Dendy, F.R.S.; some diffraction experiments, by J. W. Gordon; a series of foraminifera, by E. Heron-Allen and A. Earland; microchemical reactions of a very striking character, by Prof. Herbert Jackson; an extremely beautiful series of photomicrographs in colour, by J. W. Ogilvy, and another series of stereo-photomicrographs of water mites, also in colour, by H. Taverner. The possibility of applying his micro-spectra camera to the production of photomicrographs in colour was demonstrated by J. Rheinberg, and this exhibit attracted a great deal of attention.

Prof. Minchin, F.R.S., exhibited a series of trypanosomes which were of great interest. In the adjoining theatre, three lectures were delivered during the evening, Dr. E. J. Spitta giving a kinematographic exhibition of pond life, Prof. Hewlett lecturing on insects as carriers of disease, and Mr. Max Poser showing a beautiful series of liquid crystals by means of a projection micropolariscope, each of the lectures attracting a large audience. Apart from the social advantages of such a gathering, the exhibits were in all cases of real scientific interest, and demonstrated that the Royal Microscopical Society may look forward to doing an even greater work in the future than it has done in the past in bringing before scientific workers the possibilities of the use of the microscope. That the instrument is now a necessity in nearly all branches of science is, of course, well known, but it is often used merely as a tool and not as an appliance which demands considerable skill in its use for the best results to be obtained. If the council of the society should decide that this conversazione is to be but the first of a series of annual gatherings to be held with a similar object, then the success which has attended this function may be regarded as an indication that its usefulness in the future may be considerably increased.

THE BRITISH ASSOCIATION AT DUNDEE.

SECTION M.

AGRICULTURE.

From the Opening Address by T. H. Middleton, M.A., President of the Section.

Interest in the practice of improved husbandry was first aroused in England by the books of Fitzherbert. The extent to which this author stimulated agriculture may be inferred from the appreciation with which his works were received in his own day, and copied by others for a century. He himself does not appear to have been acquainted with the classical writers. He describes the English practice with which he was familiar; he quotes frequently from the Scriptures and refers to early religious works, but only in writing of animal diseases, when he cites the "Sayinge of the Frenche man," is there any indication that he was influenced by foreign authors. Fitzherbert's "Boke of Husbandry" and "Surueyenge," while they are free from the direct influence of Roman writers, show us, nevertheless, that the English agriculture of his day owed much to Roman traditions. The careful business methods and accounting of the farm bailiffs of the Middle Ages, with which Thorold Rogers has acquainted us, were the methods which Fitzherbert learned and counselled, as they were the methods which Columella taught.

It was between 1523, when Fitzherbert's "Boke of Husbandry" was first printed, and 1557, when Tusser published his "Points of Good Husbandry," that the classical writers began to exert a direct influence on English farming. In 1532 there appeared Xenophon's "Treatise of Householde," "ryht counnyngly translated out of the Greke tonge into Englyshe by Gentian Hervet," which at once became popular and ran through a number of editions. At least as early as 1542 editions of the works on agriculture and gardening of Cato, Varro, Columella, and Palladius[1] were published in England, and they must certainly have been known to Tusser, for in his "Five Hundred Points of Good Husbandry," composed some years later, there is clear evidence of the influence of the writings of Xenophon and Columella. From the latter author Tusser adopts the method of a calendar, and he appears now and again to adapt Roman maxims to modern conditions. Thus in his calendar Columella says of March that it "is the proper time to cleanse meadows, and to defend and secure them from cattle; in warm and dry places indeed that ought to be done even from the month of January," and Tusser in his calendar for March rhymes:—

> "Spare meadow at Gregorie Marshes at Pask
> for feare of drie Sommer no longer time ask
> Then hedge them and ditch them, bestow thereon pence,
> corne, meadow, and pasture aske alway good fence."

It might be, of course, that in discussing the same subject, a subject moreover which does not admit of much difference of opinion, the similarity of the above-

[1] A translation of Palladius into English was made about 1420, but it was not discovered and published until within recent times.

quoted passages is accidental; but many of Tusser's rhymes so closely follow Xenophon's "Householde" and Columella's Eleventh Book that I am satisfied Tusser was familiar with both these ancient writers. Here, for example, from Tusser, is the charge concerning sick servants which Ischomachus gives to his young wife:—

> "To Seruant in Sicknesse see nothing ye grutch,
> a thing of a trifle shell comfort him mutch."

And here is a maxim for the housewife that Columella enforces:—

> "The woman the name of a huswife doth win
> by keeping hir house and of dooings therein
> And she that with husband will quietly dwell
> must thinke on this lesson and follow it well."

Until the dawn of the twentieth century no mere man would have been found to question the conclusion come to in the above verse; nevertheless, the emphasis on the "quietly dwell" indicates that in this particular case the inspiration is derived from Columella rather than from Xenophon. For while the woman described by the Greek writer is likened to the queen bee, by the Roman there is much lamentation because of the emergence of the "butterfly." Columella refers to the diligent dames of ancient Rome who lived at home and studied to improve their husbands' estates, and contrasts them with their successors in the first century, who had become indolent, refused to make their own clothes, and spent their husbands' incomes on dress. He then remarks, "Is it a wonder that these same ladies think themselves mightily burdened with the care of rural affairs, and esteem it a most sordid business to stay a few days in their country houses?"

It was, then, the practice of husbandry that engaged the English agriculturist's attention from the time of Walter de Henley to Thomas Tusser, and the purpose of my digression into domestic subjects is to show that when the ancient writers were rediscovered in the middle of the sixteenth century, it was not the frequent references of Xenophon to the science of husbandry but his economic and moral teaching: not Columella's First Book, with its appeal for doctors and disciples who might apply themselves to the study of agriculture, but his Eleventh Book, with its calendar of operations and its directions for the ordering of the bailiff and the bailiff's wife, that attracted Tusser and his readers.

The awakening of interest in husbandry was largely due to the rapid changes in the economic conditions of England which set in about Fitzherbert's time.

The change in the cost of living directed men's attention to the husbandry and housewifery recommended by Fitzherbert and Tusser. The smaller landowners, who could no longer afford to live on their rents, and who saw that yeomen and tenant farmers were prospering, turned their attention to farming, and agriculture became an important occupation of the educated classes.

The yeoman and tenant farmer did not ask for textbooks on agriculture, but the new agriculturists required information, and thus there arose at the end of the sixteenth century a great demand for books. The booksellers were not slow to make provision for the demand, writers were secured, books were published, and of the more popular many editions were sold.

Sir Richard Weston, a Surrey landowner, who succeeded to his estates in 1613 and who had travelled in Brabant and Flanders, was the first English agriculturist to introduce practices approved on the Continent. He grew turnips for feeding cows, a century before the time of Turnip Townshend; nearly three hundred years ago he was experimenting, as we are still doing, with clover seed grown in different countries; he had thirty to forty acres of clover sown with barley, and he was inveighing against the sophistication of "outlandish" grass seeds and contriving plans for raising pure stocks at home in the approved fashion of to-day.

It was not only from Brabant and Flanders that travellers brought to England information about foreign agriculture. As one result of the development of commerce voyagers were introducing from distant countries such important plants as the potato and tobacco, and were exciting interest by their stories of foreign products. A desire to make experiments with these novelties was but natural, and experimental farming received a powerful impetus from the teachings of Francis Bacon, the first exponent of the inductive method. Having, as he wrote, "taken all knowledge to be my province," Bacon was himself an amateur farmer, and if he was not a successful one he was at least intent upon introducing methods of "industrious observation and grounded conclusions." It is to Bacon, I think, that Arthur Young alludes in a passage in which he describes a Lord Chancellor of England as having procured and read every published work on husbandry so that he might learn how to farm, and who, having met with ill-success, collected the offending books and lighted a bonfire! But let us not think lightly of the efforts of this distinguished amateur farmer. The agricultural writers of the succeeding century, indeed, refer to the influence of Bacon in terms that suggest for agricultural science the origin of the phœnix. We may, at least, agree that about the time of Bacon's bonfire this subject first began to attract the notice of scholars.

In spite of the political troubles of the second quarter of the seventeenth century, agriculture continued to secure increased attention, for England had learned that in war or peace the food-supply must be cared for, and the importance of corn-growing increased with the rise in prices. Thus when the Commonwealth was established everything favoured a forward movement. At peace and able to return to country pursuits, the combatants, Cavaliers and Roundheads alike, became active improvers. Engineer agriculturists, like Vermuyden, carried out great drainage-works. Many estates had changed hands, and the new owners, not a few of whom, as Harte remarks, "had risen from the plough," were glad to return to it; others were amateur farmers intent on learning. The books of the old and trusted writers, Fitzherbert and Tusser, had been followed by the works of such authors as Norden, Markham, Plattes, and Hartlib. Bacon's teaching emphasised the need for further study and experiment. Behind the political and economic changes were the powerful, moral influences of the Puritan movement; it was at this time and under these conditions that the spirit of the improver, which had animated Columella, appeared among English agriculturists

The first practical farmer to plead the cause of the improvement of agriculture was Walter Blith, one of Cromwell's soldiers, who is supposed to have been a Yorkshire landowner, but who for some years, at least, was stationed in Ireland. Blith was an ardent agriculturist, who prefaced his practical book, "The English Improver Improved," by seven epistles designed to attract the attention of all classes of his fellow-countrymen to agriculture. It is in the epistle to the "Honourable Society of the Houses of the Court and Universities" that chief interest lies for us, for here we find an appeal for the systematic study of agriculture in words that recall the classical writers. Blith showed that agriculture required the close study of the learned, and that the societies (*i.e.*, the Colleges) of the Universities might if they wished do much for its advancement. He adds, "You that have the Theorick, may easiest discover the Mysteries of the Practick, and from you have I found most encouragement to this work, and seen most experiences of good husbandry than from any, and from you too I expect and waite for more discoveries of some thing I scarce know what to name it, which lies yet in obscurity, but I will call it the Improvement of the Improver."

Were we not now concerned with the spirit rather than with the form of the improvement, an interesting parallel might be drawn between the topics which Blith considers of greatest importance and those which to-day are engaging attention. In his epistle to the society, for example, there is an appeal to the learned to give their attention to applied science. Discussing the progress of the Dutch, Blith deplores that policy which Englishmen afterwards termed *laisser faire*. He says: "Our niceness in not nursing the fruits of our own bowells hath given them the opportunity to Improve our native commodities to the advance of their Manufacturidge to our shame, their praise"; then addressing members of the universities he adds, "I speak to wise men whom I would have more publique men. . . . Let me entreat you for the Peoples and your own posterity sake . . . put your shoulders to the work, greater things remaine and larger Improvements are yet to be discovered."

The earnest advocacy of Blith, the essays of "my good friend Mr. Samuell Hartleps," and the energy of landowners like Sir Richard Weston, led to a demand for the records of experiments, and in 1659 there was issued the first series of abstracts of agricultural experiments with which I am acquainted, under the title "Adam out of Eden." The experiments recorded by the author, Ad. Speed, are of considerable interest; but I mention him for another reason. He appears to have made a living by propounding improvements of an imaginary character. He wrote tracts for noblemen and others, containing estimates of the profits to be gained by adopting new methods. Blith scathingly refers to him as "Mr. Speed that superlative Improver," and remarks that so long as his books were private "I could bear it, and suffer wiser than myself to bee fooled because I was not wise enough as to beware of him, but now that they come to be sold in the Stationers' Shops, and spread about the country, to deceive, and beguile the Nation, I cannot forbear." This was written in 1652; as my edition of "Adam out of Eden" is dated 1659, it is clear that the nation continued to be "beguiled" for a considerable period by this particular Adam, the forerunner of a numerous family. Whenever there is a revival of interest in agriculture he flourishes; the new manure, the ravaging insect, the blighting fungus, all serve to bring "Adam out of Eden," and so long as an interested and gullible public exists, "that superlative Improver Mr. Speed" will be found among us. The pamphlet and the stationers' shop have become antiquated; the Adam of to-day has other methods, which I will not venture to particularise. After all, it is a healthy sign. It is only when the public thirst is deep that Adam gets his chance, and, like Blith, we must resign ourselves now and again to "bee fooled," for is it not one of the methods by which the improver is improved?

Walter Blith's appeal for the assistance of the learned did not long remain unanswered. At the time his "English Improver Improved" was published a society of scientific men had already been formed in London, and ten years later this society first received the name Royal Society, at the suggestion of John Evelyn. On October 15, 1662, Evelyn's "Discourse on Forest Trees" was presented to the society. Five years later, when the "Sylva" was published, the author in the preface tells us that the Royal Society was then doing much for husbandry.

John Evelyn was one of the prominent members of the Royal Society, and he seems to have taken a leading part in defending it against the attacks to which, in the first years of its existence, it was subjected. With much satisfaction he points out, in dedicating the second edition of the "Sylva" to King Charles II., that his essay and the work of the Royal Society have in the past eight years resulted in the planting of more than two million timber trees, and he adds that he has preserved the testimonials he has received with the more care "*because they are* Testimonials *from so many* honourable *Persons, of the* Benefit *they have receiv'd from the* Endeavours *of the* Royal Society, *which now adayes passes through so many* Censures."

With the exception of the "Societies of Learning and Gallantry" of the "Houses of Court and Universities" addressed by Blith, the Royal Society is the earliest to which any influence on agriculture may be traced, and it is certainly the first society which definitely included the improvement of agriculture as coming within its scope. It appears to have depended in no small degree for its early successes on the public interest aroused by the writings of Evelyn and Houghton, and there is evidence that the society gave much attention to agriculture during the second half of the seventeenth century, and that its patronage was much valued.

Evelyn's "Pomona," in which he discourses of fruit trees and cider, gives an interesting glimpse of some of the early activities of the Royal Society, for the work itself is based chiefly on contributions by members of the society to its "*well furnish'd Registers, and* Cimelia." Evelyn is careful to point out that these contributions were original papers, and that it was not the design of the society to "accumulate repetitions where they can be avoided." These new observations being in the society's esteem "*and according to my Lord* Bacon's" preferable even when "*rude and imperfect* draughts" than commonplaces "*adorn'd with more* pomp." Evelyn himself was not practically acquainted with cider-making, and his own interest in the subject, like that of the majority of his fellow-members, was Baconian—*i.e.* it consisted in a search for "grounded conclusions and profitable inventions and discoveries."

In other ways the members of the Royal Society encouraged one another in making improvements; thus when in 1666 Evelyn's "worthy friend" Mr. Hake went on a journey, he returned carrying with him—for eight hundred miles—some grafts for Evelyn, together with a "taste of the most superlative perry the world certainly produces." It was by means such as these, and by a policy which approved "plainness and usefulness" rather than "niceness and curiosity," that the newly-formed Royal Society commended itself to the country.

It is indeed probable that agricultural questions occupied much more of the attention of the Royal Society in the earlier years of its existence than the printed records suggest; we are told, for example, by the Scottish improver, "A Lover of his Country," that one of its most illustrious members, Sir Robert Boyle, was an enthusiastic agriculturist; he says: "I had the Honour to be known to that excellent Person and oft in his Company. He was the greatest Lover of Agriculture I ever knew, and I wonder he never wrote of it. I heard him say, it was a Pity there was not Seminaries of that, the most useful, and except Pasturage, the most ancient of all Sciences."

Not only were agriculturists attracted by the practical investigations of the Royal Society, but impressed by the value of its methods and organisation, and Worlidge suggests that nothing would more conduce to improving agriculture than the constitution of subordinate provincial societies "*whose* *principal care and office might be to collect all such Observations, Experiments, and Improvements they find within their Province . . . which of necessity must abundantly improve* Science *and* Art *and advance* Agriculture *and the* Manufactures."

The proposal made by Worlidge was unheeded at the time, for not until nearly a century after his suggestion was made did English agricultural societies begin to appear. A retrograde movement set in soon after the Restoration, and although the Government sought to foster improvements and passed several Acts with the object of stimulating farming, Harte tells us that a "total change of things, as well as the very cast and manner of thinking, joined with immoral dissipation, and a false aversion to what had been the object and care of mean despised persons, soon brought the culture of the earth into disrepute with the nobility and gentry."

An insight into the conditions of the last quarter of the seventeenth century and the first quarter of the eighteenth is given us by Lisle, who wrote the introduction to his "Observations on Husbandry" in 1713. He begins by remarking that it is one of the misfortunes of the age that it lacks honourable conceptions of a country life; he directs attention to the fact that in the decadent days of Rome luxury increased and husbandry was neglected. He calls on the landowner to look round him and see how many fine estates are daily mortgaged or sold, "and how many antient and noble families destroyed by the pernicious and almost epidemic turn to idleness and extravagance." He discusses at length the advantages of an agricultural career, and recommends it as a profession for the eldest sons of gentlemen, who might regard it as "a school of profit and education; whereas," he continues, "it is rather looked on as a purgatory for the disobedient, a scene of punishment, to which a son, who answers not his father's expectations, is to be abandoned; or a condition of life of which none would make choice, but such whom fortune has not in other respects favoured. If the country gentlemen therefore frequently consist of persons who are either rusticated by their parents in anger, or who, making a virtue of necessity, settle on their estates with aversion or indifference, it is no wonder the comedians exhibit them on our stage in so despicable and ridiculous a figure; but this is the fault of the persons and not of the art. Were they properly initiated in the study of Agriculture, and pursued it as they ought, it would be so far from excluding them from useful knowledge, and bringing them into contempt, that I may venture to assert they would find it the best school of education, and the fittest to prepare them for the service of their country in the two houses of parliament of Great Britain."

Such were the dispiriting social conditions with which the successors of Evelyn in the Royal Society had to contend. The agricultural experiments of the society therefore attracted but little attention outside the ranks of the curious. Houghton, a contemporary of Evelyn's, started a periodical publication, *Houghton's Letters*, but it soon ceased. A generation later, and about the period to which Lisle refers in the above quotation, a work on husbandry was written by a fellow, John Mortimer. It is dedicated to the society, "to whose encouragement, inquiries, and direction it owes its birth." Special thanks are given to another fellow, Dr. Sloane, who assisted the author, and "has greatly contributed to the advancement of useful knowledge."

Testimony to the activity of the Royal Society at this period is also to be found in a work on "Curiosities of Nature and Art in Agriculture and Gardening," a translation from the French of the Abbot de Vallemont by Bishop William Fleetwood, published anonymously in 1707; this work contains the passage: "The Royal Society of *England* who are so zealous for the Perfection of Agriculture and Gardening, have apply'd themselves with great Care to find out the true way to make Salt-petre, which they likewise allow to be the chief Promoter of the Vegetation of Plants."

About this time botanical questions of much interest to agriculturists were occupying the attention of the Royal Society. Robert Ball and Samuel Moreland were investigating reproduction in plants, and a few years later Richard Bradley, another fellow, professor of botany at Cambridge, but more of an agriculturist than a botanist, was explaining how, by cross-breeding, "such rare kinds of plants as have not yet been heard of" may be produced. He refers specifically to a cross between a carnation and a sweet-william, but by inference to Burgoyne's Fife and the other things "not yet heard of" that are associated with agriculture and botany in the Cambridge of to-day.

Various causes, among which the influence of fellows of the Royal Society must be given an important place, led the landowners and the educated classes of England again to turn their attention to agriculture about the beginning of George II.'s reign. The revival was associated with and followed, as it has in recent time, a development in gardening. William and Mary were patrons of horticulture, they greatly improved the Royal gardens, and the nobility, in imitation, laid out parks and *parterres*.

A writer on agriculture and gardening of this period, the Rev. John Laurence, of Bishop Weremouth, Durham, attributes the revival, not merely to progress in the art of gardening, fostered by nobles and statesmen, but to the Royal Society—of which he says that its Philosophical Transactions "are standing Memoirs of the Zeal and Activity of many Persons of Quality and Learning," whose "Discourses and Experiments" have "advanced much Light in the Art of Husbandry."

Although for seventy years after its formation, and throughout a period during which agriculture was neglected by the landed classes, the Royal Society did much to keep alive the spirit of the improver, the unfortunate apathy of the agriculturist prevented that progress which appeared to be imminent when John Evelyn wrote his "Pomona." It was not possible for a learned society in London to investigate agricultural questions in the absence of the scientific agriculturist himself; subjects of agricultural interest were therefore discussed chiefly from a theoretical point of view, and, neglecting the teachings of Bacon and the example of Evelyn, there arose that use of the deductive method which in the past two centuries has done so much to hinder the progress of agricultural science.

The first to show up the fallacy of the deductive method in studying this subject was Jethro Tull, who, though he himself fell into the errors which he condemned, was, in his understanding of the true relationships of science and practice, far ahead of any of his contemporaries. A lawyer by training, he probably took to agriculture because of his poor health. He worked at it for twenty years before he was induced to set out his views in writing, and it was years after he began farming before he read anything on the subject. Dissatisfied with the practice of his times, he set himself to reason out new methods and to make experiments. He got suggestions from foreign travel; he tells us, for example, that the first hint of the value of horse-hoeing husbandry was derived from the ploughed vineyards of France; but he was careful to submit his ideas to the test of experiment before he adopted them in farm practice. His temper, which, if one may judge from his references to his labourers, was far from serene, was much tried by his controversies with *Equivocus*, and his criticisms of the writers and scientific men of the preceding half-century are severe. He remarks, for example, on the superficial knowledge of agriculture shown by "Mr. Laurence, a divine; Mr. Bradley, an academic; Dr. Woodward, a Physician; Mr. Houghton, an Apothecary; these for want of practice could not have the true theory; and the writers who are acquainted with the common practice, as Mr. Mortimer (whether for want of leisure, or not being qualified, I do not know) have said very little of any theory." He freely criticised the writings even of "Mr. Boyle" and of that "miracle of a man Sir Isaac Newton," and in a characteristic sentence he remarks: "From Sir Isaac's transmutation arguments we may learn that a man never ought to depend entirely upon his own for support of his own hypothesis." An admirable sentiment which I am afraid that Tull himself, and many another agriculturist since his time, failed to lay to heart.

Jethro Tull's great work was published two generations after Walter Blith first endeavoured to awaken the spirit of the improver in English farmers. Throughout this period not much progress had been made, but a change was at hand. When in 1730 Turnip Townshend left politics and went down to Norfolk to farm his estate, the tide had turned, and henceforward throughout the eighteenth century there was a rapid improvement in the practice of English agriculture. Of these developments no small share may be attributed to the influence exercised by the Royal Society during the first seventy years of its existence.

The agriculture of Scotland had not shared in the revival due to the work and writings of the English improvers, and was in a very backward state in the middle of the seventeenth century. Its condition is indicated by John Ray, who, in 1661, some months before the Royal Society received its charter, set out from Cambridge to spend the Long Vacation in a Scottish tour. He crossed the Tweed on August 16, and proceeded from Berwick, via Dunbar, to Edinburgh. His first day's journal gives us his impressions of what is now, and probably was then, one of the foremost agricultural districts in Scotland. "The ground in the valleys and plains bears good corn," he says, but "the people seem to be very lazy, at least the men." Scottish women, he writes, "are not very cleanly in their houses, and but sluttish in dressing their meat." "They have neither good bread, cheese, or drink. They cannot make them, nor will they learn. Their butter is indifferent, and one would wonder how they contrive to make it so bad."

After the Union Scotchmen in increasing numbers took the high road to London, and at first with much less profit to themselves than those acquainted with the Scot in modern times might suppose. As a result of social intercourse, the upper classes began to copy the manners and customs of their rich English neighbours, and prices and the cost of living rose rapidly. These economic changes, as in England a century before, turned the attention of landowners to the improvement of their estates; but as the Scottish laird of the beginning of the eighteenth century did not take readily to farming, a few of the more enlightened men among them saw that if improvements were to be made special measures were necessary. Impressed by the usefulness of the Royal Society, these reformers conceived the idea of establishing an Agricultural Society in Scotland. This society, which met for the first time in Edinburgh on June 8, 1723, and adopted the name of "The Honourable the Society of Improvers in the Knowledge of Agriculture in Scotland," was the first association to be formed for the express purpose of promoting agriculture. Some account of its work is given in its Transactions, published twenty years later, but for a contemporary view of the problems which engaged the society's attention we must go to a book published in Edinburgh in 1729, under the title of "An Essay on Ways and Means for Inclosing, Fallowing, Planting, &c., Scotland, and that in Sixteen Years at farthest, by a Lover of his Country."

Of all old books on agriculture this is, to me, the most interesting. The anonymous writer is believed to have been Brigadier-General Mackintosh of Borlum, one of the rebel leaders of 1715, who fell into the hands of the English at Preston, was imprisoned in Newgate, and sentenced to death. But this Highlander was not to be held by English gaolers. With some of his comrades he overpowered the prison guard and made good his escape; recaptured in 1719, he spent the rest of his life in prison. The essay was written, its author informs us, in "my Hermitage"—a cell in Edinburgh Castle—and the writer remarks that he can give no better reason for his work "*than other* Enthusiasts *do, the Spirit* moves me."

The prisoner employed his enforced leisure to great advantage. He displays more familiarity with the classical authors than any of his predecessors, or for that matter than any of his successors, except Harte and Adam Dickson, and he had obviously studied all the more important works published in England in the previous century. He argues that since the Union, Scotland had not made progress, and that, while extravagance had spread and necessaries greatly increased in cost, no attempt had been made to learn good rural economy from the English. He points out that until they improve their estates Scottish lairds cannot hope to emulate English landowners. He counsels fallowing and inclosing, and recommends that skilled English labourers should be brought to teach English methods. He indicates where the best workmen might be obtained. Men from Devonshire for denshiring (paring and burning); men from Cambridgeshire for draining; men from Hertfordshire for ploughing; from Hereford for fruit planting; and from Shropshire for hedging. He estimates that six hundred and forty men would be required for Scotland. A "regimental number," he facetiously remarks, but a welcome regiment, for they would be armed only with spade and shovel! He would apportion a group of these men to every county in Scotland and place them under the guidance of county supervisors. "And if I might have my wish," he says, "we should not go on by Halfs, and all *Europe* should be quickly disabused of the Reproach they load us with of *Idleness* and *Poverty*." In another passage he prophesies that "*Scotland* from one of the poorest, ugliest, and most barren Countries of *Europe*, is, in a very few *Years*, become one of the richest, most beautiful and fertile Nations of it," and who would now assert that the old rebel's prophecy has not been fulfilled?

As already mentioned, the Society of Improvers was constituted at a meeting held on June 8, 1723. A council of twenty-five members was elected, the council was divided up into subcommittees, each of which was charged with the care of a special branch of agriculture; the rules set out that the members of committees were to "chuse different subjects in Agriculture and mark down their thoughts thereon in writing." They were also to correspond with the most intelligent agriculturists all over the country and to endeavour to get small local societies formed. The chief duty of each subcommittee was, however, to give advice on the means of carrying out improvements. Members were asked to send in an exact statement of their difficulties, and answers were forwarded by the society. If the suggestions proved useful, the recipient of advice was expected to report the result for the benefit of his fellow-members.

The volume of "Select Transactions," published in 1743, contains a number of specimens of the questions sent in and the answers supplied. Such subjects as the draining of boggy land, the use of marl and lime, the effects of seaweed as manure, the cultivation of potatoes, hops, sainfoin, and flax; the feeding of cattle and the employment of steeps for corn were dealt with. Most of the correspondence is with Scotchmen, but occasionally letters from others occur, including an interesting communication from Jethro Tull in which he says that "twenty years ago there was much the same way of tillage in England as is now in Scotland, but it has since been exploded by experience, and the farmers have enriched both the land and themselves by plowing it more than they were wont." Directions for lime-burning are contributed by Mr. Lummis, "who came from England and made the Rotheran Plough." The Transactions have an advertisement of this plough, from which it appears that the Earl of Stair had sent one of his men to be taught by "the best Plough and Wheel-Carriage wrights in England," and that Rotheran ploughs of very superior workmanship were being made at Newliston, West Lothian. The Earl of Stair further laid agriculturists under obligation by introducing turnips, cabbages, and carrots as field crops, and he bred very good Galloway cattle. Another notable man among these early improvers was the Earl of Islay, who gave special attention to the cultivation of peaty soils and succeeded in producing good corn and grass on land previously thought to be of little value. He also planted extensively, and, according to Maxwell, introduced the larch, among other trees, to Scottish foresters.

The society did not confine its attention exclusively to agriculture. It noted a natural connection between the agricultural and fishing industries, and did much to promote the latter, thus establishing an early precedent for the association of agriculture with fisheries for administrative purposes. Manufacturers, too, were encouraged, and in this connection there stands out the name of the Duke of Hamilton, who moved the following "Overture": "That all of you and all under your Influence, should, for Examples to others, buy no foreign Linen for Shirting, Bed-linen, or any other Household-furniture; and that you should propagate to the utmost of your power the wearing of home-made stamped Linen." The consequence, we are informed, was that "even at Publick Assemblies of Persons of the greatest Distinction, the whole Company appeared dressed in Linen of our own Manufacture." The Duke's success with linen led him next to propose a resolution against the drinking of foreign spirits, so that the great sum annually sent to France for brandy might be kept at home! The consequences were not so immediately noticeable as in the case of linen, for the local records of the east of Scotland show that the smuggling of French brandy was a very profitable trade throughout the eighteenth century. It is, however, the case that at a later date the Duke's advice was followed, for not only linen but liquor of native manufacture came to be appreciated, "even at Publick Assemblies of persons of the greatest Distinction"; at assemblies, moreover, on both sides of the Tweed!

During the twenty-two years of its existence the Honourable Society of Improvers became a powerful and important body. Its influence, it should be noted, was obtained by educational methods, for its funds were small, it had no State subsidy, as had the Irish Society, it offered no premiums, but it drew together in the cause of agricultural improvement many of the most prominent Scotchmen of the period, and it undoubtedly laid the foundations of that successful agriculture for which Scotland has ever since been noted. In 1743 the society had 299 members, and an examination of the list reveals many well-known names representing all sections of the educated classes of Scotland, with the notable exception of the clergy.

Of all the members, those who best deserve our notice are Thomas Hope of Rankeilor, president, and Robert Maxwell of Arkland, editor of the Transactions. Mackintosh refers to Hope as a man who had taught improved agriculture to hundreds of his fellow-countrymen. He studied the subject, not only in England, but in France, Flanders, Holland, and other Continental countries, and Maxwell says of him "that it has been much owing to *Mr. Hope of Rankeilor* your Preses, that this Society was entered into and that the Spirit of it rose so high," and adds that he "has been instructing others in the Knowledge of it and been preaching up the publick and private Advantages arising from it for a continued Tract of more than Twenty Years' Time." Of the spirit which animated Robert Maxwell himself we have ample evidence in the dedication of the "Select Transactions." Reviewing what has been done by the society and considering that which might still be done, Maxwell writes, "since the Case stands thus, how much doth it concern the Publick and every Individual that Agriculture be encouraged and that the *Knowledge* of it, the efficient Cause of all those inestimable Benefits, should be taught to all who are willing to learn the Principles of this the most useful of all Sciences; to all who desire to know the secret Causes why some plants enrich, and others impoverish the Ground in which they grow; why different Methods of Husbandry produce different Effects; and in general to all who incline to study the Reasons for and against, the different Methods practised? They that do not study Agriculture as a Science do right only by chance, and that rarely happens. Why then should Reason be so little exercised, as generally it is, in this Matter of the greatest Importance?" He then refers to the opinions of Virgil, and to the views expressed by Columella on the subject of teaching agriculture, and he urges the society to take steps to found a professorship.

Maxwell proposed that the society should address a memorial to the King on the subject of a professorship. "You are," he wrote, "a great Body of loyal Subjects and generally of great Distinction, and I humbly think upon a proper Application to his Majesty, you could not fail to have sufficient Influence to get such a Professor or Inspector named or both."

But, alas! neither professor nor inspector did Maxwell see, for within two years Prince Charles Edward had landed in Scotland, the Marquis of Tullibardine was rallying the Highlanders to the Stuart flag, and the loyalty of the Honourable Society was subjected to a strain which it could not withstand. Most of the members took the advice of Duncan Forbes and held out for the King, but others, like the Duke of Perth and Lords Cromatie, Balmerino, and Lovat, followed Prince Charlie. When peace was restored, the Honourable Society, and not a few of its members, had ceased to exist; but the purpose for which it was founded had been achieved, and the spirit of the improver lived on.

One of the objects of the Honourable Society of Improvers was to develop local societies. Two of these may be traced in Scotland before 1745, one in

Buchan, the other in East Lothian. The former appears to have been started about 1730 by James Ferguson of Pitfour among his Buchan tenantry. Ferguson was a friend of Thomas Hope's and believed in his methods of "preaching improvements." He supplied the members of the Buchan Society with books, and he himself attended their meetings. In 1735 this society published a small volume which had been drawn up by the members at their meetings, entitled "A True Method of Treating Light Hazely Ground; or, an Exact Relation of the Practice of Farmers in Buchan containing Rules for Infields, Outfields, Haughs, and Laighs." In many respects this is a remarkable little work. It relates exclusively to local farming, and while the inspiration may have come from Edinburgh, the book itself bears no evidence of outside influence. Their independence is indeed a noteworthy characteristic of the members of this Buchan Society. From certain references which appear in their Proceedings it may be surmised that they were well acquainted with agricultural writers. But instead of recounting the opinions of others, and speculating as to their value for Buchan, this society of tenant-farmers adopted the true scientific method, they described their practices in detail, discussed them fully, and, being satisfied that they were applicable to local conditions, they reduced their methods to rules. In matters too deep for them, their philosophy rested on a firm basis. Here, for example, is an explanation of the early fruiting of wild oats. This pestilent weed they urge all farmers to destroy by "cropping the wild oats how soon they come out of the hose, who appear always about eight days before the tame. Thus is Providence so kind as to tack that to their nature which is the means of their own destruction."

The second of the local Scottish societies, existing before 1745, was that established by an enlightened landowner, John Cockburn of Ormistown, in East Lothian. Robertson, in his "Rural Recollections," gives July 18, 1736, as the date of its formation. With Cockburn were associated Sir John Dalrymple and other country gentlemen. From a reference made to their meetings by Henry Home, it would appear that in this society we have the origin of the "farmers' dinner." Home counsels landlords to "convene" tenants once a year to a "hearty meal," at which they were to be instructed in new methods of husbandry. "It was by such means," he adds, "that the late John Cockburn of Ormistown promoted emulation and industry among his people." But Cockburn did not confine himself to an annual dinner. Monthly meetings were held for the discussion of agricultural improvements, and these were much appreciated not only by Cockburn's tenants, but by neighbouring landowners like the Earl of Stair and the Duke of Perth, who attended regularly. Even the '45 did not suppress these monthly meetings, and after Preston Pans the Duke of Perth was mindful enough of Ormistown to send troops to protect the members, so that they might quietly continue their criticisms of Tull and their appreciations of turnips.

Maxwell tells us that the Dublin Society (established 1731) was formed in imitation of the Society of Improvers. It is clear when Arthur Young wrote that to the Dublin Society "belongs the undisputed merit of being the father of all similar societies now existing in Europe" he meant that it was the oldest of existing agricultural societies, and not the first society of its kind. The Dublin Society soon after its formation received a Government grant and could therefore spend much more on its work than its Scottish prototype. Time will not permit of a reference to the work of this society, but mention may be made of the experimental farm established by the unfortunate John Wynn Baker, under its auspices. The farm was started in 1764 and continued until about 1770. Schemes were drawn up by Baker in consultation with the society, and an annual grant of 200*l.* was made in support of the experiments; two volumes giving the results were issued.

In 1754 the Royal Society of Arts was established, and almost immediately afterwards it began to give attention to agriculture. A record of its valuable work written by Sir Henry Truman Wood has recently been published in the society's Journal.

The same year that saw the formation of the Royal Society of Arts brought together in Edinburgh a small group of distinguished men who formed themselves into the Select Society. The purposes were the discussion of philosophical questions and practice in public speaking. The idea came from Allan Ramsay, an artist and son of the poet. Alexander Wedderburn was elected chairman (as Lord Loughborough, the first Scottish Lord Chancellor of England, he affixed the seal that gave Sir John Sinclair his Board of Agriculture), and among the members were Adam Smith, David Hume, Henry Home (later Lord Kames), and William Robertson (afterwards Principal of Edinburgh University). This society soon attracted all Edinburgh residents who were in any way distinguished. But in one respect it was a failure; certain members, we are informed, always talked, and the wisdom of others was in danger of being suppressed and unavailing. It is said, for example, that Adam Smith and David Hume never opened their lips! It appears, therefore, to have been decided that the society's genius should be turned to practical objects, and within the Select Society a new organisation, the Edinburgh Society, was formed in 1755, "for the encouragement of Arts, Sciences, Manufactures and Agriculture"—*i.e.* for the same purposes as the Society of Arts had been established in London a few months earlier.

An account of the Edinburgh Society is given by Ramsay in his "History of the Highland and Agricultural Society of Scotland," from which it appears that the methods of this society—the offering of premiums for live-stock and implements—were those which have since been everywhere adopted. In 1759, for example, we read that at the show of horses nine stallions were exhibited, "all very good." But the goodness of the stallions and of the objects did not bring prosperity to the Edinburgh Society; talent was more abundant than money in Edinburgh in the middle of the eighteenth century, subscriptions remained unpaid, the premium list had to be reduced, and finally the Select and the Edinburgh Societies disappeared together in 1765.

Before concluding these notes on early associations let me ask your attention very briefly to some of the evidences of their influence on the agriculture of a later period.

The chief aims of the early societies were to impress upon landowners in the first place the interest afforded by the study of agriculture and in the second the duty of providing an increased supply of food for the nation. Nothing is more marked in the writings of such improvers as Blith, Worlidge, Lisle, Laurence, and Mackintosh than their insistence on the importance of agriculture as a subject of study. Until the educated among their fellow-countrymen could be interested in the principles of agriculture, it was clear to these far-seeing men that progress could not be made.

The change in the attitude of the educated classes to agriculture that took place within a century of the formation of the Royal Society is indicated in all the works published after 1750. Hirtzel, of Berne, *e.g.* in

"The Rural Socrates" (second edition, 1764) remarks: "It is no longer a controvertible point whether the science of Agriculture merits the distinguished attention of philosophical minds, and is the proper study of the most enlightened understanding; since the proof is beyond contradiction, that a judicious rural economy is one of the chief supports of the prosperity of a State." In Henry Home's dedication of "The Gentleman Farmer" to the president of the Royal Society (1776), we find this passage: "Agriculture justly claims to be the chief of arts, it enjoys beside the signal pre-eminence of combining deep philosophy with useful practice"; and in the preface to the same work he says: "Our gentlemen who live in the country have become active and industrious. They embellish their fields, improve their lands, and give bread to thousands." He contrasts these pursuits with those which formerly occupied the country gentleman: "His train of ideas was confined to dogs, horses, hares, foxes; not a rational idea entered the train, not a spark of patriotism, nothing done for the public."

How unlike the state of affairs described by Home were the conditions in a country resembling Britain, but in which the spirit of the improver had not been awakened, may be indicated by a quotation from a report on the farming of Holstein and Mecklenburg sent to Sir John Sinclair in 1794. The writer, M. Voght, states that the agriculture of North Germany was fifty years behind that of England, and explains its depressed state by saying: "Our noblemen are no farmers, and our farmers no gentlemen; our authors on agriculture possess no cultivated land, and those few who could give to the public the precious results of long experience and labour would starve their printer for want of readers."

The landowner of North Germany, towards the end of the eighteenth century, was, indeed, in very much the same state as the landowner of Britain in the first quarter; and it is when we compare the conditions described by Lisle, Mackintosh, Home, and Voght that we begin to appreciate how much British farming owes to such associations as the Royal Society of England and the Honourable Society of Improvers of Scotland. Had not the interest of landowners, and of the educated classes generally, been secured, there is no reason to suppose that the agriculture of Britain in 1794 would have been markedly in advance of that of Germany.

Both in England and Scotland the first impetus towards progress was economic in its character, and throughout the seventeenth and eighteenth centuries economic causes were constantly accelerating the improvement of agriculture; but we must not make the mistake of supposing that a rise in prices necessarily brings about improvements in husbandry. A motive for improvement is provided and more labour may be drawn to agriculture, but it does not follow that there will be a real advance, and that there will be more food produced for the use of workers in other industries. Without changes of system, *i.e.* without improvements based on new discoveries, the effect of a rise of prices in a self-supporting country would merely be to alter the proportion of the population engaged in agriculture, and to form congested districts. This was the danger that threatened England early in the seventeenth and Scotland early in the eighteenth centuries; but fortunately for each country an intellectual revival followed close on the rise in prices, and attention was directed not only to the necessity for more food, but to the need for improvements which would afford a surplus for the support of the industrial classes.

Within recent years the improvers of the eighteenth and early nineteenth centuries have been much criticised for their land policy, their enclosures, and their treatment of labourers; but one thing at least the agriculturists of 1760–1815 saw more clearly than their modern critics—they recognised that if their country was to become a great manufacturing nation, more food must be grown; and to this task they applied themselves so successfully that, as Porter points out, the land of Great Britain, which in 1760 supported about eight million inhabitants, in 1831 supported sixteen millions. When we reflect that the implements of husbandry were rude, that thorough drainage had not been introduced, that artificial manures (except crushed bones) were scarcely known, that oilcakes were scarce, that grain was too valuable to be given freely to cattle, that in bad seasons live-stock had to be starved so that men might be fed, that in good seasons prices fell rapidly, and with them farming profits, and that credit was difficult to obtain and interest high, those of us who know something about the ordinary work of the farmer can realise the strenuous efforts that must have been necessary to wring from land a sufficiency to feed this rapidly growing nation and to maintain it in health and comparative comfort. Even as late as 1836 Porter shows that it would have been impossible to feed any considerable part of the people on imported food. "To supply the United Kingdom with the single article of wheat," he says, "would call for the employment of more than twice the amount of shipping which now annually enters our ports."

Part of the additional food-supply was obtained by enclosing about seven million acres of land between 1760 and 1834; but as more than three times this area must already have been enclosed, as much of the land enclosed after 1760 was of poor quality, and as all of it had formerly contributed in some degree to the food-supply of the country, it is obvious that between 1760 and 1834 the rate of production per acre must have been largely increased.

Improvements in the art of agriculture cannot be rapidly introduced; there is first of all an experimental stage, and when improved methods have been learned they pass but slowly from district to district. Before any marked advance in the art can take place, there must therefore occur a period during which a foundation is being laid. It was about 1760 that our population began to increase rapidly, and it was then that agriculturists were called upon to produce more food. As we have seen, they were able to double the food-supply in seventy years. It cannot be doubted that this marvellous feat was rendered possible by the pioneer societies of the preceding century, or that it was the spirit of the improver, which the early associations had fostered, that animated the men from whom Arthur Young and Sir John Sinclair learned. If, in place of those enterprising agriculturists whose improvements are described in the reports of the first Board of Agriculture, our shires had been occupied by the dull-witted country gentlemen referred to by Lisle, or the "upstart sparks" condemned by Mackintosh, the history of this country must have been very different. Behind the military and naval victories which made Britain a great Power, was a commissariat supported by the agricultural classes. For the great industrial army which the genius of Arkwright, Watt, and other inventors provided with employment there was raised an ever-increasing food-supply. Political and industrial development alike depended on the rate of increase of the population, and this again on the rate at which the means of subsistence could be raised from British soil.

Although the economic position has undergone a revolution there is still work for the improver; no longer indeed do our industrial classes depend for subsistence on the surplus products of the British farmer, but after a long period of forgetfulness, once again it has been recognised that a progressive agriculture is essential to the well-being of the nation. This is not the time to discuss the nature of the questions which press upon us to-day; but let us not forget that they are our questions. To this newly-formed section of the British Association has descended the task of the early associations; it is the privilege of its members to preserve, and to hand down to their successors, that spirit of the improver which animated alike the ancient writers of Greece and Rome and the British societies of the seventeenth and eighteenth centuries; and to-day we may take to ourselves the exhortation of Walter Blith, for his words apply to Section M as they did to its predecessors, "from you, too, I expect and waite for more discoveries of some thing, I scarce know what to name it, which lies yet in obscurity, but I will call it the Improvement of the Improver."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The electors to the Isaac Newton studentships give notice that in accordance with the regulations an election to a studentship will be held in the Lent term, 1913. These studentships are for the encouragement of study and research in astronomy (especially gravitational astronomy, but including other branches of astronomy and astronomical physics) and physical optics. The persons eligible are members of the University who have been admitted to the degree of Bachelor of Arts and are under the age of twenty-five years on the first day of January, 1913. The studentship will be tenable for the term of three years from April 15, 1913. The emolument of the student will be 200*l.* per annum. Candidates for the studentship are invited to send in their applications to the Vice-Chancellor between January 16 and 26, 1913, together with testimonials and such other evidence as to their qualifications and their proposed course of study or research as they may think fit.

The Arnold Gerstenberg studentship has been awarded to A. E. Heath, of Trinity College. The Gedge prize has been awarded to A. V. Hill, of Trinity College, for his essay entitled "The heat production of amphibian muscle and of cold-blooded animals."

SOCIETIES AND ACADEMIES.

London.

Royal Society, August 23.—F. W. **Aston**: The influence of the nature of the kathode on the length of the Crookes dark space. (1) The relations between the values of pressure, voltage, current, and the length of the dark space are determined for plane kathodes of many different materials, and found to satisfy the same form of equations as those previously given for aluminium, the constants varying considerably. (2) Roughness of the kathode surface does not appear to affect the discharge, if the dimensions of the irregularities are small compared with the length of the dark space. (3) The length of the dark space is shown, in the cases examined, to be greatest for silver and least for magnesium, the metals following the same order as in the case of the kathode fall. (4) The rate of change of length of the dark space with change of current density at the surface of the kathode seems much the same for all kathodes. (5) Difficulties in the way of arriving at a satisfactory explanation of these and other data connected with the dark space are indicated and shortly discussed.—F. W. **Aston**: The discharge between concentric cylinders in gases at low pressures. (1) The relations between pressure, voltage, and the length of the Crookes dark space in the discharge between concentric cylinders take much the same form as those in the discharge between parallel planes. (2) Curvature of the surface of the kathode appears to have no influence upon the rate of alteration of the length of the dark space with change of current density, *so long as the latter is measured at the surface of the kathode.* (3) *Ceteris paribus*, the length of the dark space is greater for a convex cylindrical surface than a plane, and for a plane than a concave one.

Manchester.

Literary and Philosophical Society, October 1.—Prof. F. E. Weiss, president, in the chair.—Prof G. **Elliot Smith**, F.R.S.: Ancient stone monuments. There is, stated the author, no longer any room for doubt that the monuments known as "megalithic," which are to be found along the coast-lines of Europe, North Africa, and Asia, ranging from the Atlantic to the Pacific, embody the same general idea which has been elaborated in various ways amongst the different peoples. The repetition of apparently insignificant details in these monuments in countries as far apart as France and India, and Ireland and Japan, makes it quite certain that no theory of independent evolution of the idea of erecting these curious monuments can be entertained. All the evidence we possess tends to prove quite definitely and conclusively that the farther away from the eastern Mediterranean, whether east or west, north or south, the more recent the date of their construction. Thus, there can be no doubt that the idea of erecting such monuments originated somewhere in the region of the eastern Mediterranean. Now, so far as we know, the art of building in stone was cultivated in Lower Egypt at an earlier period than elsewhere. It is also known that every stage in the evolution of the burial customs associated with stone mausolea and every phase of the gradual development of the craft of stone-working have been preserved in Egypt. Further, in Egypt, the people were making a variety of stone tombs and mortuary chapels, which are obviously the prototypes of every kind of megalithic monument, long before any such monument is known to have been erected elsewhere. The conclusion is that the idea of building such monuments originated in Egypt.

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts 5 and 6 for 1912, contain the following memoirs communicated to the society:—

May 18.—P. **Hertz**: A proof by Boltzmann of the second law of thermodynamics.—W. **Voigt**: Electric and magnetic double-refraction (i.), with an appendix by P. Langevin. Th. **Brandes**: Plesiosaurus (Thaumatosaurus) aff. megocephalo Stutchbury from the lower Lias of Halberstadt.—W. **Blaschke**: Proof of the undeformability of closed convex inextensible surfaces. —K. **Försterling**: The theory of the Zeemann effect in any direction.—E. **Landau**: The number of integer-points in certain regions (*i.e.* the number of points with integral coordinates included within given regions of any number of dimensions).

July 20, 1912.—P. von **Liebermann** and G. **Révész**: Binaural combination of tones.—J. **Thomae**: The convergence of a Fourier's series.

The business communications (part 1 for 1912) contain the prize-subjects proposed by the society, the eleventh report of the Samoa Observatory for 1911–12, and a memoir of Sir Joseph Dalton Hooker by A. Peter.

THEORIES OF SOLUTIONS.

Theories of Solutions. By Svante Arrhenius. Pp. xx+247. (New Haven: Yale University Press; London: Oxford University Press, 1912.) Price 12*s.* 6*d.* net.

THE publication of Prof. Arrhenius's Silliman lectures on "Theories of Solutions," delivered at Yale in the spring of 1911, will be welcomed by all who are interested in the present position of physical chemistry. The book is of special value because the author has dealt very lightly with those aspects of his theory of "electrolytic dissociation" which have been discussed over and over again during the last twenty-five years and have occupied so large a space in nearly all recent text-books of physical chemistry. Thus, although many of his illustrations are drawn from electrolytic solutions, only three of the eleven lectures deal specifically with such solutions, namely, those on "The Theory of Electrolytic Dissociation," "Conductivity of Strong Electrolytes," and "Abnormality of Strong Electrolytes."

A special feature of the lectures is the historical method of treatment, which is adopted, not only in the first lecture, on "The History of the Theory of Solutions," but throughout the whole course. The author is, indeed, anxious to demonstrate that the newer views of the nature of solutions were a natural and logical development from those that had been in vogue previously, and seeks to disclaim the idea that he and his co-workers in this field originated a revolution which was in any sense a complete break with the past

The most fascinating lecture of the series is that on "The Modern Molecular Theory." To the average chemist it will be a complete revelation to know how accurately the actual masses of the molecules have been determined in recent years. These masses are recorded most conveniently by determining the magnitude of the constant N, the number of molecules in a gram-molecule, which is, naturally, the same for all molecules. Three methods used by Perrin and based upon the behaviour of minute suspended particles gave for N the values 68×10^{22}, 65×10^{22} and 71×10^{22}; three methods based upon the study of radioactive substances, including, for instance, the actual counting of α-particles, have given the figures 62×10^{22}, 71×10^{22} and 71×10^{22}. Other methods have given 71×10^{22}, 62×10^{22} and 62×10^{22}. It is indeed remarkable that nine series of determinations should agree thus together, the extreme range being only ± 6 per cent.

Other topics dealt with are "Suspension," "Adsorption," "Velocity of Reaction," "Equilibria in Solutions," and "The Doctrine of Energy." In the introduction, the author expresses the view that modern physical chemistry is largely synonymous with "theoretical chemistry," one of its chief functions being to express in mathematical form the experimental measurements of physicists and chemists; that he himself has not lost his skill in this art is shown by the introduction of some new formulæ in the present volume; that even more far-reaching results may flow from this method of working is clear from the use which has been made by Perrin, Lindemann and others of the formulæ developed within the last five years by Einstein.

It is a matter for regret that a book of small dimensions should have been issued at so prohibitive a price as to confine it very largely to reference libraries. The trustees of the "Silliman Foundation" would fulfil the purposes of the trust with much greater efficiency if they could arrange to circulate the printed lectures on more reasonable terms to a much larger circle of readers.

T. M. L.

INTRODUCTIONS TO BIOLOGICAL STUDY.

(1) *A Guide for the Study of Animals.* By Worrallo Whitney, Frederic C. Lucas, Harold B. Shinn, and Mabel E. Smallwood. Pp. ix+197. (Boston, New York, Chicago: D. C. Heath and Co.) Price 2*s.*

(2) *College Zoology.* By Prof. Robert W. Hegner. Pp. xxv+733. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1912.) Price 11*s.* net.

(3) *Einführung in die Biologie.* By Prof. Karl Kraepelin. Dritte, verbesserte Auflage. Pp. viii+356. (Leipzig and Berlin: B. G. Teubner, 1912.) Price 4.80 marks.

(1). THE teaching of biology is much more widely spread amongst American than among British schools, and the need for systematised courses of instruction in natural history is there greater than with us. In this work compiled by science teachers of Chicago high schools a graduated course of zoological teaching is drawn up, beginning with observations on house-flies and ending with some very good suggestions on the use of domestic breeds of animals as object lessons. So far as this suggested course goes, the book may be of considerable help to teachers in search of a suitable curriculum. The greater part of the work is, however, devoted to lists of questions that any good teacher could draw up without assistance. Some of the questions are badly worded or unanswerable; for example, "Compared with a hydra, how many cells has an earthworm?"

K

We have some difficulty in judging adequately of this book, since sixteen pages have been left out in binding up the review copy.

(2) For the most part Dr. Hegner's book runs on the familiar lines of comparative anatomy, and his treatment of the structure of animal phyla does not differ essentially from that adopted in any of the recent text-books of zoology, to which, indeed, he is indebted for most of his subject-matter and illustrations. The feature that he claims to be distinctive in this work is the consideration of animal physiology alongside of animal structure. The difficulty has been to compress a treatment of two such large subjects into the compass of a handy volume. Comparative physiology is in itself a large and new subject and would easily require a whole volume of this size. The author has cut the knot by reducing both anatomy and physiology to a condensed form that can scarcely be assimilated by any student. The physiological paragraphs deal mainly with responses to simple forms of stimulation—the behaviour of Paramecium and of Hydra are excellent examples of this—but they do not attempt to show the evolution of physiology amongst animals as do the sections upon anatomy.

Some useful sections are devoted to showing the economic bearing of zoological knowledge. The statement of the food of birds is a good instance of this, though here, again, the need for brief summaries has precluded the insertion of much interesting matter. The remarks on the damage due to insects, for example, are too brief to be of much value.

Compression has been carried too far in the case of invertebrates of uncertain affinities in chapter ix. Either these groups should have been omitted or treated more fully. On the whole the chapter on insects strikes one as being the best in the work, and the treatment of the affinities of animal phyla as the least satisfactory feature of it. The use of the terms "efferent" and "afferent" in connection with the circulation of the crayfish, on p. 283, is the converse of general usage and may lead to considerable confusion. The illustrations are very good and clear; those of the honey-bee, though not original, are sure to be welcome. Fig. 369 is turned upside down. Perhaps the greatest appeal of this very carefully compiled work will be to those who wish to have a book on comparative anatomy in one volume.

(3) This work, by the director of the Natural History Museum at Hamburg, has run into three editions in less than six years, and its success is due to the clear and well-balanced treatment that it contains of both branches of biology. In the present edition the sections on comparative anatomy and on the early races of mankind have been expanded and brought up to date so as to make an exceptionally attractive and very cheap work. Dealing, as the book does, mainly with general problems, it seems rather a pity that the statement of Mendel's method is not clearly given. The essence of the method and its importance can be stated quite simply without going into details. The account that is given here, printed, as it is, in minute type and dealing with a single case, will no doubt be expanded or altered in the next edition.

PHYSICS: OLD AND NEW.

(1) *Junior Magnetism and Electricity.* By Dr. R. H. Jude and Dr. J. Satterly. Pp. vii + 288. (London: W. B. Clive, University Tutorial Press, Ltd., 1912.) Price 2*s.* 6*d.*

(2) *An Introduction to Practical Physics for Colleges and Schools.* By Prof. E. H. Barton and Dr. T. P. Black. Pp. vii + 188; illustrated. (London: Edward Arnold, 1912.) Price 3*s.* 6*d.*

(3) *Mémoires sur l'Électricité et l'Optique.* By A Potier. Publiés et Annotés par A. Blondel. Avec une Préface de Henri Poincaré. Pp. xx + 330. (Paris: Gauthier-Villars, 1912.) Price 13 francs.

(4) *Treatise on Light.* In which are explained the causes of that which occurs in Reflexion, and in Refraction, and particularly in the strange Refraction of Iceland Crystal. By Christiaan Huygens. Rendered into English by Silvanus P. Thompson. Pp. xii + 129. (London: Macmillan and Co., Ltd., 1912.) Price 10*s.* net.

(5) *Intermediate Physics.* By Prof. W. Watson, F.R.S. Pp. xiii + 564. With diagrams. (London: Longmans, Green and Co., 1912.) Price 6*s.* net.

(6) *Lehrbuch der Physik.* By Prof. Eduard Riecke. Erster Band. Mechanik, Molekularerscheinungen und Akustik. Optik. Zweiter Band. Magnetismus und Elektrizität. Wärme. Fünfte, verbesserte und vermehrte Auflage. Pp. xvi + 600 + xii + 775; illustrated. (Leipzig: Veit and Co., 1912.) Price 26 marks. 2 Vols.

(7) *Physik in graphischen Darstellungen.* By Felix Auerbach Pp. x + 28 + 213 plates. (Leipzig and Berlin: B. G. Teubner, 1912.) Price 9 marks.

(1) SO many elementary text-books of this kind appear from time to time (one of the present authors is already responsible for two) that it is very difficult to judge whether or not a new publication possesses advantages over its predecessors. The scope of the subject is so limited that all of them are bound to be very much alike, and in any one book there can only be a

few special features which demand attention. In the present case little can be said but that the authors have presented what appears to be a straightforward and clear account of the elements of the subject.

The general method of treatment is based upon the two previous text-books of Dr. Jude, more stress being now laid, however, on the practical side of the subject. Descriptions of a large number of experiments with simple apparatus are inserted in the text, and the diagrams are rather more frequent than is usually the case. It is rather a pity that some of the latter, which are evidently new, have not been printed more clearly. An unsatisfactory feature (which, however, it should in fairness be stated, is by no means peculiar to this case) is the mode of definition of the units in electromagnetism. Even if it be admitted that exact definitions are beyond the scope of this work, a *volt* should not be defined as "10/11 of the electromotive force of a Daniell's cell" without further explanation. Surely, also, the unit of current could be explained from first principles and not be defined in terms of the *volt* and the *ohm*.

(2) Here, again, we have a further addition to the numerous works on elementary practical physics. This book is, however, rather more advanced than those which have lately appeared, and, although no previous knowledge of physics is assumed, the authors claim that it contains more than sufficient matter for the intermediate examination for degrees, almost enough, in fact, for the pass final examinations. One serious objection to the publication of books of instruction in practical work is that in different laboratories different types of apparatus are usually found, a fact which would tend to limit the usefulness of the book to the students under the direction of the author, who generally bases his work upon his own course. This the present authors have endeavoured to avoid by describing experiments involving the use of standard apparatus, or that which can easily be made.

The arrangement of the book is excellent. Some 120 experiments are described and each exercise is divided as follows: apparatus, object of experiment, theory and results. It is not intended that the instructions printed should form the whole information given to the student. This also is a good feature, for it is certain that no thorough teaching of practical physics is possible if the services of the demonstrator are dispensed with.

(3) The collection into one volume of the mathematical and physical researches of the late M. Potier is certain to direct the attention of men of science, whether physicists, mathematicians or engineers, to the wonderful versatility of the author and to demand their admiration. When it is remembered that M. Potier's geological researches (which are not included in the present collection) have rendered him eminent in that subject also, his wonderful ability becomes still more apparent. As M. Henri Poincaré (himself, unfortunately, deceased since the publication of this volume) points out in the preface, Potier was a mathematician, and undertook very little experimental work, but he nevertheless kept in touch with the results obtained by others and endeavoured to conform his mathematical researches to the experimental requirements of the case. Especially is this so in his most important papers on applied electricity, which are compiled in the second part of this volume. Indeed, his services to electrical engineering are regarded as forming the most brilliant part of his work. In the first part the memoirs on electrical theory are collected, and the third part contains those dealing with many and varied questions in light.

(4) It is indeed surprising (as the translator points out) that no English edition of this treatise of Huygens has until now appeared. Two hundred and twenty years have elapsed since the original saw light, and in the interval it has produced a more pronounced effect on the science of optics than almost any other work. It is, therefore, a matter for congratulation that the long-delayed edition is an excellent one, and it will be welcomed by all those who find delight in reading the writings of the masters in science. Not the least pleasing feature of Prof. Thompson's translation is the preservation of the old-time mode of statement, which recalls the earlier English editions of Newton's "Principia." Prof. Thompson's reason for a literal rendering is, however, more fundamental than that of making reading pleasant. He wished to avoid "importing into the author's text ideas of a subsequent date, by using words that have come to imply modern conceptions." The publishers have carried out the idea of antiquity in the type and binding and have produced a really beautiful book.

(5) Here is a book which will undoubtedly fill a gap in the various publications on physics. There is a large class of students who do not carry their studies in physics beyond the intermediate stage, branching off into engineering or medicine at that point. As a general rule, no suitable text-book provision has yet been possible in such cases. The single volumes on physics already in existence are either too simple or too difficult, and the students in question have objections to purchasing separate volumes in the various branches of the subject. It appears fairly certain, therefore, that this book of Dr. Watson's will play a

part in the more elementary stages of physics similar to that which his well-known text-book has done and continues to do in the later stages.

Considering the amount of matter involved, it is, perhaps, not surprising that the treatment seems somewhat disjointed in the abrupt passages from one section to the next. This is most marked in the part on mechanics, which, however, the author tells us, is only included on account of the requirements in the main part of the book. As a consequence, it is doubtful whether it would be possible for a student to master the subject by unaided reading; but, after all, that should not be the purpose of a text-book. It should be regarded as an aid to oral instruction. The printing and diagrams are good and in many respects the book is unique.

(6) The fifth edition of Prof. Riecke's excellent text-book has been improved and extended in various ways. On one hand we have more complete treatment of such subjects as radio-activity and the conduction of electricity in gases, which in the earlier editions were only touched upon. On the other hand, there is the introduction of new matter, comprising liquid crystals, Brownian movements and the work of Michelson and of Nernst. Like most of the German standard text-books, this one is much more complete than corresponding works in English, and it is greatly to the credit of the authors that they spare no trouble to bring the new editions of their books really up-to-date. The printing and diagrams are very much above the average. Surely there could be no better testimony of the worth of a scientific book than that it is now in its fifth edition.

(7) This book is quite a novelty. It consists of nearly fourteen hundred diagrams—curves, photographs, &c.—representing physical facts, with short explanations of each collected at the end of the book. Although, of course, it could not be regarded as a substitute for an ordinary text-book, it might well be a useful companion to the latter. The arrangements of the diagrams is occasionally somewhat inelegant, doubtless due to space considerations, but they are, as a general rule, well printed, and in every case what is represented is clearly indicated.

OUR BOOKSHELF.

Modern Problems. By Sir Oliver Lodge, F.R.S. Pp. vii + 320. (London: Methuen and Co., Ltd., 1912.) Price 5*s.* net.

A COLLECTION of essays which have for the most part appeared before as articles or addresses, but which were well worth gathering together and publishing in more permanent form. The subjects dealt with are chiefly social and philosophic—the function of money, universal arbitration and the irrationality of war, Poor Law reform, the position of woman, the drink question, the nature of time, the philosophy of Bergson—these will indicate the wide scope of the book. All the chapters are characterised by the admirably lucid yet thorough exposition which Sir Oliver Lodge's writings always present; and the conclusions, definite though cool and undogmatic, are full of that ripe wisdom which only a wide human outlook on life can give.

From the scientific point of view, one of the most interesting chapters is that on the smoke nuisance, in which the author deals with the problems of combustion, and advocates the use of gas fires and the suppression of crude combustion of coal in towns. As to river and sea mists, and fogs of non-avoidable kind, Sir Oliver suggests electrification of the atmosphere on a large scale, a plan which he has brought within measurable distance of application. This matter is again touched on in the chapter "Squandering a Surplus." No one can tell for certain what would happen by this atmospheric electrification, but it is possible and even probable that the results might be of incalculable benefit; crops might be assisted, rain produced, fog dissipated. When we think of the tremendous harmfulness of fog, financially and to the health of our citizens, it seems obvious that the prospect of a cure of this evil would justify a large national grant for expenditure on trials in a large way. It is to be hoped something of the sort may yet be done.

J. A. H.

Chrysanthemums. By T. Stevenson. With Chapters by C. H. Payne and C. E. Shea. Pp. xiv + 112. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 1*s.* 6*d.* net.

THIS is the latest addition to the admirable "Present-Day Gardening" series, edited by Mr. R. Hooper Pearson. It appears at an appropriate time and will interest as well as instruct all who are concerned with the culture of chrysanthemums, whether for pleasure or profit. Though there is no reference to the existence of the plant in English gardens before 1764, it was mentioned by Confucius five hundred years or so before the commencement of our era. In the first third of the nineteenth century, about fifty varieties were known to English growers; and no attempt had been made to raise new varieties from seed. The first novelties obtained from seeds were exhibited by Mr. I. Wheeler, of Oxford, in 1832; and since then hundreds of beautiful forms have been produced. In the volume before us, details are given as to the procedure in raising seedlings and creating new varieties; and also particulars as to the care of chrysanthemums in all stages of their growth. The book will delight and assist all growers of the plant, and is a valuable addition to a series which should be known to all lovers of gardening. There are eight coloured plates showing typical flowers, and lists of varieties for cultivation as decorative plants or flowers.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Sub-Crag Flint Implements.

The series of flints from the sub-Crag detritus bed, collected by Mr. J. Reid Moir, and figured in my paper in the Phil. Trans. of May, 1912, are now placed in the Ethnological Department of the British Museum, Bloomsbury, under the care of Sir Hercules Read, K.C.B., keeper of that department. So many archæologists have been anxious to see them that I have been glad to avail myself of Sir Hercules Read's kind offer to place them on view, and to allow serious students to have access to them. They include the highly flaked, somewhat hooked specimen from the mid-glacial sands of Ipswich (Fig. 6 of my memoir), and the well-shaped rostro-carinate implement of the same age from Foxhall (Figs. 2 and 3 of my memoir). Besides seven well-marked rostro-carinate sub-Crag implements, the series includes the large and heavy flint with a "Chellean" flaking on both faces at one end (Figs. 38, 39, and 40 of my memoir) and several smaller pieces which, if found in river gravels, would be admitted at once as typical scrapers and borers; also the curious four-sided pyramid figured in my memoir (Figs. 25 and 26).

It will now be possible for prehistorians to discuss the probability of these pieces having been flaked by human agency, with the actual specimens in their hands. There is, I may say, no possibility of a doubt as to the provenance of these flints. With the exception of the two mid-glacial pieces, they all come from the remarkable and well-defined Suffolk bone-bed, or detritus bed, at the very base of the Red Crag. Further, there is no doubt that this deposit was not laid down under torrential action nor on a wave-beaten shore; nor are the pieces in it fractured by any kind of pressure or disturbance *in situ*. They were tranquilly deposited where they are, and many have the small Balanus of the Crag sea affixed to their broken surfaces.

To the question, "How have these flints been fractured so as to give them their present form?" three different answers are given by three separate groups of observers. One group maintains that they have been thus fractured by being knocked together by heavy torrential waters or by waves breaking on a beach; a second group says that they have been broken after deposition by the pressure of superincumbent deposit (or possibly by glacier-like ice moving on and above the deposit); a third group, of which I am one, points to the definite form (rostro-carinate, Chellean, scraper) given by the fracture, and considers it impossible, in our present state of knowledge of the fracture of flint, to attribute this definite and apparently purposeful fracturing to any coincidence of natural breakage, and attributes them to human design and action.

In reference to these diverging views, it is necessary to take account of the facts (1) that it is generally admitted that such forms as these are what we should expect to find as the earlier work of man, preceding the more skilfully worked implements of the river gravels; (2) that no specimens of flints fractured by torrential or by wave action of water and corresponding in size, in form, and definite shaping to the sub-Crag flints have as yet been discovered or produced experimentally. The broken flints of the flint-mill at Mantes, put forward by M. Boule, have no resemblance to them; nor have the pebbles, with an occasional small fracture on the surface, from the beach at Sherringham (Norfolk) any resemblance to them. The advocates of torrential or wave action of water have yet to take the initial step of showing that such action can actually produce anything of the sort. Moreover, they have to show that there is independent evidence of a possibility, let alone a probability, of the sub-Crag flints having been exposed to violent interconcussion by water. The "violent concussion theory" is, at present, without a single fact in its support. (3) We have to recognise that no specimens of flints fractured by pressure in natural conditions have been "laid on the table" which in any way resemble the sub-Crag implements. The fractured fragments of flint procured by M. Breuil at Bel Assize (which I have examined) have no resemblance to them. Moreover, there is no evidence to show that M. Breuil's specimens were, as he asserts, broken by the pressure of superposed deposits. On the contrary, no such fracture by the weight of superposed sandy strata can be admitted. According to ascertained facts as to the transmission of pressure by sand, there is no reason to suppose that fracture can be so produced.

In regard to this suggestion, as in regard to that of torrential action, the careful examination of the deposit in which the sub-Crag flints of Suffolk occur renders it absolutely certain that no such pressure has acted upon the flints where they at present are found. Here, again, we are referred (by M. Breuil's supporters) to some unknown and fanciful precedent conditions (of which there is no evidence) in order that the impossible crushing by a superposed sandy deposit may take place. (4) We must note that the hypothesis that these flints were purposely fractured by man is the only one which explains their special shape and the "directed" character of the blows which produced the fractures and the shape. It is also the only hypothesis which accounts for the fact, pointed out to me by Prof. Flinders Petrie, that all of these fractured flints from the sub-Crag bed, shaped according to definite and special pattern, readily fit to the hand and at once fall into position as useful picks or hammers. It may be said that we have no independent evidence of the existence of man at this epoch, just as we have no evidence of torrential waters or vast pressure. But I have reason to believe that such independent evidence of man's presence at this epoch in this country is already in the hands of competent geologists, and will soon be made public.

Lastly, I may say a word as to the remarkable scratching of the fractured surface of many of these flints. I have attributed it to the action of ice, similar to (but not precisely identical with) that which causes the scratching of rocks and rock pebbles by modern glaciers. There is other evidence, as noticed by Lyell, for the presence of ice—transporting large blocks of flint in an unrolled condition—during the deposition of the Suffolk bone-bed at the base of the Reg Crag. But the human origin of the fracturing of the flints we are discussing is not bound up with the hypothesis that the scratches on them are due to ice-action. I am not aware of any evidence in favour of any other explanation of the presence of these scratches.

It is very evident to me, from the various opinions which have been expressed in regard to the history of the sub-Crag flints, which I consider to be implements fabricated by man, that there is an extraordinary lack of precise information, at this moment, as to the properties of flint, the various possible causes of its fracture (including heat and cold, as well as blows and pressure), and the means of judging what particular causes have been at work in fracturing any given specimen. It is in consequence of the vagueness of published and approved statements on the properties of flint that we are asked to accept all sorts of indefinite appeals to natural agencies as sufficient to account for what no one, without uncommon faith in the unknown possibilities of those agencies, would be capable of imagining as due to any other agency than the hand of man.

To avoid, if possible, any misunderstanding, let me say that the sub-Crag flint implements are not "eoliths" in the sense given to that word by Mr. Benjamin Harrison, nor in that given to it by M. Rutot. Still less are they to be called "eoliths" by those who would apply that term to flints broken by cartwheels or by the mill at Mantes.

I propose to sketch in a later communication a programme of inquiry into the nature and properties of flint, the carrying out of which seems to me to be urgently needed at this moment.

October 29. E. RAY LANKESTER.

High Tropical Winds.

LAST year, in a letter to the Editor of this journal (vol. lxxxvii, p. 415), I wrote about the probable existence of "upper trade-winds," according to the observation of some high balloon flights at Batavia. Also I ventured to explain the occurrence of high westerly winds near the equator by supposing them to be only feeble winds of variable direction between the anti-trade and the upper trade. Finally, I mentioned my intention of continuing these researches by means of large pilot-balloons.

This has been done in the past year, but the average height reached by the balloons was lower than I wished, owing to the inferior quality of some of them. Notwithstanding this, the results are of sufficient interest to justify a short account of them.

Contrary to my expectations, I found the high westerly winds (first met by Berson on the Central Africa expedition) not to be of secondary, but of primary importance; moreover, not blowing under but above the anti-trades.

On four different occasions a balloon crossed the upper limit of the westerly winds and again met easterly currents.

As I had already conjectured from the observations made during the two preceding years (1910–11), the anti-trade in the dry season (June–September) lies higher than in the rainy season (December–March); thus I found the average height of its upper limit to be :—

December–March ... ... 16·5 km. (9 cases).
June–September ... ... 15·5 km. (18 cases).

In the months of transition its direction may vary a good deal, and then it is often difficult to discriminate between the various currents; notwithstanding, six cases gave an average height of 15·8, *i.e.* a height between those of the two monsoon seasons.

Regarding the upper trade, I found it to be, just as I expected, more obvious and at a higher level in the rainy season than in the dry one, its lower limit being :—

December–March ... ... 17·0 km. (9 cases).
June–September ... ... 15·3 km. (13 cases).

On the contrary, the high westerly winds were found to occur in most cases during the dry season, and at a height of more than 17 km.

Also in the months of transition their presence was proved by some balloon flights; for instance, on April 24 and 27, 1912, when two balloons burst at a height of 27·2 and 25·3 km. respectively, and westerly winds appeared to blow from 20·0 and 18·5 km. upwards.

As already mentioned above, this year on four occasions a balloon passed the upper limit of the high westerly winds, viz. on January 24 at a height of 23 km., and on September 7, 12, and 23 at about 24 km.

It is important to remark that Berson had already seen this happen (at a height of 20·2 km.) for the first time at Dar-es-Salaam, but he must have undervalued the height of the balloon, viewing it from one point only, and making use of a theoretical rate of ascent. In reality this rate increases strongly with the height, as I have found by viewing my large pilot-balloons from two points (2 or 4 km. apart).

I estimate Berson's pilot-balloon of 700 gr. must have crossed the upper limit of the westerly winds at about 23 km., accordingly at the same level as those which ascended at Batavia.

The balloon of September 12 burst at the enormous height of 30,800 m., and gave evidence of the strong easterly winds which have long been supposed to blow at a great height above the tropical belt.

Thus for the first time has been described the wind which, during the period of 1883, August 27–September 8, carried the ashes of Krakatoa around the earth at a level of ±30 km., and at a velocity of 34 m.p.sec., and therefore may properly be called Krakatoa wind.

The wind directions and velocities observed on September 12 follow below :—

Height in km.	Wind blows from	Velocity in m.p. sec.	Name of air-current
0·3	S	6	Land breeze
1	E 17° S	2	
2	E 4 N	5	Trade-wind
3	E 14 S	5	
4	E 23 N	5	
5	E 15 N	6	
6	E 20 S	9	
7	E	7

On September 7 and 23 the same wind system reigned, as was proved by two balloons which reached a height of 26·5 and 27·5 km. respectively.

Regarding the explanation of the occurrence of high westerly winds near the equator, Gold (Quarterly Journal, 1910, p. 178) reminds us of the theoretical results of Overbeck, from which, according to him, might easily be deducted that often at great heights the vast westerly whirl around the poles extends over the tropical belt. But the principles on which Overbeck built his theory are not in agreement with reality. He regards difference of temperature as the *prima causa* of the air-currents, and presumes the vertical distribution of temperature to be caused by conduction only, supposing other causes, such as radiation, vertical currents, &c., to give an analogous distribution as conduction gives it.

The existence of the stratosphere has taught us, however, that this is not the case.

Though it seems rational to presume that the high westerly winds are an extension of those at higher latitudes ($\pm 15°$), and also that the Krakatoa wind comes from still higher latitudes, being deflected by the rotation of the earth in an easterly direction, more observational data from other stations are urgently wanting for a thorough explanation of the facts.

Batavia, September 24. W. van Bemmelen.

The Blind Prawn of Galilee.

In describing the eyeless prawn from Galilee that he named *Typhlocaris galilea*, Dr. Calman stated that, according to the information at his disposal, it was found in a small pool near the town of Tiberias communicating with the lake and fed by a mineral spring (see Trans. Linn. Soc., London, 2nd ser., zool. xi., p. 93, 1909). As Typhlocaris is one of the most peculiar crustacean genera described of recent years, further particulars as to its *provenance* may be of interest to naturalists. The pool in which alone, so far as is known, it occurs is situated some two hundred yards from the Lake of Tiberias, an hour and a half's sail north of the town of that name. Originally this pool was one of the chambers in a Roman bath at some forgotten city, perhaps Capernaum or Bethsaida. It is still completely enclosed by stout masonry which gives it a symmetrically octagonal outline, but its surface is choked with gigantic floating grasses. There is now no visible outflow or inflow of water, which apparently percolates through the bottom at several places and decreases in volume by desiccation. As its temperature is distinctly lower than that of the water in the aqueduct that works a corn-mill between it and the lake, it seems improbable that there is any great outward percolation. It is evident, however, that the water, which even now is nowhere less than about 4 ft. deep, was in ancient times much deeper, and that the overflow was conducted away by means of apertures in the wall high above the present surface, while there are traces of an aperture through which it may have entered the pool in volume in a masonry platform that juts out into the pool from one of its eight sides. The water is slightly saline, but not so markedly so as that of some springs in the vicinity.

The first Typhlocaris that I saw on a recent visit to the pool was crawling on the side of the platform about three feet below the surface, making its way slowly in and out of the crevices. Apparently the claws as well as the antennæ were used in testing the surface along which it moved. A piece of bird's flesh weighted with a small stone was lowered on a string to attract it away from the stones and render its capture more easy. It seized the string in both its claws and gave it a vigorous tug. It then made its way to the flesh, but when the latter was forthwith attacked by a number of small fish (*Discognathus lamta*), the prawn moved away. Although the fish made no attempt to injure it, it invariably avoided them. When touched with a net it darted violently backwards, straightening its claws in front of it as it did so, but no great difficulty was experienced in capturing it. At the time of our visit (about 5 p.m.) the pool was in shade, but the prawn did not seem to avoid such light as reached it. A second individual was seen crawling on the bottom at dusk, but none were seen in the early morning.

There was no trace of colour on the living prawn, except that the internal organs of the thoracic region produced a dusky blotch externally. The whole body was otherwise of a semi-opaque white like that of paraffin-wax.

The appearance of Typhlocaris in the pool is most erratic. Herr Grossmann, who sent the first specimens to the British Museum and assisted me greatly in my search for more, tells me that he has often visited the pool without seeing any, and one of the German fathers who have a hospice in the neighbourhood stated that while on one occasion a Bedouin caught five individuals in a single day, on another none were seen for six months. On the whole, I agree with Dr. Calman in thinking that the real habitat of Typhlocaris is subterranean, but I have little doubt that having once made their way through some crevice into the pool, individuals are able to flourish there, hiding in crevices in the walls or under the vegetation that floats on the surface. N. Annandale.

Tiberias, Palestine, October 8, 1912.

Is the Earth Shrinking?

In a recent popular work I find the statement, "The earth is still slowly shrinking. . . ." I am aware that this statement fits in with our preconceptions and may even appear trite and commonplace, but it is sometimes just such statements that best repay investigation. I would, therefore, inquire whether there is any unequivocal evidence that the volume of the earth as a whole either is now suffering, or has in the past suffered, progressive diminution.

If there were direct evidence of progressive cooling on the part of the earth, diminution of volume would be almost a necessary inference, but on this point I understand that geological evidence is by no means favourable. As regards the presence in various regions of folding, overthrusting, reversed faulting, &c., such phenomena are evidence of surface compression in regions where they are found; and in a precisely similar manner the presence of rifts, fissures, ordinary faulting, &c., is evidence of local surface expansion, although the latter result is seldom emphasised. In a given region it is easy to picture such a combination of folding with fissures cutting across the folds as would cause the region to suffer distortion without either diminution or increase of superficial area. If such be conceivable within the limits of a local region, it is evident that the mere presence of folding and the like, unsupported by an intricate quantitative examination, will not warrant the conclusion that the earth as a whole is shrinking. On the other hand, if due regard be paid to the physical properties of the materials composing the earth's crust, is it not remarkable that extensive regions exist which do not appear—at least in geologically recent times—to have suffered compression?

October 13. H. Birrell.

For a quantitative discussion of the effects of secular cooling on the earth's crust, Mr. Birrell may be referred to a couple of papers by Dr. C. Davison and Sir George Darwin in the Philosophical Transactions of the Royal Society for 1887. He will find that though the speculative nature of the assumption is frankly confessed, yet the observed phenomena are shown to be consistent with the theory of contraction and secular cooling. On the whole, students of cosmogony (as opposed to geology), arguing to some extent from the analogy of other celestial bodies, are in agreement in accepting the hypothesis of secular cooling. A notable exception is Prof. F. R. Moulton, of Chicago. In conjunction with Prof. T. C. Chamberlin, he has developed a "planetesimal hypothesis," according to which the earth was built up by a series of solid accretions. The hypotheses of secular cooling and initial high velocity of rotation for the earth have no place in his theory. For details Mr. Birrell may be referred to "The Tidal and other Problems" (Carnegie Institution of Washington, 1909).

F. J. M. Stratton.

NEW OBSERVATIONS ON HUMBLE-BEES.[1]

THIS account of the humble-bee has a merit very uncommon in popular books of natural history; it is written by a naturalist who has spent years in observing for himself, and whose observations are numerous, original and interesting. There are set before us new facts concerning (among other things) the domestic management of several humble-bees, the packing of pollen into the collecting basket, the habits of the parasitic bee, Psithyrus, the insect-devourers of the broods of humble-bees, or of the food-supply stored in the nest, and the perfume of male humble-bees, besides many practical suggestions for the tending of humble-bee families in captivity. The different species are pictured in excellent colour-photographs, which will save trouble to observers who are not yet practised in systematic identification, and there are useful photographs of humble-bee nests, combs and incubating females.

FIG. 1.—Comb of *Bombus agrorum*, showing pollen-pockets in the sides of the bunches of larvæ. From "The Humble-Bee."

May we suggest to the author that, if an opportunity offers of revising his work, he would do well to prefix a simple account of the life-history and economy of some one humble-bee? There is a choice of such histories in Réaumur, each marked by a lucidity and grace which captivate the reader. One of these, shortened and revised, would meet a want which many readers are likely to have felt. It is singular that Réaumur is never mentioned by Mr. Sladen, though room has been found for a longish quotation from the Abbé Pluche!

Mr. Sladen's excellent matter is not always well arranged; we have found it troublesome to recover passages the place of which in the book had not been noted. Our author seems to suppose that humble-bees give out heat whenever they are active. Can this belief be supported by thermometer readings? There is a hint, too, but not more than a hint, of blood-vessels filled with a red fluid. We are convinced that this supposition (if really entertained) is a delusion. Corrigenda like these are trifles. Our main duty is to recognise Mr. Sladen as a careful and clever observer, and to recommend his work as a trustworthy account of a particularly interesting group of insects.

Buttel-Reepen (*Biol. Centralbl.*, 1903), drawing upon information contributed by many other naturalists, among whom Mr. Sladen is named, has traced the ascent step by step, from the solitary bees to the complex communities of the honey-bees. In the simplest bee families the life of all the individuals is short, and the mother dies without ever seeing her progeny. Then we pass to bees the females of which regularly outlast the winter; the cells are collected into some kind of comb, and the nest is guarded. In the humble-bees there is a further advance; the labour of the mother is now shared by parthenogenetic workers, though these are only seen during the flowering season, and perish before winter. The climax is reached in what we illogically but conveniently call the honey-bees (the humble-bees also are collectors and storers of honey); of these the hive-bee is the most familiar example. Here the workers persist from year to year, and become supreme, the mother (now called the queen-bee) being degraded to a captive, and incessantly occupied with egg-laying. If the humble-bees had not been carefully studied we could only have guessed at the stages by which the elaborate polity of the hive has been, or may have been, attained.

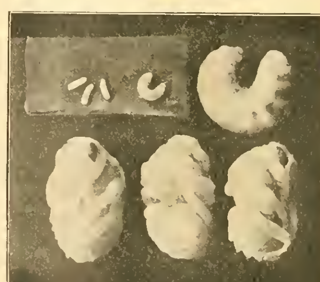

FIG. 2.—Eggs, larvæ and pupæ of *Bombus terrestris*, slightly enlarged. From "The Humble-Bee."

The last news is that Mr. Sladen is joining the staff of the Central Experimental Farm at Ottawa. We wish him all success in his new sphere, and hope that he will not be too much occupied by his work in Canada to give a thought now and then to the Hymenoptera.

THE UNVEILING OF A STATUE OF PRIESTLEY AT BIRSTALL.

THE merits of Joseph Priestley—theologian, philosopher, social reformer, and man of science—were recognised by some at least of his contemporaries. He was on terms of friendship with such men as Franklin, Wedgwood, Watt, and Banks, and he enjoyed the patronage and companionship of Lord Shelburne. In 1766 he was elected a fellow of the Royal Society, and seven years later the Copley medal was awarded to him.

To many of his fellow-countrymen, on the other hand, Priestley was but a violent and obstinate schismatic, intent only on undermining the established order of things. It was indeed the intolerant and cruel expression of this view by the Birmingham mob that led him to emigrate to the United States in the sixty-second year of his age.

Such clouds, however, as once obscured Priestley's fair fame have now entirely passed away, and the services which he rendered to the national life, whether as a pioneer of chemical science or as an "honest heretic," are everywhere recognised. Public memorials of the man and his work have been erected in Birmingham, Warrington, and Leeds, and recently another has been added to the number. For the citizens of Birstall, in the West Riding, where Priestley was born in 1733, have combined, with praiseworthy public spirit and enthusiasm, to erect a statue of their eminent townsman.

This latest memorial was unveiled on October 12 by Sir Edward Thorpe, whose ready pen has materially contributed to a just appreciation of Priestley's character and work by this generation. The ceremony was performed in presence of a large and distinguished company, and general satisfaction was expressed at the manner in which the scheme for commemorating Birstall's most famous son had been brought to a successful issue.

After the unveiling ceremony, the company adjourned to the Temperance Hall, where an address was delivered by Sir Edward Thorpe. In an illuminating review of Priestley's life and the various factors that shaped his career, emphasis was laid on the influence of his early environment. From his sixth year onward Priestley was entrusted to the care of his aunt, Mrs. Keighley, a worthy, intelligent, and broad-minded woman, to whose house the cultured people of the neighbourhood were wont to resort. For a time ill-health prevented the boy attending school with regularity, and to a large extent he had to make his way to knowledge unaided. These circumstances, cooperating with his natural keenness and diligence, developed in young Priestley that mental activity and independence which later were characteristic of his attitude towards theological, philosophical, political, and social questions.

After a suitable training Priestley entered the ministry, and worked successively at Needham, Nantwich, and Warrington. It was not until he went to Leeds in 1767 that he began those chemical investigations on which his fame chiefly rests. It is indeed remarkable, as Sir Edward Thorpe pointed out, that a man like Priestley, without previous training, with domestic utensils for his apparatus and tallow candles for his source of heat, should have made the great discoveries in pneumatic chemistry with which his name is associated.

The Priestley Statue at Birstall. Sculptor: Miss Darlington.

It was, however, during his seven years at Calne, in Wiltshire, under the patronage of Lord Shelburne, that Priestley's best experimental work was done. It must be admitted that he did not at all realise the true significance of his investigations. The discovery of oxygen was destined to revolutionise chemical science, and yet Priestley himself, to the end of his days, clung to the antiquated conceptions which his own experiments had really overthrown. In this connection Sir Edward Thorpe has emphasised the striking contrast between Priestley the social, political, and theological reformer, always in advance of his time, and Priestley the conservative and orthodox man of science.

Sir Edward holds that, great as was Priestley's merit as an experimentalist, a greater claim to our regard rests on his struggles and sufferings in the cause of liberty. Unpopularity and even persecution were his lot during his later years in England, and it is to Priestley's everlasting credit that he did not allow these untoward circumstances to disturb his serene and genial temper. In paying tribute to such a man—one whom Frederic Harrison has described as "the hero of the eighteenth century"—the citizens of Birstall have done honour to themselves. J. C. P.

THE PROPOSED MEMORIAL TO LORD LISTER.

MEETING AT THE MANSION HOUSE.

IT may be said that the life of a great man needs no permanent memorial from his contemporaries, and to some extent this is true. Poets, men of letters, and philosophers speak to posterity in their writings, statesmen and warriors have their deeds recorded in history, artists, sculptors, and architects have erected their own monuments which everyone may see. Yet even to them their fellow-men delight to raise some special token of their admiration. But there are others whose work is of a less public character, less obvious to the ordinary observer, and less easily understood, but which often has a more important effect upon the welfare of the world. Of such are the men of science, whose atmosphere is different from that of their fellow-men, and who occupy the *edita doctrina sapientum templa serena*. It is fitting that some permanent memorial should from year to year recall the names of such and remind those who come after of what it is that they have accomplished.

The great meeting which, under the auspices of the venerable Lord Mayor, himself a member of the medical profession, assembled at the Mansion House last week to sanction the project for raising a memorial, or rather some memorials, to Lord Lister, will, we are confident, meet with the approval of everyone, in all parts of the world. The names of those who attended the meeting and those who sent messages of regret at being unable to do so, indicate how wide is the sympathy that it has aroused. Statesmen, ecclesiastics, soldiers, representatives of science and of medicine, of the City companies, of hospitals, and of the general public were all enthusiastic in their commendation of the scheme. Such evidence reminds us that Lister's work was not merely one which revolutionised surgical practice, and was thus instrumental in saving his fellow-creatures from premature death and unnecessary suffering, and enabled the art of surgery to advance by leaps and bounds to a degree undreamt of before; but that its scientific value alone is so great as to justify his being placed amongst the most distinguished men of this or any other age.

The Lord Chancellor, in the unavoidable absence of the Prime Minister, paid an eloquent tribute to Lister's pre-eminence and to the far-reaching effects of his doctrines; yet the man in the street has but little notion of the benefits he has derived from them; he has perhaps learned the two words "antiseptic system," but they convey no meaning to him; and he does not appreciate the dangers which have been averted and the sorrows prevented for him and those who are dearest to him. It is for these that a speaking memorial should be raised, and it is from these, if they can be made to understand its meaning, that we feel sure an appeal for the necessary funds will not be made in vain.

A very influential committee has been formed of representatives of all classes in the United Kingdom and the Colonies and of Ambassadors and Ministers of foreign countries, and in their opinion it is fitting that whatever is done should partake not only of a national, but an international character. This committee, after careful consideration, submitted a scheme to the Mansion House meeting, which met with cordial approval.

The Dean of Westminster, who is a warm sympathiser with it, desired that Lord Lister's ashes should find their final resting-place in Westminster Abbey, but owing to his own very strict injunctions concerning his funeral, this could not be carried out. It is proposed, therefore, that a medallion with a suitable inscription should be placed in the north aisle near those of Darwin and other eminent men of science that cluster round the monument of Newton. Westminster Abbey is an international institution, and it is certain that this proposal will not appeal to Englishmen alone.

It is also thought that everyone will be in favour of the erection of a sculptured monument, not a mere statue, but something which will direct attention to the nature of his achievements, in some prominent place in London which every citizen and every visitor cannot fail to see and to observe.

But it was felt that a memorial of a still more international character was desirable, and for that the committee recommended something which would combine the merits of the Nobel Prize and those of the Carnegie Trust. Under the proposed scheme the trustees of the fund would be able to devote the interest of it at their discretion either to the promotion of research bearing upon the progress of surgery, or as awards in recognition of notable advances in this science. Naturally these awards would be open to men of all nations, and this is as it should be, for Lister's work was not in any sense insular; its beneficent effects are felt in every part of the inhabited world.

We think that the decisions of the committee are wise and will meet with general approval. It is needless to say that in order to carry them out a large sum of money will be required. We are happy to hear that already several generous donations have been made, and we have great confidence that the appeal will be widely responded to. We would point out that it is not only the large gifts of the wealthy that are sought, though they are no doubt essential to the success of the scheme, but also the smaller tributes of esteem, the thank-offerings of those who recognise that every household in the land is a debtor to the great man who has passed from amongst us.

Donations should be sent to the treasurers of the Lister Memorial Fund, Royal Society, Burlington House, W.

M. LECOQ DE BOISBAUDRAN.[1]

In the death of M. Lecoq de Boisbaudran, which took place in May of the present year, there passed from the field of activity one of the most brilliant and energetic of French investigators. Lecoq de Boisbaudran was an amateur in the true sense of the word, and he had the faculty of concentrating the whole of his energy upon the question of the moment. He was born in Cognac in 1838. His parents were of noble family in Poitou, but their circumstances prevented his receiving more than an ordinary education. While a young man, he studied mathematics under his uncle, who had been a student at l'École Polytechnique, but his interest quickly became absorbed in the science of chemistry; he eventually succeeded in gaining an entrance to the laboratory of Würtz at l'École de Médecine, and it was here that he made the discovery of the element gallium.

Among his earlier contributions to science are papers on gravitation, meteorological phenomena, and also upon matters connected with agriculture; but physical chemistry and spectroscopy received the greater share of his attention. The probable existence of gallium had been foretold by Mendeléeff, who had proposed the name *eka-aluminium,* but to Lecoq de Boisbaudran belongs the honour of the discovery and the isolation of the element. In the field of spectroscopic research his name may be classed with those of Kirchhoff, Bunsen, Sir G. G. Stokes, and Sir William Crookes, as one of the founders of the science of spectrochemistry. His "Spectres Lumineux," published in 1874, was one of the most perfect works on spectroscopy at that time, and it possesses considerable value even at the present day; although limited to the visible region, the drawings are marvellously exact, and in the index wave-lengths of all the lines in the fifty-six spectra shown are given in Ångström units to one place of decimals; the labour involved in the work was enormous.

At the time when Lecoq de Boisbaudran was in the prime of his scientific activity, the chemistry of the rare earths was receiving considerable attention, Clève of Upsala, Marignac, Demarcay, Crookes and others were hard at work in that very interesting field of research, and he devoted himself with all the energy of his nature to the work; during the period from 1880 to 1900 his communications to the Academy appeared in almost every issue of the *Comptes rendus.* He was successful in discovering and isolating the elements samarium and dysprosium, and he very completely investigated the body now known as gadolinium, which had been provisionally named $Y\alpha$ by Marignac.

In his earlier investigations he depended largely upon the indications given by the *spark spectrum,* produced by passing an alternating spark between electrodes immersed in a solution of the salts, and also upon the absorption spectrum of the solution; the spectra of didymium, erbium, holmium, &c., were very fully examined by this latter method.

At the time when the work of Sir William Crookes upon the kathode phosphorescence spectrum of the rare earths was published, he made the observation that if the condensed spark from one electrode was allowed to strike upon the surface of a liquid containing a rare earth salt, there was produced, just where the discharge struck, a faint luminous spot, which, when examined with a spectroscope of low power, gave rise to a series of faintly luminous bands, closely resembling the phosphorescent bands of Crookes; this he called the *reversal* spectrum, and the method of investigation was largely used by him in his speculations upon the constitution of the yttria earths. His conclusions in this particular were in direct opposition to those of Crookes, who, as the result of an extended series of observations on the brilliant bands produced by kathode phosphorescence, had suggested that the element yttrium was composed of a number of very closely allied bodies, which he termed *meta-elements,* each producing a distinct phosphorescent spectrum. M. de Boisbaudran, on the other hand, held the opinion that yttria, when perfectly pure, did not phosphoresce under kathode rays, and that the bands observed by Crookes were due to impurities contained in the yttria.

The origin of the band-producing earths is by no means clear even at the present day, but the fact remains that although much work has been since done upon the element yttria, no one has succeeded in producing the non-phosphorescing material of Lecoq de Boisbaudran. It is a great misfortune that the numerous researches of Lecoq de Boisbaudran, particularly those referring to the rare earths, have not been collected together and published in complete form; there are probably few of the rare earth elements about which some observation could not be found under his name; but, scattered as they are in isolated papers, they are in large measure lost, and probably many of his original observations will have to be re-made by his successors. This, unfortunately, was characteristic of the man. His method was to work and publish almost simultaneously; so engrossed was he in his work that he cared little for public recognition.

The cross of the Legion of Honour was conferred upon him for his discovery of the element gallium, but he never officially received the Order.

[1] An article from the pen of M. G. Urbain upon the life and work of Lecoq de Boisbaudran appeared in the *Revue Générale des Sciences* for September 15, and to that the present writer is indebted for several particulars not otherwise available.

He was awarded the Bordin prize in 1872, and was made correspondent of the chemical section in 1878. He received the Davy Medal of the Royal Society in 1879, and the Lacaze prize in 1880.

He died, after a painful illness, on May 28, at the age of seventy-four years.

J. H. GARDINER.

NOTES.

In our issue of April 18 last (vol. lxxxix., p. 172) the announcement was made of the appointment of a Royal Commission to inquire into and report upon the natural resources of the Empire. On that occasion it was not possible to give the names of the Commissioners, but we are now able to say that the Commissioners originally appointed were as follows:—Lord Inchcape, Sir Edgar Vincent, K.C.M.G., Lieut.-Colonel Sir C. J. Owens, Sir H. Rider Haggard, Mr. T. Garnett, Mr. W. Lorimer, the Hon. G. E. Foster, Mr. D. Campbell, Sir Joseph G. Ward, Bart., Sir David Pieter de Villiers Graaf, Bart., and the Hon. E. R. Bowring. Some changes have taken place in the composition of the Commission since it was appointed, but neither originally nor now, so far as we can find, does the Commission include a single member prominently associated with some branch of scientific knowledge. This is the more surprising because it may be remembered that in March last, a month before the Royal Commission was appointed, the British Science Guild issued a report prepared by one of its committees, under the chairmanship of Sir William Ramsay, K.C.B., F.R.S., on the question of the conservation of natural sources of energy. The British Science Guild committee was composed almost entirely of expert men of science, who had given particular attention to the study of the questions with which the Royal Commission is dealing; and it is greatly to be deplored that one or more of their number, or other representatives of pure or applied science, have not been appointed members of the Commission.

The recent publication of the "Life and Scientific Work" of Prof. Tait, of Edinburgh, reviewed in NATURE of July 13, 1911, has reawakened a desire on the part of his many old students and friends to have a worthy memorial of the "great natural philosopher." The proposal is to found a second chair of natural philosophy in Edinburgh, to be called the Tait chair, and a strong appeal for contributions towards an endowment fund has been issued by a representative committee. Accompanying the appeal there is a fine tribute on Tait and his work from the pen of Prof. Peddie, of Dundee, one of Tait's former assistants. There is also an interesting statement on the need of a second chair, in which Prof. MacGregor shows that, in comparison with other universities which have approximately the same number of students, the University of Edinburgh is far behind as regards the numerical strength of its teaching staff in experimental and mathematical physics. As early as 1872, Tait himself, in an article in *Macmillan's Magazine*, lamented the understaffing of the Scottish universities, giving it as his opinion that there should be "a professor of applied mathematics in each, and a professor of experimental physics, in place of the present solitary professor of the enormous subject of natural philosophy." This is the ideal which the committee has set before it, and for the realisation of which it has appealed to a wide public. In the days of his activity Tait was a frequent and much-valued contributor to the columns of NATURE, and in the interests of the higher development of physical and mathematical science, we have much pleasure in directing the attention of our readers to this great and worthy object. The honorary treasurer of the fund is Sir George M. Paul, 16 St. Andrews Square, Edinburgh.

The dinner given by the Fishmongers' Company on October 24 to a distinguished company, "to meet the President of the Royal Society," may well be taken as an indication of the esteem in which scientific work is held by a great City company. The assembly invited included representatives of numerous branches of science, among whom were many members of the Royal Society. The following scientific societies, for instance, were represented:—The Royal Horticultural Society, the British Science Guild, the Society of Antiquaries, the Royal Astronomical Society, the Institution of Civil Engineers, the Linnean Society, the Geological Society, the Royal Microscopical Society, the Chemical Society, the Entomological Society, and the Surveyors' Institution. Sir Archibald Geikie, in responding to the toast of "The Learned Societies," proposed by the Prime Warden, said that the City guilds have played an important part in the history of London. The learned societies, too, have had close relations with the City companies. The Clothworkers' Company has had two distinguished masters who have been presidents of the Royal Society—Samuel Pepys and Lord Kelvin. The City guilds, too, have shown great diligence in the application of their funds for educational and scientific purposes.

An account of certain red bands observed by Profs. Breuil and Sollas in Bacon's Hole, on the Gower peninsula, and apparently of prehistoric origin, appeared in NATURE of October 17 (p. 195). According to *The Cambria Daily Leader* of October 18, the markings were made by a Mumbles boatman eighteen years ago, and were produced with a brush having red paint upon it, which was part of the salvage from the wreck of a Norwegian barque. Several other explanations have since been put forward, and are referred to in a short article in Tuesday's *Times*. Whether the markings are of ancient or modern origin does not appear yet to have been decided definitely, but the position of the question is shown by the following extract from *The Times* article:—"When they observed the marks the first question which presented itself to Prof. Breuil and Prof. Sollas was: 'Are they ancient or modern?' Prof. Breuil, having wetted the surface, attempted to remove the paint by vigorous rubbing; not succeeding in this, he concluded they were ancient. Prof. Sollas closely examined the wall to see whether the paint was covered by stalactite, and convinced himself that it was. To reassure himself on this point Prof. Sollas has lately revisited the cave. He was able with a hammer and chisel to detach a fragment of the painted surface from a projecting corner. This affords an excellent section through the deposits, revealing a layer of the red paint, which covers an older layer of stalactite, and is itself covered by a later layer, in some places as much as two millimetres thick. There can be no doubt that Prof. Breuil and Prof. Sollas were scrupulously exact in their observations, and as the marks resemble in general character the accepted paintings of Upper Palæolithic age, and in particular some red bands at the extremity of the great gallery in Foul de Gaume, they were amply justified—whatever the final verdict may be—in assigning the paintings of Bacon Hole to an ancient period."

THE next meeting of the Geologists' Association will be devoted to a conversazione, which will be held to-morrow (November 1), in the library of University College, Gower Street, W.C.

THE Royal Academy of Sciences of Naples is offering a prize of 20*l.* for researches on the algæ of the Bay of Naples preferably from the biological point of view. The essays, which are to be sent in by June 30, 1913, are not returned to the authors.

THE death is announced of Prof. Paul Segond, professor of surgery in the Paris Faculty of Medicine, at the age of sixty-one years. Prof. Segond was formerly chief surgeon at the Salpêtrière Hospital, and assisted in the preparation of the "Dictionary of Medicine and Practical Surgery."

The Kew Bulletin announces that Mr. I. H. Burkill, Reporter on Economic Products to the Government of India, and curator of the Industrial Section of the India Museum, Calcutta, has been appointed by the Secretary of State for the Colonies director of the Botanic Gardens, Singapore, in succession to Mr. H. N. Ridley, C.M.G., F.R.S., retired.

IT is reported in the *Revue Scientifique* that, out of the fund raised for the recent centenary celebration of the establishment of Avogadro's law, the Turin Academy of Sciences will found a prize of 1500 lire and a gold medal for the best critical, historical, or experimental work on the discoveries resulting from the law. The prize will be awarded on December 31, 1914.

THE Liverpool School of Tropical Medicine is arranging to send an expedition to Jamaica and the West Indies. The Colonial Office is cooperating with the school in this expedition, which, it is interesting to note, is the twenty-ninth made by the Liverpool authorities. The various expeditions have cost some 30,000*l.*, but on its work as a whole the school has spent more than 100,000*l.*, nearly all of which has been raised by voluntary effort.

AT the annual meeting of the Cambridge Philosophical Society, held on October 28, the following were elected for the session 1912–13:—*President*, the Master of Christ's (Dr. A. E. Shipley); *Vice-Presidents*, Prof. Hopkinson, Prof. Wood, and Prof. Pope; *Treasurer*, Prof. Hobson; *Secretaries*, Mr. A. Wood, Mr. F. A. Potts, and Mr. G. H. Hardy; *New Members of the Council*, Dr. Marshall, Mr. G. R. Mines, Rev. Dr. Barnes, and Mr. F. J. M. Stratton.

AT the statutory meeting of the Royal Society of Edinburgh, held on October 28, the office-bearers for the ensuing year were elected, as follows:—*President*, Sir William Turner, K.C.B., F.R.S.; *Vice-Presidents*, Dr. J. Horne, F.R.S., Dr. J. Burgess, Prof. T. Hudson Beare, Prof. F. O. Bower, F.R.S., Sir Thomas R. Fraser, F.R.S., and Dr. B. N. Peach, F.R.S.; *General Secretary*, Dr. C. G. Knott; *Secretaries to Ordinary Meetings*, Dr. R. Kidston, F.R.S., and Prof. A. Robinson; *Treasurer*, Mr. J. Currie; *Curator of Library and Museum*, Dr. J. S. Black; *Councillors*, Dr. R. H. Traquair, F.R.S., Prof. J. Walker, F.R.S., Sir W. S. M'Cormick, Prof. Crum Brown, F.R.S., Prof. T. H. Bryce, Mr. W. A. Carter, Mr. A. Watt, Dr. J. H. Ashworth, Prof. George A. Gibson, Prof. R. A. Sampson, F.R.S., Prof. D'Arcy W. Thompson, C.B., and Prof. E. T. Whittaker, F.R.S. It will be noticed that Dr. Knott has been elected general secretary to the society in succession to the late Prof. Chrystal. Dr. Knott served on the council of the society for the periods 1894–97, 1898–1901, 1902–05, and was appointed one of the secretaries to ordinary meetings in 1905, which office he held until his election as general secretary.

THE annual dinner of the London School of Tropical Medicine was held at Prince's Restaurant on October 23. General Sir Reginald Talbot presided, and among others present were Lord Sheffield, Sir John Anderson, Sir Francis Lovell, Colonel Alcock, Dr. Frank Heath, Mr. H. J. Read, and Prof. Simpson. Sir Ronald Ross proposed the toast of "The School," and commented on the importance of tropical sanitation and on the debt which the Empire owed to the discoveries in tropical medicine and to the work of the doctors in this connection. Sir Patrick Manson, who responded, alluded to the efforts of Mr. Joseph Chamberlain, Mr. Harcourt, and Mr. Austen Chamberlain in the cause of tropical medicine. He reviewed the work of the school, and announced that next year a research scholarship, endowed by the bequest of Lord Wandsworth, would be available. In the course of the evening the Chairman referred to the donation of 100*l.* by his Majesty the King to the funds of the school announced that morning.

IN the second part of his usual series, "Visvakarma," devoted to the collection of examples of Indian art, Dr. A. K. Coomaraswamy gives several illustrations of statues of the god Siva, chiefly from the southern part of the peninsula. The statues of Krishnaraya and his queen from North Arcot are particularly interesting. The photographs are fairly well reproduced, but scarcely possess that delicacy which appears in similar pictures in Mr. V. Smith's "History of Fine Art in India and Ceylon."

IN *Bedrock*, the new quarterly review of scientific thought, for October, Prof. A. Keith gives a careful account of our present knowledge of prehistoric man. The recent discoveries in the region of the Dordogne have shown that Neanderthal man is confined to a restricted and comparatively late date in the Pleistocene epoch, appearing for a period, and then being replaced by modern man. But anatomical and archæological evidence agrees in showing that he could not have been transformed into modern man. Work in England proves that we must go much further back in the geological record to find our ancestral form. At least in the middle of the Pleistocene period, long before Mousterian Neanderthal man in France, modern man had appeared in England. The most likely formations from which further clues are possibly to be obtained are the Pliocene and Pleistocene strata of East Anglia. In particular, care must be taken to ensure that every quarry and excavation in that region is watched, and that no remains are discarded as lacking scientific interest simply because they resemble those of modern man.

Mr. T. Sheppard, the energetic curator of the Hull Museum, continues the issue of the series of cheap interesting pamphlets descriptive of collections under his charge, or recording new discoveries in the city and its neighbourhood. Most of the relics found in the city itself belong to the latter part of the sixteenth century and the seventeenth, and it is surprising that relics of later periods are comparatively infrequent. Hull ale has been noted for many centuries, and hence tygs or loving-cups and Bellarmine jars or "Greybeards" are particularly numerous. Another of Mr. Sheppard's pamphlets discusses, with abundant details, the early Hull tobacco pipes and their makers. Among recent additions to the museum collections may be noted a fine Neolithic celt from the neighbourhood of Knaresborough, and a remarkably fearsome man-trap, used before the prohibition of such instruments of torture by an Act passed in 1827. At Bridlington a gold half-noble of Edward III. was recently discovered.

The marvellous escape of the Danish explorer, Mikkelsen, from Greenland, in July last, after nothing had been heard of him and his companion for nearly two years, will be fresh in the memory, and it will also be recalled that he recovered the journals of the lost explorer Erichsen, which had been left at Denmark Fiord. The Danish *Geografisk Tidskrift* (No. 5, 1912), therefore, appropriately publishes maps representing the results of Erichsen's surveys in 1906–8, which, among many important features, reveal the extension of Greenland much further east than was previously believed. Working from Denmark Harbour northward to 79°, the surveyors found a much-broken coast with many islands; northward of that latitude the coast-line was found somewhat more regular. The series of maps referred to not only shows the north-east of Greenland generally, but also includes various detailed maps of Denmark Harbour and other small areas in its neighbourhood.

We are indebted to Messrs. Friedländer, of Berlin, for a sale catalogue of general scientific literature (*Naturae Novitates*), and a second devoted exclusively to entomological publications (*Entomologische Litteraturblätter*).

In the report of the Museums of the Brooklyn Institute for 1911 acknowledgment is made of the extent to which their present attractiveness is due to the efforts and energy of Dr. F. A. Lucas during the period he held the chief curatorship (1904–11). When he came the collections were little more than heterogeneous accumulations, whereas they are now a model of orderly, effective, and attractive arrangement. They have, however, already outgrown the present accommodation, which is liable to destruction by fire, and the urgent need of the institution is a new and fireproof building, specially designed for the purpose it is intended to fulfil.

The Museums Journal for October devotes an article to museum guides—that is to say, living guides, in contradistinction to guide-books—in which Mr. J. H. Leonard gives the results of his experiences in that capacity at the Natural History Museum. He insists on the importance of varying the discourse according to the nature of the particular audience, and strongly deprecates the adoption of a standard curriculum for all occasions. In addition to pointing out objects of special interest, it is urged that the elimination of popular errors should be one main object of the guide. Both at Bloomsbury and South Kensington the guides appear to be highly appreciated by a considerable section of the public.

Evidence of the intimate affinity between the faunas of Central China and North America—and therefore of the essential unity of the so-called Palæarctic and Nearctic regions—continues to accumulate, the latest instance of this occurring in an article by Mr. O. Thomas in the October number of *The Annals and Magazine of Natural History*, on certain small mammals collected by Mr. G. Fenwick Owen in Kan-su and Shen-si. Among other new forms are two specimens of a black mole-like insectivore of the size of a large shrewmouse, representing a new genus (Scapanulus) more nearly allied to the American moles, Scalops and Scapanus, than any other Asiatic form. They were obtained among the mossy undergrowth of a pine-forest in Kan-su. *Scapanulus oweni*, as the species is called, has the fore feet almost as broad, relatively, as in the true moles, with rather slender claws; those of the hind foot, with the exception of the first, being but little curved. The relatively long tail is thickly haired. The teeth may apparently be classified as

$$i.\frac{2}{2},\ c.\frac{1}{1},\ p.\frac{3}{3},\ m.\frac{3}{3},$$

or numerically the same as in the Sze-chuan Neotetracus. The lower incisors are, however, very similar to those of the desmans, a feature broadly separating the genus from Scaptonyx, an allied Sze-chuan type.

Some beautiful photographs of the secondary structure of the diatom valve, taken by Mr. T. F. Smith, are reproduced in *Knowledge* for October. The structures in question, which are only visible with the finest homogeneous immersion objectives, were first discovered by Messrs. Nelson and Karop. Mr. Smith has conducted his investigations on slightly different lines; in particular he prefers to photograph the structures at the "white dot" instead of the "black dot" focus. The photographs show a general resemblance between the secondary structures of different species, although the pretty rosettes differ considerably in their arrangement. Photographs of the fibrils detached from torn valves are given.

Mr. C. B. Crampton has followed up his recent work on the vegetation of Caithness by a series of articles in *The Scottish Botanical Review*, of which a reprint has reached us. This important paper discusses in detail the geological relations of stable and migratory plant-formations. After dealing with the conceptions of the plant-formation given by various ecological writers, the author distinguishes two classes of habitats differing in the changes or successions shown by the vegetation and in the limits set to the stability attainable by this vegetation. The two classes of plant-formations, which tend to overlap and invade each other's territory owing to the migratory nature of the geological agents of surface change, are: (1) stable formations, the plant-associations of which have their centres of distribution on ground which has for a long period been comparatively stable from the geological point of view; and (2) migratory formations, the associations of which have their distribution centres in areas within the sphere of influence of the geological agents of surface change. The author works out his conceptions in detail, applying them successfully to the various types of vegetation found in this country in particular, and gives a useful bibliography of recent ecological literature.

An interesting note on the cold August and September in London is published in *Symons's Meteorological Magazine* for October. Dr. Mill states that the long record at Camden Square (N.W. London), dating from 1858, contains no instance of any previous August or September with a lower mean temperature. The mean for August, 57·9°, was 4·4° below the average, and it was the coolest August in the fifty-five years' record. In September the mean was 54·1°, or 3·6° below the average. The shade maxima records are more remarkable than the minima; in August the mean shade maximum was 66·6°. August, 1860 and 1912, are the only months of that name in which the shade temperature failed to reach 77°. In 1912 the highest recorded was 73·2°. In September the mean maximum, 62·4°, was the lowest on record for that month, and the absolute maximum, 69·4°, was the lowest recorded in any September. Dr. Mill remarks that it is of considerable interest that fifteen consecutive months with mean temperatures above the average, May, 1911, to July, 1912, should be followed by two months of unprecedentedly low temperature.

The meteorological charts of the Indian Ocean for November, issued by the Meteorological Office and by the U.S. Weather Bureau, both contain useful articles on the cyclones of the South Indian Ocean. Both are based to a great extent on the cyclone tracks compiled by the late Dr. Meldrum, of Mauritius, and his successor, published by the Meteorological Committee. The cyclone season for this part of the ocean is from November to May inclusive, but storms are occasionally met with in other months; the maximum frequency is from December to March. The majority of the storms follow parabolic tracks, and, as a rule, recurve between latitude 20° and 22° S. Broadly speaking, the storms are found to originate somewhere along the parallel of 10° S.; "thence they travel south-westward over a track that trends more and more southerly until the vertex is attained; afterwards the track recurves to the south-eastward." The Meteorological Office chart also gives very interesting details respecting the behaviour of storms in the Bay of Bengal and the Arabian Sea.

Those who are interested in the study of the geometry of the triangle will welcome the publication of a monograph of more than fifty pages by the late Prof. G. Sidler in the *Mitteilungen der naturforschenden Gesellschaft in Bern* for 1911, published this year. The original manuscript was completed in 1902, but a difficulty occurred with the figures, which were of great complexity, and the arrangements for publication were terminated by the death of the author. The manuscript, which was in the possession of Prof. Sidler's widow, has now been edited by Dr. O. Schenker.

A paper by Mr. A. Ferguson on the genesis of logarithms, in *Science Progress* for July, should prove interesting and useful reading to mathematical teachers and others. Mr. Ferguson has carefully studied Napier's "Mirifici Canonis Logarithmorum Descriptio" and other authorities, and many of the facts brought to light are little known. The paper gives in a simple and intelligible form the methods by which logarithmic tables were constructed from first principles without the use of the modern infinite series or the calculus, and it affords historical evidence in support of the modern methods of teaching the use of logarithms without assuming the definitions of negative and fractional indices.

As is well recognised, the old system of gauging the strength of concentrated radium preparations in terms of uranium, the "activity" being expressed as so many million uranium units, is practically meaningless, on account of the impossibility of comparing together the radio-activity of two elements, so different both in the character and in the intensity of the radiations they emit. The announcement by Messrs. Hopkins and Williams, Ltd., Hatton Garden, E.C., that in future their radium preparations will be sold on the basis of the actual quantities of radium they contain is therefore a step in the right direction. We understand that they measure their preparations against a standard certified by Mme. Curie to contain a definite quantity of radium bromide, and have for disposal a considerable quantity containing from 90 to 92 per cent. of radium bromide.

Since the echelon spectroscope first disclosed the complex structure of many spectral lines previously thought to be simple, the question of the exact composition of these lines has become a serious one owing to the divergent results obtained by observers working with different instruments. The green mercury line 5461×10^{-8} cm., for example, has by various observers been resolved into from seven to twenty components. The higher numbers appear from the more recent work to be due to spurious lines produced by internal reflections in the instrument or other causes. The simple method suggested by Mr. Twyman of altering the focussing, when true lines should go out of focus and spurious lines behave irregularly, seems not to have been applied by any of the earlier observers. The favourite method has been to combine two instruments giving dispersions at right angles to each other, the two producing a series of interference points. Dr. L. Janicki, of the Reichsanstalt, using two Lummer plates, one of which was slightly wedge-shaped, has recently shown in this way that the 5461 line consists of twelve components, the line previously regarded as the principal line consisting really of a group of five.

THE study of the characteristics of the motion of a train during the accelerating period has assumed an importance indicated by the fact that the actual choice of a method of traction for services of a suburban character depends upon the suitability of the tractor to work the train during the accelerating period. Prof. W. E. Dalby, in a paper read at the Institution of Mechanical Engineers on October 25, describes a useful method by means of which time-speed, time-distance, speed-distance, and energy-distance curves may be derived from a curve of tractive force expressed as a function of the velocity. A method of reducing the data obtained from a dynamometer-car record is also considered, together with the illustration, by means of a dynamical diagram, of the principles underlying the practice of braking. The accuracy of the curves deduced can be easily checked. The whole family may be drawn rapidly by means of the integraph, starting with a curve of tractive-force.

A SECOND edition of "The A.B.C. Guide to Astronomy," by Mrs. H. Periam Hawkins, has been published by Messrs. Simpkin, Marshall, Hamilton, Kent and Co., Ltd. The book has been brought up to date, and a photograph of the zodiacal light, taken by Prof. Douglass, at Flagstaff Observatory, Arizona, U.S.A., has been included as a frontispiece. The price of the little volume is 1*s.* 6*d.* net.

A CHEAP edition of Captain Mayne Reid's "The Naturalist in Siluria," has been published by the Year Book Press. The price of the volume is 2*s.* net. From his house in the Woolhope district, the author could look over the whole series of Upper Silurian rocks, from near Hereford in the north to their southern projection by Gorstley, in Gloucestershire. Many dwellers in this naturalist's paradise, as Mayne Reid called it, will welcome this reprint of his observations.

PROF. S. W. WILLISTON'S "American Permian Vertebrates," which was reviewed in NATURE of October 24, was published in 1911. There was no date on the title-page, and therefore we printed the letters "n.d." with the bibliographical particulars at the head of the notice. The manager of the Cambridge University Press now points out that at the back of the title-page it is stated that the volume was published in Chicago in October, 1911. We cannot attempt, however, to do more than give particulars from the title-pages themselves at the head of notices in our review columns.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR NOVEMBER:—

Nov. 4. 15h. 0m. Mars in conjunction with the Sun.
5. 21h. 0m. Pallas in conjunction with the Moon (Pallas 0° 26′ N.).
7. 15h. 59m. Venus in conjunction with Jupiter (Venus 1° 43′ S.).
8. 13h. 28m. Mars in conjunction with the Moon (Mars 3° 7′ N.).
10. 6h. 50m. Mercury in conjunction with the Moon (Mercury 1° 54′ N.).
11. 1h. 21m. Jupiter in conjunction with the Moon (Jupiter 5° 5′ N.).
,, 8h. 21m. Venus in conjunction with the Moon (Venus 3° 21′ N.).
13 to 15. Maximum of Leonid Meteor Shower.
14. 7h. 59m. Uranus in conjunction with the Moon (Uranus 4° 27′ N.).
19. 1h. 0m. Mercury at greatest elongation east of the Sun (22° 14′).
20. 16h. 54m. Mercury in conjunction with Jupiter (Mercury 2° 47′ S.).
22. 18h. 0m. Saturn at opposition to the Sun.
24. 3h. 47m. Saturn in conjunction with the Moon (Saturn 6° 17′ S.).
27. 20h. 49m. Neptune in conjunction with the Moon (Neptune 5° 33′ S.).

SCHAUMASSE'S COMET 1912*b*.—The identity of the comet discovered by M. Schaumasse on October 19 with Tuttle's comet, last seen in 1899, is shown by the elements for its orbit, published in Circular No. 136, from the Kiel Centralstelle, and given below in the first column:—

	1912*b* (Fayet and Schaumasse)		Tuttle's (Rahts)	
π	= 113° 50′ 20″	1912·0	= 116° 29′ 3″	1900·0
☊	= 270 23 58	1912·0	= 269 49 54	1900·0
i	= 53 52 34	1912·0	= 54 29 16	1900·0
q	= 1·0506		= 1·0191	

According to the new elements, perihelion passage took place on October 25·3153 (Paris M.T.), when the comet was some 97·6 million miles from the sun. The previously calculated time of perihelion was January 3, 1913, and thus, as a writer in *The Times* (October 24) points out, the present revolution is the shortest on record, as was also the case with the last return of Halley's comet. The difference of seventy days between the calculated and actual returns will probably be disclosed when the planetary perturbations during the last cycle are taken into account.

The ephemeris given in the Centralstelle circular indicates that the comet will not become brighter, is travelling southwards rapidly, and will not be visible in the northern hemisphere after November 23.

Ephemeris 12h. (M.T. Paris).

1912	α h. m.	δ ° ′	1912	α h. m.	δ ° ′
Oct. 30 ...	10 30·9 ...	−12 41	Nov. 7 ..	10 54·5 ...	−22 2
Nov 3 ...	10 42·6 ...	−17 25	,, 11 ...	11 6·7 ...	−28 37

GALE'S COMET 1912*a*.—A number of observations of comet 1912*a* are published in No. 4606 of the *Astronomische Nachrichten*, and a photograph by Mr. H. E. Wood at Johannesburg is reproduced. On September 13 the comet was visible to the naked eye, magnitude 5, and had an almost stellar nucleus surrounded by an even coma 4′ in diameter. The tail was fan-shaped, with an angle of about 60°, the branch to the south being 40′ long, while the south-following branch had a length of 1°. On a photograph taken with the Franklin-Adams camera, exposure 40m., the former branch is the same length, but the latter is 4° long, and slender, having a contortion 0·75° from the nucleus. On September 15 this contortion was 1·4° from the head, and the tail, $5\frac{1}{4}$° long, was clearly double $2\frac{1}{2}$° from the head.

Ephemeris 12h. M.T. Berlin.

1912	α (true) h. m.	δ (true) ° ′	log r	log Δ	Mag.
Oct. 31	16 2·1	+23 55·2			
Nov. 2	16 3·8	+25 21·6	9·9605	0·0988	7·0
4	16 5·4	+26 45·8			
6	16 7·0	+28 8·3	9·9832	0·1052	7·2
8	16 8·6	+29 29·5			
10	16 10·3	+30 49·7	0·0057	0·1105	7·3
12	16 12·0	+32 9·0			
14	16 13·7	+33 27·8	0·0280	0·1145	7·5

Dr. Ebell calculated the brightness, by the formula $1/r^2\Delta^2$, on the assumption that on September 26 the magnitude was 6·0, but Mr. Franks found it to be a little more than 4·0 on October 11, while, in a good sky, M. Gonnessiat estimated it as 5·5 for the whole comet, on September 29. There appears to be definite evidence for an intrinsic brightening while near perihelion.

The Total Solar Eclipse of October 10.—A telegram from Prof. Morize to the *Astronomische Nachrichten* (No. 4606) states that the observations of the total eclipse at Christina (Minas Geraes, Brazil) were spoiled by rain, although some selenium-cell observations of brightness were made by Dr. Ristenpart. Prof. Perrine, cabling to Prof. Pickering from Brazil, also states that rain prevented observations. A further telegram, published in No. 4607 of the same journal, announces that the eclipse was observed under favourable conditions at Quito by Señor Tufiño.

International Standard Time.—The *Revue générale des Sciences* (No. 19) gives an outline of the present state of the question of the international standardisation of time, and the programme prepared for discussion at the International Conference which met at the Paris Observatory on October 15. The acceptation by France of the international *réseau* removed the last great obstacle to the unification of standard times, and the general distribution of time-signals by wireless telegraphy makes this unification more than ever necessary. It has been found that signals sent from different stations show inconsistencies amounting to several seconds, not very serious in ordinary affairs, but fatal in matters demanding scientific precision. To remedy this state of affairs the Bureau des Longitudes invited the International Conference to reassemble in Paris, and drew up a tentative programme of the matters for discussion. Under seven main headings this programme practically exhausts the debatable points concerning the determination of time, the methods of keeping it, and of distributing it by radio-telegraphy and otherwise, the precision necessary for different purposes, and the general question of how to organise internationally in order to gain these ends.

THE ORIGIN OF LIFE.

One of the most interesting of the recent meetings of the British Association at Dundee was that devoted by the joint sections of Zoology and Botany to the discussion of the problem of the origin of life. It should be remarked that this was not a discussion of the President's address; it was arranged before the subject of the presidential address had been made known. The President (Prof. E. A. Schäfer), who occupied the chair at this meeting, explained at the outset that his address had been written and printed before he knew that this discussion was to take place.

Prof. E. A. Minchin, in opening the discussion, pointed out that the problem of the origin of life involved two inquiries, both of which were at present of a speculative order, namely: (1) the nature and characters of the earliest living beings, and (2) the manner in which the primordial form of life took origin and maintained its existence upon the earth. The first of these problems could be considered with profit, but the second, owing to the inadequacy of the data available, appeared to him to be scarcely ripe for discussion. He observed that the cell, which might be defined as an individualised mass of protoplasm containing at least one nucleus, was generally regarded as the simplest type of organism, and as the vital unit in the composition of living beings, whether plants or animals. It was improbable that the earliest forms of life came into existence as organisms composed of two distinct structural elements—the nucleus and the cytoplasm (body-protoplasm). Which of these—the cytoplasm or the nucleus—was to be regarded as representing or containing the most primitive elements of the living substance? By most biologists the cytoplasm had been considered to represent the true living substance, and the earliest living organisms—the so-called Monera—had been supposed to be formless masses of protoplasm without nuclei.

Prof. Minchin proceeded to advance reasons for believing that the chromatin substance invariably present in the nucleus, or occurring as grains (chromidia) scattered in the cytoplasm, represented the primary and essential living matter. In support of this view he pointed out that chromatin is always present in the bodies of living organisms of all kinds, that cells cannot continue to live if deprived of their nuclei, that in reproduction by fission the chromatin divides first and is distributed among the daughter-individuals, that the complex process of division of the nucleus known as karyokinesis may be regarded as a mechanism gradually evolved and perfected for ensuring an exact quantitative and qualitative partition of the chromatin between the daughter-nuclei—an indication that the chromatin is of prime importance—that the chromatin-substance plays an essential part in syngamy (fertilisation) and probably also in heredity (as carrier of the characters of the organism), that the nucleus is essential for the continuance of the secretory activities of the cell, and, finally, that in some of the minutest living organisms—*e.g.* spirochætes and the male gamete of the malaria parasite—the body appears to consist mainly or entirely of chromatin, and cytoplasmic elements are reduced to a minimum or are altogether absent. Prof. Minchin quoted from a communication received recently from a correspondent, who pointed out that the protein molecules of the nucleus are simpler in constitution than those of the cytoplasm, and therefore may be regarded as more primitive. Further, the amido-acids characteristic of the nucleus are of the open-chain order and free from complexity, while those of the cytoplasm are of the closed order and could only have arisen from the type of acids present in the nucleus. For these reasons Prof. Minchin regarded the chromatin as the primitive living substance, and held the view that the earliest forms of life were very minute particles of chromatin, round which, in the course of evolution, achromatinic substances were formed. Within the cytoplasmic envelopes thus produced the chromatin-grains increased in number, and organisms of the degree of structural complexity of a true cell arose finally by concentration of the chromatin-grains into a compact organised mass—the nucleus proper.

As regarded the origin of the earliest living beings, it was only possible to frame vague speculations, in the present state of our knowledge, concerning the chemistry of the protein compounds, on the one hand, and the metabolism and modes of life of the simplest living things on the other. He referred to the extreme view, represented by Arrhenius, that life had had no origin in finite time, but was coeval with matter and energy, and then turned to consider the view, more prevalent among biologists, that living matter had arisen at some time from that which was not living. If life arose under conditions not now existing in nature, there seemed to be no reason why such conditions could not be reproduced artificially, but if the conditions under which life arose *de novo* were not different from those existing there seemed to be no reason why it should not do so again. Why, then, did we not see new forms of life appearing on the earth? Prof. Minchin doubted if the simplest forms of life were yet known, or even if we could recognise them or be aware of their existence at their first appearance. The first origin of life involved a synthesis of protein substances in nature by some process as yet totally unknown. For light on these problems we must look to the future advance of knowledge, and especially of chemical science. In the present state of our knowledge, the attitude towards the problem of the origin of life could only be one of expectancy for more light in the future; at present it was not possible to frame a hypothesis which could have any greater value than that of a pious belief.

Mr. Harold Wager said that the more one saw of the lower forms of life, the more remote seemed to become the possibility of conceiving how life arose. He opposed Prof. Minchin's view that chromatin was the primary living substance, and in support of his contention referred to the structure of the blue-green algæ. These, he said, were interesting as the only organisms which would survive in very hot water (*e.g.* hot springs), and had been regarded as probably the last remnants of the early vegetation of this earth. Each cell of those algæ contained an irregular network of chromatin without a limiting membrane, and not clearly differentiated from the surrounding protoplasm, *i.e.* the chromatin more nearly resembled the cytoplasm in these than in higher organisms. Further, in certain bacteria there were granules of nuclear matter, but in others there were none, the organism consisting of cytoplasm only. These facts impelled Mr. Wager to regard the cytoplasm, and not the chromatin, as the fundamental life-substance.

Prof. F. W. Keeble thought that, having regard to the highly complex interacting phenomena presented by living organisms, it was improbable that the creation of "synthetic life" would be seen in the near future.

Prof. A. B. Macallum believed, with Tyndall, that matter was endowed with the potentiality of life, and to that extent he was in sympathy with the view of Arrhenius. No doubt the organism which first came into existence was ultra-microscopic, and comprised but a few molecules. The conditions necessary to produce such organisms do not now hold, but at one time the earth's surface was a vast laboratory in which syntheses of various kinds took place, and a favourable conjunction of forces produced the combination of a number of molecules in which life was. This organism would not be a cell, with cytoplasm and nucleus, but an ultra-microscopic body. The cell was as far removed from such a minute body as man is from the cell.

Prof. Benjamin Moore said that vitalism was a purely static view of life, and was untenable. Structure was important, but something more than structure was necessary for life; dynamic energy—energy, motion, change—was essential, and was manifest in all living organisms. To suppose that life began as blue-green algæ, or some such complex organism, was nonsensical. It was necessary to begin with the formation of organic molecules from the inorganic, then to build up more complex molecules (in which all the atomic combinations were saturated), and group them into colloidal substances. The colloids, which are large aggregates of molecules, show the properties of dawning life, for in presence of sunlight colloids begin to form organic bodies, but it would be necessary to add to the colloid an energy-transformer. He regarded the problem under discussion not as metaphysical, but experimental.

Prof. J. S. Macdonald regarded the problem from the point of view of a physiologist, and said he could not accept the statement that chromatin was the most important portion of the living cell, for in muscle the contractile mechanism is located in the cytoplasm, the functional activity of a red blood-cell is resident in the cytoplasm, and the main functions of the central nervous system are also associated with the cytoplasm. He held, therefore, that the nuclear material was not concerned in carrying out the main functions of the body.

Prof. Marcus Hartog referred to the power of multiplication of organisms, and said he could see no reasonable probability of our being able to create life afresh, or, indeed, to understand how it came into existence.

Prof. Patrick Geddes put forward a plea for the psychological aspect of the inquiry, for he held that even the simplest organisms presented a dawn of psycho-biosis, and that life was not merely a question of matter (*e.g.* chromatin).

Dr. J. S. Haldane said he belonged to a school which believed life could not be explained, or interpreted finally, by the known chemico-physical properties of matter, and he could not imagine any laboratory experiment, according to our present knowledge, which would bring us any nearer to the origin of life.

The Rev. T. R. R. Stebbing pointed out that for years past many evolutionists had recognised, as a necessity of the theory, that organic life must have been derived from what was inorganic, and that it was reassuring to find that this *a priori* speculation could be supported on grounds of scientific probability.

Dr. P. Chalmers Mitchell stated that in his opinion there was not a single property of protoplasm which had not its exact physical parallel, nor a single quality of life which would show there existed in life something which was not to be found in matter.

J. H. A.

THE SCIENTIFIC THEORY AND OUTSTANDING PROBLEMS OF WIRELESS TELEGRAPHY.[1]

IN opening a discussion on the present state of the theory of wireless telegraphy and its outstanding problems, I am, to some extent, embarrassed by the wide field which presents itself for consideration.

I venture to think that we may best take advantage of the simultaneous presence here of physicists, mathematicians, engineers, and electricians, if we endeavour to focus attention, in the first place, on some of the chief scientific problems which are yet unsolved in connection with it.

Perhaps a word of explanation may be offered on the reason for giving prominence to the scientific aspect of the subject rather than its practical achievements. The achievements loom large in the public eye, and are astonishing to the uninitiated, but experts in radio-telegraphy are well aware that many of the

[1] Introductory remarks by Prof. J. A. Fleming, F.R.S., at a joint discussion by Sections A and G of the British Association at Dundee.

scientific phenomena are imperfectly understood. If we are to overcome present difficulties and limitations and make fresh advances, it can only be by a thorough comprehension of the physics of wireless telegraphy. Hence it will be more to our advantage to bring combined scientific thoughts to bear upon the matters on which even leading experts differ or are ignorant, rather than let our symposium resolve itself into a discussion on apparatus or systems or the recitation of performances and the record of results.

As the only type of wireless telegraphy which has any considerable theoretical interest at the present time is that involving the application of unguided electromagnetic waves, our attention will doubtless be chiefly directed to it.

Starting from the discoveries of Hertz and his followers, we enter a new era. Apart from Marconi's improvements in the metallic filings coherer of Hughes, Branly, and Lodge, the important element in the arrangements by which in 1896 he applied purely scientific knowledge of Hertzian electric waves to practical electric waves or radio-telegraphy was the introduction of the long, nearly vertical aerial wire, as a radiator combined with a metal plate above or buried in the earth as the balancing capacity. In this wire high frequency oscillations are created; originally by using the wire itself as one electrode of an air condenser, and the earth as the other, but later on by inducing oscillations in the wire by means of the dead-beat or oscillatory discharge in another condenser circuit including a spark gap, coupled to the air-wire circuit. Although enormous ingenuity has been expended in improving or varying every element in the appliances, we can say that with the exception of a small number of stations using the Duddell-Poulsen arc generator, nearly all the practical wireless telegraphy in the world is at present (1912) conducted by the following apparatus.

At each station there is a transmitter which comprises three elements:—

1. A source of high electromotive force which may be a continuous-current dynamo and storage battery, an alternator and transformer, or a battery and induction coil giving continuous, alternating, or interrupted high-tension electromotive force.

2. A condenser in which the generator stores an electric charge to be suddenly released when a certain potential is attained across a spark gap in the form of an electric discharge passing through a coil in series with the condenser.

3. An open or radiative circuit coupled to the condenser circuit, comprising an antenna or arrangement of elevated air wires, a balancing capacity or counterpoise often buried in the earth, the two being connected through an adjustable inductance coil.

At the receiving station we have also three elements:—

1. An absorbing antenna by which the radiation from the transmitter is picked up, creating in it high-frequency oscillations.

2. A condenser circuit having variable capacity and inductance coupled to the antenna and syntonised to it.

3. Some form of oscillation detector connected in series or parallel with the above condenser which is affected by the oscillations and sets in operation a recording or indicating device which makes a visible or audible signal.

Generally speaking, at any one station the radiating and absorbing antennæ are one and the same, and used for both purposes alternately, and each station has both transmitting and receiving apparatus. The functions are, however, not identical. What is required in the transmitting antenna is a certain height and also free or insulated ends. In the receiving antenna, not only height but surface is required, although this antenna can be laid parallel with and close to the earth and earthed at both ends; but provided it is half a wave length in length, it will still absorb a considerable amount of energy from electric waves arriving in its own direction.[2]

In the next place as to exact details, the following information may be useful to those who are not wireless-telegraph engineers.

The antenna consists of a large number of hard-drawn copper wires, which are upheld by masts or towers in such fashion that the wires form a sort of fan elevated in the air; or they may rise up for a certain height and then be bent downward on all sides, like the ribs of an umbrella. In the case of our battleships, they are groups of parallel wires kept separate by wooden stars and stretched between the masts and then led downwards to the bow and stern of the ship. In the high-power Marconi stations they rise up vertically for a certain distance, and are then stretched horizontally for a distance about five times greater, parallel with the ground.

In long-distance stations the wooden or steel lattice towers or tubular masts required to sustain these wires are elaborate structures 100 to 400 feet or more in height, and have to be well stayed to resist wind.

Associated with the antenna is a counterpoise or balancing capacity, which may consist of insulated wires stretched a little way above the earth, or radiating wires or metal nets laid in the earth, or sheets or nets of metal laid on the ground, or even the metal hull of a ship.

This counterpoise is connected to the antenna through a variable inductance coil. In virtue of the capacity of the antenna with respect to the earth or the counterpoise, the whole system has a natural time period of electrical oscillation.

It may be compared with an elastic steel strip held at the bottom in a vice and loaded at the top, which can be set in vibration by small blows administered to it at the proper rate.

There are certain rates of antenna oscillation reserved for certain purposes.

Thus, for ship or coast signalling, antennæ are used having natural time periods of one-millionth or one half-millionth of a second, and for large power stations the time period may be as large as one hundred-thousandth or one fifty-thousandth of a second.

In nearly all cases these oscillations are excited in the antenna by the intermittent discharge of a condenser. They are therefore damped or decadent trains of free oscillations, separated by intervals of silence. The group frequency, as it is called, or number of the trains of oscillations, is now usually 500 to 1000, since, when using the telephone as a receiver, the group frequency is preferably that frequency for which the telephone is most sensitive. Each train of oscillations may comprise 30, 50, or 100 oscillations having the antenna frequency. The antenna is, therefore, set in electrical vibrations, so that trains of electric currents run up and down it intermittently, say, 500 times a second, each train consisting of 50 or more decadent oscillations, whilst each oscillation or single current occupies a time between one fifty-thousandth of a second and one two-millionth of a second and its complete to and fro cycle.

These high frequency currents in the antenna are created by the induction of a nearly dead-beat or else an oscillatory discharge of a condenser. In small installations the condenser is a collection of Leyden jars, or, more conveniently, glass plates coated with

[2] Numerous patents have been taken out for methods of using an antenna at the same time for sending and receiving. The inventions of Mr. Marconi in connection with this matter are both practical and important, and are being carefully developed by him.

thin sheet zinc or tin, the plates being immersed in a metal or stoneware box of oil.

In the case of some high-power stations, Mr. Marconi employs large air condensers consisting of sheets of metal hung up on insulators in a room. At Nauen and at the Eiffel Tower stations tubular or plate-glass condensers are used.

The condenser is charged by the source of electromotive force to a high potential, and then discharged across a spark gap, with or without oscillations, and this discharge passes through a coil which may be one coil of a two-coil transformer, the secondary being inserted in the circuit of the antenna, or else a single-coil transformer, then called an auto-transformer, may be made to do duty for the two separate coils in the circuits of the antenna and the storage condenser.

An important element is the spark gap. In early days when only small powers were employed, this consisted simply of two stationary brass balls. When large power first began to be applied, as at the Poldhu Station in 1901, it was soon found that the oscillatory discharge started an electric arc across the balls which had to be extinguished before the condenser could again become charged. Also the balls became rapidly worn away. To remedy these defects, various inventions were introduced. An air blast was applied to the spark gap to quench the arc.

I devised for the Marconi Co. in 1902 a discharger with revolving balls or discs driven by an electric motor which overcame some of the difficulties, and this type of slowly rotating disc discharger using low-frequency sparks was used for some considerable time at Poldhu.

Later on Mr. Marconi invented his high-speed studded disc discharger which is far more efficient, and creates a quenched musical spark of the required character. In this discharger a steel disc having studs on it revolves at a high speed between two other revolving electrodes and the passage of the studs starts a condenser discharge in which any true arc is instantly quenched. The kind of discharge required for effective work is one in which rapidly repeated, strong, highly damped discharges take place in the primary condenser circuit, and these excite prolonged trains of free oscillations in the antenna. This is only possible if any true arc discharge in the primary circuit is entirely prevented.

This is also achieved by the Wien or Telefunken, the Peukert and Von Lepel dischargers consisting of flat metal plates in close proximity. In these dischargers the discharges succeed each other with great regularity and at the rate of several hundred per second. When the condenser circuit is properly tuned to the antenna circuit and coupled to it not too strongly (with about 20 per cent. coupling), we have powerful intermittent oscillations set up in the antenna, each group being very feebly damped and of uniform oscillation frequency. These rapidly succeeding groups of oscillations are cut up into groups of groups in accordance with the signals of the Morse alphabet by means of a key placed in some part of the circuit. Although nearly all the radio-telegraphy in the world is now conducted by means of these intermittent condenser oscillations, great efforts are being made to perfect suitable high-frequency high-power alternators, and the advent of a commercial machine of this kind will no doubt make it a formidable rival to the existing methods.

Deferring for the moment the consideration of what takes place in the space between the sending and receiving antenna, we may complete our description of the receiving apparatus.

In the sending antenna we have very powerful high-frequency currents at the base and high potentials at the free or upper end. Even in small stations the sending antenna current may have a value of 5 to 10 amperes, whilst in large stations the antenna current at the earthed end is 50 to 100 amperes, and large enough to raise to incandescence quite large rods of arc light carbon.

There is, therefore, a considerable expenditure of power on the antenna. A part of this is spent in heating the antenna, but a large proportion is radiated. Nevertheless, the over-all efficiency of the usual wireless telegraph transmitter using the ordinary unquenched condenser spark, meaning by that the ratio of power radiated from the antenna to power supplied by the operating dynamo or battery, is at present probably not more than 20 per cent. to 25 per cent. in actual practice, though much higher efficiencies, even up to 75 per cent., have been claimed for the quenched-spark system. But the evidence for these high efficiencies is somewhat imperfect.

An extremely small fraction of the whole radiated energy is picked up by the receiving antenna. In this latter we have currents created which are measured in micro-amperes, or, at best, in fractions of a milliampere. If the receiving antenna is properly tuned to a closed condenser circuit inductively coupled to it, the energy picked up by the receiving antenna accumulates in the associated condenser circuit.

In this last we then have feeble currents circulating which imitate in mode of variation those of the distant transmitting antenna. To detect them, it is now most usual to employ a telephone in series with some form of current rectifier, which is shunted across the condenser in the closed secondary receiving circuit, or else some form of current-operated detector, such as Marconi's magnetic detector, which is placed in the condenser circuit.

If we merely connect a telephone across the condenser circuit, no sound will be produced in it, because the frequency of the current oscillations in the receiving condenser circuit is too high to affect a telephone. If, however, we insert some device in series with the telephone which acts like a valve, it will rectify the groups of oscillations into prolonged gushes of electricity in one direction, which, coming at the rate of the much lower spark frequency, say, about 500 or 1000 per second, create in the telephone a shrill sound. As these groups are interrupted at the sending station in accordance with the Morse signals, the receiving operator hears long or short musical sounds which he can interpret into the letters of the alphabet.

Amongst the rectifiers much used, my own oscillation valve invented in 1904, or glow-lamp detector, is an interesting example. It consists of a little electric glow lamp, having a metal plate or cylinder sealed into the glass bulb. When the filament is incandescent the space between the filament and the plate has a unidirectional conductivity, and will allow negative electricity to pass from the filament to the plate, but not in the opposite direction.

Another large class of oscillation rectifiers are the crystal and contact rectifiers, the first of which, viz carborundum, was discovered by Dunwoody, others by Pierce and Pickard. Thus, for instance, a copper point pressed against a small mass of molybdenite is a good rectifier. Also the minerals chalcopyrite, zincite, bornite, anatase, and hessite possess similar properties, and a very sensitive rectifier is made by a slight contact between two small masses of zincite and bornite. Another rectifier is the galena-plumbago rectifier. Also a gold point pressed very lightly against an artificial surface of iron pyrites (ferric disulphide) makes an excellent detector.

In spite of much valuable work done by Prof. G. W. Pierce, G. W. Pickard, and others the action of these crystal rectifiers is by no means fully elucidated. It appears not to be thermoelectric, since in general the rectified current is in the opposite direction to the thermoelectric current produced by heating the junction.

In addition to these glow-lamp and crystal rectifiers another much-used detector is Marconi's magnetic detector, in which a slowly moving band of iron wires passes across the poles of a pair of horseshoe magnets. The wire at that place is embraced by two other coils of wire—one in series with the oscillating circuit of the receiver and the other with a telephone. When trains of oscillations are set up in the receiving antenna a listener at the telephone hears a sound due to the sudden change in the magnetic state of the iron. The simplicity and absence of any difficult adjustments make this magnetic detector one of the most useful for general purposes.

The wireless message is thus picked up at the receiving station by hearing telephonic sounds due to a greater or less number of trains of high-frequency oscillations in the transmitting antenna corresponding to *dashes* or *dots* in the Morse alphabet.

These long or short groups of oscillations in the transmitting antenna create similar groups in the receiving antenna, which, when rectified, cause gushes of electricity in one direction through the telephone, and therefore make sounds like ticks or musical notes of long or short duration. The pitch of this note is the frequency of the spark at the sending station.

One of the practical difficulties not yet quite overcome is the invention of a suitably simple and sensitive *call* signal. At present the operators have to sit with the telephone on their heads waiting for any message which may begin, and this is expert work which cannot be deputed to anyone else.[3] Another requirement is a simple and yet sensitive relay by which the messages may be printed down on paper tape. The photographic method employing the Einthoven galvanometer is effective but rather elaborate.

The recently invented alternating-current resonance relay of Dr. Kapp and Mr. H. von Kramer is sensitive, and can be operated with an alternating current having a frequency of about 100, and one-fifth of a milliampere in value. What is required is a relay sensitive to currents of a frequency varying between 50 and 500 or so, and a strength of about one-tenth of a microampere.

Having thus outlined the manner in which the radio-telegraphic message is sent, I now pass on to propound for your discussion certain imperfectly solved scientific questions. The first of these is:—

By what mechanism or process are the signals conveyed across the intervening space between the transmitter and the receiver? Most persons would say, at once, by electromagnetic or Hertzian waves, produced in the æther, and the answer is no doubt correct so far as it goes. The action of the sending antenna on the receiving antenna is not merely an instance of one electric current inducing another in a secondary circuit as in the magnetic induction form of telegraphy. In radio-telegraphy the energy sent out from the sender, no doubt, departs from it entirely and exists for a time in a medium before it reaches the receiver. The question is what is that medium? The whole of the actions in the sending antenna by which the distance effect is produced are consistent with the assumption that electromagnetic waves are sent out from it. But are these waves, strictly speaking, Hertzian waves or space waves? What part, of any, does the earth play in the process? Are the very long distances which can be covered by modern radio-telegraphy consistent with the properties of pure Maxwellian or Hertzian waves produced in the æther. These are the first unsettled questions I wish to throw down for discussion. As soon as Transatlantic signals had been received by the means already described, physicists began to ask how such waves, if they are true electromagnetic waves, are propagated one-eighth of the way round the earth. Since then Mr. Marconi has achieved the feat of receiving signals in South America from his Clifden station in Ireland at a distance of 6000 miles. The problem now is to explain how this effect travels one-quarter of the way round the earth. It suggests at once the query, could it go half-way round? Can wireless signals be received in New Zealand from England, and may we look forward not merely to Transatlantic or Transpacific, but to transterrestrial wireless telegraphy to the Antipodes as a practical possibility? The answer to these questions is necessarily connected with that to the more general question, how does the sending antenna affect the receiving antenna at any distance? In a year or more, when the Imperial wireless scheme comes into operation and the long-distance stations are completed, London will speak to Aden; Aden to Bangalore and Pretoria; Bangalore to Singapore; and thence the step will be easy to Australia and New Zealand. It is possible that we may yet communicate from London direct to Melbourne without the intermediate stations. In text-books and lectures it has been usual, for the sake of simplicity, to treat the problem of radio-telegraphy as if the earth were a perfectly conducting sphere immersed in free æther. A very little practical experience showed wireless telegraphists that the electric condition of the atmosphere greatly affected it, and that the receiving apparatus, so sensitive to waves intelligently sent out from transmitting stations, picked up in addition all manner of vagrant waves set going by atmospheric discharges. Also early attempts at long-distance radio-telegraphy led Marconi to the discovery of the great influence of daylight upon the distances attainable. If, however, we leave out of account for the present these atmospheric and daylight disturbances, to which we shall return presently, we have still to face the fact that the nature of the terrestrial surface between the sending and receiving station affects the result very appreciably.

Very early in the practical experience of radio-telegraphy it was found that it could be conducted more easily over sea than over land, and more easily over ordinary wet soil than over very dry sandy soil.

But apart altogether from this last effect, it has always been felt that there was something surprising in the fact that it is possible to detect electromagnetic waves created at a distance of one-eighth to one-quarter of the way round the world. It has been generally assumed that this was wholly due to an abnormally large diffraction effect. The first question of importance is, then, whether diffraction can occur to an extent sufficient to account for the observed facts. The determining factor as regards diffraction is the ratio of wave length to the earth's diameter.

In the early attempts at long-distance wireless telegraphy wave lengths of 2000 to 3000 ft. were used, but at the present time wave lengths from 10,000 to 20,000 ft. are employed, or, say, one-thousandth of the earth's radius.

Consider for one moment an optical analogue. The mean wave length of visible light is about 1/50,000th of an inch. Suppose a luminous point of infinitely small magnitude were placed at the pole on the surface of a smooth sphere a quarter of an inch in diameter or about the size of a pea, in a region otherwise not illuminated. This corresponds to the case of electric waves 1000 metres in wave length sent out from a

[3] The Marconi Co have recently introduced a call instrument, in which a signal equivalent to a prolonged *dash* on the Morse code deflects a galvanometer, which in turn closes a bell-battery circuit and rings a bell. The difficulty is, however, to prevent atmospheric discharges from making a false call, but render it sensitive only to a prearranged signal.

radio-telegraphic station on the earth's surface. Would there be any light due to diffraction at the equator or even at 45° latitude of this small sphere? It is essentially the province of the mathematical physicists to give us a solution of the above question, but the answer would, I think, be in the negative. To make the case comparable with that of the longest electric waves used for terrestrial radio-telegraphy, the sphere would have to be only the millimetre in diameter. The answer is then not quite so obvious.

The first attempt at the problem in the case of radio-telegraphic waves was made by Prof. H. M. Macdonald in 1903 and 1904.

Last year he published a second paper in the Transactions of the Royal Society on the same subject. In this last paper a table is given for waves of two wave lengths, viz., 0·2 mile and 0·25 mile, showing the ratio of the calculated amplitude of the received oscillations at a point at certain distances measured along a great circle of the earth to the amplitude which would exist if the earth were absent. For the two wave lengths, and for a distance of 651 miles, the ratios are respectively 0·06 and 0·07, or, say, 1 : 14. It may be remarked, however, that the wave length now used at Marconi's Clifden station in Ireland is nearly four miles, and that the maximum distance at which signals have been received is 6000, and not 600 miles. Hence, before Prof. Macdonald's table can be brought into comparison with the latest practice, his wave lengths must be increased twenty times, and his maximum distance ten times.[4]

In this second paper he refers to the previously published 1904 paper, in which he showed that the effect at a point on a perfectly conducting sphere due to a Hertzian oscillator near its surface was negligible in comparison with the effect which would have been produced at that point if the sphere were removed, when the point is at some distance from the oscillator, and the radius of the sphere is large compared with the wave length.

The same problem has also been discussed by Prof. H. Poincaré, whose recent decease we have so greatly to deplore, in a series of interesting lectures and papers.[5] In his latest memoir on the diffraction of Hertzian waves in the *Jahrbuch der Drahtlosen Telegraphie* for 1910, p. 445, Prof. Poincaré reaches the conclusion that the amplitude of the oscillations at a point on the earth's surface, which is separated from a transmitting station by an angle ϕ measured along a great circle through the stations, is proportional to an exponential function $\epsilon^{-m\omega^{\frac{\phi}{3}}}$ where m is some numerical constant and ω is a complex quantity the real part of which is proportional to the frequency. This at any rate agrees with one result of practical experience, viz. that to effect radio-telegraphy over long distances large wave lengths are necessary. But it is difficult to extract from his conclusions means to enable us to predict the exact extent to which diffraction really exists for waves two to four miles in length.

The problem of the bending of electric waves round the earth has also been discussed by Dr. J. W. Nicholson in a series of able and critical papers.[6]

The conclusion arrived at by him after considering the work of Macdonald and Poincaré as the result of his own analysis can best be expressed in his own words (see *Phil. Mag.*, vol. xix., pp. 277–278, 1910).

He assumes that an oscillator is placed near the surface of the sphere with its axis radial, and he says: "On the confines of the geometrical shadow within a cone of small angle cutting off but a small portion of the terrestrial surface near the oscillator true diffraction bands are found, arising from terms now important in which the order and arguments are nearly equal. But within the shadow beyond the extreme generators of the cone, the extinction of the waves is very complete." "The harmonics of a high order are found to be so disposed as to neutralise one another in a remarkable way, and the intensity of the diffracted light at a distance of a few thousand miles round the surface sinks to a minute fraction of its value when the sphere is absent. Thus, it is improbable that diffraction can explain the effects unassisted by reflection from an ionised layer in the upper atmosphere, or by some other cause.

If this result is confirmed for wave lengths of four miles, or one-thousandth part of the earth's mean radius, then it will follow that ordinary diffraction is incapable of explaining long-distance radio-telegraphy, and we must look to some other cause. Before discussing the alternative which has been suggested both by Prof. Poincaré and Dr. Nicholson, I should like to direct your attention to an explanation of a quite different nature due to Prof. A. Sommerfeld, of Munich. Mathematicians who have dealt with the problem under the assumption of a perfectly conducting earth and a Hertzian oscillator entirely disconnected from it have assumed conditions which do not hold good in practice. Hence the attempt to explain long-distance radio-telegraphy by the aid of diffraction may be a quite unnecessary effort. The actual earth has a crust composed of materials which chiefly owe their conductivity to water. When free from water these materials composing the igneous and sedimentary rocks (apart from metallic veins and oxides and sulphides of heavy metals), such as granite, gneiss, quartz, slate, chalk, and sandstone are very fairly good insulators. Although sea water is a conductor, it has a dielectric constant ($K = 80$) very far from infinite. Moreover, at no very great depth in the crust the temperature is sufficiently high to exclude the presence of liquid water, and therefore of any conduction due to it.

The numerical values which have been given for the materials composing the earth's crust are only very approximate. Experimentalists have mostly measured the resistance and dielectric constant of dry samples with continuous or direct currents. They have omitted to take account of the fact that non-metallic materials, such as quartz, felspar, mica, slate, &c., increase in conductivity with rise of temperature and also have a conductivity for alternating currents quite different from that for direct currents.

In the majority of cases these rocky materials are very good insulators. Thus dry granite has a dielectric constant about 7 to 8 and a specific resistance which may be as high as one thousand megohms per centimetre cube, and dry slate has a dielectric constant of about 12 and specific resistance of about 500 megohms per centimetre cube.[7]

[4] See H. M. Macdonald, Proc. Roy. Soc. London, vol. lxxi., A, p. 251, 1903; vol. lxxii. A, p. 59, 1904. The conclusions in the first paper were subjected to some criticism by Lord Rayleigh and Prof. Poincaré.

See Prof. H. M. Macdonald, "On the Diffraction of Electric Waves Round a Perfectly Reflecting Obstacle," Trans. Roy. Soc. London, 1910, vol. ccx., A, p. 113.

[6] See Dr. J. W. Nicholson, *Phil. Mag.*, 1910, 6th ser., vol. xix., pp. 276, 516, 757.

[7] See "Dielektrizitatskonstante und Leitfähigkeit der Gesteine," by Heinrich Lowy (see *Annalen der Physik*, vol. xxxvi., p. 125, 1911, for a number of measurements of the dielectric constants and conductivity of earth's crust materials).

It has been shown recently in a paper by the present writer, assisted by Mr. Dyke, that the alternating current conductivity of insulators is a function of the frequency, and not by any means identical with the direct current conductivity, see Journ. Inst. Elect. Eng., 1912, "On the power factor and conductivity of dielectrics for alternating electric currents." In the case of such substances as marble, slate, and probably others, the conductivity appears to increase with the frequency up to a certain point and then diminish again.

The problem of the propagation of electric waves over the earth's surface involves, therefore, three important factors which greatly influence the result, first the imperfect conductivity and rather high dielectric constant of the earth, making it a semi-dielectric. Secondly, the effects of atmospheric ionisation, natural electrification, and sunlight, and, thirdly, the earth's curvature. The German mathematical physicists have of late years considered the first of these factors very carefully, and arrived at some interesting results, which I will endeavour to epitomise. Prof. A. Sommerfeld published in 1909 a very able paper on the propagation of the waves in wireless telegraphy over the earth's surface.[8]

He supposes that a small Hertzian oscillator is placed with axis vertical at the flat boundary surface of two media, each having conductivity σ, dielectric constant K, and permeability μ, and that the bounding surface is plane and indefinite. Taking E as the electric force and H as magnetic force, we have at any point in space the two circuital or Maxwellian equations fulfilled, viz.:—

$$K\dot{E}+4\pi\sigma E=c \text{ curl } H$$
$$-\mu\dot{H}=c \text{ curl } E.$$

where $c=3\times10^{10}$. The quantities E, σ and K are measured in electrostatic units and μ and H in electromagnetic. Hence, if E and H are both simple harmonic quantities of frequency n varying as the real part of ϵ^{-jpt}, where $p=2\pi n$, and if we write

$$k^2=\frac{\mu K p^2+jp4\pi\sigma\mu}{c^2},$$

we have
$$k^2H=\text{curl}^2 H,$$
$$k^2E=\text{curl}^2 E.$$

If we then take the magnetic force to be the curl of a vector potential Π and bear in mind that for vector fields with no divergence the operator

$$-\text{curl}^2=\Delta^2=\left(\frac{\delta^2}{\delta x^2}+\frac{\delta^2}{\delta y^2}+\frac{\delta^2}{\delta z^2}\right),$$

we see that Π satisfies the differential equation

$$\Delta^2\Pi+k^2\Pi=0, \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and that
$$H=\text{curl } \Pi, \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and
$$E=\frac{c}{4\pi\sigma-ipK}\Delta^2\pi. \quad . \quad . \quad . \quad . \quad . \quad (3)$$

If $r^2=x^2+y^2+z^2$, then a particular solution of (1) is

$$\Pi=\frac{1}{r}\epsilon^{jkr}.$$

To obtain a solution applicable to the case in question, we have to satisfy the boundary conditions.

These conditions are that the horizontal component of the electric force and the vertical component of the magnetic flux or induction must be continuous across the boundary. Taking suffixes 1 and 2 for the air and earth regions, these boundary conditions are

$$\Pi_1=\Pi_2\frac{\mu_1}{k_1^2}\frac{\delta\Pi_1}{\delta z}=\frac{\mu_2}{k_2^2}\frac{\delta\Pi_2}{\delta z}.$$

Sommerfeld then shows that a solution of the equation (1) is

$$\Pi=CJ_0(\lambda r)\epsilon^{\sqrt{\lambda^2-k^2}z},$$

where $r^2=x^2+y^2+z^2$ and λ is an arbitrary parameter, and $J_0(\lambda r)$ is a Bessel's function of zeroth degree.

By a series of difficult transformations, the validity of which must be tested by our pure mathematicians. Sommerfeld then proves that π can be expressed as the sum of three quantities P and Q such that

$$\Pi=P+Q_1+Q_2,$$

where the quantities Q_1 and Q_2 correspond to space waves (Raumwellen), and P to a surface wave (Oberflächenwellen).

It is, of course, not new to suggest that the waves involved in radio-telegraphy resemble electric waves on wires or are surface waves. It was long ago surmised that the sending antenna, the earth, and the receiving antenna might be regarded as one single oscillator in which oscillations were set up. This view has been held, amongst others, by A. Blondel, E Lecher, and F. G. Baily.[9]

Prof. Baily pointed out in 1903 that the energy of surface waves would decrease only inversely as the distance, and therefore at large distances survive when space waves would have vanished. The strict mathematical proof of their possibility has, however, only been lately given.

The space waves are subject to diffraction, and are hindered by obstacles. On the other hand, the surface waves pass round, and are unhindered, apart from damping, by the curvature of the surface. Also, owing to the surface waves decreasing in amplitude less fast with distance, the surface waves survive when the space waves are extinguished. If, then, Sommerfeld's investigation is valid, we need no longer seek for an explanation of such achievements as the detection of electromagnetic waves one-quarter of the way round the earth in any abnormal diffraction. If Sommerfeld is right, diffraction has nothing to do with the matter. The effect at such distances is entirely due to these "Oberflächenwellen," or surface waves, which, like electric waves or wires, are propagated along the surface, no matter what the curvature may be. There is a certain analogy between these space and surface electric waves, and corresponding effects in the case of earthquakes. From the time of Poisson it has been known that a shock communicated to an elastic solid created in it two waves, one of dilatation and one of distorsion, travelling at different speeds through the mass.

In 1885, Lord Rayleigh showed that, in addition, there was a surface wave dependent on the fact that the surface can be distorted and resists distorsion with a different elasticity to that of the interior of the mass.

These effects are recognised by seismologists as represented in the preliminary tremors and main shock in an earthquake.

In this case, two kinds of disturbance are found to be propagated through the earth, with velocities of 10 and 5 km. per second respectively. Also another main shock arrives later, which moves with a speed of about 3 km. per second. The latter is a surface wave travelling along the surface crust of the earth, and the two former are space waves travelling through the mass.

In the same manner we can say that in wireless telegraphy we are concerned with three waves—one travelling through the air above the earth, the second through the crust of the earth, and the third a surface or cylindrical wave, which is confined to a limited region at the boundary of the two dielectrics.

It is suggested, however, that long-distance radiotelegraphy is chiefly effected by means of the surface waves or "Oberflächenwellen" of Sommerfeld, which fall off in amplitude inversely as the square root of the distance and are not limited by diffraction as they follow round the surface. The earth's curvature

[8] "Ueber die Ausbreitung der Wellen in der drahtlosen Telegraphie," *Annalen der Physik*, vol. xxviii., p. 665, 1909.

[9] See A. Blondel, *Comptes Rendus du Congrès de Nantes*, 1898; also E. Lecher, *Physik. Zeitschr.*, vol. iii., p. 273, 1901, and Prof. F. G. Baily, Trans. Royal Scottish Society of Arts, February 9, 1903.

limits the range of the space waves seriously but does not so limit the surface waves.

One difficulty in reading Sommerfeld's paper is that he does not sufficiently translate his mathematical analysis into physical concepts. Hence it is desirable to consider a little in general terms how these surface waves arise.

(*To be continued.*)

MODERN PROBLEMS RELATING TO THE ANTIQUITY OF MAN.[1]

ON my bookshelves there is placed a series of old volumes containing past reports of this Association, which fortune sent my way many years ago on a Whitechapel bookstall. Among them there is one volume I prize—that which contains the history of the meeting at Aberdeen in 1859. In that volume you will find an early phase of the subject of my discourse for this evening—the antiquity of man. Sir Chas. Lyell presided over the section of Geology; in his opening address he announced that "a work will very shortly appear by Mr. Charles Darwin—the result of twenty years' observation and experiment," and that the evidence which had accumulated in recent years "made it probable that man was old enough to have co-existed at least with the Siberian mammoth." From other statements made in his address it is clear that Lyell was then convinced that man's appearance on earth was infinitely older than the limits fixed by Biblical record. I do not suppose I have a single listener who heard that address in Aberdeen sixty-three years ago, but even those who are not yet old will concede that the new doctrine, preached so moderately by Sir Charles Lyell, was not likely to be acceptable to the general membership of the Geological Section in the year 1859. You will find an exact record of what happened at the meeting—not in the official report of the year, but in the letters of Mr. William Pengelly, the explorer of Kent's Cavern. Orthodoxy was represented at the meeting by the Rev. Dr. Anderson, who, in Mr. Pengelly's words, "attempted to castigate Lyell for his opening address. There was a considerable amount of orthodoxy in the room, and Dr. Anderson got a very undue share of applause." The doctrine which Lyell and his companions championed in the face of public opprobrium in 1859 is the accepted and orthodox opinion of the vast majority of thoughtful people in the year 1912.

That splendid movement of the nineteenth century which knocked the shackles of tradition from the problems of man's origin was led by men of courage, conviction, and sound judgment. It was a progressive and victorious movement they initiated, but in every movement of that kind there comes a time when those who cleared the way turn circumspect, cautious, and more critical than constructive. Opinion tends to become fixed and conventionalised, and then a new heterodoxy raises its head. That is the phase which we, who make a special study of the facts relating to man's origin, seem to have reached now. I cannot cite a more stalwart or distinguished representative of the orthodox opinion of to-day than Prof. Boyd Dawkins, of Manchester. In his Huxley lecture in 1910 he gives very clearly his opinions on the antiquity of man—ripe convictions which are founded on a lifetime of active investigation and study. In his opinion the history of man does not extend beyond the Pleistocene period—the phase of the earth's history which immediately precedes the one in which we live. He accepts the fossil man of Java—Pithecanthropus—a being with a brain a little more than half the size of a modern man's, as representative of mankind at the beginning of the Pleistocene; before the end of that period men of the modern type appeared. In Prof. Boyd Dawkins's opinion, then, man was evolved during the Pleistocene period, and, therefore, from a geologist's point of view, is a recent addition to the earth's fauna. If we ask how long ago it is since man appeared, Prof. Boyd Dawkins replies: "It cannot be measured in years—only by the sequence of geological events and by the changes in animal life." Yet we are certain that years came cycling round in the Pleistocene period just as they do now, and that every cycle wrought some degree of change on the face of the earth and on the form of living things—a degree of change which may be imperceptible in the period of a man's life, and yet cumulative and apparent in the course of time. Men who have studied the transformations effected during the Pleistocene period have formed varying estimates of its duration, but we may safely adopt as a moderate figure the 400,000 years given by Prof. Sollas at a meeting of this Association in 1900. We may accept, then, as the orthodox opinion of to-day that the dawn of the very earliest form of humanity lies 400,000 years behind us; in that space of time man as we know him now was evolved from a crude, almost prehuman form.

For a representative of modern heterodoxy—as far as relates to the antiquity of man—we cannot do better than visit the Royal Natural History Museum in Brussels and follow the guidance of M. Rutot, who has devoted himself to the study of the stone implements of ancient man, and of recent geological formations. One civilisation succeeded another in Pleistocene as in historical times. You will admit, when you examine the handiwork of the men of the Magdalenian age—at the close of the Pleistocene—that our ancestors were then artistic and skilled workmen; as we pass backwards in time from the Magdalenian to the Solutrean, and from the Solutrean to the Mousterian, Mousterian to Acheulean, and Acheulean to the Chellean—thus passing well beyond the mid-point of the Pleistocene—that although the handiwork of man changes in form and in design, it does not lose in skill of execution; those flints of the remote Chellean period assure us that man had then a capable brain and a skilled hand. When, however, M. Rutot proceeds to show us the implements which were fashioned by men in the earlier parts of the Pleistocene, it is very probable that our orthodox companions will pull out their watches and find they have pressing engagements elsewhere. Human workmanship becomes cruder as we approach the commencement of the Pleistocene. The stones which have been wrought by man's hand (eoliths) become then more difficult to distinguish from those which have been shaped by natural forces. M. Rutot, however, is convinced that he has traced man, by means of his Eolithic culture, not only to the commencement of the Pleistocene, but into and through the two long geological periods which preceded the Pleistocene—the Pliocene and Miocene—and even well into the formations of the still older period, the Oligocene. In M. Rutot's opinion the origin of mankind must be assigned to a time as early as the Oligocene period. Prof. Sollas has made a provisional estimate of 900,000 years for the Pliocene and 1,800,000 for the Miocene. On this crude estimate the heterodox opinion as to the antiquity of man must be placed at more than 3,000,000 years. It is only just to M. Rutot to state that he would by no means agree with the estimates given by Prof. Sollas. In his opinion

[1] Discourse delivered before the British Association at Dundee on September 9 by Prof. Arthur Keith.

the duration of the Pleistocene period was not more than 139,000 years.

The modern heterodox movement, which I have sought to bring before you in the person of M. Rutot, had as its pioneer the late Prof. Prestwich—a geologist whose long experience and great knowledge were tempered with a sound and conservative judgment. In 1869 he found flints on the uplands of Kent, between the Thames and the Weald, which he recognised as certainly the handiwork of man. Thousands of these eoliths have been collected by Mr. Benjamin Harrison.[2] The deposits in which these eoliths are found were assigned by Prof. Prestwich to a Pliocene date. Fifty years ago Sir Charles Lyell expressed the opinion that "signs of man's existence" would be found in the Cromer beds of East Anglia, which mark the commencement of the Pleistocene period in England. Eoliths have been found not only in the Cromer beds, but also in the Pliocene formations of that district—in the Norwich Crags by Mr. Clarke, and under the Red Crag by my friend Mr. Reid Moir. Thus in England heterodox opinion traces man to the commencement of the Pliocene period. I need only add that eoliths, as evidence of man's existence, are rejected by many whose opinion is entitled to our respect. The usually accepted opinion, then, is that man makes his appearance in a definitely human form about the commencement of the Pleistocene period; there are also those who refer his evolution to a much earlier period of geological history.

One thing is certain, whatever period is adopted, the time must be long enough to allow mankind to be distributed and differentiated as we now see it in the world of to-day. Modern human races, white and yellow, red, black or brown, although so different on the surface, are yet so similar in their structure and constitution that we must suppose all of them to have arisen from a common stock. Let us look at the problem in a concrete form. I will take as opposite and contrasted types of modern humanity the fair-haired, white-skinned, round-headed European, and the woolly-haired, black-skinned negro of Central Africa, and set them side by side and study them from a purely zoological point of view. We must admit that both are highly specialised types; neither represents the ancestral form. Now, in seeking for the ancestral form of our breeds of dogs, of horses, or of cattle, we select one of a generalised and ancient type—such as we conceive might have been modified to produce modern breeds. We must apply the same system to human races. If we search the present world for the type of man who is most likely to serve as a common ancestor for both negro and European we find the nearest approach to the object of our search in the aboriginal Australian. He is an ancient and generalised type of humanity; he is not the direct ancestor of either negro or European, but he has apparently retained to a greater degree than any other living race the characters of that common stock from which both European and negro arose.

If, then, we accept the Australian native as the nearest approach to the common ancestor of modern mankind—and it must be admitted that it is not a low form of man we are postulating as a common ancestor—can we form any conception of the length of time which would be required to produce the African and the European from this common stock? What do we know of the rate at which mankind evolves? There is the classical instance of Egypt. During his residence in that country Prof. Elliot Smith and his colleagues—Dr. Wood Jones and Dr. Derry—had opportunities of examining the remains of Egyptians belonging to every period—from pre-dynastic times to the present day. They had thus facilities for studying the evolution of a people over a period of at least 6000 years—probably longer. They found evidence of an infiltration of foreign blood both from the north and from the south; they noted minor alterations in the configuration of the head and in the state of the teeth and jaws, but they could not say that the men at the end of that period were in any respect a higher or more specialised type than the inhabitants of the Nile Valley at the beginning of that period.

There is no need to go beyond our own country to find evidence that the evolution of man proceeds at a slow rate. We have now material enough to form a fairly accurate conception of the physical condition of the people who lived in Britain these 4000 years past. Were the prehistoric Britons to come amongst us now, dressed in our modern garb, they would pass unnoticed as fellow-citizens. The Neolithic men of France, Switzerland, and Germany were not in any wise a lower race than their successors of to-day. When we pass to examine human remains belonging to more remote periods, we are confirmed in our belief that the evolution of human races is a slow process. In this country there have been found at Galley Hill, at Bury St. Edmunds, and at Ipswich human remains which belong at least to the middle part of the Pleistocene period. These remains indicate a kind of man somewhat different from ourselves, but yet of the same type. In size of brain and in complete adaptation to an upright posture, they cannot be described as less highly evolved than we are.

Such evidence as we have, then, leads us to believe that the evolution of a new and distinct variety of mankind requires an extremely long period of time.

If we again ask: How long will it take to evolve the African, on the one hand, and the European, on the other, from a common stock?—Australoid, we suppose, in form—it is very apparent, on our present knowledge, we must make a very considerable allowance of time. My own opinion is that the whole length of the Pleistocene—a period, we shall say, of 400,000 years—is not more than sufficient. I am thus postulating, in order to explain the differentiation and distribution of modern races, that mankind, at the beginning of the Pleistocene period, had reached a physical condition which has its best modern representation in the aborigines of Australia.

Is it not possible, however, that the evolution of man's body may not be a story of slow, continuous, almost imperceptible change, but one of alternate spurt and quiescence? The human body is notoriously the subject of sport, of defects, and malformations. Many of you will recall the book which Prof. Bateson published eighteen years ago entitled "Material for the Study of Variation." The work contained many facts which seemed to indicate that the animal body was subject to violent structural changes, and that a new form of being might be produced almost at a bound. We often see men in whom there is an extra vertebra in the loins, an additional rib, or a supernumerary digit, but we now recognise that these marked structural changes are merely the extreme manifestations of a normal degree of variation of which every man's body is the subject. The bodies of men and anthropoids are notoriously liable to anatomical variation, and we are justified for that reason in regarding their bodies as particularly plastic material in the hands of evolution. When, however, we come to examine the anatomical differences which separate one race of men from another, we see that racial characters comprise, not those

[2] Mr. Harrison has informed the lecturer he first found those primitive flints in 1865.

marked variations which so frequently are seen by the students of human anatomy, but a multitude of minor structural features such as might slowly accumulate in the course of the differentiation of one race from another.

When one comes to realise the extremely complex structure and finely adjusted nature of the human brain, it becomes very apparent that any addition to the most essential structure of the human body must be the result of an extremely slow process of growth. Only one line of evidence shakes our belief in the slow rate of human evolution, and that is the study of certain diseases of growth to which man is liable. We have come to realise in recent years that we are, as regards face, figure, stature, and nature, largely what our internal glands and secretions have made us. Growth itself is definitely regulated by means of substances set free by certain glands of the body. We are absolutely certain that a marked disturbance of these glands will, in the course of a few years, definitely transfigure the individual to which they belong. Nature seems to have at her command a means for executing rapid advances, but when we survey what we know of man's past history, and mark the changes he is subject to in the present, we see no sign of her having resorted to such a means.

There is another route by which we may approach the problem of man's antiquity. Man does not stand alone—he has distant and rather despised relations—the great anthropoid apes. Although the structural hiatus between him and them is wide, yet when we compare the two types we see that there is a multitude of resemblances, so intimate and so peculiar that we cannot explain them except by supposing that man and the great anthropoids had a common ancestor at one stage of the earth's history. The great anthropoids have also a distant and primitive living relative—the gibbon. The gibbon, in turn, while foreshadowing in his body the structural peculiarities of his more august relatives, finds his cousins by descent in more lowly forms still—the monkeys of the Old World and the monkeys of the New. Of these two groups the monkeys of the New World are the nearest to the original stock which gave rise to the higher primates. It was through such a lineage that man rose to reach his present estate.

If, then, we are to ascertain the approximate date—or, to put it in other words, the possible date—at which man appeared, we must first search for the earliest traces of the basal forms of the higher primates which lead towards the human line. The earliest traces we have discovered as yet were described by Dr. Max Schlosser only two years ago. In the very oldest Oligocene formation of the Fayoum, Egypt, the teeth and jaws of three primates were discovered. Two of these are allied to the South American apes, the other is a forerunner of the gibbons. These Fayoum fossils are of the highest importance to the solution of our problem. Their discovery assures us that at such an early date in the evolution of mammals the South American apes and pro-gibbons were already in existence. They are highly evolved forms, and it is not unlikely that they appeared at a much earlier date. In European strata of the period following the Oligocene—the Miocene—many teeth and jaws of a form of gibbon, which differ only in slight and trivial details from the teeth of living gibbons, have been discovered during the past fifty years.

Here, then, we have the assurance that an animal which springs closely from the stock giving rise to man has come down to us with but little change through the leagues of time marked by the Miocene, Pliocene, and Pleistocene formations. By the middle of the Miocene we know the great anthropoids were in existence; it is most unlikely that the traces we have discovered mark their first appearance. With the evolution of the great anthropoids the appearance of a human ancestry as a separate stock is possible. From every point of view it is most probable that the human stock became differentiated at the same time as the great anthropoids. On the evidence afforded by our very imperfect knowledge of fossil forms of apes, we are justified in assuming that a very primitive form of man may have come into existence during the Miocene period—at the very latest during the early part of the Pliocene. Thus when we pursue the question of man's antiquity by studying the forms of primates contained in the Tertiary strata, we find reason to extend the possible date of his origin at least a geological epoch beyond what is allowed by the strictly orthodox. We are unable, however, to find evidence in support of the more extravagant claims of the ultra-heterodox represented by M. Rutot.

There is still another and a very important line of evidence bearing on the antiquity of man. We have, in the most cursory manner, followed the evolution of various ancestral forms of ape and anthropoid from the past towards the present; I propose now to follow the history of man's evolution, so far as we yet know it, from the present into the geological past. We are all evolutionists nowadays, and it is but natural that every one of us should expect man to become more anthropoid and more brutal the further we trace him into the past. What have we found? At the close of the Pleistocene period, which even orthodox and conservative geologists admit to have come to an end some 15,000 years ago, the men of Europe in stature and in size of brain were at least our equals. In tooth, limb, and bone they were more robust. When, however, we turn our eyes to France and pass backwards in the Pleistocene to the epoch marked by the last or fourth of the cold cycles which subdivided that period, modern man disappears; his place is taken by a human being of an altogether different kind—a human race or species to which the name of Neanderthal has been given by international consent.

During the last six years, thanks to the enthusiasm, industry, and genius of French anthropologists, the remains of four individuals of this race have been unearthed. The strata in which these remains were found contain stone implements of the type known as Mousterian, and of animals belonging to a cold climate. Neanderthal man appears suddenly in this later part of the Pleistocene, and as suddenly disappears, to be replaced by modern man. It is impossible to conceive that, just at the close of the Pleistocene period, Neanderthal man was suddenly converted into modern man. Think for a minute of the interpretation you would give of the Australian strata that are being laid down now. The older deposits contain the remains of aborigines, the newer Europeans. You do not suppose that the aborigines are suddenly transformed to European. You must apply the same interpretation to the human remains found in the later Pleistocene. There was a supersession, not a transformation of races. We must infer, then, that at the end of the Pleistocene period there were two distinct races of mankind—Neanderthal and modern. That is a fact which our French colleagues seem to grasp with difficulty.

To follow the history of modern man into the past we shall return to England. It is a mystery why Neanderthal remains have not been discovered in England; they ought to be found, and a rumour is now current that they have been found. The oldest remains so far unearthed in England all belong to the modern type of man. They take us a long way further into the Pleistocene than the era of Neanderthal man. The skull fragment known as the Bury St. Edmunds was found in strata containing Acheulean flints and remains of the mammoth; the 90-ft. terrace of the Thames, in which the Galley Hill man was found, contains flints of the Chellean type. The Acheulean and Chellean flint civilisations are attributed by Prof. Boule—a most trustworthy authority—to the long temperate interval which lies between the two last of the glacial cycles of the Pleistocene, or, if we accept the evidence of Prof. Penck, between the second and third cycles. If Mr. Reid Moir and I are right in regarding the human remains lately found at Ipswich as resting under a bed of undisturbed chalky Boulder Clay—it is right to say that our inferences are contested—then we have carried the history of modern man a step still further back in the Pleistocene period, for the chalky Boulder Clay is the product of the great cold cycle which preceded the Chellean industry. So far as the evidence in England goes it indicates the existence of a modern type of man at least as far back as the middle of the Pleistocene period.

All we know of man in Europe near the beginning of the Pleistocene is the famous lower jaw found near Heidelberg in 1907. A complete lower jaw with its full complement of teeth can tell with certainty a great deal about the individual to which it belonged. There is not a shadow of doubt that the Heidelberg man belonged to the Neanderthal type; perhaps he may best be described as pre-Neandertheloid, for in strength and massiveness of jaw he foreshadows the Neanderthal men whose remains are found in Europe towards the end of the Pleistocene. Of the Neanderthal race in the middle phases of the Pleistocene we have, so far, discovered no trace. Although in many features Neanderthal man shows resemblances to the anthropoids, in others he is highly specialised. The teeth of an Australian native make a nearer approach to the anthropoid condition than those of Neanderthal man.

We have knowledge of another fossil man belonging to the beginning of the Pleistocene. In 1891 Dr. Eugene Dubois discovered in Java the fossil remains of a man who, in stature, posture, and gait, must have been very similar to us, but so unlike us in head form that his discoverer named this new form of man Pithecanthropus. The size of his brain (855 cubic centimetres) was little more than half the size of the brain of a well-developed modern man. The Neanderthal man described by Prof. Boule had a cranial capacity of 1600 or 1625 cubic centimetres. It is usual to accept the fossil man of Java as representative of his time and race, but if we do we have to suppose that, in the early part of the Pleistocene, within a comparatively short space of time, the human brain developed at an astounding and almost incredible rate. I leave the matter there, simply asking my audience to keep in mind that there did exist in the Far East at the beginning of the Pleistocene, or perhaps close of the Pliocene, a very low form of primitive man.

Thus we have a knowledge—a very imperfect knowledge—of only two human individuals near the beginning of the Pleistocene period. The one was brutal in aspect, the other certainly low in intellect. It is hard, then, to believe that in strata belonging to the period preceding the Pleistocene there could be found fossil remains of a man of quite a high and modern type. Yet the details relating to the discovery of human remains by Prof. Ragazzoni in early Pliocene strata of North Italy are so circumstantial and supported that one cannot place them lightly aside. In 1860 Prof. Ragazzoni was searching in undisturbed Pliocene strata for fossil shells; he discovered remains of a human skull. His discovery was received with derision. Between 1860 and 1880 he found in the same strata remains of three further individuals. The only living anthropologist authority, so far as I can learn, who accepts Ragazzoni's discovery as authentic is the celebrated Italian anthropologist—Prof. Sergi, of Rome. If the remains found in these strata had been of a primitive type their authenticity would never have been called in question, but as they represented individuals as highly evolved as we are the easiest solution of the problem was to suppose that by some means these remains had been interpolated in ancient strata at a later date.

Is it, then, possible that a human being, shaped and endowed as we are, may have existed so early as the Pliocene period? If we accept as authentic all the evidence brought forward by those who have traced man backwards by means of flints which have the appearance of man's work on them, then we must admit that Pliocene man is possible, for stones apparently artificially fashioned have been found in strata as old as the Eocene. If, on the other hand, we examine the evidence relating to that group of animals to which man belongs—the higher primates—the facts, so far as we know them, render the existence of man in the Eocene and Oligocene periods impossible, improbable in the Miocene period, but quite possible in the Pliocene. If, finally, we take into consideration all the evidence relating to fossil forms of man we must confess that the antiquity of the modern form of man is still an open problem. I, for one, am convinced that we have followed him almost unchanged to at least the middle of the Pleistocene, when we find him accompanied by another form of man almost as distinct from him as the gorilla is from the chimpanzee. Still further back, at the beginning of the Pleistocene, we find at least two forms of men—the pre-Neanderthal of Heidelberg and the small-brained man of Java—but the representatives of modern man at this early period we do not know. It does seem to me, taking all the scraps of evidence at our disposal, the slow rate of human evolution and the great blanks in the geological record into account, that a man as high as the Australoid of to-day was then in existence, but I cannot bring myself to believe that human individuals so highly evolved as those discovered by Prof. Ragazzoni were in existence at an early part of the Pliocene period.

The problem of man's antiquity is not yet solved. The picture I wish to leave in your minds is that in the distant past there was not one kind, but a number of very different kinds, of men in existence, all of which have become extinct except that branch which has given origin to modern man. On the imperfect knowledge at present at our disposal it seems highly probable that man as we know him now took on his human characters near the beginning of the Pliocene period. How long ago that is must be measured, as Prof. Boyd Dawkins insists, by the changes which the earth and living things have undergone, and yet it is only human to try to find a means of measuring that period in a term of years, and the estimates at hand give an antiquity of at least a million and a half of years.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—A university lectureship in physiology is now vacant by the resignation of Dr. Anderson. The General Board of Studies will shortly proceed to appoint a lecturer to hold office from January 1, 1913, until September 30, 1917. The annual stipend is 50*l.* Candidates are requested to send their applications, with such testimonials as they may think fit, to the vice-chancellor on or before November 12.

London.—The Senate, at its meeting on October 23, made four appointments to University professorships. In one case, the appointment of Mr. Harold Hilton to the professorship of mathematics at Bedford College for Women, the new professor will continue his present work. Dr. J. W. Nicholson has been appointed professor of mathematics at King's College, and Mr. A. H. Jameson professor of civil engineering at the same college. Dr. Nicholson is at present mathematical lecturer at Girton College, and Mr. Jameson is a well-known civil engineer, trained at Manchester University. Dr. F. J. C. Hearnshaw, formerly of Hartley University College, Southampton, and at present professor at Armstrong College, Newcastle-on-Tyne, has been appointed to the professorship of history, tenable at King's College. These new appointments have been made with funds provided by the new grants from the London County Council.

The D.Sc. degree has been granted to the following students:—H. E. Watson, University College, in chemistry; C. H. O'Donoghue, King's and University Colleges, in zoology; Miss E. R. Spratt, King's College, in botany; and Miss E. M. Delf, University College, in botany.

It is announced in *Science* that 20,000*l*., to endow scholarships for young men, has come to the University of California from the estate of Mrs. Carrie M. Jones, of Los Angeles. From the same source we learn that Mount Holyoke's alumnæ committee reports that its efforts to raise 100,000*l*. for the college have met with success. The committee has transferred to President Woolley vouchers for 110,400*l*.

Owing to the appointment of Dr. W. H. Mills to the Jacksonian demonstratorship at Cambridge, in succession to Dr. H. O. Jones, who was killed recently on the Alps, the governors of the Northern Polytechnic Institute, Holloway, London, N., have appointed Dr. H. H. Hodgson head of the chemical department at that polytechnic. Mr. Hodgson was previously lecturer and research chemist at the Bradford Technical College. Also, to fill the vacancy of head of the building department caused by the appointment of Mr. Hugh Davies to be an inspector under the Board of Education, the governors have appointed Mr. J. Campbell Reid to take charge of that department. Mr. Reid was lecturer in building subjects at the Paisley Technical School, and an architect in practice in Glasgow.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 14.—M. Lippmann in the chair.—B. **Baillaud**: The seventeenth general meeting of the International Geodesic Association. The meeting, held at Hamburg, September 17–27, was attended by sixty-two delegates representing twenty countries. Details of the subjects discussed are given, and of the resolutions passed by the association.—A. **Lacroix**: Preliminary note on some Madagascar minerals, several of which have been utilised as gems. Amongst the minerals described of exceptional transparency are opal, chalcedony, orthose (golden-yellow), diopside, apatite, kornerupine, saphirine, and zircon.—Pierre **Termier**: The scientific results of the Alpine excursion of the *Geologische Vereinigung*. The lepontine strata in the Tauern. The conclusion is drawn that dynamo-metamorphism does not exist, and the name ought to disappear from science. Rocks are deformed but not transformed by dynamical action.—M. **Gouy**: The kinetic theory of ionised gases and Carnot's principle. The study of a gas, maintained adiabatically at a temperature such that a very small fraction of its molecules are decomposed with ions of opposite signs, and placed in a uniform magnetic field, leads to conclusions that are in contradiction with Carnot's principle. If this principle holds, then, alternatively, it is necessary to reject the possibility of the ionisation of a gas by a rise of temperature alone. The author regards the latter view as opposed to experiment, and points out that the magnetic field may be regarded as acting like Clerk Maxwell's demon, which, without supplying energy, exercises a directive and selective action on the particles.—Édouard **Heckel**: The influence of removal of the sex organs, male, female, and total, on the formation of sugar in the stems of maize and sorghum. The removal of both the sex organs in these plants leads to a marked increase in the proportion of sugar present.—J. **Guillaume**: Observations of the Gale comet (1912*a*) made with the Brunner equatorial at the Observatory of Lyons. Positions are given for October 9, 10, 12, 14, and 15. The comet is circular, with a central condensation round a stellar nucleus; it was about the 8th magnitude on October 9, increasing to 5·5 on October 15.—M. **Borrelly**: Observations of the 1912 Gale comet, made at the Observatory of Marseilles, with the comet-finder. Positions given for October 4 and 5.—P. **Chofardet**: Observations of the Gale comet (1912*a*), made at the Besançon Observatory with the 33 cm. bent equatorial. Positions given cr six days between September 27 and October 12. On October 10 the shape of the tail could be made out.—Ernest **Esclangon**: The orientation of photographic equatorials. It is pointed out that one method current is defective in principle, and a better alternative method is proposed.—A **Petot**: Conjugate systems.—Henri **Lebesgue**: The principle of Dirichlet.—Jules **Andrade**: A point still under discussion in the study of marine chronometers. A discussion of the variation from isochronism due to the inertia of the balance-spring.—J. de **Boissoudy**: Molecular association in gases.—L. G. **Droit**: The opacity to the X-rays of tissues suitably loaded with a dye containing lead salts. Silk is loaded with phosphostannate of lead to the extent of 68 per cent. of mineral matter, half of which is lead. Six thicknesses of this material form an effective screen against the X-rays, and for soft rays even two or three thicknesses are sufficient.—A. **Guillet** and M. **Aubert**: The electrical attraction of two conducting spheres; the properties of the families of polynomials occurring in this problem and their relations with the spherical Heine-functions of higher order.—M. **Besson**: The dissymmetry of the positive and negative ions relating to the condensation of water in an atmosphere of carbonic acid.—M. **Hanriot**: The hardness of metals. It is shown that the hardness of the metal is altered in carrying out Brinnel's test, with the result that the figures for hardness with an annealed metal come out too high.—Félix **Robin**: The production of voluminous grain in metals.—Albert **Colson**: The law of mass action. Its contradictory verifications and its defence, by M. Le Chatelier.—Georges **Denigès**: A new very sensitive reaction characteristic of free bromine. A solution of rosaniline, decolorised with bisulphite and mixed with a little hydrogen peroxide, gives a violet coloration in presence of free bromine. The colouring matter formed is soluble in choloroform and gives a characteristic absorption spectrum.—Maurice **Durandard**: Variations of the most favourable working temperature under the influence of the medium in *Mucor rouxii*.—G. **Arnaud**: The cytology of *Capnodium meridionale* and of its mycelium.—André **Mayer** and Georges **Schaeffer**: The chemical composition of the blood and hæmolysis. The corpuscles from different animals are unequally resistant to serums of different species. It has been found that the order of increasing resistance is the same as the amounts of non-volatile fatty acids present in the corpuscles. The hæmolytic power of the different sera was found to correspond with the amounts of cholesterol present in the sera.—Em. **Bourquelot** and H **Hérissey**: The synthesis of the galactosides of alcohols with the aid of emulsin. β-Ethylgalactoside.—Romuald **Minkiewicz**: A case of extraordinary reproduction in *Polyspira delagei*.—Léon **Bertrand** and Louis **Mengaud**: The existence of several superposed strata in the Cantabrian Cordillera, between Santander and Llanes.—L. **Cayeux**: The structure of the Urville (Calvados) basin and its consequences from the point of view of working for minerals containing iron.

October 21.—M. Lippmann in the chair.—H. **Deslandres**: Additional remarks on the protuberances, *alignements*, and filaments of the upper solar atmosphere. The influence of the solar electric field.—Th. **Schlœsing**, sen.: The measurement of flowing water by chemical analysis. A concentrated solution of ammonium sulphate of known strength was allowed to flow at a measured rate into the watercourse; the latter was then sampled at a point lower down, and from the concentration in ammonia the flow per second was deduced with fair accuracy.—Henry **Le Chatelier**: The law of mass action. Final reply to M. Colson.—L. **Maquenne** and E. **Demoussy**: Respiration in green plants. A critical review of the methods of determining respiration in plants. The rapid decrease in the respiratory coefficient of a freshly-cut organ as a source of error in such measurements is pointed out, and also the effects of darkness in altering the coefficient in old and young leaves.—A. **Schaumasse**: The discovery and observation of the comet 1912*b* (Schaumasse) made at the Nice Observatory. The comet was of the 11·5 magnitude on October 18; on the following day it appeared as a rounded nebulosity about 3′ in diameter, with a badly defined condensation.—M. **Giacobini**: Observations of the new Gale comet (1912*a*). Daily observations are given from October 3 to 13.—P. **Brück**: Observations of the Gale comet (1912*a*) made at the Observatory of Besançon. Positions given for October 13, 14, 16, 18. The tail was clearly visible.—Léon **Autonne**: Cremonian substitutions.—T. H. **Gronwall**: A theorem of M. Picard.—George **Polya**: A theorem of Stieltjes.—P. **Helbronner**: The complementary geodesic triangulations of the higher regions of the French Alps (second series).—E. **Mérigeault**: The influence of the velocity of combustion on the efficiency of a gas motor.—Paul **Jégou**: The use of horizontal wires for receiving Hertzian waves. A single horizontal wire 80 metres long failed to detect the time-signal from the Eiffel Tower, but with two such wires, 40 cm. apart, good signals were obtained. Telephone or telegraph wires can be utilised in this way if a small condenser is placed in the circuit to suppress parasitic currents.—P. Th. **Muller** and Mlle. V. **Guerdjikoff**: The refraction and magnetic rotation of mixtures. Further evidence is given tending to show that the expression of H. Becquerel connecting the refraction and magnetic rotation is not general.—Maurice **Billy**: A simple method for the preparation of mineral oxides. A mixture of a metal with its higher oxide, both in a finely divided condition, heated to a high temperature with precautions to prevent the access of air, gives a lower oxide. Details are given of the application of the method to the preparation of Ti_2O_3 and TiO.—Lucien **Daniel**: Grafts of the carrot on fennel.—P. **Mazé**: Researches on the presence of nitrous acid in the excretions of the higher plants.—Marcel **Mirande**: A new group of plants producing hydrocyanic acid, the Calycanthaceæ. The production of hydrocyanic acid from the leaves of three species of Calycanthus has been proved.—H. **Vincent**: The action of polyvalent antityphoid vaccine in persons in a state of latent infection by the Eberth bacillus. The injection of the polyvalent typho-vaccine never produces a negative phase. Not only do these injections never aggravate the disease, but they exercise a favourable action on the course of the disease. Taken before the infection is incurred, the immunity produced appears to be absolute.—Paul **Paris**: The presence of Herbst corpuscles in the uropygian gland of birds.—C. **Delezenne** and M. **Lisbonné**: The action of the ultra-violet rays on the pancreatic juice. Their influence on the stimulation of the juice by kinase and by calcium salts. The enzymes in the pancreatic juice present different resisting powers to the action of the ultra-violet rays. After a certain time, two to three hours, the liquid loses its property of being rendered active by the addition of calcium salts, although still reactive with kinase. At the same moment that the juice loses its power of reacting with calcium salts, it is also deprived of its lipasic properties.—L. **Lindet**: The antiseptic action of salt and sugar. A study of the amounts of nitrogen, phosphoric acid, and potash extracted from yeast cells by solutions of common salt and of sugar of varying concentrations.—M. **Lemoigne**: The fermentation of sugar by *Bacillus subtilis*. The production of 2 : 3-butylene glycol. The action of *B. subtilis* upon sugar under ærobic conditions takes place in two phases, the first a fermentation leading to the production of 2 : 3-butylene glycol, $CH_3.CH(OH).CH(OH).CH_3$, and this is then oxidised to acetylmethyl-carbinol, $CH_3.CH(OH).CO.CH_3$. By the further action of the organism the latter substance is destroyed.—MM. **Couyat** and **Fritel**: The imprints (Medusæ, Algæ) collected in the carboniferous deposits in the neighbourhood of Suez.—F. **Dienert**: The solution of silica in underground waters.

BOOKS RECEIVED.

Grundzüge der tektonischen Geologie. By Dr. O. Wilckens. Pp. viii+113. (Jena: G. Fischer.) 3.50 marks.

Alcune Misure Magnetiche Eseguite nell' Est-Africa Inglese e nella Somalia Italiana. By L. Palazzo. Pp. 37+map. (Roma: Tipografia Nazionale di G. Bertero e C.)

Visual Geography. By A. Nightingale. Pp. 48. (London: A. and C. Black.) 6*d*.

Bacon's Excelsior Map of the Mediterranean Lands. Cloth, rollers, and varnished; on cloth cut to fold. (London: Bacon and Co., Ltd.) Each 16s.

A Critical Revision of the Genus Eucalyptus. By J. H. Maiden. Vol. ii., part 6. (Sydney: W. A. Gullick.)

DIARY OF SOCIETIES.

MONDAY, NOVEMBER 4.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Nitrogenous Constituent of Para Rubber and its bearing on the nature of Synthetic Rubber: Clayton Beadle and H. P. Stevens.—The Corrosion of Metals and Alloys in various Solvents: A. J. Hale.—The Viscosity of Lubricating Oils: A. E. Dunstan and J. F. Strevens.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Geography of Japan and its Economic Development: Miss E. C. Semple.

ARISTOTELIAN SOCIETY, at 8.—The Notion of Cause: Hon. Bertrand Russell.

SOCIETY OF ENGINEERS, at 7.30.—The Generation and Electrical Transmission of Power for Marine Transportation: W. P. Durtnall.

TUESDAY, NOVEMBER 5.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Inaugural Address by the President (Mr. R. Elliott Cooper) and Presentation of Medals awarded by the Council.

WEDNESDAY, NOVEMBER 6.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Detection and Estimation of Arachis Oil: N. Evers.—The Examination of Chinese and Japanese Wood Oil: A. Chaston Chapman.—The Estimation of Manganese by the Bismuthate Method: H. F. V. Little.

GEOLOGICAL SOCIETY, at 8.—A Contribution to our Knowledge of Wealden Floras, with special reference to a Collection of Plants from Sussex: Prof. A. C. Seward.—Notes on the Discovery of Fossiliferous Old Red Sandstone Rocks in a Boring at Southall, near Ealing: E. Proctor. With an Appendix on the Upper Devonian Fish-Remains: Dr. A. Smith Woodward.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 7.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Radiation and Absorption of Light in Gaseous Media, with Applications to the Intensity of Sky Radiation: L. V. King.—A Standard Measuring Machine: Dr. P. E. Shaw.—A Spectro-photometric Comparison of the Emissivity of Solid and Liquid Gold at High Temperatures with that of a Full Radiator: E. M. Stubbs and Dr. E. B. R. Prideaux.—Optical Properties of Substances at the Critical Point: C. Smith.—Absorption of Helium and other Gases under the Electric Discharge: Hon. R. J. Strutt.—(1) The Discharge between Concentric Cylinders in Gases at Low Pressures; (2) The Influence of the Nature of the Kathode on the Length of the Crookes Dark Space. F. W. Aston.—The Determination of the Absolute Unit of Resistance by Alternating Current Methods: A. Campbell.—Some Unclassified Mechanical Properties of Solids and Liquids: A. Mallock.—Tricbromatic Theory of Colour Vision. The Measurement of Fatigue of the Retina: Sir W. de W. Abney, K.C.B.

FRIDAY, NOVEMBER 8.

PHYSICAL SOCIETY, at 8.—On a Method of Measuring the Thomson Effect: H. R. Nettleton.—An Improved Joule Radiometer and its Applications: F. W. Jordan.—Note on the Attainment of a Steady State when Heat Diffuses along a Moving Cylinder: Miss A. Somers.—The Thermomagnetic Study of Steel: S. W. J. Smith.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—Tivella and Grateloupia: A. J. Jukes-Browne.—Some Remarkable Shell Monstrosities: G. C. Robson.—New Mollusca from the Marine Tertiary Deposits of the North Pacific Coast of America: Ralph Arnold and Harold Hannibal.—Descriptions of new species of Limicolaria and Krapfiella from East Central Africa: H. B. Preston.

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

" To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2245, Vol. 90] THURSDAY, NOVEMBER 7, 1912 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

THURSDAY, NOVEMBER 7, 1912.

MATHEMATICAL TEXT-BOOKS.

(1) *A Treatise on Plane Trigonometry.* By Prof. E. W. Hobson, F.R.S. Third edition. Pp. xv+383. (Cambridge University Press, 1911.) Price 12*s*. net.

(2) *A Shorter Geometry.* By C. Godfrey, M.V.O., and A. W. Siddons. Pp. xxii+301. (Cambridge University Press, 1912.) Price 2*s*. 6*d*.

(3) *A New Geometry.* Books i–iii. By W. M. Baker and A. A. Bourne. Pp. xxii+122+iii. (London: G. Bell and Sons, Ltd., 1912.) Price 1*s*. 6*d*.

(4) *Lessons in Geometry.* Part i. By Dr. Charles McLeod. Pp. xii+212. (Aberdeen University Press, 1912.) Price 2*s*. 6*d*. net.

(5) *Examples in Arithmetic.* Part i., with answers. Taken from "A School Arithmetic." By H. S. Hall and F. H. Stevens. Pp. ix+115+xxii. (London: Macmillan and Co., Ltd., 1911.) Price 1*s*. 6*d*.

(6) *Solutions of the Examples in Godfrey and Siddons's "Solid Geometry."* By C. L. Beaven. Pp. 164. (Cambridge University Press, 1912.) Price 5*s*. net.

(7) *A B C of Hydrodynamics.* By Lieut.-Col. R. de Villamil. Pp. xi+135. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1912.) Price 6*s*. net.

(8) *A New Algebra.* By S. Barnard and J. M. Child. Volume ii. Containing Parts iv.–vi. Pp. x+301–731. (London: Macmillan and Co., Ltd., 1912.) Price 4*s*.

(9) *A Treatise on the Analytical Geometry of Three Dimensions.* By Dr. George Salmon, F.R.S. Revised by Reginald A. P. Rogers. Fifth edition. In two volumes. Vol. i. Pp. xxii+470. (London: Longmans, Green and Co.; Dublin: Hodges, Figgis and Co., 1912.) Price 9*s*.

(10) *Fergusson's Percentage Unit of Angular Measurement, with Logarithms; also a Description of his Percentage Theodolite and Percentage Compass.* For the use of Surveyors, Navigating Officers, Civil and Military Engineers, Universities and Colleges. By John Coleman Fergusson. Pp. lxvii+467. (London: Longmans, Green and Co., 1912.) Price 3*l*. 3*s*. net.

(11) *An Elementary Treatise on Statics.* By Prof. S. L. Loney. Pp. viii+393. (Cambridge University Press, 1912.) Price 12*s*.

(1) PROF. HOBSON'S treatise on plane trigonometry has for many years been regarded as the best work on the subject available for English students. There is probably no lecturer at Oxford or Cambridge who does not recommend his pupils to read it. In fact, before its publication it was necessary for those who wished for a rigorous treatment of those infinite series and products which occur in higher trigonometry to have recourse to French or German text-books. But recently much has been done in England to remedy this deficiency. Mr. Hardy's volume on "Pure Mathematics," Prof. Bromwich's work on "Infinite Series," and Prof. Hobson's "Theory of Functions of a Real Variable" are noteworthy examples. These, however, deal with a wider field, and students will still continue to gain their first insight into the problems of higher analysis from this volume.

The need of a third edition has given the author an opportunity for a complete revision; new matter has also been inserted. The theory of the measurement of circular arcs is discussed at some length in the opening chapter. Those who are interested in mathematical history will appreciate the section on the quadrature of the circle, in which is given a modified form of Gordon's proof that π is a transcendental number, thus establishing the impossibility of constructing by Euclidean methods a straight line bearing to a given straight line the ratio π. But the most important changes in the work are those which relate to the theory of series and products. Many additions have been made, further examples are given to illustrate the different cases that arise, and a number of references are supplied for those who wish to make a more thorough study of the subject. We have no doubt that this volume will retain its place as the standard text-book for many years to come.

(2) This volume is a carefully reasoned interpretation of the Board of Education circular on the teaching of geometry. The first stage aims at illustrating the fundamental concepts, the second leads to the discovery of the principal theorems, and the third builds up on this basis a deductive development of the subsequent propositions. The authors feel that too much time has in the past been devoted to purposeless drawing, and have therefore omitted much of the experimental work contained in their previous treatise; the number of theoretical exercises, on the other hand, has been increased. We shall be much surprised if this text-book is not widely used.

(3) This is an abbreviated form of the textbook on elementary geometry by the same authors published nine years ago. The only important change is the redistribution of the propositions in Book i., those on congruent triangles being now

grouped together. The supply of riders, particularly in connection with angle properties of the circle, seems rather inadequate. We are glad to see that limit methods of proof are employed for the fundamental tangent properties.

(4) There are several novel features in this text-book. It is divided into thirty-five sections, each of which professes to contain the material for one lesson; but we are inclined to think some of these sections will occupy four or five hours if an adequate amount of time is assigned to rider work. The theorems are not numbered, and no references to previous propositions are given in the proofs; a conversational method is employed which for beginners possesses obvious advantages, and the order of the theorems differs from that usually followed. The scope of the work includes the first three books of Euclid, the properties of similar figures, and the fundamental propositions of solid geometry. We are of opinion that the character of the book will render it more useful to the teacher than to the student.

(5) In order to meet the wishes of those teachers who prefer to take all book-work orally, the authors have now issued in a separate form the exercises contained in their "School Arithmetic." The work is published in two parts, the first of which deals with fractions, decimals, factors, compound quantities, and unitary method. Both in quality and variety the collection of examples is admirable.

(6) Many teachers will be glad to hear that the solutions of the exercises in Godfrey and Siddons's "Solid Geometry" have now been published. Where we have tested them we have found that they are set out very clearly. Mr. Beaven has avoided the temptation to which in such cases writers often succumb of allowing a desire for brevity to obscure lucidity of expression. The figures which illustrate the solutions of the problems on plan and elevation are drawn with great care, and the methods employed are fully explained.

(7) This is in no sense a text-book on hydrodynamics. A few formulæ are quoted from various mathematical treatises, but no proofs are given. The purpose of the author is to introduce the student to the ideas of the subject, and to point out the rather arbitrary conditions under which, in the present state of knowledge, the mathematician is compelled to work. We do not think that the novice will find the contents of this volume at all easy to understand and coordinate with his other scientific reading. The number of quotations from many different authorities and the variety of topics alluded to may well tend to confuse those who have little previous knowledge of the subject. In the hands of a skilled lecturer we think the material of this book and the lines of thought indicated would interest and stimulate a class of students of ordinary ability. The character of the work leads us to believe that the author's purpose would be achieved with a real measure of success by oral methods.

(8) The authors of this treatise have succeeded in producing a work wholly unlike any other text-book on the subject with which we are acquainted. They take as their motto a pregnant sentence from Tannery's "Leçons d'algèbre et d'analyse":—"J'ai horreur d'un enseignement qui n'est pas toujours sincère; le respect de la vérité est la première leçon morale, sinon la seule, qu'on puisse tirer de l'étude des sciences." Their contention is that the average schoolboy is fully capable of realising the fundamental ideas upon which the science of algebra and, in fact, all analysis is based, and that a powerful educative instrument is discarded if no attempt is made to discuss the base-principles of the subject. They regard rigour in fundamentals as important as variety in application, and the power to understand the meaning of a process as more valuable than the ability to apply it.

With these ideas in the abstract few people will disagree, but the majority of teachers hold that work of this character must be reserved for specialists. They consider that the mental calibre of the ordinary schoolboy, and the limited time at his disposal, are scarcely adequate to permit of the high standard required by the authors of this work. Great things can, of course, be done by an enthusiastic and able teacher; and we have no doubt at all that Mr. Barnard obtains excellent results at Rugby by following the lines here indicated. But we question whether the ordinary teacher could be expected to meet with success. We have not the space to comment in any detail on the contents of this volume, but we would urge teachers to procure a copy and study it for themselves. They will find in it much that is highly suggestive, and will gather from it a number of new ideas. It is in every respect a remarkable work.

(9) By the direction of the Board of Trinity College, Dublin, a new edition of Dr. Salmon's treatise on analytic geometry of three dimensions has been prepared. The editor has retained the substance of what appeared in the fourth edition, but has brought it into line with more recent work by inserting a number of new sections; the list of references has also been supplemented. Among the additions that have been made we note some excellent plates showing models of the various species of quadrics, a paragraph on Fiedler's pro-

jective coordinates, an account of the parametric representation of twisted cubics and quartics, Staude's elegant thread construction for confocal ellipsoids, and considerable reference to the later results obtained in differential geometry. There are a large number of minor changes, but the numbering of articles and chapters remains unaltered. Mr. Rogers is to be congratulated on the way in which he has executed a far from easy task.

(10) The author claims that the method explained in this volume abbreviates and simplifies very materially the work of surveyors and navigators. It is, of course, impossible for us to judge from a perusal of the book how far the theodolite which Mr. Fergusson has invented is successful in practical work. But Prof. Heath states that it has been tested in the engineering department of Birmingham University, and has proved extremely convenient. He also remarks that

"the reduction of the results of observations can be carried on simultaneously with the field work without reference to books of tables, thus giving the surveyor full information about any part of the field observed, while he is on the spot. For all traverse surveying, especially for rapid preliminary traverse, subject to modification, the instrument possesses distinct advantages over the ordinary theodolite."

The fundamental idea in the construction of the instrument lies in the method of graduation. To explain the system adopted, we will suppose that OA_0, OA_{100} are two radii of the circle, containing an angle of 45°. Then points A_1, A_2, . . . A_r . . . are marked on the rim such that the tangent of the angle A_rOA_0 is equal to $r/100$, where r takes all values from 1 to 100. By this means it is clear that the observer, instead of reading off the angle, obtains its tangent, which is more useful for his purpose. As a matter of fact, the new form of theodolite is also graduated in degrees so that the angle can also be obtained, if desired. The angle A_1OA_0 is taken as unit, and is called the one per cent. angle.

The first fifty pages explain very fully the theory, and numerous examples are given to show its application. The remaining 450 pages are occupied with tables, to the compilation of which the author has given nineteen years. The leading column gives the angle in the percentage form at intervals of 0·001 per cent. below 1 per cent., and of 0·01 per cent. above it. The other columns give logarithmic sines, cosines, tangents, secants with difference tables to seven places of decimals, and the angle in degrees to 0·001 of a second. A shorter table at the end contains tangents of half angles and versines. It seems almost incredible that any one man should have been able to carry through, almost single-handed, such a laborious work as Mr. Fergusson has accomplished. It undoubtedly merits the serious consideration of those engaged in survey work. The bulky size of the volume gives it rather an alarming appearance, but the processes are in reality very simple, and a single hour's work with the instrument would probably be enough to enable any practical man to gauge its utility.

(11) There is a distinct need for a treatise on statics suitable for candidates for entrance scholarships at the universities. A number of excellent introductory text-books exist, but with two possible exceptions we do not know of any work which exactly meets this demand. Many teachers will therefore welcome the publication of Prof. Loney's book, which may be regarded as a companion volume to his "Dynamics of a Particle and of Rigid Bodies," recently issued. It is assumed that the student possesses some knowledge of the methods of the calculus and the elements of analytical solid geometry. In addition to the ordinary elementary course, it contains chapters on shearing stresses, three-dimensional forces, wrenches, chains, attractions and potential, and slightly elastic beams. There is an excellent collection of examples, including some of very considerable difficulty. The author has the rare gift of writing simply, and he has chosen his material with the same skill that characterises his previous work.

PHILOSOPHY AND PSYCHOLOGY.

(1) *Scientific Method: its Philosophy and its Practice.* By F. W. Westaway. Pp. xxi+439. (London: Blackie and Son, Ltd., 1912.) Price 6*s*.

(2) *Proceedings of the Aristotelian Society.* New Series. Vol. xii. Containing the Papers read before the Society during the Thirty-third Session, 1911–1912. Pp. ii+345. (London: Williams and Norgate, 1912.) Price 10*s*. 6*d*. net.

(3) *Anales de Psicologia.* Trabajos del año 1910. Volumen ii. Pp. 360. (Buenos Aires: *La Semana Médica.* Imp. de Obras de E. Spinelli, 1911.)

(1) AN excellent book for science teachers and for the general reader who wishes to acquaint himself with scientific method. Beginning with the consideration of words and the importance of exactness in their use, Mr. Westaway enters on a sketchy history of philosophy, dealing with Plato, Aristotle, Bacon, Descartes, Locke, and Hume. Thence he proceeds to logic,

explaining its function in scientific method, and naturally giving prominence to J. S. Mill, though also quoting Whewell, Bain, Jevons, Alfred Sidgwick, and Welton. Book iii. consists of useful examples of scientific procedure, drawn from the investigations of White of Selborne, A. R. Wallace, Darwin, Harvey, Lord Avebury, and others; while book iv. deals with some elementary principles of science-teaching, and has some very sensible remarks on heuristic methods. The section on Bacon is particularly good, and the famous idols are lucidly explained. Indeed, the whole book is a model of clearness. If it has a fault, it is in the direction of excessive quotation; but this is difficult to avoid when an author is exceptionally well read, and it has the compensating advantage of giving the young student a wide range of actual "samples," some of which may lure him to the study of the authors themselves.

(2) This volume contains papers by Bertrand Russell, Percy Nunn, Boyce Gibson, Dawes Hicks, W. R. Sorley, James Ward, Bernard Bosanquet, and others, on the relations of universals and particulars, animism and the doctrine of energy, the experience of power, the time difficulty in realist theories of perception, and purpose and mechanism. Perhaps the most interesting to the man of science—particularly in view of Prof. Schäfer's British Association address and the various comments thereon—is the symposium on purpose and mechanism. Prof. Sorley, instancing a workman laying the bricks in house-building, points out that the purposive process involves (1) no creation or annihilation of matter, but only rearrangement of masses; (2) no creation or annihilation of energy; (3) no violation of the law of causation; but that it is by no means established that the laws of mechanics are valid also for purposive action; *e.g.*, the laws of motion do not explain the bricklayer. It is "ideal guidance"—guidance by the idea of the house or its parts, existing in the bricklayer's mind—that determines the place of each brick. Purposive action implies certain things which are inconsistent with fundamental principles of mechanics. "Energy is liberated, that is, passes from the potential to the kinetic form, as the result of a purpose, or mental idea, and the same purpose may control the direction of the movement. . . . If purposive action is a reality, then mechanism is an abstract or limited system, and cannot give an adequate account of the real process of things."

Mr. A. D. Lindsay, criticising, remarks that we cannot introduce a non-mechanical into a mechanical system, however much we may insist that it is only a little one; but, at the same time, we can maintain that the mechanical explanation will apply to every part of the human organism, while still holding that this is not a full account of the matter. The discussion was continued by Dr. Bosanquet and Prof. James Ward.

(3) A paper by the late Dr. Ameghino describes fossil remains of two human beings found on the Atlantic coast, 60 kilometres north of Necochea. The skeletons were small, almost pigmy, say about 1·40 metres, and of small build as to strength; skulls small, and decidedly dolichocephalic: frontal part small, face prognathous. Other articles discuss intellectualism and pragmatism, the psychology of criminals, and multiple personality.

GENERAL AND ECONOMIC GEOLOGY.

(1) *Earth Features and their Meaning.* An Introduction to Geology for the Student and the General Reader. By Prof. W. H. Hobbs. Pp. xxxix + 506. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1912.) Price 12*s.* 6*d.* net.

(2) *A Geological Excursion Handbook for the Bristol District.* By Prof. S. H. Reynolds. With an Introduction by Prof. C. Lloyd Morgan, F.R.S. Pp. 224. (Bristol: J. W. Arrowsmith, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1912.) Price 3*s.* 6*d.* net.

(3) *An Introduction to British Clays, Shales, and Sands.* By A. B. Searle. Pp. xi + 451. (London: C. Griffin and Co., Ltd., 1912.) Price 7*s.* 6*d.* net.

(4) *Graphical Solution of Fault Problems.* By C. F. Tolman, jun. Pp. 43. (San Francisco: Mining and Scientific Press; London: Mining Magazine, 1911.) Price 4*s.* 6*d.* net.

(5) *Observations on the West of England Mining Region.* Being an Account of the Mineral Deposits and Economic Geology of the Region, and forming Vol. xiv. of the Transactions of the Royal Geological Society of Cornwall. By J. H. Collins. Pp. xxiv + 683 + 18 plates. (Plymouth: Wm. Brendon and Son, Ltd., 1912.)

(6) *Types of Ore Deposits.* Edited by H. Foster Bain. Pp. 378. (San Francisco: Mining and Scientific Press; London: Mining Magazine, 1911.) Price 8*s.* 6*d.* net.

(1) PROF. HOBBS describes his new volume as "a series of readings," the substance of a course of lectures in expanded form. The title concisely expresses the character and scope of the work. The author discusses the figure of the earth, and lays stress upon the tetrahedral hypothesis. He touches lightly on rocks and their mode of formation; deals with earth movements, volcanic action, weathering, and the activities of

water and ice, desert conditions, and the characteristics of lakes and mountains. A separate chapter is devoted to the Niagara Falls as a clock of geological time. He hints that a large amount of original and unpublished material is interwoven in the older web. This may be, but much of it has either been skilfully concealed, or it has a familiar look. The book is quite pleasant reading, and the pleasure is enhanced by the abundant and excellent illustrations. There are five appendices; two on the determination of common minerals and rocks are unsatisfactory and not necessary in a book of this kind. The third describes the author's method of explaining the meaning of contoured maps by means of apparatus; it seems an elaborate way of passing the student's time. The fourth is a short explanation of apparatus for teaching the interpretation of geological maps; it consists of different shaped blocks, representing outcrops of various kinds, to be disposed on a table ruled into squares. This might be useful in setting examination exercises. The fifth outlines several fairly lengthy geological trips in the United States, and concludes with a sketch of a geological rush across Europe.

(2) A different series of geological excursions is provided for by Prof. Reynolds in his admirable little guide book. Forty excursions, all within easy distance of Bristol, are described on a uniform plan under the headings "special features," "access," "general structure," followed by, in each case, an itinerary with geological notes and a short list of references. There are numerous sketch maps and sections and an introduction to the geology of the district is written by Prof. Lloyd Morgan.

(3) The literature on British clays and sands is so meagre that any serious attempt to deal with the subject is welcome. The frontispiece to Mr. Searle's book, a "map of the chief clay works in Great Britain," is fairly characteristic of much that is to follow; it presents a medley of dots conveying no information of any value whatever, but representing, no doubt, a great deal of labour. It would be incorrect to suggest that no information can be gained from the text; Mr. Searle has produced a book containing much useful and interesting matter; one who can stand the fatigue and irritation caused by the lack of arrangement and the interminable repetitions will be able to extract a great deal. Only about half the volume is devoted to the geological position, the qualities and uses of British clays, and the small amount of space allotted to sands is not sufficient to warrant any mention in the title. The remainder of the book is concerned with ordinary geology and with the properties of clays in general. Much of the geology might have been condensed or omitted; it is very bookish, and it would be easy to point out many statements that are misleading or only half true. There are chapters on the mineral and other constituents of clays; the physical and chemical properties of clays (the table of analyses is quite inadequate); materials similar to clay (including halloysite, sillimanite, kyanite, zeolites, &c.); prospecting, mining, and quarrying; the purification and preparation of clays and the legal position of clays. There is a large but not quite trustworthy index. Throughout the work there are scarcely any references to original authorities, though many are mentioned.

(4) Prof. Tolman's small book of less than fifty pages deals with a subject of the greatest importance to all practical geologists and mining engineers. In most English text-books the movement on fault planes is usually treated as if it were quite simple, though everyone is aware that it has often been very complicated. The author explains very briefly, and on the whole clearly, how to represent the effects of faulting. He uses for this purpose two methods: the isometric projection, and the application of contouring. He introduces several terms in the nomenclature of fault movements which will be familiar to readers of American geological literature; his use, however, of the expression "pole" for axis is not fortunate. The book would have been more satisfactory in some respects if the author had permitted himself a little more elaboration in the treatment of the subject; it is none the less a useful pamphlet.

(5) On the mining region of Cornwall and Devon Mr. Collins has produced a valuable work of reference. Perhaps the most acceptable portion will be that giving short histories of individual mines. There is also a separate list of mines arranged alphabetically. A large part of the volume is occupied with theoretical matters of the usual kind, mingled with which is more interesting local information as to the character of the ore bodies. Occasionally the author launches out into elaborate estimates of the amount of certain minerals and ores contained in the rocks; they are neither of much use nor very accurate.

(6) It was an excellent idea to gather into a single volume the opinions of different mining engineers upon the type of ore formation with which each was most familiar. Separate chapters of this book are given to the Clinton iron ores, Lake Superior iron ores, the flats and pitches of the Wisconsin lead and zinc district, lead and zinc deposits of the Ozark region, native copper deposits, the Cobalt district of Ontario, the Treadwell mines, Alaska, saddle reefs, contact deposits,

the Witwatersrand conglomerates, replacement ore bodies, outcrops of ores, causes of ore shoots. A great deal of the information has appeared before, and there is naturally a certain amount of divergence of opinion among the writers.

OUR BOOKSHELF.

Leitfaden zum Bestimmen der Vögel Mittel-Europas, ihrer Jugendkleider und ihrer Nester nach leicht und sicher erkennbaren Merkmalen. By Prof. F. Dahl. Pp. viii + 162. (Berlin: Gebrüder Borntraeger, 1912.) Price 5.20 marks.

THE existing handbooks of bird-classification and description are deficient in three important particulars. They are inexact and incomplete on the distinction between immature, mating and ordinary adult plumages. Descriptive adjectives, such as "short" and "long," which have none but a relative application, are used instead of absolute descriptions. Lastly, the study of nidification is very unsatisfactory. Such defects are the cause of much error and waste of labour to the student.

Prof. Friedrich Dahl, in his guide to the birds of Central Europe, seeks to remedy these defects. It is a model of compression; its 154 pages, each fully paragraphed and subdivided, contain a very complete and well-ordered fund of data. The determination of species is the main object; the subject of life-habit is untouched. The study of nests has a section to itself. This department, naturally, is the less complete. Reference is made in every case throughout the guide to the descriptions and illustrations of Naumann.

An introductory section tabulates those crucial details of beak and pinion and claw which form the elements of classification and render the morphology of the bird unique in biology. These are well illustrated, though on too small a scale in many cases. The book is indispensable as a supplement to Naumann, and English students should make acquaintance with its method.

A. E. CRAWLEY.

Celluloid: Its Manufacture, Applications, and Substitutes. By Masselon, Roberts, and Cillard. Translated from the French by Dr. Herbert H. Hodgson. Pp. xx + 356. (London: Charles Griffin and Co., Ltd., 1912.) Price 25s. net.

THIS work, which must be judged in its English rendering, conforms with the forecast of the preface. It is a fairly complete account of celluloid manufacture, with a somewhat hesitating *exposé* of its technological basis. The authors acknowledge the collaboration of M. L. Clément in contributing (1) a theoretical study of nitration baths, and (2) a discussion of the "inflammability" of celluloid. The attendant risks of manufacture, storage, and use are treated, with full reference to the researches of Will, Vieille, Voigt, and others. Their own conclusions from the established data, in the form of "Precautions to be exercised in Celluloid Works," are practical and comprehensive.

The work is logically subdivided into:—Part i. "Manufacture," which comprises the processes involved in the production of the celluloid mass; Part ii., "Applications," deals with the production of celluloid articles, combs, handles, hollow articles, beads and buttons, and also films, including lacquers and the application of celluloid solutions in the production of filmed, or coated, and impregnated fibres; Part iii., "'Uninflammable' Celluloid and Substitutes," treats of modified celluloids, and the competing varieties of plastic colloids, such as the cellulose acetates, and xanthates (viscoid), as well as casein (galalith) and aldehyde-phenol derivatives (bakelite). In this section the authors modestly confess the insufficiency of their knowledge and information, and we shall not be thought hypercritical in remarking that this section is not to be taken "seriously."

There are unusual additions to our terminology; "pulpation" and "centrifugaliser" are instances of new words, which, however, are intelligible. But in the section dealing with the fibrous nitrocelluloses, we have "pile" (Fr. *pile*) for beater, "paste" (Fr. *pâte*) for pulp, and for the essential working parts of the beater we have "cylinder," or "drum" for roll, "slab" for bed-plate, "teeth" for bars. The general effect produced on the reader is that of *translated French*, which is not English.

The work appears at a moment which is opportune, in view of the appointment of a Royal Commission to inquire into the dangers of celluloid. The authors have dealt fully with this subject.

Atlas Photographique des Nuages. By Julien Loisel. (G. Thomas: Librairie Astronomique, Paris, 1912.) Price 18 francs.

THIS atlas contains twenty plates of beautiful reproductions from evidently very fine negatives, the size of each being $6\frac{1}{2} \times 4\frac{1}{2}$ inches. The letterpress accompanying them is extremely brief. It consists of twenty-three lines describing the methods adopted in securing the negatives, and three or four lines of description of each photograph, forming an index to the plates, in which is stated the type of cloud, general description of the formation and date of exposure.

The photographs were for the most part taken by Dr. Loisel, but they include some reproductions from negatives secured by M. L. Teisserenc de Bord, of Trappes, and by M. J. Vincent, of Uccle.

The cloud nomenclature used in this atlas is not that adopted by the International Meteorological Committee in their International Cloud Atlas, but it would have been an additional value to the present atlas if the international classification terms had been added in each case.

The photographs are so good and represent such typical clouds that the atlas should, and no doubt will, find a place not only in all meteorological institutions, but in the libraries of all interested in this fascinating application of photography.

LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Jaw from the Stalagmite in Kent's Cavern.

It is remarkable that so little notice has been taken of the important discovery by Mr. Pengelly of a part of a human upper jaw in the granular stalagmitic layer of Kent's Cavern, and even more so that some well-known anatomists appear to have been unaware of its existence.

If the deliberate evidence of Pengelly, who for so long so carefully and scientifically explored the floor of the cave, is not to be accepted on this point, his whole investigation will be rudely shaken. It is much to be regretted that Pengelly's pamphlet entitled "The Ancient Cave Men of Devonshire," containing a most clear *résumé* of his exploration, is not better known and more easily procurable. It would be most advantageous if it could be republished. On p. 9 of this pamphlet Pengelly writes as follows:—"The objects in the *modern stalagmite* were not numerous. They consisted of charred wood, marine and land shells, remains of various mammals, including the extinct cave bear, cave hyena, tichorine rhinoceros and mammoth; well-rounded pebbles of various kinds; flint flakes, implements, and cores; and a portion of a human upper jaw containing four teeth, with a loose tooth lying near it. Some of the remains of each of the extinct animals were not only in quite the uppermost portion of the stalagmite, but were not completely covered with it. The human jaw was near its base, where it was twenty inches in thickness."

From this it is clear that extinct animals were living in Devonshire up to the very end of the period during which the upper stalagmite was being deposited; and that this must have been some considerable time after the jawbone became embedded in the lowermost layers of it.

E. A. PARKYN.

October 29.

TUBERCULOSIS AND THE MILK SUPPLY.

ATTENTION has been directed to the relationship of tuberculosis and milk, and to the problem of a pure milk supply and the methods whereby this may be ensured, by a series of articles and letters which have appeared in *The Times* during September and October. We may consider the questions thus raised under three headings: (1) how far is tuberculous-infected milk a danger to the community as a whole; (2) will pasteurisation, certified milk depôts, or other means remedy the evil if it exist; (3) can a safe milk supply be ensured without revolution in present methods.

1. The menace, if it exist, of tuberculous milk chiefly falls upon children from one to six or seven years of age, *i.e.*, when cows' milk forms a staple article of diet. There can be no risk to the breast-fed infant, but, unfortunately, the natural method of infant feeding is at present out of fashion! While it is true that tubercle bacilli have been found in some 10–20 per cent. of all samples of milk examined, and while the experiments of the Royal Commissions on Tuberculosis and of others have shown that tuberculosis may be communicated by feeding with tuberculous milk, the amount of human tuberculous infection derived from milk is still uncertain. The pulmonary ("consumption," phthisis) is the most frequent form of human tuberculosis, the death-rate per 100,000 living for 1901–1909 being 117, as against 50 for *all* other forms of tuberculosis.[1]

Now Bulloch,[2] from a very careful survey of the literature of the subject, comes to the conclusion that pulmonary tuberculosis is produced almost always, if not exclusively, by tubercle bacilli of the *human* type. More than two-thirds of human tuberculosis is, therefore, certainly not due to the *bovine* bacillus or to milk infection. Bulloch further remarks that the bovine tubercle bacillus plays a relatively unimportant rôle in the production of tuberculosis in man! But it may be objected that, inasmuch as 10 20 per cent. of milk samples contain tubercle bacilli, there must be grave risk of infection therefrom. It will be found, however, that the percentage of infected samples is much lower than this for milk obtained under reasonably good conditions, such as those under which the large dairy companies get their supplies. Again, the method of detection of the tubercle bacillus employed in the examination of milk samples is by the *inoculation* of guinea-pigs (not ingestion or feeding), after *concentration* of the bacilli by centrifuging.

Many experiments prove that inoculation is a method of infecting infinitely more certain than feeding. Probably not more than twenty tubercle bacilli are required to produce a general infection in a guinea-pig by inoculation, whereas Findel found that doses of 19,000–312,000 bovine bacilli did not infect by feeding, and Reichenbach estimated that a dose of no fewer than 140 million bovine bacilli was required to infect guinea-pigs by feeding.[3] It is well known that tubercle bacilli are scarcely ever detected by microscopical examination in mixed milk, which gives a positive result with the inoculation test; yet, if they were present in anything like the numbers necessary to infect by feeding, they should be easily detected thus, for of every 100 organisms present, 1–2 should be tubercle bacilli! The fact is, we have no data indicating the infectivity by feeding of ordinary mixed milk.

The work of the Royal Commission gives no information on this most important point, for in all their experiments on the transmission of tuberculosis by feeding, huge doses of bacilli were administered. Although, of course, every effort should be made altogether to exclude tubercle bacilli from milk, it may well be doubted if the risk of infection from ordinary mixed milk is anything like as great as has sometimes been suggested, and the expensive and harassing machinery sometimes formulated to accomplish that end would probably benefit the stockman far more than the general public.

1 Rep. Med. Officer Local Gov. Board for 1910–11.
2 Horace Dobell Lecture, 1911.
3 See McFadyean, Journ. Roy. Inst. Pub. Health, December, 1910, pp. 715 and 718.

2. Assuming that a danger of tuberculous infection from milk exists, how can it be prevented? Pasteurisation has had a great deal said in its favour, and efficient pasteurisation does destroy the tubercle bacillus. But pasteurisation, as commonly carried out, is uncertain in its action, and there are various other objections to this process. These, however, will be dealt with in another article.

"Certified" milk is another solution that has been suggested. This means that the milk is produced under stringent conditions as to cleanliness of the animals, milkers, cowhouses, milking, &c., the herds are tuberculin-tested, and the milk is cooled, bottled, and packed in ice for transit. A good deal has been said about the growth of the certified-milk-depôt movement in America, but it is not perhaps realised that this has been forced upon her populace by the deplorable condition of the general milk supply there. Moreover, certified milk, unless subsidised by public funds or private benevolence, can do nothing to help those to whom a pure milk supply is of the greatest importance, viz., the poor; for it is admitted that the cost of certified milk must be from 8*d.* to 10*d.* per quart—only a few of even the well-to-do will pay such a price! When, a year ago, the price of milk was, in stress of circumstances, raised from 4*d.* to 5*d.* per quart, what an outcry there was; and every practical dairyman knows that the consumption of milk fell off, and, what is more, has not risen again on the recent decline in price to the former level. Further, if a certified milk trade became general, enormous numbers of cases of bottles would have to be handled by the railway companies, and greatly increased truck capacity would be necessary to deal with them. These and other practical points are not always realised by the armchair reformer.

3. The great question at issue is not so much whether a very carefully dairied milk, with a low bacterial content, distributed in bottles under ideal conditions, would, or would not, be an advantage to the community as a whole, but rather whether the existing milk supply in general is the cause of such damage to the public health as is frequently so confidently asserted. Save, perhaps, as regards tuberculous infection, which, from what has been stated above, cannot be regarded as a serious menace, the general milk supply is better now than it has ever been, and it is steadily improving. Two factors, which are in the region of practical politics, would undoubtedly improve matters without revolution and unnecessary expense. These are (*a*) cooperation between the farmers in a district and the treatment of their milk (cooling, &c.) at a central depôt from which it would be distributed either to the towns around, or to the railway for forwarding to a distance by regular, fast, and properly equipped milk trains, all farms being under proper official inspection; (*b*) the elimination of the street dealer or hawker by the abolition of all station trade, and the absorption of the smaller dealers into a few large companies, so that there is but one middleman between the farmer and the consumer.

It will not be possible to speak definitely of the value of "synthesised milk," a preparation of soya beans, recently placed on the market, until its nutritional value has been ascertained.

R. T. HEWLETT.

JUBILEE OF THE PHILOSOPHICAL INSTITUTE OF CANTERBURY, NEW ZEALAND.

THE Philosophical Institute of Canterbury, New Zealand, celebrated its jubilee on August 30 by holding a conversazione in the Art Gallery, in Christchurch. The institute was established on August 30, 1862, twelve years after the foundation of the Canterbury Settlement. Sir Julius Von Haast, who had only recently arrived in the colony, was the principal leader of the movement to form the institute, and he devoted to it the remarkable energy and enthusiasm with which he founded Canterbury Museum and made it the best institution of the kind in New Zealand. He was elected the first president of the institute, and was one of its most prominent officers until his death, many years afterwards.

The institute made an excellent start on its career. It was ambitious, and it is characteristic of the spirit which animated the colonists of those days that it made up its mind at once to do something quite practical. It announced that it wished to take part in the development of the resources of the province, and to help the settlers by disseminating amongst them useful knowledge. It held its first business meeting, which was numerously attended, in November, 1862, and it listened to the reading of papers on the growth of thistles, the manufacture of the native flax (*Phormium tenax*), and other practical subjects.

Besides contributing largely to the Transactions of the New Zealand Institute, the institute has undertaken publications on its own account. Amongst these are the "Index Faunæ Novæ Zealandiæ" (1897), edited by Captain Hutton, and "The Subantarctic Islands of New Zealand" (1909), a large work in two volumes, containing reports on a scientific expedition to the Campbell and Auckland Islands, south of New Zealand. This work is the result of an enterprise which the institute took in hand in 1906, when it urged upon the Government the desirableness of extending the magnetic survey of New Zealand to the different groups of islands that lie south of the mainland. The Otago Institute gave its support, and the proposal was approved by the New Zealand Institute; and later on the scope of the scheme was extended to include investigations into the geology, zoology, and botany of the islands.

The jubilee celebration in August last was attended by a brilliant gathering. Dr. L. Cockayne, F.R.S., the president, whose researches in botany, especially in regard to ecology, are well known in the United Kingdom and other countries, and who has taken a prominent part in the institute enterprises in recent years, presided. In an address, he showed how the institute had originated, and he sketched its career; he then dealt with the position of the man of science in regard to humanity and the world's progress. He said that it is true that man does not live and move and have his being at the dictates of science, but it is to science that civilisation owes its present position, and in the thickly populated centres man's very existence depends upon the progress of science. The works of science are so wrapped up in the ordinary man's daily life that he not only does not feel grateful to the scientific man, but frequently ignores his very existence. The man in the street, in fact, although he may be well informed in other directions, forgets, or never knows, that applied science must be based upon discoveries in pure science, which at first may appear to have no importance whatever for the human race. The progress of the world depends upon the number, the quality, and the zeal of the men of science. They are the ultimate makers of the people's wealth and the rulers of the people's destinies; and they must always be highly trained and enthusiastic in their work.

The Mayor of Christchurch, in a short address, congratulated the institute, and also congratulated Dr. Cockayne on being elected a Fellow of the Royal Society. Mr. G. M. Thomson, as the representative of the Parliament of New Zealand, read congratulatory messages from the Prime Minister of the Dominion and from the Hon. R. H. Rhodes to the institute and to Dr. Cockayne as the winner of the Hector medal for his researches in botany. Mr. Thomson added that he had been asked to present to Dr. Cockayne this first Hector medal, struck in honour of the late Sir James Hector. The medal had not arrived in the Dominion, and could not be handed to the recipient just then, but it carried with it a grant to help in the recipient's future work. Dr. Cockayne's researches had cost him large sums of money, and he had great pleasure in asking that gentleman to accept a sum which would help him in the great work he still had in hand.

Dr. Cockayne returned thanks, and after other addresses had been given, the gathering was brought to an end.

PLAICE FISHERIES OF THE NORTH SEA.

THE tenth meeting of the International Council for the Study of the Sea was held at Copenhagen in April last, and the *Procès-Verbaux* have recently been published. The most important subject considered was the general report on the plaice fisheries of the North Sea, which is being prepared by Prof. Heincke, of Heligoland. Only the first section of this report was, however, ready at the time of the meeting, and it was decided that another meeting should take place at the end of September for the further consideration of the matter. The section of the report laid before the meeting by Prof. Heincke in April was based chiefly on the special market statistics of plaice landed, the greater part of the material being derived from English ports. The results of the work of the special steamers remain to be considered.

From an economic point of view the study of the plaice question is undoubtedly the most important work which the council has undertaken, and it is to be regretted that such great delay has occurred in the preparation of the report. Prof. Heincke cannot be blamed for this delay, which seems to have been due to faulty organisation on the part of the council, and to a want of appreciation of the magnitude of the task. The work might well have occupied the entire time and energy of one man with a staff of trained assistants under him, and it was clearly impossible that it could be carried out within a reasonable time, in addition to his other duties, by the director of the Heligoland Biological Station. If some of the money which has been spent on the organisation and formal administration of the Council and on the less important parts of the programme had been employed to enable Prof. Heincke to devote his whole time and energy to the task and to obtain adequate assistance in doing the detailed work, the position at the present time would have been much more satisfactory.

THE PLASTIC ART OF PALÆOLITHIC MAN.

WE learn from *The Times* of October 31 that Count Begouen, the well-known investigator of prehistoric archæology, has made a remarkable discovery in the cave known as Tus Ditboubert, in the district of Montesquieu-Aventès (Ariège), where three months ago he found mural paintings of animals, presumably of Aurignacian age. On October 10 the Count and his son broke through a mass of stalactites, and in the new gallery thus exposed found two clay figures, respectively 26 in. and 30 in. long, representing a bull and cow bison. They appear to have been attached originally to a rock, as one side is rough while the other is completely modelled. They are nearly perfect; the only damage that they had received was that one of the horns of the female bison and its tail had been broken off; the tail was, however, found on the floor of the cave. A third small clay figure was also found, but it was so roughly modelled as to make it impossible to say what it represents.

In passing through the galleries the explorers found many footprints of bears and human beings. In one of the galleries, where there was a number of otherwise indistinguishable marks on the floor, some fifty imprints of human heels were discovered, and Count Begouen, in his communication to the Academy of Inscriptions of Paris on October 30, suggested that these may represent traces of ritual observances or dances similar to those which have been oberved among the savage tribes of the present day in Australia and Africa.

This is the first time clay figures of Palæolithic date have been discovered, and it affords one more example of the wonderful finds that have been yielded by the French caves. A very large number of engravings and carvings of animals on bone and ivory have been found, as well as engravings and paintings on the walls of caves, in France and Spain; mural carvings in low relief are also known, outlines of bison traced on the clay floor occur in a cave at Niaux, and now clay figurines have come to light.

There can be little doubt that many of these works of art had what we now term a magico-religious significance. Artists are not likely to have carved, engraved, painted, or modelled in the black recesses of caves merely for the joy of expression, since few of their fellow-tribesmen would see their works of art, and then but imperfectly. The only adequate solution of the problem seems to be that these delineations and representations had a significance which was at the same time practical and religious, and it is possible that some at least of them were made for the purpose of enabling their originals to be captured, or may be, as in the case of certain Australian ceremonies, to increase their numbers; in either case, their significance would be more utilitarian than æsthetic.

NOTES.

We regret to have to announce the death of Mr. Henry Groves, at his residence at Clapham, on Saturday evening, November 2, at fifty-seven years of age, after an illness extending over many months. In conjunction with his brother James, Mr. Groves was widely known as possessed of exceptional acquaintance with the small but difficult group of the Characeæ, and the opinion of the brothers "H. and J. Groves" was constantly sought by botanists of all nations. It is understood that a volume on the British species, for issue by the Ray Society, is practically ready for the press. The most conspicuous task in which both brothers engaged was the editing of the ninth edition of Babington's "Manual of British Botany," which was in many respects remodelled, and came out in 1904. Mr. Henry Groves had served on the council of the Linnean Society some years since; at the time of his death he was again a councillor, and in certain questions he took a leading part. His death removes a loyal and devoted worker, whose place will not be easily filled.

Dr. Benjamin Boss, son of the late Prof. Lewis Boss, director of the Dudley Observatory, Albany, N.Y., has been appointed acting-director of that institution.

M. Emile Boutroux was on October 31 elected a member of the French Academy. The eminent French philosopher is honorary professor of modern philosophy at the Sorbonne, and director of the "Fondation Thiers," a residential college for post-graduate study. He is known as the author of numerous important philosophical works.

The eighty-seventh Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Sir James Dewar, F.R.S., Fullerian professor of chemistry, his title being "Christmas Lecture Epilogues." The lectures will be experimentally illustrated, and the dates and subjects are as follows:—Saturday, December 28, "Alchemy"; December 31, "Atoms"; January 2, 1913, "Light"; January 4, "Clouds"; January 7, "Meteorites"; January 9, "Frozen Worlds."

Owing to bad weather, the illuminated night flying and firework display that was to be held at the London Aerodrome, Hendon, on Tuesday, November 5, has been postponed until Saturday next, November 9. Special exhibition flights, speed and altitude tests will take place from 2.30 p.m. until dusk, and the illuminated night flying and firework display will be in progress from 7.30 p.m. until 10 p.m.

The series of lectures which the Selborne Society annually arranges will begin on November 11, when Lord Montagu of Beaulieu will preside, and Mr. Fred Enock will deal with "Fairy Flies and their Hosts." Among the subjects of other lectures are:—"Minor Planets," by Dr. A. C. D. Crommelin (January 20, 1913); "Fibres and Fibre Lore," by Mr. C. Ainsworth Mitchell (February 17); and "Byways in Biology," by Mr. James Saunders (March 3). The special children's lecture will be given by Mr. Spencer Fletcher on "Dew, Hoar-frost, and Clouds" (January 9).

The death is announced, at the age of seventy-two, of Dr. William Willard Daniells, the founder of the study of chemistry at the University of Wisconsin. In 1868 he was appointed to a chair in that institution, and established its first chemical laboratory, giving daily instruction to one student, and using an old carpenter's bench in the basement. Dr. Daniells continued in active work as the head of the chemistry department until 1907, when he became professor emeritus. He also conducted the weather bureau at the University, until this work was taken over by the U.S. Government. From 1872 to 1876 he was chemist to the Wisconsin State Geological Survey.

The Weber-Parkes prize (of 150 guineas and a silver medal), founded in 1895 by Sir Hermann Weber in memory of the late Dr. E. A. Parkes, and awarded every third year to the author of the best essay "upon some subject connected with the etiology, prevention, pathology, or treatment of tuberculosis, especially in reference to pulmonary consumption in man," has been awarded by the Royal College of Physicians to Mr. J. A. D. Radcliffe, pathologist to the King Edward VII. Sanatorium, Midhurst. The subject of the next essay, to be adjudicated upon in 1915, is an original research on the treatment of pulmonary tuberculosis with substances which are especially antagonistic to the specific organism and its products. This work must have been chiefly carried on since the year 1911. The following lectures will be given at the Royal College of Physicians during November:— Dr. Raymond Crawfurd will deliver the FitzPatrick lectures on "The History of Medicine" on November 7, 12, 14, and 19, the subject being "Echoes of Pestilence in Literature and Art"; the Horace Dobell lecture by Dr. C. J. Martin, on "Insect Porters of Bacterial Infection," will be delivered on November 21.

THE extension of the Manchester Museum was formally opened on Wednesday, October 30, by Mr. Jesse Haworth, the donor of the larger part of the cost of the new buildings, when Prof. Flinders Petrie delivered an address on the *raison d'être* for the study of Egyptology. The extension consists of a central building, 65 ft. long and 35 ft. wide, comprising basement, ground and first floors, the latter with a gallery 12 ft. wide all round. This central building is connected with the old museum by a bridge 12 ft. wide, at the level of the first floor, and, balancing the bridge in front elevation, is a low building 30 ft. long and 35 ft. wide, consisting of basement, ground and first floors, communicating with the corresponding floors of the central building. The larger room on the ground floor will be devoted to a museum of economic and applied geology, which will be practically an extension of the existing geological museum on the ground floor of the old building. The smaller room on the ground floor will contain the collections illustrative of anthropology, ethnology, and numismatics. The whole of the first floor and gallery will be given over to the exhibition of the valuable and extensive collection of Egyptian antiquities, and for those illustrating the allied civilisations of the Orient. These collections, which deal with the historic period of human development, will be directly connected, by means of the bridge, with those illustrative of Palæolithic and Neolithic man, which are exhibited on the first floor of the old museum. It has been possible, therefore, to add these important departments to the museum without any reorganisation of the existing collections, while at the same time they fall into their correct place in the general scheme of classification adopted in the museum.

FOR the third month in succession October was generally cold over the United Kingdom, although it was less so in the northern and western districts than elsewhere. At Greenwich the mean temperature for the month was 48°, which is 2° less than the average, but in both August and September the mean was more than 4° below the average. The mean maximum temperature for October at Greenwich was 57°, which is 1° below the average, and the mean minimum 39°, which is 4° less than the normal. The highest day temperature was 66°, which is the lowest October maximum since 1905. There were in all only nine days at Greenwich with the temperature above the average, and on three days at the commencement of the month the deficiency of temperature exceeded 10°. The aggregate rainfall at Greenwich for October was 1·86 in., which is 0·99 in. less than the average, and rain fell on fourteen days. The duration of bright sunshine for the month was 123 hours, which has only been exceeded twice in October in the last thirty years, and never by more than ten hours.

THE factors concerned in the ripening of cheddar cheese are discussed by Messrs. Hastings and Hart and Miss Evans in Research Bulletin 25 of the University of Wisconsin Agricultural Experiment Station. The ripening seems to be brought about first by the action of bacteria belonging to the *B. lactis acidi* group, and subsequently by that of another group of acid-forming bacteria, the *B. bulgaricus* group.

IMPORTANT studies on dietetics are being carried out by the U.S. Department of Agriculture. One of the latest bulletins (Yearbook for 1911) deals with the nutritional value of green vegetables. While they do not add greatly to the total nutrient and fuel values, they increase the wholesomeness of the diet in three ways, viz., by supplying necessary mineral matters less abundant in other food-stuffs, by supplying bulk desirable for the normal digestion of the more concentrated food materials, and by rendering the diet more varied and attractive.

A VALUABLE report on isolation hospitals, compiled by Dr. H. Franklin Parsons, has been issued by the Local Government Board. Many isolation hospitals all over the country have been inspected, and full details are given as to construction, cost, and maintenance, with plans. The utility of these hospitals is discussed, and the question of combination between adjacent authorities is considered. The architect of the Board (Mr. Kitchin) points out that the cost of a rod of stock brickwork in mortar has risen from 12*l*. 10*s*. in 1859 to 16*l*. 10*s*. in 1905 and 16*l*. 5*s*. in 1911. Suggestions are made for cheapening construction, *e.g.* by the use of steel or timber framework covered with patent slabs, which might result in a saving of 30 to 40 per cent., but this kind of construction is at present hampered by the building bylaws now in force.

THE effect of smoking on the physique of college undergraduates is discussed in a paper by Dr. Frederick J. Pack in *The Popular Science Monthly* for October, under the title "Smoking and Football Men." The author's reason for singling out football men for special study is that it is impossible to draw definite inferences from comparing students some of whom are athletes and some of whom are scholars, and, on the other hand, he considers that the football squad forms a very nearly homogeneous group on which observations can well be based. Further collections of statistics are given referring to the effects of smoking on scholarship as tested by examinations, and to the lung capacities of smokers and non-smokers. In every case the evidence is against smoking. In the football trials only half as many smokers as non-smokers were successful. In the case of able-bodied men smoking was associated with diminished lung capacity amounting to 10 per cent. Finally, in examinations it was found that about 70 per cent. of the candidates obtaining highest marks were non-smokers, while 70 per cent. of those obtaining lowest marks were smokers.

IN *The Nature Photographer* for October Mr. F. J. Koch gives an interesting photograph of a herd of chamois in the Alps, taken with a telephoto lens.

DR. C. C. HOSSÉUS, of Berchtesgaden, has favoured us with a copy of a paper from the *Nachrichtsblatten der Deutschen Malakozoologischen Gesellschaft* on land and marine shells collected during an expedition to the Malay Peninsula and Siam. The most important result appears to be the evidence of the molluscan fauna that the islands of Koh-Si-Chang and Koh-

Kam-Yei formerly constituted a portion of the Siamese mainland.

In a paper on the origin of asymmetry in Cetacea published in vol. xli. (pp. 45–54) of the *Anatomischer Anzeiger*, Prof. G. Steinmann argues that the horizontal tail-fin of that group has been produced by torsion from the perpendicular type characteristic of the Mesozoic saurians. As the author believes cetaceans to be a convergent group derived from three of the Mesozoic marine reptilian orders (Ichthyosauria, Plesiosauria, and Thalattosauria), it is, to say the least, not a little curious that a similar torsion of the tail-fin should have occurred in each group. The same author has also sent us a copy of a pamphlet, by himself, published by Engelmann, of Leipzic, and entitled "Die Abstammungslehre, was sie bieten kann und was sie bieten."

The interesting and rare fresh-water alga *Phaeothamnion confervicolum* has recently been found near Edinburgh by F. L. M'Keever, who describes (Trans. Bot. Soc. Edinburgh, vol. xxiv) the first recorded appearance of this plant in Great Britain. The genus Phæothamnion has by the majority of recent systematists been placed at the base of the brown algæ, and may be regarded as one of the intermediate forms in the ascending scale of brown organisms arising from the Flagellata with brown chromatophores (Chrysomonads), and giving rise to the true brown algæ (Phæophyceæ), hence it is a type of special interest from the phylogenetic point of view. Hitherto this genus has been found only in Sweden, Germany, Austria, and Italy. As the alga disappeared from Mr. M'Keever's cultures before its zoospores could be carefully studied, it is to be hoped that the plant will be found again, and further investigations made in order to determine its systematic position and affinities with greater certainty.

Prof. W. E. Ford has edited the thirteenth edition of "Dana's Manual of Mineralogy" (New York: Wiley and Sons, 1912, price 8s. 6d. net), which continues to be one of our best elementary text-books. The photographic illustrations of actual specimens, printed as separate plates, are distinctly helpful. As is usual in the smaller works on mineralogy, crystallographic considerations remain somewhat loosely stated. The problem of isomorphism outside the cubic system is not touched on in the three pages devoted to the subject, and the statement on p. 11 that "in general the ratio of the intercepts of a crystal face upon the crystallographic axes can be expressed by whole numbers or definite fractions" is surely, in this abbreviated form, misleading. Useful tables for the determination of minerals occupy nearly seventy pages.

The Deutsche Seewarte has added another lustrum (1906–10) to the valuable results of the meteorological observations made at the stations of the second order under its control. The lustra previously dealt with cover the thirty years 1876–1905, and some of the former have already been combined into longer periods, *e.g.* in 1904 the results included the twenty-five years 1876–1900. The observations are made at 8h. a.m., 2h. and 8h. p.m., local time, and excepting at two stations, where the English-pattern (Stevenson) screen is used, the thermometers are installed outside suitable windows. The results are calculated for months, seasons, and the year.

A lengthy article (in Japanese) on observations of air currents appears in the Journal of the Meteorological Society of Japan (xxxi., No. 7, 1912). The author, Mr. Sato Junichi, describes some experiments which he carried out in January and February last on the summit of Mount Tsukuba (2925 ft.), both with small hydrogen balloons, known as "pilots," and with pyrotechnic balloons. The latter, devised by himself, are balloon-like firework pendants, which are released at various heights, determinable from the nature and quantity of explosives used. It is claimed that whereas "pilots," being released at ground-level, are at the mercy of surface winds from the start, the firework balloons are carried through the lower strata and begin their journey several hundred metres high. For the observation of these balloons the author uses a special form of theodolite, also designed by himself, provided with a sighting attachment and a plummet, and costing only a few pence. In the experiments referred to, when comparative observations were made with both types of balloon, air currents in the opposite direction to those at ground-level were found at heights of from two to five hundred metres. Details are given of numerous observations, the information obtained embracing speed and direction of air currents, the location of upward and downward eddies in the atmosphere, height of surface currents, &c. The meteorological conditions, nature of clouds, force and direction of the wind prevailing on each occasion are also given.

In recording observations of periodic phenomena, it is very usual to make a certain number of groups of regular observations and to take the arithmetical mean of each group. In a note on the application of the method of harmonic analysis (Journal of the Meteorological Society of Japan, xxxi., 5), Mr. Y. Tsuiji shows that when the results are used for the purposes of harmonic analysis the coefficients thus obtained are too small, and formulæ and tables are given for the necessary corrections.

Under the title "Surfaces of Revolution of Minimum Resistance," Dr. E. J. Miles, writing in the Bulletin of the American Mathematical Society, discusses the form of an airship or other figure of revolution which experiences the least resistance in its motion through a resisting medium. The assumption made is that the pressure on any surface element is a function of the inclination of that element to the direction of motion, and is unaffected by the currents set up by the remaining portions of the surface, and in this respect the problem differs essentially from that presented by an airship or body moving through a material fluid medium. The problem is, however, a classical application of the calculus of variations dating back to the time of Newton.

A series of articles on the origin of the earth's magnetic field have appeared in *Terrestrial Magnetism* during the last two years from the pen of the editor of that journal, Dr. L. A. Bauer. The subject has been recently dealt with by Prof. Schuster in his address to the Physical Society of London, and by Dr. W. F. Swann in the July number of *The Philosophical Magazine*. The conclusion to which each examination leads is that none of the present theories offers a satisfactory explanation of the earth's magnetic state. In the September number of *Terrestrial Magnetism* Dr. Bauer shows that if the mean values of the magnetic elements be calculated for successive parallels of latitude between 60° N. and 60° S., these values are represented to within 1 per cent. by an expression for the magnetic potential which involves only the first and third zonal harmonics; that is, it involves the first and third powers only of the cosine of the colatitude. This fact serves as a very severe test of any theory advanced, and none of them appears capable of surviving its application.

An interesting paper on the occurrence, analysis, and genesis of iridosmine obtained from the New Rietfontein Mines is communicated by Mr. C. Baring Horwood to vol. xv. of the Transactions of the Geological Society of South Africa. Iridosmine is an intimate mixture of iridium and osmium, found in small quantities, as small grey particles, associated with gold. Specimens microscopically examined by the author showed a decidedly crystalline character, but the metal has never been recognised *in situ* or in hand specimens; "panning" experiments show that in the New Rietfontein it chiefly occurs in a very narrow banket reef, known as the carbon leader, wherein the gold is always associated with carbon. Spectroscopic analyses, made for Mr. Horwood at the Solar Physics Observatory, South Kensington, indicate that the iridosmine is mainly composed of osmium, ruthenium, and iridium. A concentrate examined quantitatively at the Imperial Institute had a specific gravity of 19, and contained 95 per cent. iridosmine, of which 45 per cent. was iridium. The metal does not occur in paying quantities, and it took six months to collect 910 grains at the Rietfontein Mine, during which period 102,800 tons of ore were treated, and more than 52,500 oz. of fine gold were recovered. Mr. Horwood concludes that these metals of the platinum group are certainly of secondary origin, formed as primary segregations by magmatic concentration in the basic eruptives of the mines, and extracted from the dykes by active superheated gases during the pneumatolytic phase of eruptive activity. Probably, at a later stage, hydrothermal action was an important factor in concentrating them in the banket reefs.

Attention may be directed to an article on isomerism by Werner Mecklenburg in *Naturwissenschaftliche Wochenschrift* for October 20. The article, which extends over ten pages, and occupies the larger part of the issue, deals with the phenomena of position isomerism, optical isomerism, stereo-isomerism, and dynamic isomerism, together with the Walden inversion and the isomeric derivatives of cobalt and other metals as investigated by Werner.

We have received from Messrs. A. Hermann et Fils a reprint of a series of lectures "Sur quelques Thèmes choisis de la Chimie Physique pure et appliquée," delivered by Prof. Arrhenius at the University of Paris from March 6 to 13, 1911. Some of the subjects are identical with those of the Silliman lectures delivered at Yale in 1911 and published recently under the title "Theories of Solution"; this statement applies to the lectures on molecular theory, on suspension and the phenomena of adsorption, and on free energy. But different ground is covered by the lectures on the atmospheres of planets and the physical conditions of the planet Mars. The five lectures cover 112 pages, and are issued at the modest price of three francs.

The yearly memorandum issued by Mr. C. E. Stromeyer, chief engineer of the Manchester Steam Users' Association, deals with the relative costs of burning fuel or oil under boilers, and exploding oil or gas in engines. With the ruling prices of oil, it will not be profitable to burn it in preference to coal until the price of the latter has risen to 38*s*. per ton; but oil can be profitably used in internal-combustion engines whenever and wherever the price of coal exceeds 15*s*. per ton. The greater part of the memorandum deals with the valuable experiments of Profs. Heyn and Bauer on corrosion, or rather on the influence of about forty dissolved salts in reducing or increasing corrosion. The phenomena associated with corrosion are too erratic to permit of definite conclusions being drawn, but Mr. Stromeyer gives an excellent analysis of the experiments mentioned which will be of great service to steam users who are troubled with corrosive feed waters.

We have before us twenty-two volumes belonging to the series "Aus Natur und Geisteswelt," published by the firm of Mr. B. G. Teubner, of Leipzig and Berlin. The series now includes nearly four hundred volumes dealing with many aspects of literature, art, music, history, law, philosophy, science, and technology. The price of each volume is one mark, or 1.25 marks in cloth covers. A distinguishing characteristic of the series is the attention given to present-day problems. Among the subjects of recent volumes, for instance, are directions of modern physics, experimental cytology, regeneration, biochemistry, milk and its products, problems of modern astronomy, astronomy in relation to practical life, surgery of our time, practical mathematics, spinning, light-railways, wireless telegraphy, aërial navigation, brewing, and kinematography. Each volume is simply written and suitably illustrated, and the whole series forms a remarkably comprehensive collection of manuals of modern thought and progress. Both the editor and publisher are to be congratulated upon the production of the volumes, which should do much to promote interest in science, art, and letters among German readers.

A new issue of the list of second-hand microscopes and other instruments which they have on sale has been issued by Messrs. Clarke and Page, 23 Thavies Inn, Holborn Circus, London, E.C.

A catalogue of works on anthropology, ethnology, primitive society, &c., also mythology and folk-lore, including a portion of the library of Sir H. H. Risley, K.C.I.E., has just been issued by Mr. Francis Edwards, 83 High Street, Marylebone, London, W.

A SECOND edition of Mr. A. H. Mackenzie's "Theoretical and Practical Mechanics" has been published by Messrs. Macmillan and Co., Ltd. The first edition was reviewed in our issue of May 16, 1907 (vol. lxxvi., p. 50). While the general character of the book has been preserved, the new edition has been much enlarged, and in its preparation Mr. Mackenzie has had the cooperation of Mr. A. Forster. The price of the volume remains 1*s*. 6*d*.

OUR ASTRONOMICAL COLUMN.

A NEW COMET, 1912*c*.—A telegram from the Kiel Centralstelle announces the discovery of a new comet by M. Borrelly at Marseilles on November 2. The position at 7h. 39·9m. (Marseilles M.T.) was:—

R.A. = 17h. 47m., decl. = 38° 57′ N.,

which lies about 2° N.W. of θ Herculis. The motion is said to be south-east, the magnitude 10, and the comet transits at about 3 p.m.

A second telegram from the Centralstelle states that the comet was observed by M. Abetti, at the Arcetri Observatory, on November 3, when its position at 7h. 7·6m. (Arcetri M.T.) was:—

R.A. = 17h. 55m. 12·8s., decl. = 37° 21′ 5″,

and the magnitude was estimated at 9·5. The position, at present, is favourable for observations during the evenings, when the comet is fairly high up in the north-west sky.

GALE'S COMET 1912*a*.—Photographic observations made at the Hamburg Observatory, Bergedorf, on October 9 showed the coma of Gale's comet to be elongated in the direction of the chief tail, position angle 79°, and to be about 1·1′ in diameter; a plate taken with a 5-inch objective of 25-inch focal length showed a tail 5·4° long, which was 2′ broad until it reached about 1° from the head, and then broadened out to 11′ at a distance of 5°. A shorter tail emerged in position angle 122°, and another was suspected at position angle 50°; the magnitude of the whole comet was about 5·5.

Spectrographic observations on October 10 and 15 showed a bright image of the head at 387 $\mu\mu$ ±, and the bands at 474 and 563 $\mu\mu$, the blue band being essentially brighter than the yellow; the band at 516 $\mu\mu$ was much fainter. The continuous spectrum was much fainter than the bands named, but could be seen extending right along the spectrum from 387 to 563 $\mu\mu$, and was brightest between 397 and 410 $\mu\mu$. Prof. Schwassmann states that on the whole the spectrum obtained is very similar to that given by Kiess's comet at the beginning of July, 1911. (*Astronomische Nachrichten*, No. 4608.)

SCHAUMASSE'S COMET 1912*b*.—In No. 4609 of the *Astronomische Nachrichten*, M. Fayet shows that if the comet recently discovered by M. Schaumasse is not identical with Tuttle's comet, the two objects are moving in very similar orbits. If the identity is accepted, there is an error of about 5° in the mean anomaly, and nearly 4″ in the mean motion, according to M. Raht's elements for Tuttle's comet as given in these columns last week. A tentative calculation by M. Fayet does not indicate the near approach of the comet to any great planet during the recent revolution, and he suggests the possibility that the comet may have split up, the object discovered by M. Schaumasse being only one part. It would be of interest to search for the main body near the calculated positions given in M. Miličevič's recently published ephemeris; on October 20 the position of comet 1912*b* was α = 10h. 3m., δ = -0° 43′, whereas the ephemeris position for Tuttle's comet was α = 9h. 37m., δ = +73° 27′.

In a later note (*Astronomische Nachrichten*, No. 4610), M. Fayet states that he finds that near the end of 1900 Tuttle's comet was near Jupiter, the minimum distance being 0·8, and a rough calculation gives October 9, 1912, as the resulting date of perihelion passage, three months earlier than the date indicated by the 1899 orbit; the new value for the mean motion (μ) is 263·94″. M. Fayet concludes that the identity of 1912*b* with Tuttle's comet is very probable, but his hurried calculations of the Jovian perturbation are necessarily only approximate. M. Schaumasse's new ephemeris gives the following positions and distances:—

Ephemeris 12h. (M.T. Paris).

1912	α h. m.	δ ° ′	log r	log Δ
Nov. 7	10 54·5 ...	−22 2		
11 ...	11 6·7 ...	−26 27 ...	0·0371 ..	0·1040
15 ...	11 19·1 ...	−30 41		
19 ...	11 31·9 ..	−34 39 .	0·0536 ...	0·1218

SUNDIALS.—Several interesting articles on sundials are published in the October number of *L'Astronomie*. M. Roguet describes an elaborate dial recently erected on the south façade of Juvisy Observatory, and also discusses the history of this instrument, which he believes was invented about 550 B.C.; this article is illustrated by several interesting photographs and diagrams, the former depicting a large number of ancient, or especially interesting, dials. M. d'Aurelle Montmorin describes the "Auto," a new portable sundial, and M. Joyeux gives an interesting and detailed description of the sundial erected on the communal school at Sèvres.

VARIABILITY OF SOLAR RADIATION.—Mr. C. G. Abbot, director of the Smithsonian Astrophysical Observatory at Washington, has just returned from a five months' astronomical expedition to Bassour, Algeria. The object of the expedition was to confirm or disprove the supposed variability of the sun. The Astrophysical Observatory has been for seven years making observations on Mt. Wilson, in California, on the daily quantity of heat received from the sun. The observations are arranged in such a manner as to indicate not only the quantity of solar heat reaching the earth, but also the quantity of heat which would reach a body like the moon, which has no appreciable atmosphere.

The observations have indicated that the sun is probably a variable star having a range of variation amounting to from 5 to 10 per cent. within an irregular interval of from five to ten days. Last year Mr. Abbot observed in Algeria, while his colleague, Mr. Aldrich, observed on Mt. Wilson, in California. The object of thus duplicating the measurements was to avoid being misled by any local atmospheric conditions which might have affected Mt. Wilson observations. As nearly one-third of the circumference of the earth lies between Mt. Wilson and Algeria, it could not be expected that a similar local disturbance could affect both stations on the same day in the same manner. The observations of 1911 supported the belief that the sun is variable, but owing to cloudiness their number was not sufficient fully to establish this point. Hence it was thought best to return to Algeria this year.

The observations made by the Smithsonian party in Algeria this year were apparently very satisfactory. They occupied sixty-four days, and on more than fifty of these days Mr. Fowle made similar observations on Mt. Wilson, in California. The results of the work of 1911 and 1912 are expected to establish the supposed variability of the sun, or to show conclusively that this hypothesis can no longer be held.

OPENING OF THE NEW LABORATORIES OF BACTERIOLOGY AND PUBLIC HEALTH OF KING'S COLLEGE, LONDON.

THE completion of the arrangement by which primary and intermediate medical studies at Charing Cross Medical School are transferred to King's College, and the public health staff at King's College is afforded accommodation in their place, was marked on October 31 by the formal presentation of the laboratories by Prof. Simon Flexner, on behalf of the Medical School Committee, to the University of London, King's College.

Mr. H. A. Waterhouse presided, and in an introductory speech Dr. William Hunter, the Dean of Charing Cross, traced the development of the scheme, and suggested that the new laboratories would forward the ideal of Huxley, namely the progress of biological science.

Prof. Flexner expressed his pleasure at being present, for in so doing he considered that he would be helping the progress of public health, a science the knowledge of which is essential in all great cities, and especially in London. He spoke of the interest with which this science is regarded in America, and of the large sums of money given in order to forward research in that country, and expressed the hope that England, from whom America has learnt so much, might now follow her example in this respect.

The Hon. W. F. D. Smith (treasurer of King's College) expressed his agreement with Prof. Flexner's remarks, and said he was convinced that this day was a great one in the history of public health. He referred to the monumental skill and energy of Dr. Hunter, which had made the opening of the laboratories possible. The day, he argued, marked a stage in the policy of concentration which he was sure was a right one, as leading to a saving in labour and expense. The new laboratories would be used for research and for post-graduate teaching.

Dr. Headlam (principal of King's College) emphasised the advantages of this policy of reciprocity both to Charing Cross Hospital and to King's College. He supported a policy of concentration because he thought there was danger of money being squandered on new buildings which were not always needed. He reviewed the foundation of the Bacteriological Laboratory in 1887 by Dr. Edgar Crookshank, the first professor, and announced that Prof. Crookshank had presented his valuable library to the department. Their hope was that in time they would build up a fitting institute of hygiene within the University.

Sir Henry Miers (principal of the University) pointed out the need there was for willing cooperation of all available forces within the University, and held that Charing Cross and King's College had given a real example of what could and ought to be done in London.

The new laboratories and several structural and other improvements at the Charing Cross College were afterwards inspected by a large number of visitors.

PROBLEMS IN INFECTION AND ITS CONTROL.

THE Huxley lecture was delivered at Charing Cross Hospital (where Huxley studied) by Prof. Simon Flexner, director of the Rockefeller Institute, New York, who took as his subject "Some Problems in Infection and its Control."

After a reference to Huxley's work and to his Baltimore lecture in 1876, the lecturer alluded to the fact that we are still ignorant of the causes of several important infective diseases, and after quoting the example of scarlet fever, proceeded to discuss the biological investigation of poliomyelitis, or infantile paralysis.

This disease occasionally occurs in epidemic and pandemic form, and arose in America in the Atlantic coast cities and other places which receive the emigrant population from Europe. On clinical grounds it had been regarded as infectious, but this remained uncertain until Landsteiner and Popper in 1909 found that it could be transmitted to monkeys by intraperitoneal injection of matter taken from the spinal cord of a fatal human case. This method of transmission is, however, an uncertain one, but if intracerebral inoculation be substituted, the disease is transmitted with certainty to monkeys. No parasite, bacterial or protozoan, can be detected in the diseased tissues microscopically, and it is found that the filtrate from an emulsion of the infected cord, filtered through a porcelain filter, is capable of infecting; the organism, therefore, is ultra-microscopic. Some eighteen diseases are now known the micro-parasites of which are ultra-microscopic or invisible with the best optical appliances; these include yellow fever, rabies, and vaccinia.

The virus of poliomyelitis is resistant to drying, light, and chemical action. Animals which recover from the disease are immune from a further attack. The poliomyelitis virus can be detected only in the central nervous system, in the mucous secretion of the nose and throat, stomach and intestine, and in the mesenteric glands—nowhere else. The virus probably gains access to the body by the nose and thence to the brain *via* the olfactory nerves. Carriers, either healthy and unaffected persons, or slight and abortive cases, exist, and serve to transmit the disease. It has been suggested that insects may help to spread the disease, but at present there is no evidence of this, though the virus remains active in the bed-bug for some days. Nor is there any evidence that the domestic animals spread the disease. Proof has been given that the sporadic (*i.e.* isolated or scattered) cases of infantile paralysis are caused by the poliomyelitis virus by the fact that the blood of these children contains the same immunising substances as are present in the epidemic form of the disease, and in inoculated monkeys. There appear to be biologically different strains of the poliomyelitis virus. Attempts have been made to devise a chemo-therapy for the disease, and urotropin, a drug which has some antiseptic action and is secreted into the cerebro-spinal fluid, has been found to be of some value in preventing infection experimentally.

METEOROLOGY IN SCOTLAND.

MR. A. WATT contributes to the Journal of the Scottish Meteorological Society (vol. xv., No. xxviii.) a valuable discussion of the mean annual rainfall of Scotland. The discussion is accompanied by a table giving for 594 stations the mean annual rainfall and the number of years used, and for 129 of the stations for which records for forty years were available the amount of the maximum and minimum annual rainfall and the years of their occurrence. 1872 appears to have been for Scotland, as for Great Britain as a whole, the wettest year, and 1887 the driest. A map showing the distribution of mean rainfall over Scotland, based upon the values given in the table, forms the frontispiece to the volume. The region of greatest rainfall is near to the west coast, north of the Caledonian Canal, where the width of the high ground from west to east is relatively small, so that east winds as well as west winds can contribute to the rainfall before they have precipitated their moisture on other mountain ranges.

Mr. Watt contributes also an interesting note on the early days of the society, from which we learn that the society was contributing meteorological reports to the Registrar-General for Scotland so long ago as 1856. We note also that for a short period in 1858 the late Prof. Everett was the secretary of the society.

Dr. Aitken gives an account of some experiments on radiation temperatures. The black-bulb thermometer has always been regarded with some suspicion as possessing some of the qualities of a toy and some of a scientific instrument. The fact that a sheet of white paper, held near the bulb on the side away from the sun, produced a rise of temperature of 37° F. will give additional weight to the arguments of those who would relegate the instrument to the toy category. A very valuable result for meteorologists with grass minimum thermometers is Dr. Aitken's discovery that a piece of blackened metal tube slipped over the upper end of the thermometer prevents condensation of spirit in the upper part of the tube.

Among other contributions may be mentioned Dr. Mossmann's discussion of the climate of Chile, including some valuable tables of monthly rainfall and temperature, and Prof. Knott's review of Pernter and Exner's "Meteorological Optics," in which he ably defends the Ben Nevis observers against Pernter's criticism that they repeatedly sought for colours in their observations of optical phenomena.

The Journal includes tables giving the monthly meteorological statistics for about seventy places in Scotland, and a very valuable table of monthly rainfall at about 500 stations. According to the accounts published on p. 358 of the Journal, the collection of these statistics and the publication of the Journal have been carried out at a cost of less than 500*l.*, including all the expenditure incidental to the operations of the society.

THE FOURTEENTH INTERNATIONAL CONGRESS OF ANTHROPOLOGY AND PREHISTORIC ARCHÆOLOGY.

THE fourteenth Congress of Anthropology and Prehistoric Archæology met at Geneva on September 9–14, with a total registered membership of 555. The previous congress was held at Monaco in 1906. Since that date, numerous and important discoveries which deserved careful presentation and discussion in open session have been made throughout the world.

The congress met, in general sessions, in the Aula, or Lecture Hall, of the University of Geneva, whilst a number of lecture-rooms and halls were placed at its disposal by the federal and cantonal authorities, who spared no pains or money in helping to make the meetings a decided success. There was an honorary committee of ten, including Forrer, the President of the Swiss Republic, and Henry Fazy, President of the State Council of the Republic and of the Canton of Geneva, an executive committee of thirty eminent men of science, with Edouard Naville, hon. president; Dr. Eugène Pittard, president; Dr. Emile Yung and Alfred Cartier, vice-presidents; Dr. Deonna, secretary; Albert Lombard, treasurer; together with a distinguished *commission de réception*, comprising Théodore Bret, State Chancellor of Geneva, Chapuisat, Fatio, Favre, and Reverdin, the whole forming the machinery of the congress.

The following countries were officially represented by delegates:—*Germany*, Prof. Felix von Luschan; *United States of America*, Dr. Alès Hrdlička, Dr. Charles Peabody, and Prof. G. Grant MacCurdy; *South Australia*, Mr. Ramsay Smith; *Austria-Hungary*, Prof. M. Hoernes and Dr. Bela-Posta; *Belgium*, Baron de Loë and Prof. A. Rutot; *Cuba*, Prof. L. Montané; *Spain*, Prof. Manuel Anton-Férrandez and Prof. L. de Hoyos-Sainz; *France*, Prof. Marcelin Boule, Prof. Cartailhac, Dr. L. Capitan, and Prof. R. Verneau; *Mexico*, Señor Genaro Garcia; *Algeria*, M. Joly; *Monaco*, Prof. Marcelin Boule; *Roumania*, Prof. Tsigara-Samurgas; *Sweden*, Prof. O. Montélius.

Besides, there were official representatives or delegates of 163 scientific bodies and universities from Germany, United States of America, Argentina, Austria-Hungary, Belgium, Brazil, Canada, Egypt, Spain, France, Great Britain (England, Scotland, and Ireland being represented), Italy, Japan, Mexico, Portugal, Roumania, Russia, Sweden, and Switzerland, together with 392 unattached members of the congress from the above-mentioned countries, besides Denmark and Uruguay, who constituted the whole membership of the congress.

By a majority vote at the first session, French was made the official language of the congress, but verbal communications or papers before the congress could be presented in English, French, German, or Italian. Spanish was also added by a majority vote at a later session.

At the opening session of the congress, in the name of the Federal Council of Switzerland and of the State Council of Geneva, M. H. Fazy extended a hearty welcome to all the members present. Prof. Pittard recalled the 1866 meeting of the congress held at Neuchâtel, in conjunction with the fiftieth annual meeting of the Swiss Society of Natural Sciences. Prof. Giovanni Capellini, the venerable professor of geology in the University of Bologna, one of the founders of the congress, and sole survivor of the first meeting at Spezzia in 1865, replied to the address of welcome on behalf of the visiting delegates.

Upwards of 200 papers, read in full or in abstract, were presented by nearly as many congressists, a number altogether too great for fair treatment and discussion in open session. It was agreed that forthcoming congresses be divided into sections dealing with (1) *La pierre*; (2) *les métaux*; and that the last two days of the meetings be devoted to (3) *anthropology*.

Space will not allow us to do justice to the character of the papers presented and subjects discussed. Among the papers of wide interest to anthropologists and archæologists may be mentioned that of Prof. Marcelin Boule, director of the Institute of Human Palæontology, recently established in Paris, on the subject, *Homo neanderthalensis*. A thorough diagnosis of this ultra-human species was given by that eminent master of vertebrate palæontology. Of all the recorded specimens illustrating remains of this species available to the student of anthropology, there exist only twenty truly authentic. Neanderthal man was short in stature, with long face, bulky head, primitive characters of dentition, verticality complete, nose salient (ultra-human). *Homo neanderthalensis* goes out and disappears after the Middle Pleistocene. In the architecture of his cranium he does not resemble the short-faced Australian Bushman, as suggested, who, on the contrary, is *one* with Europeans. *Homo neanderthalensis* is *one* with the chimpanzee, and represents an archaic type, constituting in all probability a stage or phase in the series or evolution of *Homo heidelbergensis*.

Discussing the value of human palæontology, Prof. Boule stated that this new science had already taken man out of his zoological isolation and placed him in the front rank of a company of varying types constituting a human branch of vast proportion. We were far from having, as yet, a complete palæontological series of the genus Homo. In closing his remarks Prof. Boule paid a tribute to the excellence of the work done by British investigators in the field of anthropology, among others noting Huxley and Lankester.

In Victoria Hall, and under the presidency of M. S.

Reinach, of the Institut de France, Prof. O. Montélius, the distinguished delegate from Stockholm, gave an interesting lecture on Italy and Central Europe during the Bronze age. Prof. Montélius surveyed the influences of Etruscan art and industry as they spread northward from the Alps to the Baltic, especially at the time when amber became an important article of commerce. A comparative study of the various weapons, daggers, knives, and blades used previous to the evolution of the sword proper was presented by means of diagrams and photographs projected on the screen, showing the gradual spreading of the Italian influence northward. Traces of Mycenian (Greek) articles were also present in the collections covering the same period.

On Friday evening, September 13, "Cave Man" formed the subject of Prof. Cartailhac's public lecture, held in the same hall, under the presidency of Dr. Felix von Luschan, of Berlin. Prof. Cartailhac limited his observations to Palæolithic man and his culture as revealed in the discoveries made during more recent years. The artistic skill of prehistoric man was practically unknown up to 1895, when the savant Rivarré directed attention to the great importance of the discovery made in 1880 by M. Sotisla and his little daughter in the Santander cave. Some *forty* caves and more have since been searched and carefully studied by Abbé Breuil, M. Capitan, and the lecturer, who illustrated his remarks by means of lantern slides showing engravings, as well as pictures in line and colour, depicting various hunting scenes, in which the bison, reindeer, elephant, horse, and bull played a conspicuous part. Mural decorations included pictures illustrating archers, impressions of hands on the cave walls, together with figures of men and women, made by the remote occupants of these caverns.

A question radically affecting the chronology of the Stone age was raised by Mr. Reginald Smith, of the British Museum, on the strength of certain resemblances noticed between worked flints found on the surface of the chalk area and those of the Aurignacian period from caves in France.

Abbé Breuil, who has just visited England, gave a description of recent excavations in the Castillo cave in Spain. Fifty feet of accumulated deposits in the cavern had been carefully examined, and various stages determined above the base—three Aurignacian levels, and one *typical* with bone implements, followed by three Mousterian layers, separated by variant materials and stalagmitic deposits. Near the junction of these two series a warm fauna was found; then four Magdalenian levels with materials, separated by stalagmitic layers, below which came a Solutréan layer. Several hundred specimens were obtained, amongst others nests of worked quartzite implements.

References were made to the timely and generous foundations by his Serene Highness Prince Albert of Monaco of the chair of human palæontology in Paris, and to his achievements in the science of oceanography. Prince Albert, as is well known, has undertaken at his own expense the publication of the volumes describing and illustrating prehistoric man and his habitations, not only in the south of France and in Italy, but also in Spain. Several references were made to the Institut de paléontologie humaine recently established in Paris as an international institute, with Boule, Breuil, Obermaier, Verneau, Manouvrier, and others attached, marking a new era in researches pertaining to man.

A marked result of the last two congresses, held in Monaco and Geneva, is found in the earnest desire to gather together none but the most accurate information on the subjects dealt with. All materials collected and discovered in caves, tumuli, &c., must be treated as so many geological or palæontological specimens. Their precise mode of occurrence, relative position, and condition of deposition, together with a close record of all factors bearing upon the problems presented in each individual instance, must be ascertained and records made without bias or prejudice.

The Museum of History and Art of Geneva, containing valuable collections in archæology, was visited, and a reception held in its magnificent halls. The collections are admirably displayed and carefully classified. A State banquet, a reception at L'Ariana, and a garden-party at Prof. Naville's gave the congress opportunity to meet Genevans "at home."

Besides an excursion round the lake and to Chillon Castle, archæological excursions were organised by the committee to a number of lacustrine and other stations of prehistoric interest. The Station de Treytel at Bevaix and the Station de la Tène at Préfargier were visited on Monday, September 16. On the Tuesday and Wednesday following, the Museums of Bâle and Zurich (the National Museum) were visited, and their excellent collections examined. On Wednesday excavations were made in "the tumuli of Grueningen," for the benefit of the excursionists, whilst the next two days were spent in Lucerne and Berne, where the well-known anthropological and historical museums are located, the party returning to Geneva by way of Lausanne, where the historical museum proved of much interest in its collections from prehistoric sites.

Spain figured conspicuously at the congress, not only in the attendance, but also in the importance of papers presented, dealing with the wealth of recent discoveries made in that country. Following a strong representation and invitation to the congress on the part of the Marquis de Cerralbo that Spain be selected as its next place of meeting in 1915, a strong feeling in favour of that country was openly expressed. Italy withdrew its application for the fifteenth congress. It was rumoured that an anthropological or ethnographic congress will "take shape" in 1914 in the city of Washington, the membership and adherents thereto to be called together for 1916. Strong representation was made by officers and members of the fourteenth congress, held in Geneva, to consolidate and reduce the number of congresses rather than divide them.

The best side of a congress lies in the opportunities it affords men to meet and discuss outstanding problems. Much time seems to be wasted in listening to papers presented by congressists and read at breakneck speed, as these can be read to greater advantage when published. It was in the halls and lobbies of the University of Geneva, in quiet nooks and corners, alongside the numerous exhibits, and even at private functions and public receptions, that groups of two, three, and more, met one another, compared notes, became better acquainted with methods and means, discussing questions of special interest, and unravelling knotty points.

THE SCIENTIFIC THEORY AND OUTSTANDING PROBLEMS OF WIRELESS TELEGRAPHY.*

If we have two media of different dielectric constants in contiguity, and if a line of electric force crosses the boundary, then it is well known that the conditions to be fulfilled are that the tangential component of the electric force on either side of the boundary must be continuous, and also the normal component of the electric displacement or flux must be continuous. This involves a refraction of the line

* Introductory remarks by Prof. J. A. Fleming, F.R.S., at a joint discussion by Sections A and G of the British Association at Dundee. Continued from p. 268.

of electric force in crossing the boundary. It is bent away from or towards the normal, and if K_1 and K_2 are the dielectric constants and θ_1 and θ_2 the angles the line makes with the normal, then

$$K_1 \cot \theta_1 = K_2 \cot \theta_2.$$

The law of refraction of light is

$$\mu_1 \sin \theta_1 = \mu_2 \sin \theta_2.$$

Hence, in the case of light, the velocities of the rays in the two media respectively are proportional to the sines of the angles of incidence and refraction. In the case of the electric force, the velocities are inversely as the square roots of the tangents of the angles of incidence and refraction of the lines of electric force.

If, then, we consider a Hertzian oscillator which is partly in one medium and partly in another of greater dielectric constant, there will be a distortion at the boundary of the loops of electric force which are thrown off at each oscillation. If the upper medium is air and the lower medium is a material of greater dielectric constant, then corresponding to a normal semi-loop of electric force or air, there will be a completing semi-loop in the other material which is sheared backward, as shown in Fig. 1. If in the air at the boundary surface the force is normal to the surface, it will not be normal just below that surface in the medium of greater dielectric constant. It will have a longitudinal component. As the oscillations take place, these longitudinal components of the force are periodic in space and time, and constitute the surface wave which is similar to the electric waves produced on wires.

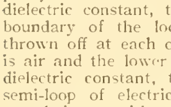

FIG 1.

If the earth were a perfect conductor, say, a ball of copper at the absolute zero of temperature, these surface waves would be confined merely to the surface skin. In the case of the actual earth, even sea water is a sufficiently poor conductor to allow the penetration of the surface wave to some little depth in it. Although the "numerical distance" is small, it is not so small as to extinguish altogether the surface wave.

The objection has been raised (see Dr. Eccles, *The Electrician*, April 5, 1912, vol. lxviii., p. 1064) that no experimental proof has been given of the actual existence of Sommerfeld's surface waves. Against this it should be noted that Sommerfeld has carefully explained that the surface waves are not separated sharply from the space waves, and may be regarded merely as a particular distribution of the moving electrostatic field near the common surface of the air and earth and accompanying electric currents in the earth. It is easy to prove that we can have surface electromagnetic waves on a *sheet*, similar in nature to electromagnetic surface waves on wires, of the existence of which we have abundant experimental proof. An argument in favour of the existence of these surface waves may perhaps be derived from the experience that high antennæ do not seem necessary for the *reception* of signals, even over long distances, thus indicating that there is a concentrated electric and magnetic field near the surface of the earth.

P. Epstein has delineated from Sommerfeld's equations a portion of the field of electrostatic force round an oscillator placed first over a perfectly conducting earth, and, secondly, over an earth of finite conductivity.[10] In the first case the loops of lines of electrostatic force are seen to terminate perpendicularly on the earth, and are divided symmetrically by the surface plane. In the second case they are distorted so that the lines at spaced intervals do not terminate perpendicularly. If, however, they have a component parallel to the earth's surface this is equivalent to a combination with a true space or Hertzian wave of a surface wave, similar to the electric waves on wires, which latter can travel along the guiding surface, irrespective of curvature of that surface.

If these conclusions are valid there is nothing to prevent the surface waves going half round the earth. It may, therefore, be quite possible to communicate by radio-telegraphy direct from England to New Zealand. There is one matter which may be of importance. Since the surface waves started from any one point reach an antipodal point by different paths it may be that unless the position of the receiving station is rightly selected, interference will arise between surface waves reaching it by different lengths of path, and hence extinction of signals for some places but not others in the same region. According to this theory, then, we need not endeavour to explain long-distance radio-telegraphy by diffraction, because true space waves are very little concerned with it.

We pass on then to consider the next question, viz. the influence of the nature of the surface in radio-telegraphy—why, for instance, it is conducted with certain wave lengths so much more readily over sea than land.

This matter has been particularly considered by Dr. Zenneck in an interesting paper. Assuming for the sake of simplicity a plane earth and plane electromagnetic waves, he discusses the effect of the conductivity and dielectric constant of the earth's crust on the wave propagation.[11]

Starting from the same equations as Sommerfeld, he arrives at an expression which enables him to calculate the damping of the waves along the horizontal boundary surface. He shows that this damping is determined by the dielectric constant and conductivity of the earth's crust. He calculates the distance the plane wave must travel before its amplitude is reduced to $1/\epsilon$ of that at the transmitter, and exhibits the results for various values of the dielectric constant and conductivity in the form of curves. Waves 1000 ft. in length over a sea surface would travel 10,000 km. before reduction to $1/\epsilon$ in amplitude, but over very dry soil only for 10 km. or less. The analysis shows that there is a considerable penetration of the wave into dry soil, but into so good a conductor as sea water the penetration is at most a metre or two. Moreover, Zenneck shows that over sea surface the lines of electrostatic force terminate nearly perpendicularly to it, but over a dry surface this is not the case. There is then a considerable rotating component, and the direction of the electric force is represented by the rotating radius vector of a semi-ellipse, the major axis of which slopes forward in the direction in which the wave is travelling. Zenneck's results have been extended by F. Hack, who has shown that underground moisture has the same effect as surface moisture in preventing degradation of amplitude.

The general result of these investigations, compared with practical experience, is to show that we can by no means consider the earth to be a perfect conductor in the case of radio-telegraphy, but that it has an extremely influential action in degrading the amplitude of the waves deforming the travelling electrostatic field, and in creating a type of surface wave which

[10] See P. Epstein, "Kraftliniendiagramme für die Ausbreitung der Wellen in der drahtlosen Telegraphie bei Berücksichtigung der Bodenbeschaffenheit," *Jahrbuch der Drahtlosen Telegraphie*, vol. iv., p. 176, 1910. Epstein has, however, only delineated the field in the air. He ought to have indicated the nature of the field just below the surface in the sea or earth, as well as to show the refraction of the lines of force at the surface.

[11] J. Zenneck, "Ueber die Fortpflanzung ebener elektromagnetische Wellen langs ebenen Leiterflache und ihre Beziehung zur drahtlosen Telegraphie," *Ann. der Physik*, vol. xxiii., p. 846, 1907. This paper was freely translated, with expository notes by J. A. Fleming, entitled "The Function of the Earth in Radio-telegraphy." See *Engineering*, June 4 and 11, 1909.

attenuates much less fast than a pure Hertzian wave and can travel round the curvature of the earth quite easily.

On the whole, we may say that the theory, as given by Zenneck and Sommerfeld, is a valuable attempt to bridge over the very serious gap in our knowledge of the reasons for certain well-ascertained facts in radio-telegraphy. Nevertheless, there are still unexplained difficulties.

Another unsolved problem in radio-telegraphy is the explanation of the effects of the atmospheric conditions and daylight upon it.

The suggested explanations are in many respects imperfect. In the earliest days of radio-telegraphy it was found that atmospheric electric discharges produced irregular and false signals, which sometimes greatly interfered with working. These were more objectionable at the time when the receiving instrument was a coherer of some kind associated with the Morse printer. Nowadays, when the reception is by telephone, it is usual to have the spark frequency at the sender high enough to give a shrill note in the telephone. The receiving operator can then distinguish, to a great extent, between the clear musical note of the right signals and the lower squeaks or grunts in the telephone due to atmospheric discharges. Nevertheless, at certain times and in certain regions the so-called atmospherics present serious obstacles to radio-telegraphic communication.

When we turn to the effect of sunlight on the propagation of radio-telegraphic waves, which was discovered and described by Mr. Marconi in 1902, we find that even after ten years we are still, intellectually speaking, very much in the dark as to the reason for this daylight effect.

The first observation made by him in 1902 was that by night signals could be received over sea from the Poldhu station at a distance of 2099 miles, whereas by day the same kind and type of signal ceased to be detectable at about 700 miles; also that at the time when the sun rose over the sending station the signals at 700 miles' distance quite quickly became very weak.[12]

Of recent years he has noticed that in the morning or evening, when the boundary between light and darkness occurs, about half-way across the Atlantic signals sent across become weak.

Also he has noticed that in sending with a coupled transmitter radiating waves of two wave lengths, whereas the longer wave length is the one generally received, there are certain periods at sunrise and sunset when the shorter wave gives the best signals.

It has also been pointed out, both by Mr. Marconi and G. W. Pickard, that soon after the time of sunrise at the sending station there is a very pronounced decrease in the strength of the signals received a few hundred miles', or at some considerable distance from a power station, but that after sunrise there is a partial recovery of strength. There is also a gradual rise in the strength of the signals soon after sunset, and a very pronounced maximum value after or about midnight. An interesting curve has been given by Prof. Pierce in his book on "Wireless Telegraphy," p. 135, taken from Pickard's observations showing the general variation of the strength of received signals at a distance of 600 miles from the Marconi station at Glace Bay during the hours of the day and night. It appears that the current in the receiving telephone at midnight was about thirty times greater than by day. Confirmatory observations have been published by the Telefunken Co.

[12] See G. Marconi, Proc. Roy. Soc. Lond., June 12, 1902. A note on the effect of daylight upon the propagation of electromagnetic influences over long distances.

Two theories have, so far, been proposed to explain this effect:—

1. The original suggestion of Mr. Marconi (which has been tentatively adopted by Prof. Zenneck) was that it is due to the effect of light in discharging the sending antenna, so that it does not reach at each oscillation such a high potential by day as in darkness.

2. The theory that the daylight effect is due to the ionisation of the air by sunlight giving it increased conductivity, and so producing absorption of the electric waves.

Neither of these theories seems to meet all the facts. If the daylight effect were an action of light on the sending antenna alone, it should be produced independently of the distance of the receiving station, whereas it is essentially a cumulative or long-distance effect.

Again, so far as measurements of the electric conductivity of air have been made, they do not give support to the theory that the daylight effect is due to air conductivity produced by ionisation, because measurements of this conductivity show it to be too small to account for the observed wave attenuation.

Prof. G. W. Pierce has made calculations which show that the air conductivity would have to be 100,000 times greater than it actually is to account for even a part of the observed effect at 3000 km. distance.

Prof. Zenneck also agrees that atmospheric conductivity by ionisation cannot account for the phenomena.

Let us, in the first place, consider theoretically the propagation of an electromagnetic wave through a medium possessing dielectric constant (K) and conductivity (σ).

It is quite easy to obtain an expression for the absorption coefficient of such a medium. Starting from the Maxwellian equations as above, we have the quantity denoted by k on a previous page defined by the equation—

$$k^2 = \frac{\mu K p^2 + j4\pi\mu\sigma p}{c^2},$$

since k is a complex, it can be represented by $k = \alpha + j\beta$.

Hence we have—

$$\beta^2 = -\frac{\mu K p^2}{2c^2} \pm \sqrt{\frac{16\pi^2\sigma^2\mu^2 p^2}{4c^4} + \frac{\mu^2 K^2 p^4}{4c^4}},$$

and if $\frac{\sigma}{pK}$ is a small quantity, as it is when the conductivity is small and the frequency $p/2\pi$ is large, we have then—

$$\beta = \frac{2\pi\sigma}{c\sqrt{K}}.$$

If we consider a plane wave the amplitude of which varies as $\epsilon^{j(kx-pt)}$, it attenuates in amplitude to $1/\epsilon$ of its initial value in travelling a distance—

$$\frac{1}{\beta} = \frac{c\sqrt{K}}{2\pi\sigma}.$$

If ρ is the resistivity in ohms per c.c., then $\rho = (9 + 10^{11})\sigma$, and we have—

$$\frac{1}{\beta} = \frac{\rho\sqrt{K}}{60\pi}.$$

We can therefore determine at once the absorption effect of any conducting dielectric of which the resistivity in ohms per c.c. and the dielectric constant are known. Thus, supposing the dielectric constant is 9, and the resistivity 500 megohms per centimetre cube, the value of $1/\beta$ would be nearly 80 km., or fifty miles. This is, then, the distance in which the wave amplitude would be reduced to about one-third of that at the origin. It is clear, therefore, that to propagate waves for any considerable distance through the earth's crust the specific resistance would have to be as high as 1000 megohms per c.c. Also it is evident that unless the resistivity of the air as produced by ionisation is less, say, than 20,000 megohms per c.c., or considerably less than 10^{20} electromagoetic units, the ionisation cannot be the cause of the daylight absorption.

I believe no one has observed so low a resistivity for air near the earth's surface, or even a thousand feet up, as 10^{19} C.G.S. electromagoetic units per c.c. The point, however, requires further investigation.

On certain assumptions this atmospheric resistivity can be determined by elevating a captive balloon to the required level by a wire, and measuring the potential of the balloon when the wire is insulated, and also the current flowing through the wire when the wire is earthed. The ratio of the current in amperes to the potential in volts gives us the total conductivity S of the air. If C is the electrical capacity of the balloon, and if σ is the conductivity of the air, then it can easily be shown that $S=4\pi C\sigma$ (see J. A. Fleming, "Principles of Electric Wave Telegraphy and Telephony," second edition, p. 725). Accordingly $\rho=4\pi C/S=4\pi CI/V$, where I is the total electric current flowing along the wire to the earth, and V is the potential of the balloon.

Some useful measurements of this kind made by Messrs. A. J. Makower, W. Makower, W. M. Gregory, and H. Robinson, in 1910 ("An Investigation of the Electrical State of the Upper Atmosphere made at Ditcham," see Quarterly Journal of the Royal Meteorological Society, vol. xxxvii., October, 1911) showed that the total resistance from a certain kite at a height of 1400 ft. on a certain day was 1000 megohms. Assuming a kite capacity of 100 electrostatic units, this corresponds to a resistivity of the air equal to $12{\cdot}5\times10^{11}$ ohms, which seems rather small. A plane electric wave would, however, have to travel nearly 60,000 km. in the air to have its amplitude reduced to 1/E. Hence even this conductivity is not enough to account for the observed attenuation by daylight of long radio-telegraphic waves.

Unless, therefore, there is very much greater atmospheric conductivity than one billionth of a mho (1 bimho) per c.c. at or about 1000 ft. or so above the earth's surface, it does not appear as if air conductivity caused by ionisation due to ultra-violet light could account for the diminished amplitude of radio-telegraphic waves during daytime.

The careful measurements of the air conductivity at various heights, and at various hours of the day and night over sea and land, would give us valuable data for further testing this matter.

Sommerfeld suggests that the daylight reduction is due to the increase in the value of the coefficient k for the air by the production of conduction due to ionisation. The effect of this is to increase the value of the "numerical distance," and therefore to reduce the intensity both of the surface and the space waves. He supports this view by an observation made by Ebert, who states that he measured the conductivity of the air in brightest sunshine at a height of 2500 m. during a balloon ascent and found it to be twenty-three times greater than at the ground level.[13]

It is possible that some part of the effect may be due to actions taking place quite close to the sending antenna. This view may be supported by the interesting observations made during the nearly total solar eclipse on April 17 last, on the effect of the temporary diminution of daylight on the strength of radio-telegraphic signals.

[13] See *Ann. der Phys.*, vol. v., p. 721, 1901.

Whilst visiting the Eiffel Tower station at Paris, Commander Ferrié, who is in charge of this station, informed me a slight increase in the strength of the signals at distant receiving stations had been noticed at the time of greatest observation of the sun at Paris.

Also in Denmark, Mr. H. Schledermann stated in a letter to *The Electrician* that observations made between the Royal Dockyard station in Copenhagen and the Blaavands Huk Lighthouse on the North Sea, at 300 km. distance, showed that during totality the signal strength was increased.

Also in England, Dr. Eccles noted an increase in the strength of atmospheric strays and signals from Clifden observed in London during greatest obscuration. These observations show that even a partial diminutioo of the sun's light is sufficient to increase the strength of radio-telegraphic signals, possibly by an action on the air between the stations, and especially on that near the transmitting station.

I suggest that it would be well worth while to erect temporary transmitting stations on and off the line of totality during the future total solar eclipses, for the purpose of observing the effect on radio-telegraphic signals sent out from them to other receiving stations.

Another possible explanation of this daylight diminution has, however, occurred to me which I should like to submit to you. It is well-known that sound is better heard when the wind is blowing from the source to the observer than when it blows in the opposite direction. It is also known that there are curious vagaries in sound transmission whereby loud sounds are heard sometimes better at great than at short distances. These effects were explained by Sir George Stokes as due to the fact that the velocity of sound is greater when moving with the wind than against the wind. Now, owing to friction and other causes, the velocity of the wind is generally greater at a height above the earth's surface than at the ground level. Hence, if a sound wave is travelling outwards from a centre against the wind, the upper parts move more slowly than the lower parts of the wave front, and hence the ray direction is tilted up and the sound passes over the observer's head.

The suggestion I venture to make is that when the upper layers of the air are ionised, the ions act as condensation nuclei for water vapour, and the presence of these numerous water spherules gives the upper air a larger dielectric constant.[14] Therefore an electric wave moves more slowly in it than in non-ionised air. Hence, if a plane wave is moving parallel to the earth's surface and the upper layers of air are ionised by light, the greater velocity of the wave front at the lower levels causes it to slope backwards and the direction of the ray is elevated, so that it may pass over above the receiving antenna and not affect it.

Accordingly, if in the upper region of the air the ionisation of the air by ultra-violet light increases the dielectric constant so as to retard slightly the wave velocity, the wave front would be tilted backwards and at long distances the waves might pass so far above the receiving antenna as to weaken very greatly the signals.

This tilting up of the ray will occur when the ionisation of the upper air has taken place over a part of the interval between the stations. It will be most pronounced when the greatest difference exists between the dielectric constant at the earth level and that at the level a few miles up in the air. At very large distances, say 2000 miles, an extremely small

[14] See Sir J. J. Thomson, "Conduction in Gases," p. 217, who says that air exposed to ultra-violet light may be regarded as full of extremely minute drops of water.

difference in the dielectric constant of the air at low and at high levels would be sufficient to give the wave front a sufficient tilt to make the waves pass far above a receiving antenna 200 ft. high, and so weaken immensely the received signals because the effect is cumulative, and noticeable therefore only at very great distances. As an experimental contribution to the subject I have made some preliminary observations on the dielectric constant of air filled more or less with damp steam or warm mist. A tubular condenser was constructed of such kind that steam from a small boiler could be blown between the tubes, and the tubes were so supported that the condensation of the steam could cause no loss of insulation. The electrical capacity of this condenser was determined carefully by the Fleming and Dyke capacity bridge, using a telephone as a detector, and alternating currents having a frequency of 2760.[15] Employing all necessary precautions, and comparing the dielectric constant taken as unity of air nearly saturated with water vapour, with air having water globules or damp steam in it, we found that the dielectric constant of air filled with water spherules varied from 1·026 to 1·004, according to the amount of damp steam present in the space. In other words, an electric wave would travel more slowly in the steam-impregnated air than in the ordinary saturated air in the ratio of 980 to 1000, or 998 to 1000, or anything between these limits.

If, then, we consider a plane electromagnetic wave travelling with plane vertical and its lower end in ordinary air and its upper end in air containing minute water spherules, the upper end would travel more slowly than the lower, and the wave front would acquire a backward tilt sufficient, in a distance of a few hundred miles, to carry the wave right above an ordinary receiving antenna. If the ionisation of the upper air by ultra-violet light results in the production of condensation nuclei, which condense water vapour round them, then it is highly probable that the upper levels of the air have a slightly greater dielectric constant than the lower, and a difference of even a very small fraction of 1 per cent. will be cumulative in its action on the wave in giving the wave front a backward tilt in travelling over long distances.

Mr. Marconi states that over the Atlantic he has found the maximum daylight effect to occur when the shadow boundary was about half-way across the Atlantic, the sending station being in daylight and the receiving station in darkness. I think the well-known "sunrise nick" in the signal intensity curve is due to the fact that the effect is at a maximum when the greatest difference exists between the state of the upper air as regards ionisation and that near the earth. Later in the day convection currents arise to churn up the air and bring it more into a homogeneous condition, which, whatever may be the state of ionisation, is unproductive of any tilt in the wave front.

It has been frequently suggested that an explanation of long-distance radio-telegraphy may be found in the reflection of the electromagnetic waves at the under surface of a layer of ionised air in the upper atmosphere. No proof, however, has been given that this hypothetical layer of ionised air has a sufficiently defined surface to cause wave reflection. Hence, it is improbable that anything like copious reflection of long electromagnetic waves could take place at the under surface of a layer of ionised air producing an inverted mirage effect. This point, however, is one open for discussion. It is true that refraction may produce a change of ray direction which simulates reflection, as in the case of the phenomenon of the mirage. In this case the intense heat of the earth expands the layer of air next to it, and lowers its refractive index. Hence, the lower end of a plane wave of obliquely incident light travels faster than the upper end, and may do so to an extent sufficient to swing the ray right round, as if it were reflected from the layer of heated air. For a similar effect to occur with radio-telegraphic waves, it would be necessary for the upper end of the wave front to travel much *faster* than the lower end. In other words, the upper end must be in a region of less dielectric constant than the lower end.

Since the above remarks were put in type, a valuable paper has been published by Dr. Eccles (see Proceedings Roy. Soc., vol. lxxxvii. A, p. 79, 1912, on the diurnal variations of electric waves occurring in nature, and on the propagation of electric waves round the bend of the earth), in which a theory is developed of electric wave propagation in ionised air. He gives a mathematical proof that under certain assumptions as to the mass ot these ions the wave velocity would be increased as compared with that in un-ionised air, and hence that a plane vertical wave front travelling with lower end near the earth and upper end in air more or less ionised by sunlight would be caused to lean forward by the increased velocity of its upper end. Hence he proves that, according to wave length and circumstances, the wave may be better able to follow round the earth's curvature, or may be prevented from doing it.

On this basis he has developed a theory of long-distance radio-telegraphy and of the inhibition of daylight upon it. The chief criticism to which I think his theory is open is that he assumes that the dielectric constant of the air is unaffected by the ionisation or condensation of water vapour on these ions. This is not absolutely certain. We know that in the case of ionisation, such as dilute solutions in a state of ionisation, such as dilute solutions of metallic hydrates in water, the dielectric constant of the solvent is considerably increased. As a rule, anything which increases conductivity in a dielectric increases also the dielectric coefficient. Hence ionisation may do so in the case of air. If the dielectric constant (K) is increased by ionisation, then in the expression given by Dr. Eccles for the wave velocity that velocity may be more reduced by this increase in K than it is increased by the presence of the ions.

It would seem, therefore, most necessary to settle by experiment whether the wave velocity is increased or diminished by the presence of the inns due to ultra-violet light before we can base a theory upon the constancy of the dielectric coefficient.

There is no doubt, however, that the earth's atmosphere contains something which acts at times towards radio-telegraphic waves like a fog or mist towards light waves.[16]

There are also occasions of unusual transparency when waves of 300 or 600 metres in length seem to travel round the world in an extraordinary manner. Ships provided with the ordinary ship transmitters and receivers occasionally pick up signals sent 1000 miles away. This is not due to special operative skill but to a temporary transparency of the atmosphere to radio-telegraphic waves.

The next question to which I should like to direct attention is to the present state of the theory of directive antennæ. I need not go very fully into the early history. Mr. Marconi pointed out in 1906 the special qualities of an antenna consisting of a long wire arranged so that part is vertical, but the greater

[15] For a description of this bridge and method of using it, see the paper by J. A. Fleming and G. B. Dyke, on the power factor and conductivity of dielectrics for alternating electric currents of telephonic frequency and at various temperatures, Journ. Inst. El c. Engineers, 1912.

[16] Interesting observations have been made on this matter by Admiral Sir Henry Jackson, F.R.S. See Proc. Roy. Soc., Lond., vol. lxx p. 254, 1902.

part horizontal, and that radiation takes place most energetically in the opposite direction to which the free end of the horizontal wire points.[17] Also by the law of exchanges a bent antenna which radiates unequally absorbs unequally in different azimuths. The question is as to the explanation of the action of this bent antenna.

In 1906, starting from a suggestion by Sir Joseph Larmor, I gave a theory based on the view that the bent antenna is equivalent to a combination of an open and closed circuit and assumed the earth to be a perfect conductor. The objection has been raised to this theory that it implies that the directivity should fall off with distance.

Experiments have not yet been made, so far as I am aware, on a sufficiently large scale and at sufficiently great distances to settle this point, and the experimental problem is undoubtedly complicated by the effect of the nature of the soil surface over which the waves travel in different dielectrics or regions. Nevertheless, Mr. Marconi's experiments show that the directivity persists for several hundred miles. Recently the problem has been discussed by H. von Hoerschelmann in the *Jahrbuch der Drahtlosen Telegraphie* (see vol. v., p. 15, 1901). According to his theory, the effect of a bent antenna is entirely due to vertical electric currents which are produced in the earth just under the horizontal part of the bent antenna. Hence the directivity depends on the conductivity of that region of the earth.

Starting from the same system of equations as Sommerfeld, he obtains expressions for the vector potential or Hertzian function which show that the function which determines the vertical field in the earth and in the air is dependent on the azimuthal angle, in such manner that there is no directivity if the earth is a perfect conductor, but that if the earth has a finite conductivity under the antenna then an unsymmetrical radiation takes place and the directivity, once created, persists even though the waves travel out later on over a good conducting surface. The mathematical work in Hoerschelmann's paper needs careful consideration by pure mathematicians to test whether the transformations of the Besselian functions he employs are valid and his analysis correct. He points out that as a consequence of his theory a bent antenna situated over a sea surface should not have the same degree of directivity as one situated over a poor conducting soil. These conclusions could easily be checked experimentally.

The general result of all the theoretical investigations of Zenneck, Sommerfeld, and Hoerschelmann is to show that the function of the earth in radio-telegraphy is by no means confined merely to guiding a space wave, but that it fulfils a most important function in assisting to create surface waves and in permitting earth currents which have directive effect. Recent experiments with antennæ laid on the ground or under the ground by Dr. Kiebitz have directed attention afresh to the matter, although many of Kiebitz's results seem only a repetition of those obtained by Marconi in 1906 with antennæ laid on the ground or a little above it.[18]

Kiebitz used as receiving antennæ wires carried on insulators placed in ditches about one metre deep. The ends of the wires were earthed through condensers. The receiving appliance was at the centre.

By such antennæ properly oriented he found he could receive signals from all the principal radio-telegraphic stations in England, France, and America.

There is no need to assume that these received waves are propagated through the deep strata of the earth. The effects are exactly what might be expected from waves travelling over the surface.

The chief interest of Kiebitz's experiments lies in the confirmatory proof they give that an elevated antenna is not necessary for *reception*. On the other hand, for long-distance *transmission* an elevated aërial wire or one raised above the earth is requisite.

The chief problem yet to be faced in connection with sending antennæ is to find a form of antenna which will radiate a large power, say, 100 to 500 kw., at a relatively low frequency or long wave length consistently with high antenna efficiency.

There is room for an immense amount of research yet on improved forms of antenna. When we consider that the function of a sending antenna is something like that of a gas mantle or gas-fire radiator, viz. to transform into radiation of desired wave length as large a fraction as possible of the supplied energy, and remember what has been done in the corresponding luminous problem, it is easy to see that countless questions of great practical value in connection with antennæ for radio-telegraphy remain unsolved.

The ingenious methods of directive telegraphy due to Bellini and Tosi deserve mention, and suggest that, in the case of wireless plant erected on ships means for instantly locating the direction of the arriving waves is a matter of the greatest importance. Although the practical problem is to some extent solved, there is room for further invention in connection with it.

We can scarcely leave this discussion without some mention of the state and prospects of wireless telephony.

The essential condition of success in transmitting speech is the possession of means for creating undamped oscillations or alternating currents a frequency not less than 20,000. When the Poulsen arc generator was first introduced it was hailed as a solution of the problem, but practical experience has shown that whilst experimental feats can be performed with it, it has not the simplicity and ease of manipulation required for commercial work. The modification recently introduced by Mr. E. L. Chaffee, consisting of a copper-aluminium arc in damp hydrogen, the arc being formed between two closely adjacent plane surfaces, appears to be an improvement. The practical solution seems, however, to be in the perfection of some simple, easily managed form of high-frequency alternator. The ingenious inventions of Goldschmidt in utilising the properties of the polyphase motor to increase frequency have been developed by the Lorentz Company of Berlin, and seem likely to result in the production of a practical form of extra-high-frequency alternator suitable for radio-telegraphy and radio-telephony in a practical high-frequency machine.

In addition to the generator, inventors have wrestled with the difficulties of making a microphone transmitter which shall be able to carry a large current without heating. To conduct wireless telephony over any distance we have to modulate in accordance with the wave form of the speaking voice a very large antenna current. The problem has to some extent received solution in the liquid microphone of Majorana, the relay microphone of Dubilier, and a recently invented heavy-current microphone of Rühmer.

We seem to be, however, on the track of mechanical means for generating undamped oscillations and microphonic means for modulating them, and wireless telephony is therefore even now a practical matter

[17] See G. Marconi on methods whereby the radiation of electric waves may be mainly confined to certain directions, etc., Proc. Roy. Soc. Lond., vol. lxxvii., p. 413, 1906.

[18] See Dr. F. Kiebitz's "Recent Experiments on Directive Wireless Telegraphy with Earthed Antennæ" *The Electrician*, March 8, 1912, vol. lxviii., p. 868.

for a few hundred miles of distance. It is quite within possibility it may yet be conducted across the Atlantic.

As regards other inventions, we are still in want of more simple means for recording telegraphic messages. Since the coherer fell out of use the reception is mostly conducted by ear. Somewhat elaborate photographic methods, suitable for large land stations which employ the Einthoven string galvanometer, have been introduced, but what is still required is a means of calling up the operator and of recording the message on board ship which is at least as sensitive as the telephone plus the human ear, for ordinary shipboard communication.

The receiver current is, however, very small, and available power is at most a few microwatts in the form of a current of a few microamperes.

There are, therefore, innumerable practical and scientific problems in connection with radio-telegraphy which await solution. These require mathematical, physical, and radio-telegraphic knowledge of a high order to overcome them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. F. R. MILLER has been appointed lecturer in physiology in McGill University, Montreal.

THE bequests provided by the will of the late Mr. Thomas Bartlett, of Liverpool, include one of 20,000*l.* to the University of Liverpool for the purpose of establishing scholarships of the value of 40*l.* per annum for engineering students.

AT its meeting on October 28, a letter was read by M. Liard to the council of the University of Paris from Mr. Andrew Carnegie, offering to the University the last 4000*l.* necessary for equipping the new Institute of Chemistry, in course of erection in the Rue Pierre Curie, Paris.

THE Royal Agricultural College, Cirencester, having been recognised as the centre for advisory work in forestry in the counties of Cornwall, Devon, Somerset, Gloucestershire, Wiltshire, Monmouthshire, Herefordshire, and Worcestershire, Prof. H. A. Pritchard has been appointed technical adviser, and Mr. A. D. Hopkinson lecturer in forestry and forest mycology. The vacancy caused by the promotion of Prof. R. G. Stapledon to the post of research botanist at University College, Aberystwyth, has been filled by the appointment of Mr. C. B. Saunders (London), who has for some years been lecturer in biology at Holmes Chapel Agricultural College.

PROF. A. KULIABKO, of the University of Tomsk, Siberia, informs *The Times* of the inauguration at Tomsk, on October 20, of an institution, founded by the munificence of Peter Makoushin, which aims at the instruction on a large scale of the people of Siberia. The institution in question is called the House of Science, and is meant to be a popular university, where anyone may obtain instruction, from the elementary to the secondary standard, free of charge. It includes also a section for instruction of the kind usually given at universities. The institution will give hospitality to the conferences of teachers in elementary schools; it will contain a library to be used free of charge; special evening classes will be held; while the dissemination of knowledge of sanitation and hygiene will have a leading place in the programme. A museum of practical knowledge and many other means of instruction will render the Tomsk House of Science a boon to Siberia.

THE calendar of the University of Sheffield for the session 1912–13 provides another striking example of the efforts being made by the authorities of modern universities to keep in close touch with the educational needs of the industrial centres in which they are located. At Sheffield, for instance, in addition to the comprehensive faculty of pure science, there is a faculty of applied science, in which, under suitably arranged conditions, the degrees of bachelor, master, and doctor of engineering, or bachelor, master, and doctor of metallurgy, can be secured. Students who for various reasons do not graduate in the faculty of applied science may, by attendance at day or evening classes, on complying with the regulations, secure an associateship in engineering or in iron and steel metallurgy. In mining and architecture, too, diploma courses have been arranged. It is interesting to note that arrangement has been made with the Imperial College of Science and Technology by which the University of Sheffield is recognised as being in association with the Imperial College for such of their students as may desire to specialise in the study of the metallurgy of iron and steel for the associateship of the Royal School of Mines. To meet the special needs of women a two-years' course of work in the University and the Sheffield Training College of Domestic Science has been inaugurated, and a diploma in domestic science is awarded to successful students at the end of the course. While the applied subjects are encouraged so successfully, the other departments of university work are in no way neglected, and the faculties of arts, medicine, law, and so on, are equally complete.

THE council of King's College, London, has received from the Rev. A. C. Headlam the intimation of his intention to resign the office of principal and dean of the college at the end of the present year. In the House of Commons on Monday, Sir E. Cornwall asked the President of the Board of Education whether his attention had been directed to the letter from the Rev. A. C. Headlam to the Bishop of London, dated October 11, in which Dr. Headlam alleged, as one of the reasons for his resignation, peremptory and arbitrary action on the part of the Board in requiring the removal of the college to another site; and whether he would state on what ground the Board had made such requirement without first consulting either the college or the Senate of the University on the subject. In reply, Mr. J. A. Pease said:—"I have seen the letter referred to. The Board have expressed their concurrence with the opinion of the Advisory Committee on University Grants that the present site of King's College does not admit of such extension as will enable the college to take its proper place in the University. The Board have indicated their readiness to receive a deputation from the Senate of the University of London upon the question of site, but apart from this they have taken no action in the matter, and they have made no requirement. There is no foundation whatever for the charges of discourtesy and peremptory and arbitrary action contained in the letter referred to. The Board and their Advisory Committee have no intention of interfering with the conditions of freedom and independence which are necessary to enable a university to perform its proper functions."

THE Government of India recently decided, we learn from *The Pioneer Mail*, that the time had come to endeavour to connect Indian educational institutions more closely with business firms, railways, and other employers of labour, to inquire how the former can better meet the requirements of the latter, and to point out the way to further employment of Indians in them. For this inquiry Colonel Atkinson and Mr. Dawson were selected as having special practical experience. They have completed their investigations and issued a report. The great need which the report emphasises is that education should be made more practical, not only in technical institutes, but also in primary and secondary schools. Among special recommendations made in the report, the following may be noted:—(1) That the present system under which State technical scholarships are granted to Indians for education in technical institutions in England and elsewhere should be discontinued. That suitable stipends should be granted to Indians who have completed successfully their theoretical and practical education in India to enable them to be apprenticed for practical experience with firms of repute in England. (2) That minor technical institutes should be placed under the control of one central institution in each province. (3) That the education of skilled workmen should only be carried up to vernacular reading, sufficient elementary arithmetic for accounts and sufficient knowledge of drawing to understand a dimensioned sketch. (4) That the most promising method of training skilled workmen is to establish manual training schools for children in big centres and near big workshops; the boys to be apprenticed in workshops from the ages of twelve to fourteen years. During the apprenticeship they are to be obliged to attend afternoon classes to complete their literary education, and finally to obtain some theoretical knowledge of their work.

SOCIETIES AND ACADEMIES.

LONDON.

Institution of Mining and Metallurgy, October 17.—Mr. Edward Hooper, president, in the chair.—J. W. **Ashcroft**: The flotation process, as applied to the concentration of copper ore at the Kyloe Copper Mine, New South Wales. As a consequence of the oxidised ore at this mine being practically exhausted, the original method of treatment was found to be inadequate, and the present management introduced an experimental flotation process with the view of obtaining a better recovery and higher grade concentrate. As first planned, the plant for this flotation process was divided into a grinding section and a flotation section, and the paper deals at length with the defects which manifested themselves in the first experimental stages, and with the rearrangements dictated by experience. The chief defects were the excessive amount of oversize in the feed of the stirring boxes, the excessive dilution of the pulp, the irregularity of the overflow from the flotation chambers due to the irregularity of the feed and of the speed of the impellers, and a want of proper means to control the supply of oil. To remedy these, the grinding pans were altered to the positive feed type, and were arranged to discharge on to revolving screens, so as to keep the feed to the flotation machine more even in size; the pulp thickener was moved and placed between the screens and the flotation machine so as to keep an even feed to the stirring boxes and to regulate its density; the flotation machine was controlled by a sensitive governor to keep the speed of the stirrers constant, and an apparatus was devised to secure an even flow of oil. The results of this reorganisation proved satisfactory, and this paper gives interesting details of costs of operation, &c., and some observations on the successful working of the process.

Physical Society, October 25.—Prof. C. H. Lees, F.R.S., vice-president, in the chair.—Prof. H. **Nagaoka** and T. **Takamine**: The constitution of mercury lines examined by an echelon grating and a Lummer-Gehrcke plate. The authors have photographed the principal lines of mercury, using an echelon spectroscope crossed by a Lummer-Gehrcke plate. They find that the 5790 line consists of eight, the 5769 line of four, the 5461 line of nine, the 4359 of eleven, the 4078 of six, and the 4047 of seven components, the positions of which in general agree with those found by recent observers. They point out a simple relation between the distances of the components from the principal line in each case, and a further relation between the quotient of each of these distances by the wave-length of the principal line, which holds for all the lines.—Prof. H. **Nagaoka**: Note on the mutual inductance of two coaxial circular currents. Methods are given for the rapid calculation of the mutual inductance of two coaxial circular currents. Maxwell's first formula is converted into theta-functions, and then expanded in a Jacobian q series. The logarithmic values of this series for various values of q have been tabulated in a previous paper by the author. When the circles are near one another a series for M is given in terms of q_1, where q_1 is the complement of q. In this paper the author treats Maxwell's second formula in a similar way. A table of the values of these series found, computed to six decimal figures by T. Tishima, is given.—S. E. **Hill**: The absorption of gases in vacuum tubes. This paper is an account of experiments carried out to determine whether the absorption of gases caused by passing a discharge for some time through vacuum tubes is the result of a chemical action or is a mere physical absorption. In order to eliminate all electrode complications, the electrodeless discharge was used throughout. The bulbs examined were of soda, lead, Bohemia and Jena glass. The absorptions were noted at different pressures and curves plotted. Continued passage of a discharge causes a "saturation" effect in all the glasses. After two months none of the bulbs had recovered any of their absorptive power. That chemical actions are present is shown by peculiar deposits on the necks of the bulbs, these being unfortunately too small for analysis. The conclusion arrived at is that the disappearance is not due to physical absorption, but to definite chemical action.

MANCHESTER.

Literary and Philosophical Society, October 15.—Mr. Francis Jones, vice-president, in the chair.—A. **Adamson**: An apparatus which can be used for the exact trisection of an angle.—D. M. S. **Watson**: The larger Coal Measure amphibia. The author described the skulls of *Loxomma Allmani* and *Anthracosaurus Russelli* (Pteroplax), now preserved in Newcastle-on-Tyne Museum. The skulls had been previously described by Embleton and Atthey, but the important structure of the palate had not been made out. This was described in detail, and compared with that of other Carboniferous amphibia. It was shown that a solid, bony palate, with an articular connection between the large pterygoids and the basisphenoid was characteristic of the group. The palatines and prevomers bear large teeth with a characteristic mode of replacement. The pre-maxillæ and maxillæ are confined to the margin of the palate, and bear smaller teeth. The large vacuities of the later Stegocephalia are absent. The skulls present remarkable resemblance to those of Seymouria and also of the Crossopterygian fishes. The relations of the quadrate were clearly determined, and seemed to indicate that the tetrapod skull was not autostylic in the ordinary sense.

PARIS.

Academy of Sciences, October 28.—M. Lippmann in the chair.—E. **Jungfleisch**: Inactive and racemic dilactylic acids. The crude acid arising from the interaction of sodium ethyl lactate and ethyl α-chloropropionate is neutralised with magnesium hydroxide. The inactive magnesium salt, being much less soluble in hot or cold water than the racemic form, separates first. The crystallographic properties of these salts, and of the corresponding acids are described.—Edouard

Heckel: Cultural bud mutation of *Solanum immite*. The mutation of the tubercles was obtained after only one year's culture.—A. **Schaumasse**: The provisional elements of the comet 1912*b*.—G. **Fayet**: Probable identity of the new comet 1912*b* with the Tuttle periodic comet. By its approach to Jupiter the Tuttle comet would appear to have undergone perturbation which would account for its advance by eighty-six days.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the first quarter of 1912. Observations were possible on sixty days, and the results are summarised in three tables, showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—M. **Borrelly**: Observations of the Gale comet (1912*a*) made with the comet-finder at the Marseilles Observatory.—A. **Petot**: Certain conjugate systems.—Maurice **Gevrey**: Remarks on certain theorems of existence. A discussion of a class of functions previously considered by Holmgren.—Georges **Rémoundos**: The theorem of Picard and multiform functions.—A. **Guillet** and M. **Aubert**: An electrometric spark-gap consisting of two conducting spheres. Calculation of the charges, the potentials, the mutual action, and the disruption.—Ch. **Féry**: The principle of a new method of measuring the velocity of light. An application of the rotating mirror method, in which an electrically-controlled tuning-fork measures the angular velocity of the mirror.—A. **Boutaric** and C. **Leenhardt**: Cryoscopy in decahydrated sodium sulphate. Measurements of the molecular lowering of the freezing point with urea as the solute gave 32·05 as the value of the Van't Hoff constant; the figure 32·08 was obtained by the application of the usual formula to the latent heat of transformation of sodium sulphate.—Paul **Job** and Marcel **Boll**: The photochemical hydrolysis of very dilute solutions of chloroplatinic acids.—M. **Hanriot**: The tempering of metals. The author extends the meaning of a tempered metal to any metal which, after sufficient annealing, changes its physical properties, chemical changes being excluded.—Daniel **Berthelot** and Henri **Gaudechon**: The different modes of photochemical decomposition of glucose and galactose according to the wave-length of the radiations. A comparative study of the quantity and nature of the gases evolved from glucose and galactose in solution under the influence of ultra-violet light of three different wave-lengths.—H. **Baubigny**: Study of the double sulphites of mercury and the alkalis. The decomposition of solutions of the double sulphite of mercury and sodium differs from that of the corresponding salts of silver and copper in that no trace of dithionic acid is produced.—Maurice **Lanfry**: The action of hydrogen peroxide upon dithienyl-thiophene.—A. **Guyot** and A. **Kovache**: The action of formic acid upon the triarylcarbinols. All triarycarbinols, heated with a mixture of formic acid and a little dry sodium formate, are quantitatively reduced to the corresponding hydrocarbon, the amount of carbon dioxide produced being an exact measure of the reduction. The generality of the reaction is shown. André **Meyer**: Some new derivatives of phenylisoxazolone.—Marie **Korsakoff**: Researches on the methods for the estimation of saponines.—Leclerc du **Sablon**: The influence of light on the transpiration of green leaves and of leaves without chlorophyll.—M. **Ringelmann**: Calculation of the yield of small water channels in irrigation.—R. **Fosse**: Researches on urea. Urea is frequently present in the higher plants, although in very small proportions. It cannot be considered as proved that the urea is a physiological product of the plant cell.—Victor **Henri**, André **Helbronner**, and Max de **Recklinghausen**: A new, very powerful lamp for the production of ultra-violet light and its utilisation for the sterilisation of large quantities of water. The U-shaped lamp can be used on a 500-volt circuit, and requires 1150 watts, giving a candle-power of about 8000.—Em. **Bourquelot** and M. **Bridel**: Syntheses of glucosides of alcohols with the aid of emulsin. β-*iso*Propylglucoside and β-*iso*amylglucoside.—M. **Tiffeneau** and H. **Bosquet**: The rôle of caffeine in the diuretic action of coffee. Coffee loses the greater part of its effects on the renal secretions if the caffeine has been removed. Caffeine is the principal, if not the exclusive, agent of the diuretic action of coffee.—Robert **Odier**: Sensitised streptococcus and sarcoma.—B. **Sauton**: The mineral nutrition of the tubercle bacillus.—Max **Kollmann**: Some points on the anatomy of the male genital organs of Lemurs.

Registered as a Newspaper at the General Post Office.]

THURSDAY, NOVEMBER 14, 1912.

ELECTRONS AND THE ELECTROMAGNETIC FIELD.

Electromagnetic Radiation and the Mechanical Reactions arising from it. Being an Adams Prize Essay in the University of Cambridge. By Dr. G. A. Schott. Pp. xxii + 330. (Cambridge: University Press, 1912.) Price 18*s*. net.

PROF. SCHOTT'S original essay is, in this book, supplemented by a series of valuable appendices, which amply justify the delay in its publication. The work is deductive in plan; its foundations are the electromagnetic equations of Maxwell and Hertz, together with the Larmor-Lorentz expression for the mechanical force on a moving charge. The "retarded potentials" of the electromagnetic field are transformed so as to yield Schott's solutions, in the form of "modified Fourier integrals," and most of the calculations are performed from these as starting point. They lead simply, and with considerable mathematical rigour, to many results obtained by other writers; in particular, the "point laws" of Liénard and Wiechert are deduced, and are used to illustrate the general features of the electromagnetic field in a number of special cases. The exact calculations, however, are more readily executed with Schott's expressions, and various simple cases of motion of electrons are thus dealt with, as, *e.g.*, uniform or uniformly accelerated rectilinear motion. Periodic motions, such as uniform circular motion of a single electron, or of a ring of electrons, are also discussed. More complex cases, like pseudo-periodic or aperiodic motions, cannot be solved completely, but the distant field is approximated to. Specially interesting are the problems relating to the pulse theory of the X-rays, and the precessional motion of a ring of electrons, as applied to Ritz's theory of the Zeeman effect.

The velocities of the electrons are not restricted to be less than the velocity of light, chiefly because the mathematical expressions require no such condition (though the work is far simpler in the restricted case). It is pointed out that no experimental evidence, either way, has been brought to settle the question of the possibility of velocities exceeding that of light; if the Lorentz mass-formula were universally true, indeed, the question would be decided in the negative, but this formula has been verified (by Bucherer) only for velocities considerably less than that of light. Moreover, the theory of relativity, which is based on this formula and has proved useful in explaining aberration phenomena and the behaviour of moving optical systems, neglects the loss of energy by radiation from accelerated charges; this, however, becomes very important for velocities approaching that of light.

In the appendices several theorems are proved which lead up to an interesting discussion of the possible mechanical explanations of the electron. It is shown that the Lorentz deformable electron is more easily explained mechanically than the electrons of Abraham and others, as it only requires an invariable hydrostatic pressure of the æther over its surface to enable it to subsist. This pressure is estimated (p. 269) as 10^{25} atmospheres. Moreover, the mass-formula for such an electron is practically the only one which can be applied in the mathematical theory of the mechanical forces and the radiation.

For the mathematician the book abounds in problems and suggestions of interest and importance; especially does it clearly display the need for the cooperation of the pure analyst in the study of the summation and convergence of the difficult series and integrals which occur in its investigations. The physicist will, perhaps, find it rather tedious to unearth the physical conclusions (which are pointed out from time to time in the course of the work) from the mass of complicated mathematics in which these remarks are involved. The great value of the book would have been increased if the physical bearing of the results had been summarised in an extra chapter; this is done to a slight extent in the preface. A greater number of numerical calculations would also have been advantageous in giving a clearer grasp of the results, but the great labour required for such an undertaking sufficiently explains the omission.

THE LAND AND ITS LORE.

(1) *Common Land and Inclosure.* By Prof. E. C. K. Gonner. Pp. xxx + 461 + 5 maps. (London: Macmillan and Co., Ltd., 1912.) Price 12*s*. net.

(2) *Byways in British Archaeology.* By Walter Johnson. Pp. xii + 529. (Cambridge: University Press, 1912.) Price 10*s*. 6*d*. net.

(1) SCIENTIFIC studies of the history of land-holding have a peculiar importance at the present moment, when legislative innovations in ownership are so widely mooted on *a priori* grounds. By supplying valid inductions from the past, science here, as in other spheres, provides the statesman with a solid foundation for political principles, and a sure test for fallacious schemes.

The entire history of English agriculture, so far as it is connected with national progress and advance in civilisation, is bound up with "common" and inclosure, and the passage from the former to the latter. The land question, it is not too much to say, cannot be begun to be understood until this relation has been worked out.

"Common" in early times was "in entire contrast to the ideas associated with it in the present day. . . . Its existence now is taken as denoting the claims, somewhat vague and precarious, of the public as against those holding the land and engaged in its cultivation. But this finds no sanction in a time when . . . common was a result of a claim to land, and formed a necessary condition of its proper management. . . . The early rights of common were anything . . . rather than a general claim on the part of the public. . . . The common right was an essential part of agriculture, and it was only as, owing to changes in circumstances, this became less apparent, that casual profits and gains and the so-called rights of the poor, these latter being in many instances a trespass and not a right, came to be important."

Thus Prof. Gonner defines his subject. The history of the method of common and of the gradual progress of inclosure occupies two-thirds of the volume. The rest is devoted to the effects of the evolutionary change. Inclosure is part of "a wider economic movement." Its "beneficial effect on farming is undoubted . . . particularly in the increased utilisation of what is, after all, the distinctive agricultural wealth of England, rich grazing and dairy lands." Of particular importance is its connection with "the change whereby agriculture, from being a means of subsistence to particular families, had become a source of wealth to the nation." It is particularly interesting to the sociologist to note that rural population "did not vary with inclosure, and that this movement was not, at any rate, the main cause of the increase in poor relief expenditure."

Prof. Gonner has written an invaluable study, which is final, and should become a classic. No sociologist and no statesman can afford to ignore it.

(2) The author of "Folk Memory" devotes 400 pages to answering the question: In what ways may the church-fabric be regarded as the social centre of early English life? There is abundance of original observation, and in controverted matters, such as round towers, the author's judgment is eminently reasonable. For he treats these radiating paths of folklore—they are this rather than byways—from a wide sociological outlook. In "The Folklore of the Cardinal Points," and "The Labour'd Ox," he treats new ground. "The Cult of the Horse" is an interesting compilation of palæontological data and early English horselore. The "White Horse," and what amounts still to a tabu against eating horseflesh, receive illumination. Mr. Johnson believes that folk-memory is on the wane, since "the printed book and the daily newspaper . . . remove the need for its lawful exercise." It would be more scientific, perhaps, to regard the ultra-popular reactions to these modern influences as being themselves a new stage of folk-thinking and folk-memory.

A. E. CRAWLEY.

ENGINEERING HANDBOOKS.

(1) *Reference Book for Statical Calculations (Rapid Statics), Force-diagrams for Frameworks, Tables, Instructions for Statical Calculations, &c., for all Classes of Building and Engineering.* By Francis Ruff. Pp. 136; illustrated. Vol. i. (London: Constable and Co., Ltd., 1912.) Price 4*s.* net.

(2) *Les Nomogrammes de l'Ingénieur.* By Ricardo Seco de la Garza. Avec une Préface de Maurice d'Ocagne. Pp. xii + 195 + 85 plates. (Paris: Gauthier-Villars, 1912.) Price 12 francs.

(3) *Laboratory Instruction Sheets in Elementary Applied Mechanics.* By Prof. A. Morley and W. Inchley. Pp. v + 50. (London: Longmans, Green and Co., 1912.) Price 1*s.* 3*d.* net.

(4) *A Handbook on the Gas Engine.* Comprising a Practical Treatise on Internal Combustion Engines. By Herman Halder. Translated from the German and Edited by W. M. Huskisson. Pp. xii + 317. (London: Crosby Lockwood and Son, 1911.) Price 18*s.* net.

(5) *Concrete Costs.* Tables and Recommendations for Estimating the Time and Cost of Labour Operations in Concrete Constructions and for Introducing Economical Methods of Management. By Dr. Frederick W. Taylor and Stanford E. Thompson. First edition. Pp. xxii + 709. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1912.) Price 21*s.* net.

(1) THE usual graphical methods for determining the stresses in framed structures form the subject of this little book. With the exceptions of the wind pressure on roof trusses, the load on a framework column, and pressure upon retaining walls, the structures are subjected to symmetrical loads concentrated at the joints. Each form of roof, bridge truss, girder, or cantilever occupies a separate page, together with its reciprocal figure, the construction of the force polygons being described on the opposite sheet. There are some thirty examples of the usual forms of truss, covering the ordinary cases that occur in engineering practice. The method adopted of forming the reciprocal figures loses much by the notation employed, and is far less satisfactory

than Bow's notation, in which the spaces between the members of a structure are designated by a letter or numeral. The concluding third of the book contains a short dissertation on reinforced concrete (in which the ratio of the moduli of elasticity of steel to concrete is taken at the low value of 10), and this is followed by tables usually found in engineers' handbooks on the geometrical properties of structural shapes, such as moments of inertia. There are many blemishes due to imperfect translation, and we find such expressions as "10-fold security" for "factor of safety of ten." The translation does not extend to weights and measures, which are in the metric system.

(2) The preface to this volume is, for the most part, a reprint of remarks made by M. Maurice d'Ocagne, Ingénieur en chef des Ponts et Chaussées, at the Fourth International Congress of Mathematicians, in Rome, 1908. In this paper he defines the word "nomogramme," which is probably new to most English mathematicians, the nearest English equivalent being an abacus, known as an instrument for performing calculations by balls sliding on wires, which are still employed in Russia, China, and Japan. M. d'Ocagne has brought forward this system of graphical calculation by published researches extending over twenty-five years, and the author of this work employs the method for solving problems in military engineering, though many of the examples are of wider application, and are of extended use in the solution of equations of three or four (or more) variables. The interest in the work would therefore lie chiefly in the method as such, the particular applications of the method to the solution of equations used by the military engineer being of secondary importance, though, as a handbook for rapid calculation within the limits of the chosen field of utility, it would certainly serve a useful purpose to many. The reader will doubtless find himself constructing nomogrammes to suit particular problems of his own, and thus the work before us is extremely suggestive, and a fruitful stimulus to the use of a graphical method of varied application.

There are eighty-five nomogrammes in the work, each on a separate sheet and consisting for the most part of straight lines upon which divisions are marked. A loose celluloid sheet marked off in rectangular coordinates is provided for laying upon the nomogramme, and upon placing it in such a position that the known values of the variables in the equation are cut by the lines, the value of the unknown variable may be ascertained by intersection upon the scale provided for that variable. Thus, for example, the solution of plane triangles may be taken as being a problem of general application. Given the two sides and included angle, the opposite side (a) may be found directly by the application of the rectangular coordinates to the nomogramme; in other words, the equation $a^2 = b^2 + c^2 - 2ab \cos A$ may be solved for all values of b, c and A. Besides the usual problems in mensuration, the safe loads on columns for given values of the ratio of length to least radius of gyration for various materials, the bending of beams, stresses in roof trusses and bridges and numerous other problems may be solved without calculation. The printing of the scales on the nomogrammes leaves much to be desired, but the work as a whole is a most interesting contribution to graphical methods of solution.

(3) This little book is made up of twenty-five single perforated sheets bearing upon each a concise description of a simple laboratory experiment in applied mechanics with an illustration of the apparatus. The experiments are of the usual kind for the elementary mechanical laboratory and comprise statics, efficiency of lifting machines and friction, forces in braced structures, moduli of elasticity, spring vibrations, pendulum, and others. Prof. Morley states that they are selected from instruction sheets used in his laboratory, and may be usefully employed in conjunction with his text-books on elementary applied mechanics. However opinions may differ concerning the expediency of giving a student cut-and-dried directions concerning his laboratory work and leaving little to his own judgment and talent, those who favour this plan of instruction will find all that they desire in these well-arranged experiments. It saves much time and needless explanation on the part of the demonstrator to have the experiments written out, and as these are selected by experienced teachers they should prove useful in the elementary laboratory.

(4) This work contains a mass of constructional detail on the gas engine which should find favour with engineers and draughtsmen engaged in the design of such motors. It represents the results of much practical experience, and on the part of both the author and translator it shows a very careful scrutiny of the best engineering practice. The thermodynamics of the subject is somewhat neglected, but this omission is counterbalanced by the exhaustive treatment of the forces developed by the engine when running. The effect of the inertia of the reciprocating parts, turning moment diagrams for calculating fly-wheel masses, and balancing, are discussed with the view of assisting the draughtsman in his design, and the effects of various combinations of cylinders receive more attention than usual in works of this kind. Minute details are set forth with painstaking care, and

there is no part of the anatomy of the engine which has not a place in the work. Metric measures have been converted by the translator, but the tabulated dimensions of Continental engines have been retained in millimetres in parallel columns.

(5) The cost of mixing and laying concrete is essentially governed by local circumstances, and it would be unsafe to generalise from isolated results, however carefully they may have been collected. The authors have been at great pains to collect information based upon work done in the United States, and no doubt with due allowance for the difference in the cost of labour and materials and the varying rate of output of work, much of their conclusions would be applicable to other conditions and places. But the work is not wholly confined to questions of cost, for it contains much valuable, if incidental, information concerning the making of concrete in bulk, form of moulds, reinforcement for ferro-concrete and other matters pertaining to construction in this material. It is to be regretted that so much prominence was given to costs, though the title of the work very clearly points to this as the dominant feature. Nevertheless, with due allowances, as a reference book there is much in it for the architect and engineer, and it is eminently satisfying to know that the figures were obtained by close application and systematic study of construction work for many years.

OUR BOOKSHELF.

Manual Training Woodwork Exercises Treated Mathematically. A Scheme for Linking up Practical Mathematics with Woodwork; including a Complete Course of Mensuration. By F. E. Drury. Pp. xi+215. (London: G. Bell and Sons, Ltd., 1912.) Price 2*s*. 6*d*.

As is indicated by the title, the author's object in preparing this volume has been to show how practical mathematics may be linked up with woodwork in the form of mensuration, &c. The book is intended for use in preparatory day trade schools, some secondary schools, and in evening continuation and technical courses of an elementary character. It is stated that the work of calculation is intended to be an application of the principles received in lecture and experimental classes, but it will be seen that these may, in a large measure, be imparted by the woodwork teacher if he has a generous allowance of time. With this end in view, the book contains a very good systematic course in mensuration, elementary algebra, and the construction and properties of simple graphs; the application of these principles to the course of woodwork exercises provided is clear and good, and the book should be very useful to manual instructors who are expected to train boys both in practical mathematics and woodwork.

As to the desirability of adopting this course there may be difference of opinion, especially with reference to evening schools, where the time permitted for actual work in the wood shop is very limited. Any reason which may be advanced for bracketing together woodwork and mathematics may equally well be applied to other branches of practice, with a consequent multiplication of the number of classes in practical mathematics carried on in the same building, each no doubt selecting those portions which appear to suit the particular trade involved. It is fairly obvious that such a plan—already adopted in some institutions—cannot fail ultimately to lower mathematical standards. The author has been successful in carrying out his views in the book, and, if it be regarded as a further means of interesting students in the woodwork shop in their work in classes under the supervision of mathematical teachers, it can be highly commended. The woodwork examples are good, and the book is well and clearly illustrated.

Compendio Elemental de Zoología. By Ángel Gallardo. Pp. 360. (Buenos Aires: Ángel Estrada y Cia, 1912.)

PROF. ÁNGEL GALLARDO has prepared a useful elementary text-book of zoology, specially adapted for the Argentine Republic. After an introduction contrasting organisms and inorganic things, comparing plants and animals, describing cells and tissues, and the early stages of development, discussing the factors of evolution and other generalities, the author passes to a rapid survey of the animal kingdom. The book is very clearly and tersely written, with numerous illustrations, for the most part admirable. In the classification adopted, "Tipo vii., Lofostomas," includes the three classes—Rotifers, Bryozoa, and Brachiopods—characterised by the tentacular apparatus at the mouth. Still more doubtful is "Tipo viii., Gusanos," which includes Annelids and Plathelminthes, characterised by having trochosphere larvæ.

Twelve Moons. By Frances A. Bardswell. Pp. 90. (London: Elkin Mathews, 1912.) Price 2*s*. 6*d*. net.

IN twelve short sections devoted to the respective months of the year, the author expresses pretty sentiments upon the changing beauties of the countryside. She loves the poetry of nature; and her words will awaken sympathetic response in readers who are content to contemplate the surface of things. The old proverb "February Fill-dyke" leads her to say: "To brim the ponds and flood the waterways is the mission of the month." As a matter of fact, the average rainfall of February in England as a whole is less than that of either January, August, October, November or December, though there are local differences. Possibly the explanation of the proverb is not that "deluges of rain" actually fall in February, but that the watercourses begin to fill up during that month as the result of the rise of the water-table due to the rainfall of preceding months.

Radium and Earth History.

It would appear that radium has landed geologists and biologists in a difficulty greater than that from which it was hoped it would deliver them. There is radium in the earth, and radium in disintegrating gives out heat. Therefore a once molten globe will cool down more slowly than if it contained no such independent source of heat. Lord Kelvin's calculations were made on the supposition that there was no source of heat except what the earth possessed as a molten globe. Hence we are at liberty to extend the time that has elapsed since the earth became the possible theatre of geological change to 500,000,000, 1,000,000,000, or even more, years ago. Radium has given us a blank cheque on the bank of time.

So far so good. But when the actual calculations were made as to how much the radium known to exist in the outer shell of the earth would effect its cooling, this was found to be too great. It would, in fact, *raise* the temperature of the earth the fraction of a degree annually.

Two suggestions in the way of explaining the difficulty have been made by Prof. Joly in his "Radioactivity and Geology." We do not think that either will bear the test of careful examination.

It is only the outer shell of the earth that can be examined for radium, and though there appears to be no diminution with depth, there may be less, or none, in the lower parts. If, then, we have to spread the heating effects of the radium of the outer shell over the whole earth, it will obviously be insufficient to raise its temperature. The only possible result of its disintegration will be a retardation of its cooling to an indefinite extent, which is what is wanted. This is the first suggestion.

The second, admitting that the proportion of radium in the interior may be the same as at the surface, avails itself of the fact that vast masses of the central earth may be thermally isolated for immense periods of time. The rise in temperature of such parts—due to their radium—need not, then, affect the rocky crust. In the course of prolonged ages, however, such internal reservoirs of heat might, so to speak, overflow. Great rushes of heat might reduce the outer shell to a molten state, and inaugurate a new geological era. To quote Prof. Joly:—

"With an interest almost amounting to anxiety, geologists will watch the development of researches which may result in timing the strata and the phases of evolutionary advance; and may even—going still further back—give us reason to see in the discrepancy between denudation and radio-active methods, glimpses of past æons, beyond that day of regeneration which at once ushered in our era of life, and, for all that went before, was 'a sleep and a forgetting.'"

But let us look at these interesting suggestions a little more closely. If the radium contents of the outer shell were spent in heating the whole earth—or any considerable portion of it beyond the shell containing it—then we might suppose it just sufficient to retard its cooling indefinitely. But as the temperature of the earth increases with depth, we cannot suppose that any of the radium-generated heat of the outer shell passes downwards. It must *all* be spent in heating its *own mass*. Therefore, according to calculation, this outer shell should be rising in temperature. There seems to be no escape from this conclusion. And this applies also—and even more forcibly—to the second explanation. For with an interior rising in temperature it is still more difficult to imagine any of the radium-generated heat of the outer shell passing downwards. The radium heat of the crust must all be spent on itself.

Even this does not express the full extent of the difficulty. The theory of the radio-active elements is that they have their periods in which they lose half their substance. The period of radium is 1760 years, and that of uranium 5,000,000,000 years. Now, since we know of no source whereby the supply of uranium in the earth is replenished, we must suppose that there was twice as much uranium 5000 million years ago as there is to-day. And whatever length of time we go back we must suppose there was more uranium, and hence a greater heating effect, than there is to-day. A molten globe could not *begin* to cool until the radium contents of its outer shell were *less* than that of the earth to-day.

The moon presents another difficulty. Our satellite is generally held to be a bit of the earth thrown off some fifty-six million years ago. It was then molten, and the drag of the tides produced in its molten mass by the earth gradually reduced its rate of rotation. Now it only turns once on its axis in the course of a revolution round the earth. The moon's radium has not prevented it reaching a stage of cooling far beyond that of the earth. And yet the moon may be supposed to have had the full proportion of radium known to exist in the outer shell of the earth. Yet it has cooled down from a molten state in fifty-six million years in spite of its radium! And it would appear that the earth has done the same, although it has not reached the same stage. For if the moon was molten when it began its separate existence, so must the earth—which gave it birth—have been.

And it would appear that there must be *more* radium in the sun than in the earth. For helium, the product of the disintegration of radium, was discovered spectroscopically in the sun years before it was known on earth. It must surely, therefore, exist there in much larger quantities. Hence the sun should be getting hotter at a greater rate than the earth.

The difficulties introduced by radium into earth history are greater than that which it was hoped it would remove.

G. W. Bulman.

The Moon and Poisonous Fish.

May I ask for a little space in your columns to inquire if any of your readers can give any information as to the origin of a belief, very widespread in South Africa, that fish exposed to the influence of moonlight becomes poisonous? I have not yet attempted any experiments to test the truth of the statement, nor have I been able to obtain actual evidence of illness or death following the eating of such fish. The belief is very firmly rooted here among all classes of persons, but no one seems able to say how or when it originated, or on what grounds it is based. One very trustworthy witness told me that he had accidentally left some fresh fish out in the moonlight one night, and that it was quite bad in the morning; he admitted, however, that the closeness of the atmosphere might have occasioned the effect, and, of course, he did not divide the sample so as to keep part of it unexposed. I intend to test the statement experimentally when opportunity offers; meanwhile possibly some of your readers can say whether the belief in this ill-effect of moonlight is found in other localities.

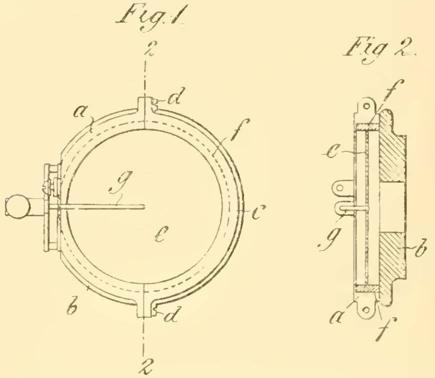
Gramophone Experiments.

FOR some time I have been experimenting with the gramophone sound-box, and I came to the conclusion that with a diaphragm nipped firmly between two rubber rings there was a tendency for a vibration from the stylus bar to be cannoned back from the edge so held, and that one did not get a true ring. I made a sound-box as shown below (Figs. 1 and 2) in



FIGS. 1 and 2.—a is half a split ring connected to the sound box b; c is the other half of the split ring connected to a by screws $d\,d$; the diaphragm e is held in position by an elastic ring f, which is secured to sound box by means of the two halves a and c; g is the stylus bar. The sound box is protected by patent.

which the diaphragm is only held on its edge, and by cutting the front of the box in half it enabled me to mount the diaphragm free from distortion. With this box there is a very marked difference.

In a band record one can differentiate each instrument more readily.

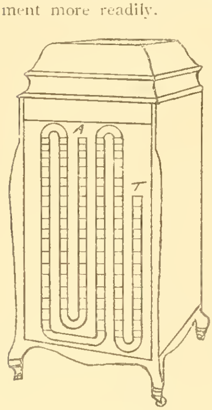


FIG. 3.—A connected with tapered arm: T with horn.

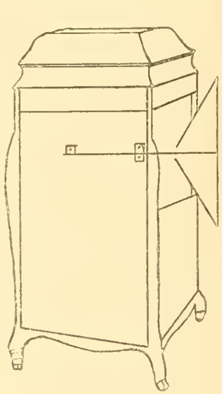

FIG. 4.—Showing position of conical reflector.

Working on Prof. McKendrick's experiments, as described in NATURE of April 20, 1911, I found that with an enclosed horn machine, as shown in Figs. 3 and 4, by passing the sound waves through about 17 ft. of 2-in. flexible metallic voice tube (the tubes all being inside the cabinet out of sight), all the noises which he eliminates by the use of peas are done away with, and the sound much increased by not using peas. In addition to this, to augment the sound I place a 2 ft. by 8 in. deep conical reflector with the apex of the cone cut off, leaving a 4-in. opening pointing to horn, as shown in Fig. 4. The result is that a musical effect is produced free from overtones and harsh sounds.

ERNEST DE LA RUE.

WITH reference to the above interesting communication by Mr. Ernest de la Rue, I have to say that the method he has adopted for fixing the diaphragm of the sound-box is a marked improvement. Mr. de la Rue has kindly sent me a specimen of the sound-box, and it has given me great satisfaction, both as to quality and volume of tone. I have not had the opportunity of hearing the arrangement he has devised for removing friction noises, but no doubt it will be satisfactory. I am quite pleased with my own method, which gives excellent results, and it is adapted to the older form of gramophone which I use. The tones are sufficiently loud for a room of ordinary dimensions, and the quality, with Mr. de la Rue's sound-box, is excellent. A witty friend of mine has called my plan the pipe of peace (peas)!

J. G. MCKENDRICK.

Reported Occurrence of the Dartford Warbler at the Tuskar Light Station.

I HAVE recently returned after nine weeks' residence at the Tuskar Light Station, off the south-east coast of county Wexford, where I have been prosecuting the study of bird-migration. I obtained several interesting records, including those of some rare species. To these may be added a highly interesting and at the same time important record of the occurrence of a Dartford warbler. Owing to the sedentary habits of this species its appearance at the Tuskar Rock was quite unexpected, and heretofore the bird was unknown in Ireland.

This warbler was obtained on October 27, as I am informed by the principal lightkeeper, to whom I owe my cordial thanks for the kind aid he has so often and cheerfully given me in connection with my work on bird-migration.

THE CRYSTAL SPACE-LATTICE REVEALED BY RONTGEN RAYS.

DURING a visit to Munich at the beginning of August last the writer was deeply interested in some extraordinary photographs which were shown to him by Prof. von Groth, the *doyen* of the crystallographic world, and professor of mineralogy at the university of that city. They had been obtained by Dr. M. Laue, assisted in the experiments by Herren W. Friedrich and P. Knipping, in the laboratory of Prof. A. Sommerfeld in Munich, by passing a narrow cylindrical beam of Röntgen rays through a crystal of zinc blende, the cubic form of naturally occurring sulphide of zinc, and receiving the transmitted rays upon a photographic plate. They consisted of black spots arranged in a geometrical pattern, in which a square predominated, exactly in accordance with the holohedral cubic symmetry of the space-lattice attributed by crystallographers to zinc blende.

Prof. von Groth expressed the opinion, in agreement with Herr Laue, that owing to the exceedingly short wave length of the Röntgen rays (assuming them to be of electromagnetic wave character), they had been able to penetrate the crystal structure and to form an interference (diffraction) photograph of the Bravais space-
