VOLUME I, 1920.

JANUARY TO JUNE.

London :

PRINTED AND PUBLISHED AT THE OFFICE OF THE BRITISH MEDICAL ASSOCIATION,
429, STRAND, W.C.

LIST OF ILLUSTRATIONS.

SPECIAL PLATES.

	PAGE
Deficiency Disease (R. McCarrison) ..	facing 823
Detection of Suture Material Embedded in Tissues (M. J. Stewart) ..	facing 663
Fraser, Sir Thomas ..	facing 100
Heart Disease: The Passive Mechanical Factor in (A. Blackhall-Morison) ..	facing 822
Horsley, Sir Victor ..	facing 260
Nutrition of Articular Cartilage (T. S. P. Strangeways) ..	facing 662
Osler, Sir William ..	facing 30

ILLUSTRATIONS IN THE TEXT.

Actinomyces: Simple Method of Cultivating the Micro-Organism of (M. H. Gordon) ..	435	Harvey, William ..	371
Ankylosis of the Mandible (Gilbert Chubb) ..	257	Head Lamp ..	472
Appendicectomy by a New Route (R. H. Anglin Whitelocke) ..	211	Health Services, Diagram of an Area ..	741
Banks, George ..	127	Heat Hyperpyrexia (W. H. Willcox) ..	393
Caius, Jobannes ..	370	Herpes Zoster and Greyness of Hair (Sir G. Lenthal Cheate) ..	219
Cambridge, Views of ..	17, 125, 505, 651, 772, 845	Maternity Homes and Hospitals ..	299
Dietaries, Deficient, Effects of on Monkeys (Lieut.-Col. Robert McCarrison) ..	249	Needle for Artificial Pneumothorax, a New (Frederic C. Coley) ..	433
Facial Trophoneurosis with Deformity of the Hand (I. H. Lloyd) ..	735	Newton, Sir Isaac ..	505
Flail Joints and their Treatment (Sir Robert Jones) ..	177	Oxygen in Pulmonary Lesions, Value of (Jonathan C. Meakins) ..	325
Gall Stones (R. P. Rowlands) ..	665	Penetrating Wound of Chest, Thoracotomy, Suture of Pericardium (J. B. Hayercraft) ..	184
Gastric and Duodenal Ulcer (Arthur F. Hurst) ..	559	Physiological Cost of Muscular Work (A. D. Waller) ..	537
		Poison of the Spiny Dog-fish (H. Muir Evans) ..	287
		Public Health <i>versus</i> the State (Bertram G. M. Basket) ..	41
		Rhinoplasty and Cheiloplasty (Rushton Parker) ..	12
		Rock Tombs or Caves in Palestine ..	97
		Sedimentary Cell for Microscopical Examination of Cerebro-spinal and other Fluids ..	708
		Soldier's Heart and War Neurosis (Sir James Mackenzie) ..	491, 530
		Tonsil Bayonet ..	472
		Tuberculosis, Epidemiology of (William Gordon) ..	595
		Tumours Complicating Pregnancy, Labour, and the Puerperium (Herbert R. Spencer) ..	179, 320
		Turner, Sir William ..	439
		Urethroscopic Tube ..	771
		Young, Thomas ..	774

INDEX TO VOLUME I FOR 1920.

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma, Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocele, Goitre, and Thyroid; Diabetes, Glycosuria and Sugar; Light, Roentgen, Radium, X Rays; Status Lymphaticus and Thymus; Eye, Ophthalmia and Vision; Bicycle and Cycle; Motor and Automobile; Association, Institution, and Society; Paris, France; Berlin, Prussia, Germany; Vienna, Austria, etc. Subjects dealt with under various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, "Correspondence," "Leading Articles," "Reviews," etc. Original Articles are indicated by the letter (O).

- A.
- ABBOTT, Charles C., "herbal specialist," legal proceedings against, 659
- Abdominal cases, three acute: polypus of stomach, large haemorrhage into wall of caecum, and large ovarian cyst (J. Lionel Stretton), 80 (O)
- Abdominal emergencies (Rutherford Morison), 425, (O)
- Abdominal tuberculosis. *See* Tuberculosis
- ABERCROMBIE, R. W.: Physiopathic paralysis of the hand and its causation, 764, (O)
- Aberdeen, proposed institute of research in animal nutrition at, 438
- Abortifacients, sale and advertisement of (leading article), 192—Correspondence on, 242
- Abortion, attempted, sudden death at, 624
- Abortion, cervical (Glady J. C. Russell), 363
- Abortion, etiological factors in (Daniel Dougal and J. W. Bride), 632, (O)
- Abortion, factors in (Drs. Dougal and Bride), 540
- Abortionist sentenced (Devi Dayal Sasun), 589, 754
- ABT, Isaac A.: *The Baby's Food*, rev., 368
- Académie de Médecine, centenary of, 161—Election of members and corresponding members, 589
- Academy, Royal, 645
- ACADEMY, ROYAL, OF MEDICINE, IN IRELAND: *Section of Medicine*.—Exhibition of cases, 736—Dr. Speara: Mixed functional and cranial palsy, 736
- Section of Obstetrics*.—Bethel Solomons: Uterine cancer, 48—Dr. Ashe: Ovarian insufficiency, 48—Sir W. Smyth: Schultz's forceps, 48—Hastings Tweedy: Tubal sterility, 604—Spencer Sheill: Circumcision as an ancient rite and as a surgical procedure, 768
- Section of Surgery*.—Cases and specimens, 519—A. E. Boyd: Oil ether colonic anaesthesia, 768—Sir W. I. de C. Wheeler: Arthroplasty of the knee-joint, 768—Seton Pringle: Early symptoms of cancer of colon, 768
- Acari from lungs of *Macacus rhesus* (F. Martin Duncan), 276
- Accidents, rare, presumed due to negligence, 554
- ACHARD: Lethargic encephalitis, 193, 241
- Achilleion palace at Corfu now known as the Triboudeau hospital, 458
- Acidosis in certain nervous disorders (B. H. Shaw), 695, (O)
- Aene vulgaris, x-ray treatment of (H. C. Semon), 700, (O)
- Acoustic tumour. *See* Tumour
- Acta Societatis Medicorum Fennicae Duodecim*, 512
- Actinomyces, simple method of cultivating the micro organism of, 435
- ADAMI, J. G.: The diphtheroid group, 14—Elected honorary Fellow of Christ's College, Cambridge, 785
- ADAMS, John: Ante-natal and post-natal syphilis, 603
- ADAMSON, James, obituary notice of, 313
- ADDISON, Right Hon. Christpher: Appreciation of Sir Robert Morant, 455
- Addison and Harley on the colour of a cat, 72
- Adenoids, nasal drill in treatment of (Gertrude H. Hickling), 147, (O)—Correspondence on, 238, 310, 349, 487
- Adenomyoma of recto-vaginal septum (M. H. Phillips), 224
- Adjusting the matter, 278
- Adrevalin mydriasis (Loewi's) as a sign of pancreatic insufficiency (W. L. Cockcroft), 669, (O)
- Advertisements for medical officers. *See* Medical
- Advertising's artful aid, 558
- Aeroplane in medical investigation, 230—Aerial expedition to make journey from Cairo to the Cape, 230 *See also* Mitchell, Chalmers
- Aesculapian Club, Toronto, election of officers, 725
- APFLECK, Sir James O.: Appreciation of Sir Thomas Fraser, 101
- Afghanistan dispatch, 422
- Africa, East, Indian medical practitioners in (parliamentary question), 482, 650
- Africa, sleeping sickness in (Captain Basil Spence), 205
- Africa, West, the white man in, 411
- "After-care," 650. *See also* Sanatorium treatment
- Air Ministry: *The Medical Examination of Civilian Pilots, Navigators, and Engineers*, 608
- Air raid claims (parliamentary question), 808
- Air-way infections (T. H. C. Beniada), 668, (O)—Correspondence on, 812
- AITKEN, Captain C. J. H.: Night blindness in scurvy, 526
- ALBERT-WEIL, E.: *Éléments de Radiologie*, rev., 770
- ALCOCK, A.: *Entomology for Medical Officers*, rev., 707
- Alcohol, supply of to doctors in America, 623
- Alcohol as a therapeutic agent (Dr. Dale), 294—Discussion, 295
- Alcohol for power and traction purposes: Investigation officer appointed, 112
- Alcoholism, acute, in man, toxicological investigation of, 411
- ALDERSON, Reginald: Severe angio-neurotic oedema, 828
- Alien enemy practitioners (New South Wales), 233
- Alimentary canal, needle in (Heywood Smith), 81—(W. M. Feldman), 206—Pin in (H. B. Pope), 242—(A. B. Roberts), 424
- ALBUTT, Sir Clifford: Appreciation of Sir William Osler, 64—Appreciation of Charles Louis Taylor, 101—Medical literature for Vienna, 484—Elected an honorary member of the Association of American Physicians, 779—Presentation portrait of, 876—Writes a preface to *Industrial Colonies and Village Settlements for Consumptives*, 885
- Alopecia, 138, 173
- ALSTROM, Hedda: Mechano-therapy, 366
- AMARD, L.: *Physiologie normale et pathologique des reins*, rev., 606
- Ambassadors to the United States, medical, 410
- Amulance Service, the Home, 716
- Ambulances, 1st and 2nd South Midland Field, dinner, 687
- Ambulances for civil work in the United Kingdom, 434—Correspondence on, 784
- Amenorrhoea, pregnancy during, 278
- America. *See* United States
- American Froese life-size anatomical charts, 16
- Amibiasine for dysentery, 190
- Amicus prize, 691
- Ammonia coefficient, high (Lady Barrett), 603
- Amoss: Portal for acute poliomyelitis, 343
- Anaesthesia, colonic ether (A. E. Boyd), 768
- Anaesthesia in epileptics, 526, 558, 624
- Anaesthesia in throat operations (Felix Rood), 295
- Anaesthesia for thyroid operations (Mrs. Dickinson Berry), 635
- Anaesthetics, administration of (parliamentary question), 583
- Anaesthetics, discussion at Sheffield Medical-Chirurgical Society, 539
- Analgesia, visceral, in tabes, 480
- Aoaphylaxis, severe recovery, 72
- Anatomy inspector for Scotland, appointment of, 617
- Anatomy, review of books on, 367
- ANDERSON, Daniel E.: *Epidemics of Mauritius*, rev., 298—Letter on, 383
- ANDERSON, Ford: Rupture of uterus, 829
- ANDERSON, Dr. Garrett: Surgery at the Bodell Street Hospital, 605
- ANDERSON, Kenneth: Acute oedema of lungs, 571
- ANDERSON, R.: Small-pox in Scotland, 785
- ANDREWS, Captain H. J., obituary notice of, 137
- Angio-neurotic oedema. *See* Oedema
- Ankle amputation, artificial appliance for, 590
- Ankle, fracture dislocations of, 62
- Ankylosis of mandible and its operative treatment (Gilbert Chubb), 256, (O)
- ANSON, G. E.: Haematoporphyria, 634
- Ante-natal respiratory movements, 877
- Anthrax infection by brushes, 25, 53, 276
- Anthrax Prevention Act, 276
- Antimaphylaxis in treatment of chronic disorders (leading article), 839
- Antimony intravenously in filariasis (Lieut. Col. Sir Leonard Rogers), 596 (O)
- Antipyretic drugs and cold water, 206
- Antiscorbic lemon juice tablets, 624
- Antispiritalistic vaccine, 726
- Antistreptococic serum in puerperal fever (O. Milton), 185
- Antistreptococic serum in quinsy (Noel C. Forsyth), 361, (O)
- Antityphoid inoculation (parliamentary question), 482
- Antivermin paste, 472
- Anzaca, prophylaxis and venereal disease amongst, 202. *See also* Venereal
- Aortic endocarditis and aortitis, association of (J. E. MacIlwaine), 428, (O)—Correspondence on, 586, 656, 688, 754
- Apoplexy, utero-placental. *See* Haemorrhage, accidental
- Apothecaries' Society of London: Pass lists, 204, 690, 814—Awards Gillson scholarship, 277
- Apothecary poet's house (Keats), 526
- Apparatus for man without arms, 20
- Appendicectomy by a new route (R. H. Anglin White Locke) 211, 223, (O)—(H. Stewart Brander), 293—Correspondence on, 416
- Appendicitis without protective stiffening of the abdominal wall (John D. Malcolm), 432, (O)
- Appendicular concretions (S. G. Shattock), 635
- Appendix dyspepsia. *See* Dyspepsia
- Appendix, intussusception of (Archibald Young), 365
- ARAUJO, Heraclides Cesar de Souza: *A Prophylaxia Rural no Estado do Paraná*, rev., 738
- ARWRIGHT, Dr.: Rickettsia bodies in trench fever and typhus, 709—Bacterial variation, 709
- ARMAND-DELILLE, P. (and Ph. WAPIER): *L'École de Plein air et L'École au Soleil*, rev., 154
- Armsman, apparatus for, 20
- ARMSTRONG, Henry Edward, Honorary Fellowship of Society of Medical Officers of Health conferred upon, 305

LONDON: SATURDAY, JANUARY 3RD, 1920.

An Address
ON
GUNSHOT FRACTURE OF THE FEMUR.

DELIVERED AT A MEETING OF THE AMERICAN COLLEGE
OF SURGEONS IN NEW YORK, OCTOBER 8TH, 1919.

BY

SIR ANTHONY BOWLBY, K.C.B., K.C.M.G., K.C.V.O.,
SURGEON IN ORDINARY TO THE KING; CONSULTING SURGEON TO
ST. BARTHOLOMEW'S HOSPITAL.

FRACTURE of the femur by bullets or shell fragments is one of the most dangerous injuries of war, but it must be realized at once that the danger is proportionate to the extent and nature of the injury of the soft tissues even more than to the extent of the bone lesion. Thus, it is well known that a spent bullet which glances off the femur and just breaks it may cause a minute entry and exit wound and a fracture which is much more like a simple fracture than a compound one. On the other hand, a large shell fragment may tear away the greater part of the hamstring muscles and the skin covering them, and may inflict so severe an injury that even if the femur is not fractured, the lesion of the soft parts alone may well prove fatal.

In the South African war of 1899-1902 it was the former class of fracture which predominated, for not only were there very few high explosive shells used, but the rifle bullets were generally fired at a range of over 1,000 yards, and were of a shape which caused the minimum of injury to the soft tissues and the very smallest wounds of entrance and exit. It thus happened that the majority of cases did well, and that the experience of fracture of the femur in the South African war was of but little help in 1914, although it did demonstrate very clearly the value of the "Hodge" splint and its superiority to the time-honoured "long Liston."

In the recent war, on the other hand, fractures of the femur were generally inflicted either by wedge-like bullets fired at quite short range from machine guns or rifles, or else by fragments of high explosive shells, which were often very large, being parts of shells which themselves weighed from sixty to two hundred pounds or more. Extensive tearing of the muscles was therefore the rule, and in many cases the patient had other wounds in addition. In the early days of the war shrapnel shell was extensively used by the Germans, and it was much used by both the British and the French throughout the whole war. The lower velocity of its round bullets caused it to produce much less injury to bone and muscle than the rifle bullet fired at short range or than the fragments of high explosive shell.

Another very important factor to be considered in estimating the danger of fracture of the femur is the length of time that is often liable to elapse before the patient can be adequately treated. In France a man were wounded in our own trenches or in billets there was very little delay, but, on the other hand, if he was wounded in an attack on the enemy's position it was often impossible to attempt to move him till nightfall, and he could not, of course, help himself to get to an aid post. The result was that before the patient could be treated he was often weakened by continued bleeding, by hunger and thirst, or

by exposure to cold through lying out in mud and water, or through being soaked by heavy rain.

Conditions such as these will always cause a very high rate of mortality, whatever treatment is adopted.

TREATMENT.

The treatment of these fractures falls naturally into two divisions—treatment at the front and treatment at the general hospitals.

I. TREATMENT AT THE FRONT.

At the beginning of the war the splints supplied at the British front were very inefficient as well as very few, for the only splints available were long wooden splints of the Liston type, but both too thin and too narrow to be satisfactory. A rifle made a better splint. Within a few months I was able to obtain supplies of stouter splints made with a metal bracket 8 in. long so as to permit access to the wound, and these proved very serviceable, and were employed for nearly a year and a half at the aid posts and field ambulances. In 1915 Lieut.-Colonel Max Page devised a splint made of flexible metal and of the "Thomas" type, and by the end of the same year Sir Robert Jones's advocacy of the "Thomas knee splint" had resulted in its employment in many units. At about the same time Sir Cuthbert Wallace, in conjunction with Colonels Richards and Frankau, perfected the now well known "stretcher-suspension-bar," which enabled the patient to be carried on a stretcher with the lower extremity suspended. The use of the Thomas splint was soon adopted throughout the entire front, and was demonstrated to medical officers by the consulting surgeons in every field ambulance in the British army. The application of what came to be called the "Thomas outfit"—that is, Thomas knee splint and suspension bar—was also taught everywhere to all the field ambulance orderlies and regimental stretcher-bearers; and it was further ordered, on the suggestion of Captain Kenneth Walker, that when a man with a fractured femur was found on the battlefield the splint was always to be applied before the trousers were cut open or the wound dressed, and that the boot should also be left on the foot. The object in view was to immobilize the fracture before the limb was much handled, and also to apply the splint with as little loss of time as possible. A back splint or a kettle-holder splint was often applied in addition.

When the use of the "Thomas outfit" became general the transport of the patient to the casualty clearing station was very greatly simplified, for, as soon as the limb was fixed in extension and slung, pain was either altogether prevented or reduced to a minimum, bleeding was soon checked and the steadying of the fragments effectually prevented further injury to the soft tissues and the spread of sepsis. The consequence was that patients arrived in infinitely better condition than previously, and shock was no longer so serious. The value of this early splinting of fractures was unexpectedly demonstrated when, in May, 1918, several French divisions came to the Kemmel area. Their journey had been hurried, and efficient splints had not been provided, so that when fighting began many patients arrived in British casualty clearing stations with fractures of all kinds unsplinted. The condition of these men was an object lesson to those who had not been at the front in the earlier days of the war, for evidence of shock and loss of blood predominated in them, and

many died, whilst the cases arriving at the same casualty clearing stations from the British field ambulances were in good condition. The necessary splints were at once provided.

The method I have sketched of applying first aid treatment to cases of fractured femur was not materially altered in the British army during the last two and a half years of the war. It is of course very probable that further improvements will be developed, but it appeared to us when hostilities came to an end that for the time being we had developed a very efficient method of treating these fractures on the battlefield.

We found that the best means of applying traction on the field was by steel callipers fixed to the sole of the boot below the instep. In the absence of these a steel skewer may be passed through the boot leather, but has the disadvantage of spoiling the boot. Either a clove hitch bandage or a so-called "surgical spat" was liable to cause too much pressure on the thin skin of the dorsum of the foot and consequent sloughing if left on for long.

On arrival at the casualty clearing station the routine treatment was to anaesthetize the patient, then take off the splint and dressings and thoroughly remove with knife and forceps all damaged tissues and foreign bodies. Before this could be done it was often necessary to employ measures to combat shock or loss of blood, and in most cases gas and oxygen was the anaesthetic of choice.

After the operation was completed the Thomas splint was again applied, but this time the extension was fixed to the skin by strapping or glue. Then, as soon as the patient's condition permitted, he was removed to the ambulance train *en route* for the general hospital area.

Primary Amputation.

In a large number of cases of fracture of the femur primary amputation is absolutely necessary, and should be performed as soon as the state of the patient permits. In the latter half of the war the employment of improved methods of transport and of resuscitation enabled amputation to be performed on many more patients than in 1914-15.

The conditions which commonly necessitate early amputation may be briefly summed up as follows:

1. Complete smashing of a large area of bone.
2. Extensive comminution of the lower articular end of the femur.
3. Laceration of the femoral vessels.
4. Extensive destruction of muscles or skin.

It must be recognized that primary amputation for fracture of the femur is attended with a very much higher death-rate than is amputation in the thigh for injuries of leg, and also that the higher up the limb is removed the greater is the mortality. Primary amputation at the hip-joint is so uniformly fatal that it had better not be performed at all.

II. TREATMENT AT THE GENERAL HOSPITALS.

The first duty of the general hospital surgeons was to operate on those cases which had not been operated upon at the front; and for a short time at the end of March, 1918, when all the casualty clearing stations of the Third and Fifth Armies had been forced to retire, the bulk of the operating work fell to the lot of the general hospitals. If, however, thorough excision had been satisfactorily performed at the front in good time, as was usually the case, then the patient on arrival was put to bed and allowed to remain undisturbed for a day or two, to recover from all he had gone through. During this period many patients improved very rapidly in every way.

In many cases, after this period of rest, another apparatus was substituted for the Thomas splint, and in the putting up of these fractures an immense amount of ingenuity and skill was developed throughout the whole of the bases in France. The names of Major Sinclair and Major Pearson must be given a special place in this relation, because they were the earliest and most ingenious of the pioneers, but many other surgeons became equally deserving of distinction subsequently.

The detail of the methods employed have been so well described and illustrated by various surgeons that it would serve no good purpose if I were to follow in their footsteps. I will therefore only attempt to indicate the general

principles which were common to most centres, merely premising that the greatest benefit and progress resulted when, at the end of 1917, certain hospitals in every area were specially selected and equipped for the treatment of fractures of the femur, and when the surgeons of these hospitals had acquired experience in the work.

PRINCIPLES OF TREATMENT.

1. The first general principle which was universally adopted was that the apparatus employed should be a skeleton metal splint, and that this should be used so as to enable traction to be applied either directly downwards or else in various degrees of abduction or flexion. This was the essential foundation upon which all else was based.

2. The direction of the traction and the amount of flexion or abduction required were guided throughout by frequent radiograms. These were always taken by a movable x-ray apparatus brought to the side of the bed, and by the aid of these the position of the fragments was altered, so as to obtain accurate apposition. Without the frequent use at the bedside of x-rays it is not possible to obtain uniformly good results.

3. The length of the limb was at first measured daily and afterwards less frequently, and it was found most useful to keep a "chart of shortening" (or lengthening) over the patient's bed. It became the custom to apply extension until the injured limb was definitely longer than its fellow, as it was found that this gave the best end results. It is most important to bear in mind that even when the main fragments of bone are separated by an interval of as much as one or two inches the gap can be completely filled by new bone.

4. "Fixed" extension proved to be not so good as "continuous" extension. The traction can be employed either by fixing the foot, and then lifting the end of the bed and letting the weight of the patient act as the extending agent, or else by applying weight traction. On the whole, the use of the patient's own body weight was the method most in favour.

5. Movements of the knee-joint were begun early, and slight flexion of the knee was always preferred to traction on the fully extended limb. The early experience of the war had shown us that unless special precautions were taken a permanently partially stiff knee-joint was extremely common. This might be due to (a) mild sepsis; (b) fracture near the articulation; (c) scarring, shrinkage, and adhesion of muscles, tendons, and skin. Captain Watkin Williams devised a very simple metal apparatus, which was attached to the main splint, and enabled the knee to be freely moved or fixed at any angle of flexion. Colonel Besley, of the Chicago unit, gave great help by the callipers which he devised. These were fixed above the condyles of the femur, and were especially valuable for cases of fracture of the lower third of the femur, for their use completely overcame the flexion so common in these cases, and they also enabled the knee joint to be freely moved without disturbing the traction on the femur. Many surgeons employed "calliper extension" for all their cases. It should be noted that if callipers are employed the following precautions are necessary: (a) rigorous asepsis; (b) avoidance of the synovial membrane; (c) avoidance of the thin articular bone of the condyles by fixing the callipers on the denser bone at the level of the adductor tubercle; (d) the use of any simple method for preventing the too deep penetration of the bone by the points of the callipers.

6. For fractures about the upper third and the neck the patient was placed either upon the hammock-like swing cradle invented and described by Major Sinclair, or else upon the special segmented mattress designed by Major Pearson. This latter was adopted late in 1918 by the Army Medical Department for the treatment of all cases of fracture of the femur under treatment in England, and has been fully figured and described by Major Pearson in his book *Fractured Femurs* (Pearson and Drummond, 1919).

7. When union was sufficiently advanced it was the custom to get patients out of bed while maintaining the length of the limb by the application of "walking calliper splints" fixed to the heel of the boot. If these were employed the use of the limb accelerated the formation of callus, but if they were not provided many limbs yielded and became bowed in attempts to walk.

8. The treatment of the wounds was on general principles, but in the year 1918 very great benefit resulted from early "delayed primary suture" or from "secondary suture." Cases so treated showed a more rapid union of the fracture and a great shortening of the period of pyrexia. They also were much less liable to late necrosis of fragments and to secondary abscess. The natural result was a decreased mortality in sutured cases as compared to those unsutured and a great diminution in the amputation rate. In cases which could not be sutured the period of suppuration was often shortened by the employment of Carrel's methods.

9. The question of the removal of bone was not entirely settled when the war ended. There was no doubt of the advisability of removing badly smashed fragments which had been completely separated. But, while most surgeons did not advocate the removal of more than this, some operators followed the advice of Leriche and practised subperiosteal removal of many of the partially detached fragments also. There seems no doubt that, on the one hand, the removal of all fragments which might necrose hastens the healing of the wound, whilst, on the other hand, this removal delays the union of the fracture, and, in the opinion of some very competent observers, has been responsible for permanent non-union in not a few instances.

RESULTS.

In the year 1917 a report by Lieut.-Colonel Max Page was read at a meeting of the Inter-Allied Conference in Paris. It was founded on an inquiry he had been commissioned to make in England as to the results of fracture of the femur; the report made it evident that in many cases the results were very unsatisfactory. A large percentage of the patients were suffering from one or more of the following conditions:

- (a) Shortening of the limb of more than one inch, and sometimes of two or three inches.
- (b) Union of the fragments in bad position.
- (c) Stiffness of the knee-joint.
- (d) Sinusitis.

In a smaller number of cases there was stiffness of the hip-joint, necrosis of large fragments, or imperfect union. A large proportion of the patients walked very badly.

These results made it evident that the methods of surgical treatment and the conditions for the hospitalization of patients in 1914, 1915, and 1916 were not satisfactory, although before this inquiry made early in 1917 many improvements in splints had already been adopted in France.

The previous conditions and methods of treatment may be very briefly described. In the years 1914, 1915, and 1916 it had been necessary to send all patients to England as early as possible, owing to the fact that there was not, at the time, sufficient accommodation in France for the large numbers of the wounded; there is, however, no doubt that the journey was bad for the patients.

During the earlier part of the same period the splints most commonly employed, both in France and England, were long wooden splints of the type known in England as "Listen's." Towards the end of 1915 skeleton metal splints began to be used in France, and during the year 1916 the "Thomas" splint came into universal use at the casualty clearing stations. During this year also the "stretcher-suspension-bar" for use with the Thomas splint (so long as the patient remained on his stretcher) became a part of the regular equipment.

It was during the battle of the Somme in 1916 that, for the first time during heavy fighting, both these appliances were supplied to the field ambulances (of the Fourth and Fifth Armies). Subsequently both were sent up to the regimental aid posts of all armies, and were commonly applied as soon as the stretcher-bearers found the wounded man.

During the year 1917 the patients at the bases in France were generally treated by skeleton metal splints and extension by the methods demonstrated to the Paris Conference by Major Sinclair, but it became evident that better results could be obtained, and this object was achieved in 1918 by retaining patients in France as long as possible before the journey to England, and by the creation of special hospitals with specially trained staffs of surgeons and nurses. Special hospitals for fractured femurs

were created in June, 1918, in England, and the effect of these various measures was that many lives and limbs were saved and that the limbs saved have shown very much less permanent disability than formerly.

Mortality.

The mortality at the front in the early days of the war cannot be directly compared with the mortality at the front in the year 1918, because the conditions were totally different. In the latter year and in 1917 all the worst cases were retained in the casualty clearing stations, and many died there, while in 1914 and 1915, whenever there was heavy fighting, practically all patients, however bad their condition, were at once sent to the base hospitals by ambulance trains, because the casualty clearing stations were far too few and too small to accommodate them; very large numbers of patients merely passed through these units on their way to the train. Yet, even then, it was found that not less than 16 per cent. of 1,000 consecutive cases died at the front, and it was estimated that the total mortality in France was at least 40 per cent., exclusive of those who subsequently died in England, so that the death rate was altogether not less than 40 to 50 per cent.

These figures are, however, rather misleading, for all cases of fractured femur are included in them; and amongst these not less than 20 or 30 per cent. had either such serious local complications as injury to the main vessels, extensive comminution into a joint, or widespread laceration and destruction of large masses of muscle, whilst many other patients had multiple wounds involving either limbs or the viscera of the thorax or abdomen. It is not always possible to distinguish between all these conditions, and it must be understood that the figures here given include all patients in whom the femur was fractured, whatever complications there might have been.

It has been found impossible to ascertain the results in all the field ambulances and casualty clearing stations in 1918 because of the difficulties encountered in the retreat of March and April, but sufficient records have been obtained to enable satisfactory conclusions to be drawn. The total mortality in the year 1918 may be estimated from the following figures:

I. At the Front.

Of 3,141 cases 550 died—that is, 17.5 per cent. Of these cases approximately 21 per cent. were treated by amputation.

The mortality of the amputated cases was about 33 per cent. These are included in the total of 550 deaths recorded above.

It was estimated that in between 20 and 30 per cent. of the total number of 3,141, there were multiple wounds or such other serious complications as have been alluded to above. The mortality was very much higher in this class than in the remaining 70 per cent.

II. At the Base Hospitals.

During the year 1918 there were treated in the general hospitals at the bases in France 5,025 patients; of these, 547 died, = 10.8 per cent.

Of these 5,025 cases, 513 were treated by amputation = 10.2 per cent.

The mortality of the amputated cases was about 33 per cent. All these are included in the figure of 547 given above.

III. In England.

Inquiry in England shows that the mortality in the special hospitals more recently created was very low, and generally 1 or 2 per cent. The reasons were, first, that in 1918 the majority of all the cases were kept in France till union had occurred and the wounds had healed; and second, that, even in times of stress, the worst cases were always retained in the special hospitals in France. For the same reasons amputations in England were few.

From a consideration of the above figures it may be concluded that during the year 1918 the total mortality of all cases of fracture of the femur (I) at the front, (II) at base hospitals in France, and (III) in England, amounted to, approximately, 30 per cent.

It must, however, be again pointed out that a very large proportion of the deaths occurred in men who had other serious injuries, and there is no doubt that in not a few of these death was not due to the fracture of the femur but to wounds of the viscera or to the shock caused by multiple injuries. My own impression is that the mortality of uncomplicated fractures of the femur due to "gunshot" wounds and treated throughout by the most modern

methods is not more than 15 to 20 per cent., and this conclusion has been reached after an examination of many statistics.

AMPUTATIONS.

A very large number of the deaths followed amputation, and about 30 per cent. of all the patients with fracture of the femur lost the limb, either by primary or secondary amputation. It will be noted also that in one-third of all the amputations the operation failed to save life.

At the front the most common reason for amputation was that the extent and severity of the injury rendered it impossible to save the limb. In other cases laceration of the main vessels was the reason. In many cases the operation was performed for gas gangrene. Many lives were saved by the employment of blood transfusion and by the use of gas and oxygen as an anaesthetic.

At the base hospitals the presence of gas gangrene was almost as often the cause of amputation as at the front, but in a good many cases the development at a later stage of intractable sepsis called for the removal of the limb. It must, however, be remembered that in March and April, 1918, several hundred cases had to be sent to the base for operation which would ordinarily have been performed in the casualty clearing stations.

The following figures of one general hospital may be taken as examples. Out of 72 amputations gas gangrene caused 24; acute sepsis, 29; dry gangrene, 3; secondary haemorrhage, 9; osteomyelitis, etc., 6.

FINAL RESULTS.

The final results obtained in the limbs that were saved show a very great improvement on those of the early part of the war. They may be briefly summarized as follows:

1. Shortening.

The methods of treatment of 1918 guarantee that unless there has been very extensive loss of bone *no shortening need occur*. It has been shown that even when one or two inches of the femur have been destroyed the gap can be filled by new bone, and that consequently there is no objection to maintaining the fractured ends in full extension.

It had formerly been the practice of some surgeons to allow the separated fragments to come together so as to promote union, but it is certain that this should not, in the future, be a regular practice.

Practical experience has also shown that it is more difficult to obtain a full-length limb in cases of simple fracture, such as occur commonly in civil practice, for the uninjured muscles offer far greater resistance than those in a limb wounded by shell or bullet, and more extension is consequently required. The amount of shortening following gunshot fractures is shown by the following figures to have steadily decreased in each year of the war; for the New Zealand figures we are indebted to Major Stout, N.Z.M.C.; they include every case of fractured femur in the New Zealand Corps:

New Zealand Figures.

1916	..	54 cases; average shortening =	1.345 in.
1917	..	116 cases;	0.957 in.
1918	..	90 cases;	0.25 in.

Two Special British General Hospitals in France, 1918.

(a)	334 cases; average shortening	0.2 in.
(b)	60 cases; average shortening	0.2 in. Of these 60, 36 had no shortening.

A Special Hospital in England, 1918.

Major Pearson, S.A.M.C., has supplied the following figures:

Number of cases	68
No shortening in	39
Average shortening of the remaining 29 cases	0.5 in.

Other hospitals show similar results, and it will be seen that the majority of the patients recovered without any shortening, and that only in about 5 per cent. of all cases was there more than one inch of shortening. Thus, of the 90 New Zealand cases in 1918, only two had more than an inch of shortening, and both of these patients had lost a good deal of bone.

The records of the various special hospitals necessarily vary somewhat, but the figures quoted are sufficient to prove that the previous difficulties in obtaining limbs of good length after gunshot fractures of the femur have

been completely overcome, and that equally good results should be generally obtained in civilian practice as well as in war.

2. Malposition.

The commonest displacement was a falling back of the lower fragment. The difficulties of correcting malposition almost disappeared in France as soon as a full length limb could be secured. A small percentage of the fractures near the knee and the hip recovered with some displacement remaining, but at least 80 per cent. of the whole of the cases recovered with good position.

In fractures of the shaft good position can practically always be secured, but it is most important thoroughly to support the bone at the site of fracture so that the natural anterior curve of the femur is either very fully maintained or even slightly exaggerated.

3. Stiffness of Knee-joint.

Major Pearson reports that, of 68 cases, 55 had a range of knee flexion over 90 degrees; 10 had a range of flexion of 60 to 90 degrees; and 3 had a range of flexion of 30 to 60 degrees. None had less than 30 degrees of movement at the knee.

Of the New Zealand cases Major Stout reports that the average range of flexion of the knee over the whole series was 43 degrees.

Many other hospitals showed similar results, and it is evident that the number of cases in which the knee was left permanently stiff was greatly diminished. There is no doubt that if suitable precautions are taken during treatment stiff knees in cases of fracture in the shaft of the femur should be very few.

4. Stiffness of the Hip-joint.

This has not been a frequent complication, and it should never occur except in cases where the fracture involves either the neck of the bone or the trochanters.

5. Stiffness of Ankle-joint and Toes.

This can always be avoided if care is taken not to keep the foot cramped by bandages, and to allow and encourage daily movement at the joints.

6. Sinuses and Necrosis.

Sinuses were seldom met with in the absence of necrosis; as it became the custom to remove sequestra earlier than in former years, the total number of patients with sinuses was greatly diminished.

7. Non-union.

This was decidedly rare, and did not occur in more than about 1 per cent. of the cases retained in France.

8. Nerve Injuries.

These were much more common than was generally appreciated. Out of a total of 297 cases of fractured femur observed by Major Stout, important nerve injuries were found in 12 per cent.—that is, in 36 patients. The injured nerves were—the sciatic in 13 cases; the internal popliteal in 3; and the external popliteal in 20.

THE parasite *Filaria conjunctivae* has for its normal host the horse and ass, but occasionally, though rarely, it has been found in man. Forbes has now published, in the *Journal of the Royal Army Medical Corps*, two cases, apparently the same as he reported to the Society of Tropical Medicine in October, 1918. In his first case a small tumour was found firmly embedded in the subcutaneous tissue overlying the head of the radius and the sheath of the supinator longus muscle; in the other a small tense cystic swelling, not adherent to the skin, was present on the right side of the nose just below the right lacrymal sac. A male adult worm was found in the first, an immature female in the second. At first these tumours were supposed to be due to *Onchocerca volvulus*, a parasite which gives rise to such lesions on the West Coast of Africa, but when the worms were submitted to Dr. Leiper he decided that they were examples of *F. conjunctivae* (Addario). This would appear to be the first recorded instance of the male worm being found. No embryonic filariae were found in the peripheral blood, which was examined both by day and night. The old error of considering *Stegomyia fasciata* an intermediate host of *F. bancrofti* is perpetuated in Forbes's paper. The paper is illustrated, and the facts recorded may lead to the discovery of other examples.

Remarks
ON
SOME CLINICAL TYPES OF ABDOMINAL
TUBERCULOSIS.*

BY

K. W. MONSARRAT, M.B., F.R.C.S.ED.,

LECTURER ON OPERATIVE SURGERY, UNIVERSITY OF
LIVERPOOL, ETC.

MUCH has been written on the subject of tuberculous peritonitis, and the limitations of the usefulness of surgical interference in the condition are well known. It is rather with the accidents or complications which arise in connexion with abdominal tuberculosis that surgery finds itself concerned.

It has been established by clinical experience that tuberculous peritonitis associated with massive exudation is favourably influenced by simple evacuation of the fluid; this drainage of the inflammatory area being followed by a reaction which arrests if it does not cure the progress of the disease. Occasionally—very occasionally I think—in the course of this operation a primary focus of visceral disease is found and perhaps removed. This fortunate event has never happened to me, although I make it a practice to look for any obvious visceral disease in the abdomen and the pelvis. Of course, the bowel and mesentery can hardly be searched with any pretence to completeness. Clinical experience goes to show that the widespread exudative type of peritoneal infection is not commonly secondary to lesions of the bowel, mesentery, or tubes, at any rate not to gross disease in these situations; the probability is that it is in most cases primarily a blood-borne serous infection.

The Ileum.

The lower end of the ileum is the commonest site for the disease in the alimentary canal. Here the primary site is incoons, and necrosis and ulceration of the mucous membrane follow. Cases do not come to the notice of surgeons in the early stages of this type of the disease, and I should like confirmation or otherwise of the view that it is not often widespread; in other words, that tuberculous ulceration of the ileum usually concerns a small length of the bowel only, that it is a local disease, and rarely takes the form of a widespread florid infection.

The disease proceeds towards the peritoneal coat of the ileum, and a local tuberculous peritonitis results. Acute perforation is undoubtedly rare; I have met with one such case in a child of 4 years, admitted to hospital with acute peritoneal infection, in whom an ulcer in the ileum close to the caecum had perforated. It was associated with other ulcers in the ileum which *post-mortem* examination showed to be tuberculous.

The common event is a chronic penetration of the bowel wall by the disease, and following this a matting together of bowel surfaces occurs, which may be first revealed by obstruction.

The two following cases illustrate two alternative methods of dealing with the condition.

CASE I.—Obstruction of Ileum: Lateral Anastomosis.

A male patient, aged 15, was seized with acute general colicky pains on March 29th, 1911. He did not admit any symptoms of abdominal disease before this date. He vomited frequently during the night of onset, and these two symptoms—pain and vomiting—continued for three days until he was brought to hospital. He then had all the signs of acute intestinal obstruction, distended coils of bowel were plainly visible about the central part of the abdomen, the flanks being empty.

The abdomen was opened at the edge of the right rectus; distended ileum was traced to a matted mass of bowel covered with tuberculous deposit; the ileum beyond this mass was collapsed. A simple lateral anastomosis was made between bowel proximal and distal to the mass.

The further clinical progress was satisfactory, the temperature was apyrexial after the fourth day. The bowels acted naturally forty-eight hours after the operation.

This method simply avoids the disease and deals with the complication. A more direct way of dealing with both is illustrated by the following case.

CASE II.—Obstruction of Ileum: Excision of Mass of Tuberculous Bowel.

A female patient, aged 65, had had an umbilical hernia for eighteen years, and six years previously had had an operation for this. A week before admission to hospital she had an attack of acute pain in the night and vomited. The day following the bowels acted loosely four times. She did not vomit subsequently, but was nauseated. The bowels continued to act twice a day until the day of admission; on this day they did not act. A large ventral hernia was present in the situation of the operation scar. The part of this tumour to the right of the middle line was tense and tender, that to the left was soft and reducible.

An operation was performed on the day of admission. There were two distinct sacs, one on either side of the middle line: the small intestine occupying the left sac was healthy and reducible; the right sac was occupied by a matted mass of small bowel covered by tuberculous deposit. The sac wall was also infected. The whole mass was drawn forwards and removed between clamps. The intestinal ends were closed and invaginated and a lateral anastomosis performed. The hernial openings were repaired. This was a case of limited tuberculous ileal disease with obstruction in a hernial sac; there was no strangulation at the neck of the hernial sac.

The bowels acted naturally in thirty hours. Subsequently for a month she had some irregular pyrexia but her general condition remained good. The mass removed consisted of 2 ft. of small intestine, covered with tuberculous deposit, in part in the form of discrete tubercles but for the most part patches of coalesced tubercles matting the coils.

There was a mild degree of infect on in the abdominal wound. Two months later an abscess formed under the scar which took eight weeks to heal. With this exception her recovery was satisfactory.

I do not think any law can be laid down as to whether exclusion or resection should be preferred in these cases of local ileal tuberculosis with obstruction, but obviously resection has great advantages over exclusion, in that it deals radically with the disease. The extent of bowel involved, the ease with which the mass can be isolated, will be guiding factors. The isolation of a mass which is not only matted by tuberculous disease but is also adherent to more or less distant coils is a precarious process. It is well known that separation of adhesions in a tuberculous abdomen is very liable to be followed by faecal fistula.

Caecum and Large Bowel.

The next most common seat of bowel tuberculosis is the caecum. Here, and at the other extremity of the colon, its pathological anatomy is different from the type in the ileum. Usually massive tumours are built up, the caecal wall becomes greatly thickened and infiltrated, and following, and in consequence of, this infiltration stenosis of the bowel lumen results.

Three cases, two of the caecum and one of the sigmoid colon, illustrate this type.

CASE III.—Tuberculosis of Caecum and Adjacent Parts of Small and Large Bowel: Section of Mass: Colostomy: Death from Pulmonary Phthisis.

A female patient, aged 36, was admitted to hospital complaining of pain in the right side of the abdomen. A tender swelling about the size of a kidney was to be felt in the right iliac region. She had a rigor on the day of admission. The pain had been present for three months, and was intermittent and associated with constipation. Two days after admission she had a severe attack of diarrhoea, the temperature rising to 102°.

On the fourth day the abdomen was opened and a mass exposed which involved the caecum, adjacent ascending colon, and six inches of the ileum. The whole mass was removed between clamps on the ileum and on the hepatic flexure of the colon and Paul's tubes fixed in each end of the gut. There was a good deal of shock, but she progressed fairly well, and a fortnight later an enterotome was fixed to break down the spur preparatory to closure.

The mass removed was tuberculous; there was extensive ulceration in the region of the ileo-caecal valve and terminal ileum, and of the caecum and about four inches of the ascending colon; there were also many tuberculous glands in the mesentery in the angle between ileum and caecum.

The operation was done on August 30th; on October 9th the artificial anus was closed under local anaesthesia, and the bowels acted through the natural channels next day. By this time, however, phthisis had been demonstrated in the left lung, and her general condition was bad. She died eighteen days later. *Post-mortem* a large cavity surrounded by necrotic lung was found on the left side.

This operation of excision is severe, and in the presence of acute obstruction probably never advisable—certainly not if the patient is a child. The alternative is illustrated by the following case.

* A paper read to the Liverpool Medical Institution.

CASE IV.—*Tuberculosis of Caecum: Lateral Anastomosis: Death from Pulmonary Tuberculosis.*

A boy, aged 3, had been attacked every five days or so for several weeks before admission with vomiting and abdominal colic. The attacks were treated by enemata and aperients. The attack in consequence of which he was admitted was severe, the symptoms being again general abdominal pain, distension, and vomiting. He was in a medical ward at first, and was transferred later in consequence of the discovery of a tumour in the right iliac fossa.

On opening the abdomen the tumour was found to be caecum infiltrated with exudation due to active tuberculosis. A lateral anastomosis was made between ileum and transverse colon. The bowels moved with the aid of a simple enema on the fourth day.

The abdominal condition was relieved, but six weeks after his discharge from hospital he was readmitted with bronchopneumonia affecting the right lung. The condition spread from the right base to the whole of the lung, and was tuberculous. He died three months later from the pulmonary condition.

At the other end of the colon the disease also takes the form of a stenosing infiltration. In the following case, although the precise condition has not been demonstrated, I think there is no doubt as to the nature of the lesion.

CASE V.—*Recurrent Attacks of Obstruction: Expectant Treatment.*

A lady, aged about 40, was under treatment during 1913 for a tuberculous focus in the lung; the nature of the infection was demonstrated bacteriologically. In June of that year she was sent to me with the history that for the previous two months she had had several attacks of severe left-sided abdominal pain, the attacks being associated with vomiting and watery diarrhoeas. They were intermittent, and for several days at a time she had no pain. The sigmoid colon in the left iliac fossa was palpable, tender, and infiltrated. She continued to have similar attacks, all associated with distension and vomiting; in the intervals mucus was often noticeable in the stools, but there was no history of any bloody discharge. Towards the end of the year chronic constipation became marked. During the early part of 1914 the attacks of definite intestinal obstruction continued; they lasted usually about twenty-four hours, and then subsided.

The question of operation was considered but not urged in consequence of her pulmonary condition. I have only recently seen her again. The condition of the colon appears to have become stationary; her general health is good, but she still suffers from recurrent attacks of obstruction, the severity of which, her friends say, she minimizes. They are all associated with vomiting, distension, and abdominal pain. There is still to be felt, just inside the left anterior superior spine, a swelling of the bowel about the size of the normal spleen, firm and moderately, not acutely, tender.

I think there is no doubt that in this case we have to do with a stenosing local tuberculous enteritis of the upper part of the sigmoid loop. A good result should be obtained by excision, but to this she will not at present agree.

Rectum.

In tuberculous disease of the rectum surgical treatment can do little; excision is impossible unless it takes the form of colostomy, and excision is out of the question. If the lesion goes on to abscess formation in the pelvis, as it not infrequently does, then the whole course of the disease may be favourably influenced by drainage. The following case is illustrative:

CASE VI.—*Rectal Tuberculosis: Pelvic Abscess: Laparotomy: Improvement.*

A young woman, aged 21, had been ill ten weeks before admission to hospital, the diagnosis being enteric fever. The symptoms throughout had been pain in the lower abdomen associated with diarrhoea. Occasionally the pain had been acute, and on two or three occasions she had vomited. For five weeks before admission she had had offensive vaginal discharge. The clinical course of the disease had therefore been subacute.

Five days after admission a sinus in the posterior fornix was demonstrated; it was enlarged with dressing forceps and a drainage tube inserted. There was considerable improvement after this, but diarrhoea persisted and also a nightly rise of temperature. For the next two months she remained in this condition, interrupted by a single rigor.

At the end of this time the abdomen was opened, and in the pelvis an abscess cavity with thick walls was demonstrated and drained. The discharge from this abscess persisted, and two months later the abdomen was reopened to the right of the sinus. After extensive dissection the abscess cavity was isolated, an adherent and damaged coil of small intestine being dealt with by suture. Scattered tuberculous deposits were present on the visceral and parietal peritoneum around. It was then clearly demonstrated that the primary focus of disease was rectal, and not tubal as had been thought probable. The cavity was scrubbed with iodoform paste and drained both above the pubis and through the vagina. The day after opera-

tion a faecal discharge came from the hypogastric wound, but the discharge was copious only for a short time. When she was discharged from hospital the house-surgeon's note says: "During the last few weeks patient's condition has improved considerably, and she has also begun to put on flesh. The fistula is almost healed, the wound only requires dressing once a day, and there is very little discharge."

Two and a half years later this patient came to hospital again with an abscess over the sacrum, which was opened. In the interval her health had been good, but recently the old sinus above the pubis had reopened, and there had also been some vaginal discharge. She complained of no pain except during the formation of the sacral abscess. There was some intermittent diarrhoea during her stay in hospital. Her later history I do not know.

Mesenteric Glands.

Without demonstrable intestinal lesions, the mesenteric glands are frequently the site of abdominal tuberculous disease. Frequently it is widespread; sometimes it is local, and when local it may be dealt with favourably by operation. A common site for a local deposit is the mesenteric angle between caecum and ileum. It happens to every one from time to time to meet with this condition, the diagnosis before operation being chronic appendicitis. Attacks of sharp darting pains, without any other symptom and with long intervals of freedom, associated with quite definite and localized tenderness about the caecum—these are the usual phenomena. It is good practice, I think, to remove such a gland group, but this means the most careful enucleation of the enlarged glands separately, and is both difficult and laborious. Before setting out on such a proceeding one should satisfy oneself that the disease is apparently local and capable of being dealt with completely. The alternative to enucleation is excision of a mesenteric segment with its glands together with the corresponding length of bowel.

CASE VII.—*Excision of Tuberculous Mesenteric Glands.*

A boy, aged 11, was admitted to hospital with the history that during the previous year he had had occasional attacks of colic, pain being about the centre of the abdomen. A week before admission he had had a severe attack, and again three days before, accompanied by vomiting. A tumour was at this time found in the abdomen; it measured 2 in. vertically and 3½ in. transversely and was situated just below and to the left of the umbilicus. It had irregular rounded margins and was freely movable with the hand.

Two days after admission the abdomen was opened in the middle line and the tumour was found to consist of a local mass of tuberculous mesenteric glands, the central part being a thick-walled abscess cavity to which omentum was adherent. The mass was removed entire together with 3 ft. of corresponding ileum and an end-to-end anastomosis was done. An attack of bronchitis complicated convalescence. The bowels acted forty-eight hours after operation. He was discharged five weeks later.

I have not included in this survey the simple stricture of the small intestine which results from the cicatrization of tuberculous ulceration for the reason that I have never met with a case demonstrably of this nature. Nor have I included the cases of intestinal obstruction due to strangulation by bands originating in tuberculous foci, because they are of fairly frequent occurrence and the problem is usually that of simple relief of the strangulation. I offer the following suggestions on the surgical treatment of the conditions described.

SUMMARY OF RECOMMENDATIONS.

1. When tuberculous disease, either of ileum or large bowel, is associated with definite intestinal obstruction, operation is always necessary, and the choice lies between occlusion by anastomosis and excision. If the obstruction is acute, excision by anastomosis is to be preferred; if the obstruction is subacute the exact local condition must decide; a mass that is easily isolated is better removed.

2. When such tuberculous bowel lesions are not associated with obstruction, or with an obstruction that is chronic and capable of relief by aperient, the advisability of operation will depend on whether the bowel disease is or is not the sole demonstrable lesion in the body. If the lung is also affected it will probably be wiser to decide against operation.

3. With regard to disease of the rectum I know of no actual evidence that a remedy is to be found in the establishment of an artificial anus. This has been recommended and practised on the ground that keeping the rectum empty affords a better prospect of resistance and recovery. I know at any rate of one instance in which this procedure added to the patient's discomfort without

obvious benefit to the rectal condition. Before recommending this method of treatment we should require a body of evidence that cure of the rectal disease can really be anticipated in a fair proportion of cases. When the rectum is affected above the peritoneal reflection, and is associated with abscess, evacuation of the abscess by the intraperitoneal route is to be recommended, but except for the treatment of this complication operation has no service to offer.

4. Lastly, in selected cases, operation gives good results in limited tuberculous disease of mesenteric glands. According to the extent and stage of the focus this will take the form either of enucleation or of excision of the mesentery involved, together with associated bowel.

SPHENOIDAL EMPYEMA AND EPIDEMIC CEREBRO-SPINAL FEVER.*

BY

DENNIS EMBLETON, M.A., M.B.,

BACTERIOLOGIST TO UNIVERSITY COLLEGE HOSPITAL.

THERE are four varieties of the clinical course taken by cerebro-spinal fever.

First, there is the type which, commencing as an acute illness, may then go on to recovery or may result in death.

There is, secondly, the type of case that, after having shown considerable improvement from the acute stage, suffers from a recrudescence, both in general symptoms and in the condition of the cerebro-spinal fluid. This usually occurs from the fifth to the twelfth day, and may subsequently lead to recovery or death.

Thirdly, there is the type of case that, after convalescence from the acute stage, still retains a tendency to suffer from malaise, headaches, and vomiting, which gradually become more pronounced. The patient becomes extremely emaciated and death occurs from hydrocephalus.

Fourthly, there is the case that, having entirely recovered from the preliminary attack, months later has a relapse which may prove fatal.

Thirty-four *post-mortem* examinations were made in the Netley district between 1915 and 1919, on cases of cerebro-spinal fever dying as a result of one of these four types of the disease. These are all grouped in the accompanying tables under three of these types:

- A. Those dying during the acute illness ... 21 cases
- B. Those dying during a recrudescence ... 6 "
- C. Those dying from hydrocephalus during convalescence ... 7 "

One case only (22) died as a result of a relapse occurring months after the preliminary attack, but as he suffered from an apparently typical attack of the disease with a recrudescence he is grouped under heading B for convenience.

Of these 34 deaths only 11 occurred within the first week of illness. In this observation we differ from Rolleston,¹ who states that "more than half the fatal cases occur during the first week of the disease." A possible explanation of this difference is that at Netley we were fortunately able to insist that every case in which the least suspicion of cerebro-spinal fever was entertained should be immediately admitted to the isolation hospital. On admission, lumbar puncture was performed as a routine within a few minutes of arrival, antimeningococcic serum being administered there and then to cases showing turbid cerebro-spinal fluid. A bacteriological diagnosis was only waited for when there was middle-ear disease or a head wound. This very early administration of serum, often within an hour or two only of the suspicion of cerebro-spinal fever being present, probably saved many cases who would otherwise have died during the first week.

In a previous paper² it was shown that of 36 cases in which it was possible to obtain cultures from both the nose and the cerebro-spinal fluid, in 35 the types of meningococci in the two sites were identical, as proved by both agglutination and saturation tests. The irregularity shown by the remaining case has been discussed.

In no case was any inflammatory process discoverable about the cribriform plate of the ethmoid by naked-eye examination. The contents of the pituitary fossa showed

Note.—In no case was the cribriform plate of the ethmoid affected. The contents of the pituitary fossa were inflamed in every case. In Case 8 there was inflammation of the middle ear, and in Case 9 pus; in all other cases the ear was not affected.

inflammation in every case. The middle ear was seen to contain pus in one case, and there was congestion of the bone but no pus in another case.

There was an empyema of the sphenoidal sinus in

A. Acute case deaths	20 out of 21 cases
B. Recrudescence deaths	5 out of 6 "
C. Hydrocephalus deaths	7 out of 7 "

An empyema of the sphenoidal sinus is taken to mean a cavity filled with pus, muco-pus containing fresh and autolyzed pus cells, or glairy fluid showing pus cells, and the mucous membrane of the sinus showing congestion.

In 34 necropsies an empyema of the sphenoidal sinus was present in 32 cases. In the pus from the sphenoidal sinus—

Meningococci were proved serologically in	...	8 cases
Meningococci were cultured but were not tested serologically in	...	2 "
Meningococci were seen but not grown in	...	10 "
No meningococci were seen or grown in	...	12 "

Inflammation of the sphenoid bone over the empyematous sphenoidal sinus was not found at all in recrudescence and hydrocephalus deaths, but was found in 7 cases of deaths from the acute illness. In these 7 cases the meningococcus was only found three times, and the type of the meningococcus was only able to be proved once, but was in this case the same as that found in the nose and cerebro-spinal fluid.

The association of sphenoidal sinus inflammation with cerebro-spinal fever was first noticed by Westenboffer,³ who only found it to occur in one-third of his twenty-nine necropsies. Other workers have also reported cases showing empyemata of the sphenoidal sinus, but have generally considered that this condition is not the cause of the disease, either because they have been unable to find an empyema in all cases or because they have been unable to trace the meningococcus in the walls of the sphenoidal sinus or in the body of the sphenoid bone. Very great improvements have recently been made by Mervyn Gordon in the culture medium for the propagation of the meningococcus, so that a meningococcus can now, under suitable circumstances be made to grow as rapidly and luxuriantly as a *Bacillus coli*. These improvements were not available for most of the workers in this connexion. In spite of these advantages the meningococcus was not demonstrated in the sphenoidal empyema in 12 of these cases. This was possibly due to the length of time that elapsed between death and the necropsy in many cases, and also to the chilling of the plates during transport from a distant camp to the laboratory in very cold weather. The majority of deaths occurred during cold weather, and meningococci are difficult to cultivate in primary culture unless precautions against chilling are taken.

Thus in 34 deaths from cerebro-spinal fever empyemata of the sphenoidal sinus were found 32 times; meningococci were found 20 times in the sinus and 3 times in the sphenoid bone. In no other diseases were empyemata of the sphenoidal sinus observed, except during the epidemic of "Spanish influenza," when empyemata of the sphenoidal sinus were frequently found.

The relationship between an empyema of the sphenoidal sinus and cerebro-spinal fever may now be considered. The primary site of a meningococcus infection in the human body is undoubtedly the nasopharynx. The meningococcus has been demonstrated in this position not only early in the acute attack, but also in the incubation period,⁴ in carriers who never develop meningeal symptoms, in meningococcal pneumonia, etc. The infection is propagated from person to person, as is a common cold, from nose to nose. The frequency of the carrier condition and the relative infrequency of the disease is noteworthy. It is probable that the whole population of England has been a carrier at some time or other during the last five years, and yet the total number of cases is relatively small.

At the time when contacts to cases of cerebro-spinal fever were examined for the carrier condition, it was always noticed that the people under examination were suffering from coughs and "colds." Many of the contacts gave pure cultures of the meningococcus in the nasopharynx. This suggested that the "colds" were in some cases due to the meningococcus. Also several carriers, when first isolated, suffered from a profuse watery nasal discharge, from which only the meningococcus could be isolated. Chronic carriers nearly always had a glaucous nasal discharge, which was apparent on examination of a nasal

swab. It thus appears that the meningococcus can give rise to a nasal catarrh. It seems probable that this is the natural disease produced by this organism, and it is only when some other factor comes into play that meningitis or septicaemia results. This other factor does not seem always to be a rise in virulence of the meningococcus, for of the camp epidemics about Southampton and Winchester during the war it was only in one epidemic that all the cases of meningitis were due to one serological type of meningococcus. Usually two or three serological types of meningococcus were recognized in the cases of one epidemic, the carriers found in the camp corresponding with the serological types of meningococcus in the cases.

Thus, in the Winchester epidemic of the spring of 1917 there were 8 cases, 3 due to Gordon's Type I coccus, 2 due to Gordon's Type II, 2 due to Type IV, and one in which the type was not proved. The carriers found were all infected with one of these three types of meningococcus; no Type III carriers were found.

On another occasion two cases occurred in one ward in a hospital within four days of one another. If serological tests had not been performed, it would have been felt certain that either one case infected the other, or that both were infected from the same source. This was not so, as the first case was due to Gordon's Type II, and the second due to Gordon's Type I or III coccus.

Some epidemics in other parts may have been produced by a particularly virulent meningococcus of one serological type, but it is evident that this is by no means a necessary condition for the outbreak of an epidemic.

The frequency of the appearance of a sphenoidal sinus empyema suggests that this might be the determining factor in the onset of the meningitic form of the disease at any rate. The empyema may be the result of an inflammatory reaction to the meningococcus on the part of the mucous membrane lining the ostia. The fact that the meningococcus was several times isolated in pure culture from the sinus suggests that for the inflammatory closure of the ostia a mixed infection is not necessary, although streptococci and staphylococci were also found on occasions to be present. Thus a sphenoidal empyema might be produced by a meningococcal infection of the nasal mucosa of an individual whose resistance to the meningococcus was such that the infection resulted in a vigorous inflammatory reaction. Anatomical or pathological peculiarities in this region might also favour the production of an empyema.

In cases dying from cerebro-spinal fever an empyema of the sphenoidal sinus was common, in only 2 cases (17 and 26) in this series, out of 34, was this condition not found. Both these cases died at a considerable number of days from the onset, 27 and 48 respectively; 47 completely recovered cases, on the other hand, were examined by rhinological experts, Dr. Peters and Dr. Bryant, who found that no sphenoidal empyemata were present. Chronic carriers⁵ were also carefully examined bacteriologically, and no meningococcal infection of the sinus was found. Thus in dying cases an empyema was frequently found; in completely recovered cases no empyemata were discovered. A series of five cases showing symptoms of hydrocephalus were operated on for drainage of the sphenoidal sinus.⁶ Of these cases all showed the presence of a sphenoidal empyema. The meningococcus was only cultivated and proved serologically in one of these cases from the sphenoidal pus obtained at the operation; a typical Gram-negative diplococcus was seen only, but not grown, in another case. But in two other cases, subsequent to the operation, the meningococcus reappeared in the throat in pure culture, after it had entirely disappeared for some weeks previously. Subsequent to the operations all cases appeared temporarily worse, three made complete recoveries, two died with typical hydrocephalus *post mortem*. Of the recovered cases one went through a typical relapse after the operation, with reappearance of the meningococcus and pus in the theca, subsequently completely recovering.

From this it would seem that if early and vigorous serum treatment be given, and if the sphenoidal empyema disappear, recovery will probably occur. If, however, the empyema persist, the case will, if it recover from the acute illness, either relapse or go on to hydrocephalus.

In order to see if draining the sphenoidal sinus during the acute stage of the illness would accelerate recovery, three cases of cerebro-spinal fever were operated on; a sphenoidal empyema was found in each case, but each case died. This discouraged further operative procedure during the acute stage.

The next point under consideration is, how do the meningococci get from the nasal mucosa to the meninges?

There are many possible routes:

1. The arachnoid prolongations round the olfactory nerves.
2. The perineural lymphatics.
3. Direct inflammatory extension.
4. The pituitary.
5. The systemic lymphatics.
6. The blood stream.
7. The middle ear.

1. The Arachnoid Prolongations Round the Olfactory Nerves.

This route is favoured by Netter and Dobré and Flexner. Netter and Dehré show that dyes, Indian ink, and meningococci can get from the cerebro-spinal fluid into the nose by this route, but they do not show that the reverse can take place. Their experiments show that the natural direction of the current is from the cerebro-spinal fluid to the lymphatics; it is thus difficult to see how the meningococci could progress against the stream to gain access to the meninges except by inflammatory extension. In none of this series of *post-mortem* examinations was there any naked-eye appearance of inflammation about the cribriform plate of the ethmoid.

2. The Perineural Lymphatics.

In papers by Orr and Rows,⁷ Teale and Embleton,⁸ it has been shown that not only dyes and toxins, if injected into a nerve, will travel up the perineural lymphatics to the cord, but also particulate material, such as washed spores. These spores can be traced up the perineural lymphatics into the substance of the cord itself. In this way it might be possible for the meningococci to travel up the perineural lymphatics to the brain substance. Cerebro-spinal fever does not, however, appear to start as an encephalitis, so, although this route would be a satisfactory one for polio-encephalitis, it does not seem suitable for cerebro-spinal meningitis, especially as it has been shown that neither toxins, dyes, nor particulate material, when passing up a perineural lymphatic, get into the cerebro-spinal fluid.

3. Inflammatory Extension.

It has been suggested that meningococci could gain access to the cerebro-spinal fluid by a process of inflammatory extension through the bone separating the nose and accessory sinuses from the meninges. In this series of necropsies there is evidence of direct spread from the sphenoidal sinus to the sphenoid bone, and so to the overlying meninges. In seven cases there was inflammation, and the meningococcus was found three times in the bone. In the other cases no evidence, as viewed by the naked eye, of inflammatory extension could be discovered.

4. The Pituitary.

An infection from Luschka's pharyngeal tonsil along a possibly patent connexion between this and the pituitary gland has been suggested. Luschka's tonsil is one of the sites in the nose most richly infected with the meningococcus. In this series of necropsies the pituitary body always showed infection, but it is obvious that this would certainly occur anyhow from its intimate relationship with the cerebro-spinal fluid.

5. The Systemic Lymphatics.

The ordinary flow of lymph from the nasal passages is away from the brain, and in connexions between the subarachnoid space and the lymphatic system the current is away from the meninges. If bacteria⁹ are injected into the arachnoid space they rapidly appear in the lymphatics of the head and neck. If, however, a process occurs, such as an empyema of the sphenoidal sinus, the ordinary direction of lymph flow might be reversed, and bacteria be thus forced from the lymphatics of this neighbourhood towards the meninges, without showing any sign of inflammatory extension. In the case of a sphenoidal empyema large numbers of meningococci would get into the lymphatics, and by this means would also get into the blood stream. It would only be necessary for a sphenoidal empyema to exist for a very short time to produce these effects, possibly only for half an hour. If the sphenoidal empyema discharged at the end of a short time into the nose, and if the meningococci that had reached the meninges were destroyed, a recovery would ensue. If, however, the sphenoidal sinus empyema persisted, and kept on pouring fresh infection into the meninges, the case would probably die.

6. The Blood Stream.

Many workers have considered that the infection of the meninges occurs by way of the blood stream, the meningococci gaining access to the blood from the nasopharynx. This suggestion has been based partly upon the early appearance of the meningococci in the blood, and partly on those cases of meningococcal infection where no meningitis occurs. The blood stream, however, would receive meningococci very early in the infection of the nasal mucosa, at any rate as soon as an empyema of the sphenoidal sinus occurred. The meningococci would reach the blood stream from this region via the deep cervical lymphatic trunks, which join the thoracic duct just before it enters the venous system in the neck. Also, as soon as meningococci gained access to the cerebro-spinal fluid, they would appear⁹ in the blood stream, both direct, via the Paccionian bodies, and also by way of the lymphatics, through their junctions with the subarachnoid space. The blood then

would, from the very earliest stages of the disease, receive repeated and heavy showers of meningococci from the sphenoidal region and the cerebro-spinal fluid. Thus it can be said that the early finding of the meningococcus in the blood stream is no indication that the meninges are primarily infected by this route.

In the recent outbreaks of "Spanish influenza" empyema of the sphenoidal sinus was a common finding in the fatal cases, but meningitis was rarely found. It is not necessary, then, that an empyema should be followed by meningitis. It is thus possible that the meningococci can gain access to the blood stream from a sphenoidal empyema, and so be carried round to the meninges and set up inflammation.

7. The Middle Ear.

Inflammation in this region was only found in two necropsies in this series. It is unlikely that this is the portal of entry of the meningococcus to the meninges.

Thus it would appear improbable that the meningococci gain access to the meninges through the arachnoid prolongations round the olfactory nerves, or by way of the perineural lymphatics. It is probable that the meningococci pass by way of the lymphatics from the sphenoidal sinus direct to the meninges, with or without naked-eye signs of inflammation. It is possible also that they can be conveyed to the meninges by the blood stream.

The relationship between a persistent sphenoidal empyema and hydrocephalus may now be considered.

In the seven deaths from this condition an empyema was found in each case. Five cases were operated on, and pus was found in the sphenoidal sinus each time; two of these cases died, and are grouped in with the *post-mortem* cases. There were thus a total of 10 cases of hydrocephalus, and in each case a sphenoidal empyema was found. The cerebro-spinal fluid in the ventricles of each of the cases which died contained pus cells. The cerebro-spinal fluid taken from the lumbar region was usually quite clear.

This suggests that there is a close relationship between empyema of the sphenoidal sinus and the hydrocephalus that develops after an attack of cerebro-spinal fever. The hydrocephalus develops as a result of a chronic infection about the foramina of Luschka and Magendie. This chronic infection also appears to exist in the ventricles. The exact path by which the meningococci in the sphenoidal sinus empyema reach the interior of the ventricles is not clear, unless it be by the blood stream. But there would appear to be some relationship between the two positions, inasmuch as the only three cases who recovered from the hydrocephalus condition did so after an operation for drainage of the sphenoidal sinus. It might be argued that these three cases who recovered were not examples of hydrocephalus at all. Against this it is urged that all five cases operated on were advanced cases with typical symptoms; the two that died showed typical necropsies, and all other cases showing these symptoms died with typical necropsies.

The course of events in a case after infection of the nasal mucous membrane with the meningococcus might be as follows:

1. A simple catarrh, followed either by recovery or a chronic infection.
2. A vigorous local reaction in the nasal mucosa followed by sphenoidal empyema. This may produce a general blood infection, with or without infection of the meninges.

If the sphenoidal empyema disappear, the body, with or without the aid of antiserum, may be able to deal with the meningococci that have gained access to it, or death may result. If the sphenoidal empyema persists, and very heavy discharges of meningococci are poured into the body, death will probably result. If, however, the empyema remains quiescent, improvement may occur, but at any time a recrudescence or a relapse may supervene. A quiescent empyema may also keep up a smouldering infection which will lead to hydrocephalus.

Operation on the sphenoidal empyema always produced an increase in general symptoms. During the acute stage of the disease this increase in symptoms appeared to accelerate, at any rate, a fatal termination. In hydrocephalus cases recovery did occur in three cases, though one case went through a severe relapse.

The author wishes to acknowledge his indebtedness to Miss Iris Harmer for her valuable work in connexion with this research.

Summary.

1. In thirty-four necropsies on persons dying from cerebro-spinal fever, empyema of the sphenoidal sinus was found thirty-two times.

2. In ten cases of hydrocephalus following cerebro-spinal fever an empyema of the sphenoidal sinus was found in every case.

3. In forty-seven completely recovered cases of cerebro-spinal fever no sphenoidal empyemata were present.

STERILITY IN THE MALE.

BY

KENNETH WALKER, F.R.C.S.,

LECTURER IN VENEREAL DISEASES AND OFFICER IN CHARGE OF
VENEREAL DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL.

WHEN a marriage is infertile it is still sometimes too readily assumed that the woman is at fault, although all writers on the subject recognize that the defect may rest with the husband. The object of the following summary is to emphasize the fact that no operative procedures on the wife are justifiable until the male has been properly examined, and until it can be definitely stated that his semen contains live, healthy, and vigorous spermatozoa.

It is difficult to obtain reliable statistics as to the frequency with which the male is at fault in childless marriages. The figures given by different authorities show great discrepancies, but at any rate they indicate that the fault of the childless marriage lies far oftener with the man than is commonly supposed. Hubner, in his investigation of 129 childless marriages, discovered a male sterility of 59 per cent., and Kehlers, amongst 40 similar couples, one of 35 per cent. Gross, in figures collected from various authors, convicts the husband in 17 per cent. of childless marriages, whilst Vedder places it as high as 70 per cent. Barney, in investigating 40 childless unions, found 20 sterile husbands, and, what is still more suggestive, discovered that the wives of 4 of these (20 per cent.) had undergone more or less severe operations for sterility! Even if the lowest of the above percentages be taken as correct, it is sufficient to support the dictum that "the investigation of childlessness should begin not with the curttage of the wife, but with the microscopic examination of the husband's semen" (Belfield).

The investigation of sterility in the male necessitates no small amount of labour and skill. Such gross lesions as epispadias, hypospadias, cryptorchism, malignant disease, bilateral tuberculosis, and gummata of the testis, require no consideration beyond the noting of the fact that tuberculous epididymitis, even although it be unilateral, causes azoospermia in 85 per cent. of cases. This fact depends on the frequent association of a unilateral tuberculous epididymitis with disease of the prostate. It is the case where no gross lesion of the male genitalia is present that calls for careful investigation.

Whereas with the female it is Nature that plays the chief role in producing sterility, with the male the condition is more often the legacy of disease. A careful history of previous illnesses is the first step in the investigation. The orchitis of mumps, especially when it occurs about the age of puberty, is, as a rule, followed by atrophy. Fortunately such an orchitis is generally unilateral. Alcoholism, exposure to rays, debilitating diseases, and sexual excesses, whether from natural coitus or masturbation, produce an azoospermia or oligospermia which is temporary in nature. Prolonged and absolute continence has been said to have a similar result (Barney). Non-venereal infections of the testicle and prostate, whether by typhoid, *Bacillus coli*, or staphylococci, may similarly result in azoospermia, oligospermia, or necropermia, as the case may be. In a few cases it would appear that the otherwise healthy testicle of a normally active and sexually vigorous man may be entirely unproductive of spermatozoa (Janet).

But although non-venereal causes may sometimes be responsible for sterility in the male, by far the commonest

cause is a previous attack of gonorrhoea. When it is remembered that in many countries the incidence of this disease is from 50 to 75 per cent. of the total adult male population, its importance as a potential cause of sterility amongst males cannot be exaggerated. All authorities recognize the frequency with which the posterior urethra becomes implicated in gonorrhoea, and it is with posterior infections that sterility is usually associated.

The frequency with which gonorrhoea, and especially gonorrhoea affecting the posterior urethra, produces sterility is borne out by many observers. In this connexion figures published by Benzler (*Arch. f. Derm. und Syph.*, 1898, xlv) are especially interesting. This observer followed the history of German soldiers who had suffered from gonorrhoea and had been subsequently married for three years or over. Especial attention was paid to a previous history of epididymitis.

Of those who had escaped epididymitis ...	10.5% were childless.
Of those who had had unilateral epididymitis ...	23.4% were childless.
Of those with previous bilateral epididymitis ...	41.7% were childless.

Clinical observations on the husbands of childless women with normal genitalia support these figures. The majority of these, when sterile, will be found to have suffered from gonococcal prostatitis, with or without epididymitis. It is often the prostatitis rather than the epididymitis that is the determining factor, and, when the proximity of the ejaculatory ducts and their liability to occlusion is remembered, this is not surprising. Moreover, even when no mechanical obstruction has been produced, pathological changes in the prostatic fluid resulting from inflammation are alone capable of producing necropermia or oligospermia. Even healthy spermatozoa lose their vigour in the presence of pus or blood, and when, in addition to this, the activating secretions of the prostate are deficient, necropermia and asthenospermia are extremely probable.

The second step, therefore, in the investigation of a case of male sterility is a careful and complete examination of the genitalia and urethra for evidence of past or present gonococcal infection. This must invariably conclude with a urethroscopy of the posterior urethra, for it is in the presence of a prostatitis, a vesiculitis, or a colliculitis, that the explanation of sterility will often be found.

The final step in the examination includes a microscopic examination of the male secretions. As a preliminary the secretions expressed as a result of prostatic massage are subjected to examination. Attention is paid to the presence of pus cells, and the appearance of such spermatozoa as may be present is noted. This examination is, however, but a preliminary to the more detailed investigation of the seminal fluid obtained after coitus with a condom. This examination, although it gives valuable information, is unfortunately open to error. The condition of spermatozoa some hours after evacuation into a condom does not necessarily reflect their condition when deposited in the vagina. For this reason Wolbarst urges the advisability of examining the vaginal and cervical secretions at various intervals after coitus has taken place. Such an examination is not always obtainable, but when suitable arrangements can be made the results are invaluable. Details of the examination are beyond the scope of this article, but as a result of observation of the spermatozoa, with reference to their number, freedom from imperfect or degenerate forms, mobility, and vigour, the question of the fertility or non-fertility of the male can in the great majority of cases be put beyond doubt.

In the above summary no attempt has been made at completeness. The subject of sterility in the male is far beyond the limits of a brief note. What has been attempted is merely to emphasize two facts which, although they may be known, are apparently too often forgotten. The first of these is the relative frequency with which sterility occurs amongst males; the second is the lack of justification in subjecting any woman to operation for sterility unless her husband has undergone a careful preliminary examination.

THE SIGNIFICANCE OF THE POSITION OF A "CONTRACTION RING"

IN CASES OF EXTREME PELVIC CONTRACTION WITH
VERTEX PRESENTATION.

BY

C. D. LOCHRANE, M.D., F.R.C.S. Ed.,
SURGEON, DERBYSHIRE HOSPITAL FOR WOMEN, DERBY.

A RING of contracted uterine musculature is liable to form the region of the junction of the upper and lower uterine segments in delayed labour.

One of the commonest conditions in which delay occurs is contracted pelvis. When, in addition to a marked degree of pelvic contraction, the fetus presents by the vertex, the position of this ring, in relation to the fetal parts, is of considerable importance, both from the point of view of etiology and of treatment.

In obstructed labour due to contracted pelvis with a vertex presentation it is at least doubtful if a true "retraction ring" (Bandl) ring can form before sufficient upper uterine segment retraction has occurred to elevate the site of the ring above the level of the fetal shoulders. But cases are occasionally seen in which the formation of a "ring" has become so marked before this stage, that it is found constricting the fetal neck more or less closely. The trunk and limbs of the fetus are then imprisoned above the ring in an unretracted, but often apparently normally contracted, upper uterine segment. With a markedly contracted pelvis, the head, in these cases, is held in purchase between the ring above and the pelvic inlet below.

The most recent view is that a "ring" forming in this position under these circumstances does not merit the name of "retraction ring" (Bandl), but is rather of the nature of a "contraction ring" due to local spasm of the uterine muscle (with or without contraction—but without definite marked retraction—of the upper uterine segment). In the opinion of the adherents of this view the chief cause of this spasm, before marked retraction has taken place, is over-irritation of the uterus by excessive manipulations in efforts to deliver.

Though opinion is not even now unanimous on this point, there is undoubtedly much to be said in its favour. Budin,¹ Cheron,² and Demelin,³ in 1898-9 (and more recently White⁴), have described a type of case in which such a ring occurs with apparently unretracted, and even flaccid, upper uterine segment. Berkeley, Russell, and Fairbairn⁵ speak of it as an established clinical entity. In Germany von Rosthorn⁶ and Bumm⁷ state that a "contraction" ring begins to be evident on the inner surface of the upper part of the lower uterine segment from the onset of uterine contractions in every labour—that is, before such retraction has occurred. On the other hand, Veit⁸ denies the occurrence of rings of this type (and Williams agrees with him). He says in effect that all such rings are true retraction rings, and that the views of Budin and others are the result of faulty observation.

Jardine⁹ (quoting four cases, apparently of this type) discusses the subject fully. He points out that retraction of the upper segment is always occurring *pari passu* with contraction. He speaks of the retraction (or Bandl's) ring varying in position with the degree of retraction which has occurred. But he speaks of it always as a retraction ring, wherever formed. In some of his quoted cases it is interesting to note that there was no obvious evidence—that is, no marked pelvic contraction—of obstructed labour.

Whatever the exact pathogenesis of the ring may be in these circumstances a very serious proposition is undoubtedly encountered when it develops in association with a markedly contracted pelvis.

I have had the opportunity of treating one case of this type and of observing the treatment of another. In both the conjugate diameter was so small that the indication was absolute for Caesarean section had the cases been seen at or before the onset of labour. There had, however, been much intrauterine manipulation in both during previous attempts to deliver. A ring in both cases tightly constricted the fetal neck (vertex presenting). It appeared quite impossible that the head could be delivered upwards through the ring if Caesarean delivery were attempted. It appeared equally certain that, even were it possible to deliver the head *per vias naturales*, it would have

been quite unsafe to attempt extraction of the trunk through the narrow ring, however extensive the previous embryuleia.

In the case I treated personally the upper uterine segment showed some evidence of thickening above the ring as compared with the part below, the fetal trunk being somewhat difficult to palpate distinctly. The ring sulcus was quite marked on external palpation, and indeed to the eye.

In such cases an unusually difficult situation is presented, the fetal head being absolutely fixed and impacted between the "ring" above and the true brim below. By the time the case reaches this stage the fetus is usually dead, owing to the cutting off of the maternal blood supply—the result of tonic uterine contraction. An accessory factor in one of the quoted cases was an unreplaced prolapsed cord, which, with premature rupture of membranes (both cases), is a not unusual occurrence in marked degrees of pelvic contraction.

In considering treatment of this condition it must be remembered that, while the usual death of the fetus gives the widest latitude in choice of procedure, the patient is generally in rather bad shape physically. There is danger in extensive or prolonged manipulations both of general collapse and of uterine rupture. The type of interference involving the least shock, and that capable of being performed most rapidly, is that to be chosen. The lines of treatment calling for consideration are the following:

1. Craniotomy alone.
2. Craniotomy with embryuleia.
3. Caesarean section alone.
4. Caesarean section after craniotomy.
5. Caesarean section after craniotomy and decapitation.

Craniotomy alone will not help for obvious reasons.

Craniotomy with embryuleia, under deep chloroform-morphine anaesthesia, to relax the uterus (morphine gr. $\frac{1}{4}$ to $\frac{1}{2}$ given at least half an hour before operation), might allow of delivery *per vias naturales* in cases with less than the most severe degrees of pelvic narrowing. Under unfavourable conditions for better forms of treatment (for example, unsuitable rooms for operations) this line of treatment might be tried, but it should only be considered under such conditions and then only in conjugates of $2\frac{1}{2}$ in. or more.

It is not the best treatment because, apart from the danger of deep chloroform anaesthesia in such poor subjects—

- (a) Time may be lost in waiting and in the process of manipulations.
- (b) Necessary manipulations may possibly cause recurrence of spasm.
- (c) The danger of uterine rupture (now imminent) is great.
- (d) I have reason to believe, from personal observation (see below), that relaxation of the ring is not always attained to a useful extent.

Caesarean section without preliminary craniotomy will not in the vast majority of cases allow of delivery, as the "ring" will rarely allow of extraction of an uncrushed head.

The best choice for the patient lies between craniotomy followed by Caesarean section, and craniotomy *plus* decapitation and Caesarean section. Preliminary craniotomy should be done in any case. Decapitation will be difficult, and not without danger in such cases. It will prolong the interference, though no doubt it removes the possibility of trouble in subsequent upward withdrawal of the crushed head through the retraction ring during Caesarean section. The former method is the better, as in any case the neck could be more rapidly divided from above if necessary, and the head extracted later in the unlikely event of its not being deliverable upwards through the ring.

All cases of this type which have been "handled" to any extent (as many will have been before coming under observation) are so likely to become septic that it will often be safest to do Caesarean hysterectomy (or, if preferred, the Porro operation). If supravaginal hysterectomy be the operation chosen the peritoneum over the cervical stump should alone be sutured, the stump itself being left open to secure better drainage of the parametria.

In the unlikely event of the fetus being alive, an effort must be made to save it, even at added risk to the mother.

Under suitable conditions immediate abdominal Caesarean section, with rapid incision of the ring internally, would be the correct treatment. The site of incision being under immediate control, the choice of immediate suture or hysterectomy would then be guided by the probability of previous septic infection.

The following is the type case, the story of the other particulars of which I am not at liberty to publish) being almost exactly similar.

Mrs. M., 29 years, primipara, was seen in consultation in a nursing home. The doctor reported the patient twenty-four hours in labour, and that membranes ruptured early; the os was fully dilated. The head was quite above brim, marked overlapping, but beld down firmly on to brim and not movable to any extent. The cord was prolapsed and pulsation absent.

The marked retraction ring was very palpable and visible above fetal head but below the shoulders. Fetal parts could not easily be made out by palpation. Tonic, slightly tender upper uterine segment. Forceps had been applied several times without result. (Blunt-hook traction under chin had been tried for some time, and the hook was still in position when I first saw the case.) The temperature was 99°, and the pulse 100. Pelvic mensuration showed: Interspinous diameter, 10 in.; intercrystal, 10 in.; diagonal conjugate, 2½ in. Markedly oblique rickety flat type of pelvis.

The indications were absolute for Caesarean section, but there had been much handling before I saw the case, and considerable laceration and oedema of the soft parts were present. It appeared certain that the patient must be extensively septic.

Operation.

I therefore hesitated to do abdominal Caesarean section at once and decided to give the patient another chance of delivery *per vaginam*. The head was first thoroughly broken up. Then, under deep chloroform-morphine anaesthesia (in the hope of relaxing the ring and thus of being able to get the shoulders past it and do an extensive embryulcia) steady traction of moderate force was tried for a short time. The ring showing no sign of relaxing, and the patient being in indifferent condition, it was decided to waste no more time, and abdominal Caesarean section was performed as quickly as possible. During the operation, though the anaesthesia was deep and the patient still under morphine, the fetal neck was still closely beld in the ring, and the well-broken-up head was only extracted upwards through the ring with some difficulty. The ring did not appear very dilatate. The uterine wall appeared rather thicker than usual (not markedly so) during incision. Supravaginal hysterectomy was done. Both adnexa were left *in situ*.

Infection of an acute septicaemic type began on the third day of convalescence, and the patient had a stormy passage for three weeks, when the temperature subsided.

The patient was given *Streptococcus phylacogen* during the first week, and as this appeared to have no effect on the condition, she had two injections of a heterogeneous polyvalent streptococcal vaccine at intervals of a week. Continuous breast saline was given throughout.

I do not doubt that the removal of the uterus saved the patient from a still more violent sepsis and a worse fate.

In closing, it appears appropriate to point the moral that prevention is better than cure. A careful measurement of the most important diameters of the bony pelvis should be made in all primiparae, and in pluriparae with a history of previous difficulty in labour. Of more importance still is to note the position of the fetal head and its fit in the brim from ten to seven days before the expected date of labour. These should not nowadays be regarded as counsels of perfection. The necessary investigations are neither highly technical nor difficult, and are constantly practised by some practitioners (and they not the least busy). If they were carried out by all we should see far fewer of these "regrettable" cases than we do at present.

BY an Act dated October 20th, 1919, every Frenchwoman admitted to maternity benefit under the law will receive during the twelve months following delivery a supplementary allocation of 15 francs a month at the cost of the State. The allocation will be granted as long as the law relative to indemnity for the increased cost of living continues in force, on condition that the mother suckles her infant and takes proper hygienic care of herself and her child.

RHINOPLASTY AND CHEILOPLASTY.

BY

RUSHTON PARKER, M.B., B.S., F.R.C.S.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF LIVERPOOL;
LIEUT.-COLONEL R.A.M.C.T., MERSEY DEPENCES.

An intelligent apprentice engineer, aged 16, whose nasal cartilage and the skin over it had disappeared under the ulceration of lupus, and who had a patch of lupus still remaining, was taken under my care into the Liverpool Royal Infirmary, where I scraped away the small patch of disease on May 25th, 1887.

The result is shown in Fig. 1, where the upper lip is seen to be scarred, and so deficient as to leave his mouth almost permanently open. To remedy these defects I

FIG. 1.—Taken in August, 1887 Showing defect of nose and upper lip; also the lines of incision in the plastic operation.

FIG. 2.—Taken in November, 1890. Showing final state of new nose and augmented upper lip, twenty-seven years before blindness occurred.

performed rhinoplasty and cheiloplasty on April 27th, 1888, the lines of incision being marked in the illustration, photographed on August 27th, 1887. To enlarge the upper lip the scab left between the nose and upper lip was cut out; the lip itself was freed somewhat to permit its depression to meet the lower lip, and the skin dissected off the nasal bones while remaining attached at both cheek ends to provide vascular pedicles, and stitched to the raw edge of the upper lip, thus making that lip wide and substantial, as shown in Fig. 2. A flap for the new nose was taken from the forehead over the right eye, and having a curved pedicle on the left to permit the flap to be turned down to cover the exposed nasal bones and the rest of the raw surface. Much care was taken to fashion the alae and septum, which gave quite a presentable shape to the new nose on the day of operation.

But this attempt at an approach to elegance failed, as the distant corners of the flap sloughed. All other attachments healed well, and the raw surface on the forehead granulated up quickly. Much trouble was also spent in trying to keep open the nostrils by means of rubber tubes, but this also failed, and the nostrils became permanently closed.

This, however, proved not to be inconvenient, and I found that, as no nasal mucus accumulated, there must have been little or none formed beyond what could easily escape unobserved into the pharynx, the absence of draught and attendant dust apparently keeping the mucous membrane quiescent.

Though the nose and augmented lip never became elegant they answered their purpose, and are well shown in Fig. 2, photographed in November, 1890. This young man became a skilled engineer, and volunteered for foreign service at Chatham Dockyard in 1900, serving as a marine engineer in Bermuda, Nova Scotia, and Newfoundland.

He married in 1905, and lived for a time in the south of England, coming several times to see me when visiting his father in Liverpool.

In September, 1916, he was second engineer in a tug patrolling the North Sea. In July, 1917, I met him in Liverpool, led about by his wife on account of permanent blindness due to glaucoma which had not been remedied by operation in time to save his sight. For this he has since been taken care of in St. Dunstan's, Regent's Park, by which he is enabled to make a living for himself, wife, and family. He has perseveringly served his country, which took him in hand until able to shift for himself, which he does in a country poultry farm.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

A CASE OF DIPHTHEROID SEPTICAEMIA.

THE following case is of interest, as it illustrates an unusual form of infection with a diphtheroid organism.

The patient was admitted to No. 36 Stationary Hospital, Palestine, with a temperature of 104.6° F. The sister on night duty took a blood film from his ear for examination for malaria. The slide was stained by Leishman's stain, and when it was examined many bipolar bacilli were seen. The leucocytes were not evenly distributed, but they were found in clumps with a very large number of bacilli amongst and around them. A second slide was stained by Neisser's method and the bacilli stained like typical diphtheroid bacilli.

I went immediately to the patient, but his temperature had fallen by crisis, and, although I made blood cultures and more blood films, I failed to find any more bacilli. The patient had a septic sore on the right hallux, and from it I obtained a few diphtheroid bacilli, but I failed to get them in pure culture.

There was no possibility of getting two slides contaminated with leucocytes and a pure culture of diphtheroid bacilli, the septic sore not yielding a pure culture. Therefore the bacilli must have been in the circulating blood.

This seems to have been a generalized infection with the diphtheroid bacilli of low virulence so common in Palestine. The slides were taken just when the bacilli were being overcome, as is indicated by the clumping of the bacilli with masses of leucocytes and by the fact that the temperature fell by crisis soon after the slides were taken.

GASTRIC ULCER AFTER GASTRO-
JEJUNOSTOMY.

SIR BERKELEY MOYNIHAN, in his interesting paper on gastric ulcer, published in the *BRITISH MEDICAL JOURNAL* of December 13th, mentions the fact that he has operated on two cases where fresh ulcers have occurred in the stomach after gastro-jejunosomy, and he tells me that since he wrote the paper he has had a third. A few weeks ago I met with a similar case, where persistent and severe pain recurred a few years after gastro-jejunosomy for duodenal ulcer. On exploration, a large chronic ulcer was found surrounding the anastomosis but entirely confined to the stomach, the mucous membrane of the jejunum being quite healthy. I excised the ulcer freely and repaired the stoma.

Such cases as these prove that gastro-jejunosomy alone is not reliable in gastric ulcer, and that it is essential to combine it with excision of the ulcer, or, as Sir Berkeley Moynihan suggests, to perform a partial gastrectomy.

Leicester.

F. BOLTON CARTER.

MITRAL STENOSIS IN SOLDIERS.

IN his illuminating paper on mitral stenosis in soldiers (p. 840) Dr. Cotton enumerates causes of breathlessness other than D.A.H. or cardiac failure. We may take it that in any case the exercise tolerance test will be found effective and reliable. No reference, however, is made to the condition of pulmonary emphysema, which, without any discoverable cardiac disability, gives rise to breathlessness after exercise proportionate to the degree of emphysema. I have over and over again noted the frequency with which a slight degree of emphysema is overlooked, especially if no pulmonary symptoms are complained of. In the case of the soldier this condition is far from infrequent, as may be readily understood, and either by itself produces breathlessness after the exercise test, or else makes a substantial contribution to it, when coexisting with D.A.H.

For purposes of accuracy, therefore, any signs of emphysema should be investigated, and the elasticity of the lungs tested.

Reports of Societies.

INTRATRACHEAL CHLOROFORM.

A MEETING of the Section of Anaesthetics of the Royal Society of Medicine was held on December 4th, 1919, the President, Dr. L. L. POWELL, being in the chair.

Mr. CLARENCE MOTT read a paper on intratracheal insufflation of chloroform, based upon 357 cases. He showed that the insufflation method might be expected to suit chloroform particularly well, and he had not been disappointed in his expectations. At first he had worked with varying properties of chloroform and ether together, using them both intrapharyngeally and by the trachea before he arrived at pure chloroform by the trachea. A Vernon Harcourt inhaler containing chloroform was placed between the motor and Kelly's intratracheal apparatus containing ether. Finally, Down Brothers added a second chamber to Kelly's apparatus. A flow-meter has since been added which gives readings up to 30 litres of air per minute, and, thanks to the great kindness of Dr. Waller, Mr. Drew and Mr. Mott have been able to grade the dial on the chloroform tap, showing the actual percentages of chloroform vapour when the motor is delivering 10, 20, 30, or 40 litres of air per minute, with 16 ounces of chloroform in the chamber. The majority of the cases had morphine and atropine, and the catheter was passed into the trachea, whilst anaesthesia was maintained by intrapharyngeal methods. When untoward symptoms supervened—and these were on rare occasions—increased or decreased of the chloroform, more frequent or longer reductions of the air stream to zero, alterations in the volume, or pressure of air stream, or slight withdrawal of the catheter, effected the desired improvement, and at any moment ether or oxygen could be added at will.

Regions.—Of the 357 cases there were 135 intraperitoneal (11 gastro-enterostomy, 10 gall bladder, 10 hysterectomy), 15 limbs, 12 haemorrhoids, 10 kidney, 10 breast amputations, 7 glands of neck, 7 thyroid, 3 bladder, 3 month.

Respiratory Complications.—307 cases had no complications; in 23 they were very slight; in 22 they were more serious. One patient contracted pneumonia, and died six days after an operation for hysterectomy; this patient had a cough before operation, which lasted an hour and a half.

Vomiting.—114 cases did not vomit at all; 129 vomited one to three times; 60 vomited four to six times. Children appeared to take the method as well as adults.

Deaths.—There were 8 deaths—none of these could be attributed to the anaesthetic; 2 died from haemorrhage, fourteen hours and six days after operation respectively; 2 from heart failure, thirty-six hours and three days later; 1 from peritonitis (perforated duodenal ulcer); 1 from intestinal obstruction, five days later; 1 from pulmonary embolism, four days later; 1 from pneumonia (mentioned above).

Mr. REGINALD ALCOCK said that complete relaxation was not so uniformly found with any other anaesthetic as it was with intratracheal chloroform. The excursions of the abdomen were almost absent, a great gain in such operations as gastro-jejunosomy. Also there was absence of congestion and of haemorrhagic oozing, and the anaesthetist and apparatus were conveniently distant from the operator in head and neck cases.

Mr. W. C. ALLARDICE had operated some hundred times with the method, the ages of the patients ranging from 9 to 65 years. He had come to value Mr. Mott's administration of chloroform very greatly, but regarded it as a method solely for the expert. Mr. Mott provided him with everything that a surgeon was entitled to ask of his anaesthetist.

Mr. NORMAN PATTERSON pointed out the great value which the method should have in the treatment of malignant disease of mouth and pharynx by diathermy.

Dr. BLOMFIELD regarded Mr. Mott's work as a most valuable confirmation of the work done upon animals to determine physiologically safe percentages of chloroform vapour. He deprecated any general comparison as to the relative safety of chloroform and of ether based upon these three hundred cases.

Dr. F. E. SHIPWAY pointed out that the post-operative results compared unfavourably with those due to intratracheal ether, and he asked where, except in the matter of abdominal stillness, was there any advantage in using chloroform, particularly in mouth cases. He did not

believe that it was a scientific procedure to procure complete muscular relaxation by general anaesthesia alone.

The paper was further discussed by the PRESIDENT, Mr. H. C. VANCE, Mr. ROOD, Dr. SILK, and Mr. C. T. W. HIRSCH. A collection of apparatus designed and used by the late Mr. J. T. Ord was exhibited to the meeting, and an appreciation of him written by Dr. Dudley Buxton was read by the PRESIDENT.

THE DIPHTHEROID GROUP.

AT a meeting of the Liverpool Medical Institution (Pathological Section) held on November 27th, 1919, with the President, Mr. THELWALL THOMAS, in the chair, Dr. J. G. ADAMI, F.R.S., read a paper on diphtheroids. He gave a historical sketch of the research work done towards classifying the diphtheroid group, and pointed out that we were still in a transitional state of knowledge as regards these, in common with the dysenteric, choleraic, meningococcic, coliform, and other groups. Differentiation by the old-fashioned method of staining after culture on Loeffler's blood serum was unsatisfactory; morphology did not safely differentiate the infinite range of variations found by other methods. So far as fermentation reactions could help it was best to employ only four or five (particularly dextrose, dextrin, saccharose, and lactose), but the results from these were suggestive and directive rather than definitive. The development of toxicity for guinea-pigs in a Dean's broth culture, more especially a haemorrhagic adrenal lesion, was the only accurate test, and was recommended for all doubtful cases. He detailed an investigation, directed by himself, of diphtheroid wound infection occurring among Canadian soldiers. Of 306 open and infected wounds, 2 showed true Klebs-Loeffler bacilli and 56 diphtheroids; 2 of these latter gave all the reactions of Klebs-Loeffler, except the virulence test. It was demonstrated that a wound might yield no membrane and yet harbour virulent diphtheria, or develop membrane and yet be merely diphtheroid. Dr. Adami considered it probable that true relationships would eventually be defined by complement fixation tests, and suggested, as a further method likely to clarify the field, the adoption of sensitization reactions, a weakly form being used to sensitize the guinea-pig to the inoculation at a later date of the strain under investigation.

Spirochaetes in Bronchiectasis.

At a subsequent meeting of the Section held on December 18th, with Dr. HUBERT ARMSTRONG, Vice-President, in the chair, Mr. KEITH MONSARRAT read a note on two cases of massive calculous deposit in the urinary channels, which had developed in soldiers while under treatment for fractures. Radiographs showed the development and retrogression of the calculi. The speaker was of the opinion that such cases did not belong to the domain of surgery, but could be cured by medical measures and exercise. Mr. NEWBOLT recounted a similar case where cure resulted after continuous treatment with potassium citrate. Professor E. E. GLYNN contributed a paper on the presence of spirochaetes in the sputum of a case of bronchiectasis. The sputum was airless and purulent, but not nummulated, and contained round yellow granules consisting of bacteria and spirochaetes, the latter sometimes in enormous numbers. It seemed clear that these granules were formed not in the mouth but in the lung, and formed an airless medium wherein spirochaetes could develop. It was suggested that they were a variety of Dittrich's plugs, which would probably be found to contain spirochaetes if examined with that possibility in view. Graphs of the morphological features of these spirochaetes, obtained by the measurement of large numbers of camera lucida drawings, were shown and compared with graphs of other spirochaetes. They supported the suggestion that the condition was not the chronic stage of a previously acute bronchial spirochaetosis, but was a secondary mouth infection. Professor Glynn was inclined to the view that the spirochaetes in the granules were pathogenic—at least to the extent of increasing the severity of the disease. A similar condition had been found in a second case of bronchiectasis.

CLINICAL DEMONSTRATION.

A CLINICAL meeting of the Portsmouth Division of the British Medical Association was held in the library of the Royal Portsmouth Hospital on December 3rd, 1919, with Dr. A. E. MARWOOD in the chair. Mr. C. P. CHILDE showed

a case of excision of the hip-joint in a lad, done ten years ago, with excellent functional result; the lad is now about 18 years of age and can walk well—two miles easily. Also a case of congenital deformity of the wrist-joint due to paralysis of the extensor muscles of the forearm, treated by shortening the extensor tendons of the hand and fixing the wrist-joint in good position by excision of the joint. Mr. C. A. S. RIDOUT showed a case of sarcoma of the ethmoidal region for which both external operation through the orbit and internal operation through the nose had been performed with satisfactory result, the patient being in good health and at work again several months after operation. Also a case of acute frontal sinusitis treated by external operation preceded by submucous resection of septum nasi which was blocking the affected side. Radiographs of various affections of the nasal sinuses, with note on the value of radiography in diagnosis of sinusitis, were shown by Mr. RIDOUT and Mr. E. BEVERLEY BIRD, D.S.O. Dr. A. CABELL showed cases of (1) tabetic fractures, (2) gummatous synovitis of knee, (3) congenital specific periostitis combined with optic atrophy in a boy 12 years of age. Radiographs illustrating the foregoing cases were also shown. Dr. L. COLE-BAKER read the clinical notes of three cases of ectopic gestation presenting unusual features for diagnosis. Dr. R. J. LYTLE read notes on a case of pernicious anaemia treated by intravenous novarsenobenzol with most marked and rapid recovery. Dr. D. A. SHEAHAN read a note on a case of fracture of femur in a man aged 78. Lastly, Mr. DINNETT showed for Surgeon Admiral Eames the radiograph of a case of gunshot wound of spine followed by expectoration of bone fragments.

RESULTS OF HYSTERECTOMY FOR FIBROIDS.

AT a meeting of the North of England Obstetrical and Gynaecological Society held in Manchester on December 19th, 1919, Dr. J. W. BRIDE read a paper on the after-results of the removal of one or both appendages in hysterectomy for fibroids. Three hundred cases operated on at St. Mary's Hospital, Manchester, between the years 1909 to 1913 inclusive, for fibroids or, in a few instances, for chronic metritis, had been circularized. Dr. Bride based his paper on the 231 replies received. The questions put varied in importance, and included the following: General health, temperament, headaches, digestion, nervous stability, pain, capability for work, nutrition as regards fat, hot flushes, sexual inclination and comfort, and memory. The first six of these appeared to favour the radical operation, but, with the possible exception of pain, the distinction was not very marked. The replies to the next four questions, particularly as regards flushings and sexual inclination and comfort, suggested the advantage of a conservative operation. The last question put produced indeterminate replies. In general there appeared to be very little to choose between the two operations. It was noticeable that flushings, both immediate and remote, were complained of in a good number of cases where a conservative operation had been done. Drs. DONALD, GEMMELL, and FOTHERGILL instanced objections to a conservative operation, the last-named observing that, as the ovary after hysterectomy ceased to function at the end of two years, it did not seem worth while to conserve it for that short period. He suggested as a sound rule for all operations involving removal either to leave a "working set" or to make a clean sweep.

An exhibition of radiographic prints by members of the Röntgen Society will be opened at the house of the Royal Photographic Society, 35, Russell Square, W.C.1, on January 6th. At 7 p.m. on that day Dr. George Rodman will give a lecture on "The x rays approached from the popular standpoint." The exhibition will be open daily from 11 to 5, and will close on February 7th. The Röntgen Society will hold its general meeting on January 13th, at 7 p.m., when the exhibition will be open in the evening and Major G. W. C. Kaye, D.Sc., will open a discussion on radiology and radiometallography. On February 26th the Society will hold a joint meeting with the Electro-Therapeutic Section of the Royal Society of Medicine to discuss electric apparatus in relation to x rays; the meeting, which will be held at the Institution of Electrical Engineers, will begin at 5 p.m. and conclude at 10, with an interval of an hour and a half for dinner. The Silvanus Thompson Memorial Lecture will be given by Professor W. H. Bragg, F.R.S., probably in March.

Reviews.

INGUINAL HERNIA.

MR. PHILIP TURNER'S small book upon *Inguinal Hernia; the Imperfectly-descended Testicle and Varicocele*,¹ aims at an improved technique in the now very commonly performed operations for these conditions.

His operation for inguinal hernia is based upon the generally accepted view that removal of the sac is the essence of cure. He points out, as has already been pointed out by Bird of Melbourne, and Chienc, that the sac can be dealt with—can in fact be completely removed—without division of the decussating fibres of the external oblique insertion; and that in suitable cases it is unnecessary to suture the conjoined tendon to Poupart's ligament. The method is probably more widely used than Mr. Turner seems to think, and, on the other hand, for a book with the primary title *Inguinal Hernia*, too little attention is paid to the large class of hernias for which such an operation is inadequate.

The section devoted to the imperfectly-descended testicle is written with judgement and lucidity, whilst the operation advocated is an ingenious attempt to overcome one of the commonest sources of failure—retraction of the organ up to, or towards the external ring. Mr. Turner's method is to displace the testicle through the scrotal septum into the opposite half, relying upon the elastic character of the septum to permit of passing the organ through a hole smaller than itself, and to exert, together with the weight of the other testicle if present, a continuing though slight strain upon the tense parts of the cord. Whilst the likelihood of success is greater in unilateral cases, it has been found effective in bilateral, the testicles being transposed.

The improvement he advocates in the performance of the varicocele operation is the substitution for the usual method of raising the testicle—namely, approximation of the divided ends of the ligated veins—of shortening of the sheath upon which the testicle normally depends for suspension. He does this very simply by suturing transversely the longitudinal incision made in the sheath for exposure.

In each section Mr. Turner devotes a chapter to results, early and late; although, as is generally the case, he has to lament an untraceable portion of each series, it is obvious that he has every right to be satisfied with the outcome of the technique he describes.

It is a good book, and its form so pleasant to the literary mind that perhaps the author will forgive a comment upon his unnatural fondness for the split infinitive.

THE PATHOLOGY OF THE PERITONEUM.

INTEREST in the peritoneum is still as lively as it was twenty years ago, and, although many of its functions are now definitely settled and the treatment of its diseases established, many matters concerning it remain debatable.

Dr. HERTZLER, of Halstead, Kansas, presents us with two large and profusely illustrated volumes, entitled *The Peritoneum*,² dedicated to its anatomy, physiology, and pathology. This vast subject would tax the resources of any man, and the author may be said to have emerged from the struggle with credit. The first volume is devoted to the histology, physiology, development, and gross anatomy of the peritoneum. Some parts of this are definitely good, notably the sections on the so-called "stigmata and stomata," the genesis of adhesions, and the functions of the omentum. Other parts, where clear direction from one so well acquainted with the literature would have been of the greatest value, go haltingly. In these places the reader is frequently tripped up by a series of proper names, many of which could have been left out without injustice, as a feature of both volumes is the bibliography, from which there are, however, curious omissions.

In Vol. II the clinical varieties of peritonitis are dis-

¹ *Inguinal Hernia; the Imperfectly-descended Testicle and Varicocele*. By Philip Turner, M.S., F.R.C.S. London: J. and A. Churchill, 1919. (Med. 8vo, pp. viii + 104; 22 figures. 9s. 6d. net.)

² *The Peritoneum*. Vol. I: *Structure and Function in Relation to the Principles of Abdominal Surgery*. Vol. II: *Diseases and their Treatment*. By Arthur E. Hertzler, M.D., F.A.C.S., Surgeon to the Halstead Hospital, Halstead, Kansas. London: Henry Kimpton, 1919. (Med. 8vo, pp. 870; 230 figures. Two vols. 50s. net.)

cussed first under a general heading and then as produced by diseases of various organs (appendix, gall bladder, tubes, and so on), concluding with a chapter on peritoneal tumours. All this is well enough done, differential diagnosis being very fully discussed. As might have been expected, the work is uneven in quality and the literary style at times obscure. This is particularly the case in the more academic portions where clear and interesting writing is so important and, be it said, so difficult. At other times Dr. Hertzler expresses himself racily and well. An innovation in this respect, which perhaps gives the key to the whole work, is the legend to Fig. 47, "Aeroplane view of the pelvis," this being the ordinary view from above. These volumes are, in a way, an aeroplane view of the author's subject. We do not get to grips but see it all float past us pleasantly enough, some prospects more arresting and more pleasing than others. We alight at the end of our journey with a widened outlook but without much detailed knowledge.

The book is well produced, furnished with an index, and clearly illustrated by Mr. Tom Jones, some of whose drawings are particularly satisfactory.

GYNAECOLOGY.

DR. BETHEL SOLOMONS has essayed a difficult task in his *Handbook of Gynaecology*³—namely, to write a short book for students which, without being a mere cram book, will help them in their examinations and be of some use to them in their earlier years in practice. It is easy to criticize such books in a superior way and to find fault with them, but the fact remains that they are a help and comfort to final year students; and that being so, it is satisfactory to find one clearly written and presenting such sound teaching as this. The early sections are devoted to a brief description of the special anatomy of the female pelvic organs. On the first page Dr. Solomons gravely points out that it is well for those who have not studied Latin to know that "labium" is the correct term when speaking of one of these parts. It is therefore a little unfortunate that, ten pages on, he himself should write of the "ligamenta transversales colli." Genders have their value as well as numbers! The description of the vaginal and bimanual examination postulates the use of a gynaecological chair, which is such a characteristic feature of Dublin practice. There are one or two points in regard to which improvements might be made. There is, for example, a list of prescriptions at the end of the chapter on menstrual disorders with no particular indication as to the special type of case in which each is useful—with, indeed, no direction but that the prescriptions should be given only after a diagnosis has been made! Again, the author teaches inflammation of the ovaries as a separate entity, and, not content with that, divides the acute form into the three varieties—cortical, interstitial, and parenchymatous. Does Dr. Solomons expect his students to make an intelligent diagnosis of, say, acute interstitial ovariitis, and if so, is the exact diagnosis of any practical advantage? We do not find that the differential diagnosis is explained in the text, and the wisdom of burdening the student with a piece of very doubtful information may be questioned. It is just the sort of thing that an unwary student would attempt to memorize. The book is freely illustrated and the figures are mostly good; it will certainly prove useful to students, and we hope to see it made still better in the subsequent editions which we prophesy for it.

Professor HIRST's long experience as a gynaecologist, as a teacher, and as an author, have enabled him, with the adequate assistance of Mrs. Chase, his artist, to make his *Atlas of Operative Gynaecology*,⁴ a most attractive volume, full of instruction for those making their first ventures into the field of gynaecological surgery. The publishers have done their share of the work equally well, and are to be congratulated upon the general appearance of the book. The opening chapters deal with such general matters as

³ *A Handbook of Gynaecology*. For the Student and General Practitioner. By Bethel Solomons, B.A., M.D. Dub., F.R.C.P.I. London: Baillière, Tindall, and Cox, 1919. (Deny 8vo, pp. xii + 236; 196 figures. 10s. 6d. net.)

⁴ *An Atlas of Operative Gynaecology*. By Barton Cooke Hirst, M.D., Professor of Obstetrics, University of Pennsylvania, Philadelphia and London: J. B. Lippincott Company, 1919. (Med. 4to., pp. vi + 232; 164 plates; 46 figures. 30s. net.)

the operating room, the table, instruments, the preparation of the patient, and operative technique. The first subject is illustrated by a chart of the ground plan of the new operating clinic at the Maternity Hospital of the University of Pennsylvania, and will prove of great interest to those who are interested in schemes for the building or reconstruction of similar institutions. Then follow sections dealing with the operative treatment of diseases peculiar to women, and covering the whole field from operations on the breast to pnbotomy and an operation for anus vestibularis. Each operation is illustrated by a series of coloured drawings of the more important steps, and this graphic teaching is supplemented by a short running commentary in the text. On the book itself we would offer only two criticisms. One is that some of the drawings are unnecessarily complicated by forceps and threads. This is generally the result of trying to show in one figure what are really two steps in an operation. The second is that the restriction to methods of operating approved by and practised by the author must, with all respect to him, diminish in some degree the value of the volume in other schools. In no two schools are exactly the same methods followed, although the fundamental plans of the operations are the same. We are not familiar with any other atlas of a similar nature, except Liepmann's, and we cordially commend Professor Hirst's work to the notice of junior specialists and of those general surgeons whose work occasionally leads them into the recesses of the female pelvis.

A MEDICAL HISTORY CLUB.

THE fifth volume of the *Proceedings of the Charaka Club*,⁵ which was founded in 1901, contains lists of the present members and of articles in the previous volumes showing that it is devoted to medical history and scholarship. The twenty-three present members are many of them well known to English readers: Professor Harvey Cushing, Dr. F. R. Packard, Dr. Fielding Garrison, and Dr. L. S. Pilcher being famous book collectors. Many of the titles in the earlier issues are attractive, such as "The Medicine of Horace" and "The Evil Spoken of Physicians," both by Dr. Dana, and some, notably Sir William Osler's "Frascatortins" and the late Dr. S. Weir Mitchell's "Books and the Man," are familiar favourites.

The opening article in the present volume, on "The Military Surgeon in the Middle Ages," contains three reproductions of the quaint drawing "the Wound Man," a figure showing the various wounds caused by the weapons of the time; the author, Dr. L. S. Pilcher, acknowledges his indebtedness to Sir D'Arcy Power and Mr. Stephen Paget for much of the interesting material he presents. Dr. C. L. Dana's contribution on "Military and Civil Surgery among the Ancient Romans" is well illustrated by figures of instruments from Pompeii and Herculaneum. Dr. Fielding Garrison's essay on "The Gods of the Underworld in Ancient Medicine" recalls his article on the "Greek Cult of the Dead and the Chthonian Deities" in *Annals of Medical History* (vide this JOURNAL, January 5th, 1918); from consideration of Hippocrates and of the debt of Beethoven, Brahms, and the great Russian composers for their emotional effects to the Lydian and Phrygian modes, he concludes that in nearly all the activities of the mind the Greeks are still our elders and our betters. There are two psychological studies: "The Confession," by Dr. Pearce Bailey, gives a tragic dialogue between an innocent girl and her lover, the belief of the lover that the girl committed a murder so convincing her that she stabs herself at the moment that her supposed victim turns up unhurt. The other, on "Magic Above and Below," by Dr. Ely Jelliffe, is based on Chesterton's well known play at the Little Theatre, and *inter alia* deals with repression. Dr. A. P. Gerster writes about the oldest known Latin version of Aristophanes and two academic curmudgeons; and the tastefully got up volume, which is somewhat unusual in being without a revealed editor, closes with Dr. Dana's "Eminent Physicians, a Statistical Study."

⁵ *The Proceedings of the Charaka Club*. Vol. V, 1919. New York: Paul B. Hoeber. 500 copies published for members and their friends. (Rev. 8vo, pp. 101; 17 figures; 4 dollars net.) Copies of Volumes III and IV can still be obtained, at 4 dollars a volume.

NOTES ON BOOKS.

THE second edition of Dr. CARTER'S *Diet Lists of the Presbyterian Hospital*⁶ provides the medical man with a first-rate guide for the feeding of patients and convalescents. Special diets for typhoid, enteric, nephritis, and many other diseases are set out, and special diets poor in purin or calcium are also described, with notes on special dishes. The book is well arranged and thoroughly practical, and the chapter on diets in diabetes has been thoroughly brought up to date. It may be recommended to the attention of not only hospital physicians, but also general practitioners of medicine and those who have to order the food and regimen of sick people.

The late Dr. E. WEIN'S book on the diagnosis and treatment of tuberculosis by antitoxins⁷ deals with the use of Marmorek's antituberculosis serum and K. Spengler's "I.K." in all sorts of affections that he describes as primarily or secondarily tuberculous. The number of such affections he finds to be very large; he includes among them the malnutrition, sleeplessness, and maldevelopment—probably rickety?—of children, Basedow's disease in most instances, most cases of migraine, dysmenorrhoea, nocturnal enuresis, and so forth. The connexion between tuberculosis and these and other affections is proved, if Dr. Wein's argument be accepted, by the fact that patients suffering from them benefit or are cured by "I.K." treatment. Thus he records (p. 337) a family in which he treated with brilliant success a tuberculous mother, cured a father with chronic articular rheumatism, cured a grandmother who had absolute insomnia, and cured a daughter of nocturnal enuresis, all by "I.K." injections; it may be added that the treatment in the last case was continued for twenty-two months, with intermissions. The book is full of painstaking argumentation, repetition, and detail, but not, perhaps, entirely convincing.

Professor FRÄNKEL'S textbook of medical chemistry⁸ gives an account of the chemistry of the substances met with in physiology, pathology, and forensic medicine, with methods for their preparation and estimation. The volume appears to be one for laboratory use by laboratory experts.

Professor FISHER of Yale has recently republished a little book⁹ written twelve years ago, in which he related experiments showing, as he concludes, that slow mastication with a diet containing little protein increased bodily endurance. It may be read by all who are interested in food economy, and read with profit.

The *American Frohse Life-size Anatomical Charts*¹⁰ are seven large well drawn and beautifully printed maps of the human anatomy, containing seventeen separate charts. These depict the skeleton, the muscles, the nervous and circulatory systems, the circulation, the viscera, and other important structures. They may be described as most successful in design and in achievement, and have been drawn or revised by MAX BRÖDEL, the well-known illustrator who is professor of anatomical drawing in the Johns Hopkins Medical School. Diagrams such as these are of the greatest service to all who have to teach the elements of anatomy and physiology to nurses or school children, and to such they may be confidently recommended.

In a little book on *Christianity and Christian Science*,¹¹ M. CARTA STURGE makes out as good a case for Mrs. Eddy's so-called Christian Science as can be made out, no doubt on the principle that it is unreasonable to throw away the child with the bath-water. As rescued from the flood the child is certainly a puny specimen.

⁶ *Diet Lists of the Presbyterian Hospital, New York City*. Compiled, with notes, by Herbert S. Carter, A.M., M.D., Consulting Physician to the Lincoln Hospital, etc. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company, Limited. 1919. (Post 8vo, pp. 165. 6s. net.)

⁷ *Feststellung und Behandlung der Tuberkulösen Infektion mittels Antitoxischer Heilkörper*. By Dr. Emanuel Wein, Dozent an der Universität in Budapest. Berlin and Vienna: Urban and Schwarzenberg. (Cr. 4to, pp. 608. M. 25.)

⁸ *Praktikum der medizinischen Chemie*. By Dr. Sigmund Fränkel, Professor der medizinischen Chemie an der Universität in Wien. Berlin and Vienna: Urban and Schwarzenberg. (Med. 8vo, pp. 448; 38 figures, 2 plates. M. 18.)

⁹ *The Effect of Diet on Endurance*. By Irving Fisher, Professor of Political Economy in Yale University, etc. New Haven: Yale University Press. London: H. Milford. (Cr. 8vo, pp. viii+55. 2s. 6d. net.)

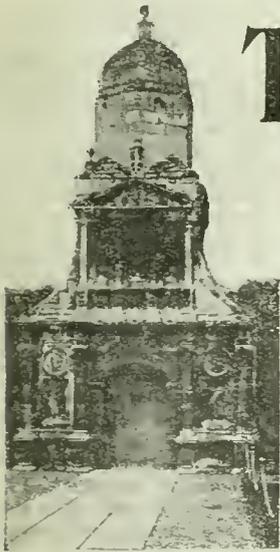

¹⁰ *The American Frohse Life-size Anatomical Charts*. With key. Chicago: A. J. Nystrom and Co.; Edinburgh: W. and A. K. Johnston, Ltd. (£11 net the set.)

¹¹ *Christianity and Christian Science: A Contrast*. By M. Carta Sturge. London and Edinburgh: T. C. and E. C. Jack, Ltd.; T. Nelson and Sons, Ltd. 1919. (Fcap. 8vo, pp. 123. 1s. 3d. net.)

BACK OF KING'S AND CLARE COLLEGES.

EIGHTY-EIGHTH ANNUAL MEETING
of the
British Medical Association.
CAMBRIDGE, 1920.

GATE OF HONOUR, CAIUS COLLEGE.

THE eighty-eighth Annual Meeting of the British Medical Association will be held at Cambridge next summer, under the presidency of Sir Clifford Allbutt, K.C.B., F.R.S., Regius Professor of Physic in the University, who will deliver his address on the evening of Tuesday, June 29th. The sectional meetings for scientific and clinical work will be held on June 30th, July 1st, and July 2nd, the mornings being given up to discussions, and the afternoons to clinical and laboratory demonstrations. There will be twelve Sections, of which five will meet on each of the three days, and the remainder each on one day. The Annual Representative Meeting will begin on June 25th. The annual dinner has been fixed for July 1st, and on the evening of July 2nd Dr. G. S. Graham-Smith, F.R.S., will give the popular lecture. Saturday, July 3rd, the last day of the meeting, has been set apart for excursions to places of interest in the neighbourhood. We publish below the first of a series of historical and descriptive notes on Cambridge, which it is hoped will prove of interest to members of the Association.

ORIGIN OF THE TOWN AND UNIVERSITY.

In the minds of most people the idea of Cambridge is associated only with that of a university, and it is a surprise to them to learn that the university was a comparatively late development in a town which for centuries, even for ages, had been a centre of traffic and commerce. Its written history begins in Saxon times; but its existence as a centre of population in Roman, British, and prehistoric times is evident from the quantities of relics of all ages which have been and continue to be dug up in and around the town. It owed its origin and its importance in ancient times to the advantage of its site; for when the Fen-land was an impassable swamp, all the land traffic between Eastern Britain and the Midlands had to pass southward through Cambridge, where the ground was dry on both sides of the river. In addition, the navigable river Grant (now called the Cam) placed the town in communication with the sea and with the group of rivers that flow into the Wash.

Even now, though the fens are drained and are crossed by several roads, Cambridge is still an important centre of traffic; for four great railway systems meet here in a single station, from which the lines radiate to East Anglia, London, the Midlands, and the North.

The town probably originated as a fort on the north-west side of the river, where the ground rises rather steeply to an altitude of about 60 ft. above the valley. A road crossed the river at this point, doubtless by a ford at first, but later

by a bridge, the fort defending the passage of the river, and commanding a wide view of the approaches thereto. On the site of this fort William the Conqueror built a castle; and it was probably he who increased the height of the hill by raising upon it an artificial mound, which extended the view and also gave advantage to the defenders in case of an attack. The mound is still in existence, but the castle is replaced by a prison, the finest site in the town being thus foolishly sacrificed.

A second town arose on the opposite or south-east side of the river, where the ground is lower but nevertheless well raised above the bottom of the valley. This is the part in which the University arose, and which thenceforth became the centre of activity; the older and higher town is now so suburban that the majority of visitors to Cambridge never make acquaintance with it.

The name of the fort on the hill was in British times *Caer Grant*, that is, Fort by River Grant. In Saxon times this was translated as *Granta-ceaster* (spelt *Grantacaestir* in Bede's Ecclesiastical History).¹ In 875 the name *Grantabrygge*, that is, Granta-bridge, appears and from this time the history of the town is continuous. The change of name is taken to indicate that at some time between the seventh and ninth centuries the ford was replaced by a bridge.

In 1142 a remarkable change of name appears, the town being called *Cauntebrugge*; from that time till 1400 the two names are used contemporaneously, with several minor varieties of spelling, such as *Grantebrugge* and *Cauntebrugge*; after 1400 the forms with initial C alone survived, giving the form *Canbrugge*, then *Cambrugge*, and lastly the present day spelling.

The history of the name is of exceptional interest, and has been very thoroughly discussed by Professor Skeat² and by Mr. Arthur Gray,³ Master of Jesus College. The change from initial *Gr* to *C* is contrary to all precedent; so much so that Mr. Gray holds that the name *Cambrugge* had an independent origin, being possibly the name of a second bridge over a collateral arm of the Granta, for it is known that the channel of the river was formerly subdivided.

The name "Cam" for the river is of modern invention, and is apparently a bit of university slang. It first appears, after 1500, as *Camus* in university Latin. The English form *Cam* does not appear until about 1600. Before that time the river was always known as the *Grant* or *Granta*. Thus the name of the river, like that of the town, is of peculiar philological interest.

So far as is known, learning was first represented in Cambridge by the monastic houses, of which a considerable number existed in the town. Four of them were founded before the middle of the twelfth century—namely, Barnwell Priory, 1092; the Nunnery of St. Radegund, 1133; the Hospital of St. John, 1135; and the Sturbridge Hospital for Lepers, about 1125. It may be noted that these houses provided the opportunities for the study of divinity and medicine (and may we add, for the education of women?), and in connexion with them, or under their influence, the University may have arisen.

The nine other houses of later foundation may have been attracted by the University, but may have contributed also to its development. The evolution of the University seems to have been so gradual that its inception is not recorded; but in 1209 a large number of scholars seceded from Oxford to Cambridge, and by 1231 Cambridge had blossomed into a full-blown university with a chancellor of its own.⁴ The word *universitas* in mediæval times was applied to a body of men united for some particular purpose, and corresponded nearly to our present words *union*, *association*, and *club*. The University existed at Cambridge long before there were any colleges. The students and teachers were scattered in the town. The first college was founded in 1281 by Hugh de Balsbam, Bishop of Ely, after the model of Walter de Merton's college, then recently founded at Oxford. It was for graduates only; its members were at first lodged in the Hospital of St. John, but three years later they were transferred to a building connected with St. Peter's Church, just outside the southern or Trumpington gate of the town. The college was hence called "Peter-house."

The non-graduate members of the university still continued to lodge in the town, many of them in "hostels"—institutions in which the needs of students were specially provided for. Undergraduates were not generally received into colleges until the sixteenth century; then the hostels, which had been numerous, gradually ceased to exist, or were annexed to the colleges. The further development of the university and the colleges will be dealt with in a future number of the JOURNAL.

SITUATION AND CLIMATE OF CAMBRIDGE.

It is necessary to disabuse the visitor of the common misconception that Cambridge is situated in the fens. The town stands on a dry platform, which extends from the foot of the chalk downs on the south to the borders of the fen on the north. It is well raised above flood level—for example, the railway station is 30 ft. and the north-west town (or Castle end) 60 ft. above the river. Through the dry platform the river flows in the midst of a shallow depression of the land of varying width. In the town this depression is only a few yards wide: its deep peaty soil is favourable to the growth of trees, hence the splendid timber in the College Backs, which are laid out on the depression and its gently sloping banks. The river formerly meandered in multiple and changeable channels through this low ground, but in its present form it is canalized, widened, and straightened.

Below the bridge from which the town was named the aforesaid depression gradually widens towards the fens, but high ground occurs on one side or the other of the river at least as far as Fen Ditton, three miles north-east of Cambridge. From thence to Ely the fen occurs in patches divided by dry areas, and only beyond Ely does the open fenland begin. Thus the site of Cambridge is always dry; there is next to no floodland adjacent to it, and the fen does not begin until three or more miles to the north.

The immediate neighbourhood of the town is neither hilly nor level, but merely tame; its chief defect is not flatness but lack of trees, for the ground is kept clear for agricultural purposes, as it is some of the best wheat land in England. But where planted with trees or laid out in

THE RIVER AND ST. JOHN'S COLLEGE TOWER.

¹The name has been transferred in recent times to the village of Grantchester, formerly called *Grantacaestir*, two miles south of Cambridge.

gardens the tame country is beautiful for its fertility. Three miles to the south, east, and west of Cambridge the chalk downs begin, and though their altitude is very moderate (mostly under 300 ft., but occasionally exceeding 400 ft.) their scenery is pleasing and characteristic, consisting of a number of small steep hills bounding broad fertile valleys. Where there are no high hills a moderate elevation commands a wide view, and hence the extent and beauty of the panoramas are notable features of South Cambridgeshire.

Not only is the site of Cambridge dry, but the town is within the area of least rainfall in England, and it seldom suffers from fog. It has an abundant supply of pure water from the chalk downs, and its air is clean and free from factory smoke, except when the wind blows from London. It has thus the physical conditions required to make a healthy town, and the Registrar-General's returns show that its standard of health is high. And yet it is fashionable to speak of Cambridge as "relaxing," none being more prone than the university folk to cry stinking fish in this respect. But why should they do so? The explanation is that in a university town the work is abnormally concentrated during the terms. For a few weeks everybody does too much, whether in work, play, eating, drinking, smoking, or even domestic service or slopkeeping, so that by the end of term everybody feels done up, and blames the locality instead of the mode of life. Those inhabitants of Cambridge whose lives are not subject to university stress find the town very healthy and bracing. Even among the university men the rarity of serious illness is notable; and although at the beginning of each term the students pour into the town from thousands of homes, with as many contingencies for importation of infection, nevertheless infectious maladies are not prevalent among them. A tacit acknowledgement of the healthiness of Cambridge is its increasing popularity as a residential town, which is evident from the many good private houses which have recently been built in its suburbs.

PREVENTION OF INFLUENZA.

MEMORANDUM BY THE MINISTRY OF HEALTH.

IN view of the possibility of a further outbreak of influenza this winter the Ministry of Health has been studying the measures which should be taken to prevent the spread of infection and lessen mortality from the disease. The memorandum on the prevention of influenza which was issued by the Local Government Board in February last, and noticed in our issue of March 1st, p. 248, has accordingly been revised.¹ The introduction gives a brief account of the nature and extent of previous epidemics, together with a statistical note on the three waves of the epidemic of 1918-19. The difficulty in securing a continuous record of the occurrence of true influenza is given as one of the factors which have made it impossible to forecast with any confidence the arrival of the next epidemic wave. The Ministry has taken measures to obtain intelligence on the subject from various sources, and these data are constantly reviewed. There is at present, however, no sign of the emergence of a fourth wave to which serious importance can be attached. Nevertheless, past history suggests the need of being prepared for the possibility that a further definite epidemic wave period may before long be encountered.

Research into the causation of influenza, into its spread in epidemic form, its pathology and its remedy, has been energetically pursued by many workers in this and other countries. Steps have been taken by the Ministry of Health to keep in touch with the results of this research, and to take some part in epidemiological inquiries. The main difficulty, however, remains. As yet we do not know the nature of the living virus to which this highly infectious disease is due, and the laboratory has not yet furnished a specific form of treatment or of protection. Although in a period of world-wide prevalence exposure to infection can hardly be avoided, it is yet the duty of the individual, so far as in him lies, to do the best for himself in case of an attack and also to protect others. It is likewise the duty of public health authorities to take all possible steps during an epidemic to lessen the opportunities of infection, to assist in the treatment and nursing of individual cases,

and to help to mitigate the hardships arising when several members of a household are attacked at one time. The memorandum accordingly restates for the information of the public some of the principal known facts regarding influenza, and reviews the experience gained by local authorities in their attempts to deal with the recent outbreaks.

With regard to causation, the memorandum shares the belief that Pfeiffer's bacillus (*B. influenzae*) cannot on present evidence be regarded as the essential causative organism of influenza, but for present purposes it is looked upon as an important secondary or coincident agent responsible for many of the fatal complications of influenza. Since infection is known to be conveyed by the secretions of the respiratory surfaces, overcrowding of every kind should obviously be avoided so far as this can be done. The evidence collected by the Ministry of Health tends to show that in civilian populations acute and temporary overcrowding in trains, trams, omnibuses, and places of entertainment is a more important factor in the spread of epidemic influenza than overcrowding in the home. The dangers of influenza are, of course, greatly increased by the complications, and the memorandum lays stress on the point that much can be done to avoid or to mitigate these: "Carefulness does undoubtedly decrease and carelessness increase both sickness and death." The advice as to throat gargles and nose douching is repeated. While the public are not advised to make general use of face masks, it is recommended that these should be worn by all attending the sick.

Vaccine Prophylaxis.

So long as the primary cause of influenza remains uncertain, it follows that no form of inoculation can be guaranteed to lessen materially the incidence of the disease; but something may perhaps be done to mitigate the severity of the infection and to diminish its mortality by raising the resistance of the body against the chief secondary invaders, including provisionally under this term the Pfeiffer bacillus. There appears to the Ministry to be some reason to believe that a standard polyvalent vaccine prepared from strains of Pfeiffer's bacillus, pneumococcus and streptococcus, does reduce very materially the liability to complications and the risk of death. It is therefore regarded as a measure of precaution which it would be unwise to neglect. The bacteriologists of the Medical Research Committee believe that in the previous Local Government Board vaccine the proportion of Pfeiffer's bacillus was too small, and that more favourable results might follow the use of a vaccine in which this micro-organism forms the dominant constituent, and of which a much larger dose is given. The Ministry has accordingly made arrangements for the preparation of a considerable quantity of prophylactic vaccine made from the new formula. This will be issued, in bottles of 25 c.cm. each, to medical officers of health for distribution on demand and free of charge to medical practitioners in their districts, who will be expected not to charge their patients for the vaccine used. Supplies of the vaccine should be available this week. It will be distributed from the Government Lymph Establishment, Colindale Avenue, The Hyde, London, N.W. 9; each bottle will be accompanied by a form on which certain desired particulars should be recorded by the doctor. The Ministry further proposes, where this seems possible, to arrange for the preparation of vaccines in selected localities from the strains of microbes associated with local cases of influenza.

The precautions to be taken by the individual when attacked are recapitulated: He or she should go to bed at once and remain there under medical advice until all fever has gone for two or three days. Recovery should be fully established before returning to work. "No drug has as yet been proved to have any specific curative effect on influenza, though some may be useful in guiding its course and mitigating its symptoms."

Action by Sanitary Authorities.

The prevention by quarantine of the importation of influenza from abroad is dismissed as impracticable. Health authorities should distribute information to the public by leaflets, posters, notices, and lectures; they are specially urged to make widely known full and exact information as to the local facilities provided in each

¹ Memo. 2 Med., shortly to be obtained through any book-seller, or from H.M. Stationery Office.

district. Details, for instance, should be given of how to apply for nursing assistance, special arrangements for providing domiciliary medical attendance, how to apply for home help for a stricken household, special arrangements for public kitchens and crèches, hospitals available for sudden or severe cases, ambulance or first aid service available.

After weighing all the considerations the Ministry has decided that it is not advisable to make influenza compulsorily notifiable throughout the country; but in some places it may be possible to arrange usefully with local practitioners for voluntary notification to the medical officer of health of all cases in which the aid of the local authority is needed, whether in the form of nursing, home help, or institutional treatment. Acute primary pneumonia and acute influenzal pneumonia are now compulsorily notifiable in all districts in England and Wales. The memorandum is cautious with regard to the value of such measures as closing schools, at least in populous centres. Permanent through ventilation of public vehicles, says the memorandum, should be generally advocated and adopted. The routine disinfection of premises and of articles used by patients is not called for, but the sickroom and its contents, as well as washable articles, bedding, or apparel, should be thoroughly cleansed. The practice of spraying halls and places of public resort is held to be of doubtful utility, tending only to create a false sense of security.

In Sheffield, during the last epidemic, a "pool" of unattached medical men was formed with good results, their services being placed at the disposal of practitioners as required. In the larger areas part of such a pool might be formed from the health authority's own staff. With regard to the provision of institutional treatment, a point that has to be borne in mind is that influenza patients with pulmonary complications often bear removal badly. Screening should be adopted in hospital wards, and the attendants should observe all the precautions usual in treating acutely infectious respiratory diseases. It is observed that the setting up of emergency hospitals in schools, halls, and large unoccupied private houses may effect much economy in the supply of doctors and nurses, especially the latter.

Forewarned is Forearmed.

The concluding section summarizes the lines of action that should be considered in advance by a sanitary authority. It is held that the most important services that can be rendered consist in the organization of the available nursing service and the provision of assistance to influenza-stricken households. Influenza waves come with such rapidity that action of this kind, to be efficacious, must be prompt, and should, therefore, be prearranged. The measures advocated include the setting up of a small emergency committee (acting with the medical officer of health, and given full powers of organization and expenditure), consultation and co-operation with the medical practitioners and voluntary health workers, and the division of a town or district into areas for domiciliary nursing purposes. The other recommendations have, for the most part, been referred to in the foregoing paragraphs.

In a circular issued to sanitary authorities, together with an advance copy of the memorandum, it is pointed out that any such authority can, with the sanction of the Ministry, provide medical (including nursing) assistance, for the poorer inhabitants of its district. The Ministry of Health sanctions, generally, the provision of this assistance for persons suffering from influenza, and such assistance may include free dispensing of doctors' prescriptions. The circular emphasizes the importance of planning out all arrangements with considerable detail in advance before any sign of an epidemic appears, so that the scheme may be ready to be put into immediate effective operation as soon as the necessity for it arises. The chief need is held to be an adequate number of nurses immediately available whenever and wherever required.

AN APPARATUS FOR A MAN WITHOUT ARMS.

The lot of the man who has lost both arms and who has no stump long enough to be useful is most pitiable. He is far worse off than the blind man, who is able to employ his other senses in place of sight. The totally armless man is tutalized by the sight of things he would like to reach but cannot. Without help he might starve in the

midst of plenty, and he is dependent upon others for every necessary attention to his person, however intimate it may be. He can have no privacy. Fortunately for mankind at large, but unfortunately for themselves, such cases are very few. As they are rare they attract little public notice, and as they offer no field for profitable commercial enterprise, only the philanthropic inventor is likely to try and help them.

Some two or three years ago Mr. C. A. Sheehan devised a table, and at the request of the Munitions Inventions Department a description of it, with a drawing, was published in our columns of May 5th, 1917, p. 583. In this contrivance a lever passed through the top of the table, to which it was fixed by a ball joint, and at its lower end bore a footpiece. By means of this machine the inventor demonstrated that a great many things could be done by the use of the feet alone, but we are not aware that the machine has been put to any practical use for armless pensioners.

Lately Mr. G. Thomson, a gasfitter of Edinburgh, who had already invented a writing machine for the blind, was struck by an appeal for help from an armless man which appeared in a newspaper. He set to work to devise an apparatus that could be worked by the feet, and succeeded in producing an ingenious machine which he submitted to Colonel Cathcart of the Edenhall Limb-fitting Hospital, who was so much impressed with the possibilities of the apparatus that he arranged that Mr. Thomson should exhibit it at the Pensions Ministry and also, with the co-operation of Sir James Cantlie, at the College of Ambulance in Queen Anne Street, where we recently had the opportunity of seeing a demonstration. Mr. Thomson, who had not heard of Mr. Sheehan's machine, fixes his apparatus to a small ordinary table and works it by the feet, but there all resemblance to the other invention ceases. The man sits at the table and works a set of levers with each foot independently. One of these is used to hold appliances while the other is generally used to steady objects, although it can also pick up such objects as a piece of paper. The upper lever of each set having its fulcrum at the back of the table can be brought down upon it and also rotated horizontally, thus giving an effective compound movement. The levers are rigid, but very light, and consequently little fatigue should be caused by prolonged use of the machine. At the edge of the table furthest from the patient are holders for the appliances, from any one of which the tool wanted can be picked up and replaced by the lever by means of a most ingenious but simple spring catch.

Mr. Thomson showed an interested audience how he could feed himself, write a letter, wash his face, and do many other things. To the looker-on there was something almost uncanny about the two levers which ministered with such speed and apparent ease to the wants of the man sitting in the chair, and they almost seemed to belong to a separate intelligent organism unconnected with the feet below the table. It is estimated that the cost of the table machine would be considerably less than that of some artificial arms; but in these rare cases cost is a secondary consideration.

Although it is possible to write quite well with this machine, Mr. Thomson has invented a special apparatus for those who have much writing to do, which he also showed to the meeting. In this the pen—a fountain one—remains stationary while the paper, which is held on an oscillating plate, is moved from side to side. Mr. Thomson devised before the war a writing machine for the blind, in which the writer traced large copy-book letters along a space bounded by raised edges with a style connected with a pantograph and another style acting on carbon paper, and thus producing writing of the ordinary size. This apparatus is quite portable and can be used on any ordinary desk. Two forms were shown, one of which, for the sake of simplicity and consequent cheapness, produces its lines and words radially, in the relative position of the spokes of a wheel. With all four machines, no matter whether as an armless or a blind man, Mr. Thomson rapidly produced clear and legible specimens of hand-writing. We understand that his writing apparatus for the blind, which was unfortunately rejected by those to whom it had been submitted in Edinburgh before Colonel Cathcart saw it, has been approved by the St. Dunstan's authorities and is likely to be adopted by them. We consider it a most efficient and practical machine.

British Medical Journal.

SATURDAY, JANUARY 3RD, 1920.

WILLIAM OSLER.

THE death of Sir William Osler removes a great personality, a leader of international medicine. Though his influence and inspiration will live and will long be carried on by his followers, the blank created by the irreparable loss of their Master is for them difficult to realize. The man and his work were both exceptional, and his personal characteristics, which may perhaps be partially epitomized by the best definitions of charity, or, in the words he wrote once under his own portrait, "Write me as one that loves his fellow men," enabled him by his labours of the last forty-five years to advance scientific medicine and education to a degree his whole-hearted zeal deserved. At the moment his friends—and they include all those who have come within his wide circle—are mainly occupied with their own personal sense of bereavement, and are therefore reluctant to attempt an estimate of what his name will eventually represent in the history of medicine.

Osler was a humanist, and was convinced of the importance of the study of the humanities to members of his profession; he believed that the wider the view beyond the confines of professional technicalities the better a man was equipped to influence the current thought of his day, and the higher the respect he received from the men of other professions. His own interest in the history of medicine was the natural outcome of his way of looking on life, and he saw in it a means for the broadening of the culture of medical men, a door which opened every field of learning. It was natural, therefore, that he should warmly support the formation of the section of the Royal Society of Medicine founded for the study of the history of medicine, and continuously show his interest in its work.

His influence on medical education, especially in the American continent, can hardly be exaggerated, and the remarkable change that came over American medicine at the end of the last century must be mainly explained by the ideals radiating from the Johns Hopkins Hospital—itsself a lasting memorial to him—by means of his former pupils who became professors and teachers in numerous universities and medical schools. His early pathological post in Montreal, supplemented even then by visits to the most active laboratories and clinics in Europe, rendered it natural that he should make the application of clinical pathology to practical medicine a prominent feature in his hospital work. By closely linking up clinical with laboratory research he stimulated widespread original investigation.

During his last fourteen years as Regius Professor of Medicine at Oxford British medicine has come more directly under his quiet and kindly guidance in innumerable and perhaps not always fully recognized ways, and it was therefore only natural that he became the obvious leader in new projects—thus he was the moving spirit in the establishment of the Association of Physicians of Great Britain and Ireland, and of the *Quarterly Journal of Medicine*, the President of the Fellowship of Medicine and Post-Graduate Association of London, the President of the Bibliographical Society, and an active member of

many committees dealing with various aspects of medicine and its application to the public welfare.

His broad sympathies and extensive acquaintance with the profession in most countries, his delight in bringing men together, and his knowledge of the phases and methods of medicine, made him a wise and resourceful leader in all movements which commended themselves to his shrewd, yet tolerant, judgement.

MEDICINE IN THE HOUSE OF LORDS.

THE most striking announcement in the list of New Year Honours is that a peerage has been conferred on Sir Bertrand Dawson, G.C.V.O.; it is the first time this honour has been granted to a member of the profession actively engaged in hospital teaching and private practice. We make no doubt that the Prime Minister, in recommending Sir Bertrand Dawson for promotion to the House of Lords, was actuated less by the desire to confer a personal honour, however well deserved, than by the wish to ensure that the Upper House of the legislature shall, when matters affecting the health of the people come before it, have the advantage of the counsel of a member of the medical profession thoroughly sympathetic with the forward movement in science, practice, and organization. It is a practical recognition of the principle that medicine must henceforth take a larger part in the work of the body politic, and that its participation in public affairs is necessary for their effective conduct. A tendency has been increasingly shown of late years to add to the House of Lords men engaged in the varied intellectual activities which make up the life of the nation. The House has never been without representatives of the Church and of the law, and for generations it has included distinguished sailors and soldiers; more recently eminent members of the Civil Service have found a place in it, along with representatives of commerce, finance, engineering, and journalism. There is every reason why medicine should receive similar recognition, more especially at a time when big constructive changes in health policy are in contemplation.

The selection of Sir Bertrand Dawson gives us as a representative one who knows the needs and aspirations of the profession. During his long connexion with the London Hospital he has been through all the ranks of a large medical school—demonstrator of physiology, medical registrar, a pathologist, for five or six years assistant physician and lecturer on materia medica and therapeutics, and finally, some ten years ago, physician and lecturer on clinical medicine. He has now resumed his full duties in these capacities after the interruption of the war, during which he was Consulting Physician with the British Armies in France and a member of the Army Medical Advisory Council, a position he still holds. He is a member of the Council of the British Medical Association, and the reputation in which he is held by his fellow teachers appears from the fact that he is Dean of the Medical Faculty of the University of London. He is Physician-in-Ordinary to the King. He is known to the profession at large first for his writings on gastric ulcer and other abdominal diseases—his essay on infective jaundice contributed recently to our columns is probably the most complete study of that disease yet published, and his writings on paratyphoid fever have helped to clear up the diagnosis and treatment of a perplexing disease; and secondly he is known for the attention he has long given to

the better organization of medical services; in his Cavendish lectures a couple of years ago he set out the principles upon which he considered the problem should be approached. The subject is now under the consideration of the Medical Consultative Council of the Ministry of Health, of which he became chairman when it was constituted last October. It is a council which has direct access to the Minister and the power to initiate advice; it has been called into existence in order to bring to bear on the policy of the Ministry the considered opinion of the profession with regard to those social and scientific matters on which it is most competent to speak: it is designed also to bring a great profession into relation with the administrators in the Ministry of Health. Sir Bertrand Dawson stated recently that the Council would make a report to the Minister, and this report, it may be anticipated, will eventually form the basis of legislation. It will be a great satisfaction to the profession to know that during the discussions which must occupy the next few years it will have in the Upper House a man in the prime of life, actively engaged in hospital and private practice, and therefore well able to understand its needs and aspirations.

In many other countries—in France, Italy, and Spain—the Upper Chamber (the senate) contains many members of the medical profession, but in this country few have become members of the House of Lords, and in no previous case was the medical peer engaged in active practice. Lord Lister was the most distinguished surgeon of his day, but he had ceased to practise; he was a national possession, and his eminence as a man of science had caused him to be chosen President of the Royal Society. Sir Walter Foster, when he became Lord Ilkerton, had for some time relinquished his practice in Birmingham to pursue a political career in London. Lord Playfair was a graduate in medicine, but was occupied through the whole of his life in chemical research and teaching. Lord Finlay, recently Lord Chancellor, who now sits in the House of Lords as Viscount Nairn, graduated in medicine at the University of Edinburgh, but never practised, being called to the bar at the age of 25. Lord Cobham, in whose favour a barony created in 1313 was called out of abeyance in 1916, is, so far as we are aware, the only member of the medical profession who is a hereditary peer, but he has never taken any part in legislative work.

It has thus come about that the profession has had no one in that chamber qualified to present the medical view on health questions. That this want has now been made good is a matter upon which not only the profession but the legislature and the public may be heartily congratulated.

THE PARLIAMENTARY SESSION.

There are two standards by which the parliamentary session just closed may be judged—namely, by what the Government has done, and by what it has failed to do. The legislative achievements are amazingly numerous, and some of them are of far-reaching importance. On the other hand, bills of great moment have been modified, withdrawn, or postponed to an extent that has never happened before. The change in procedure, the pace, and the distractions of grave international considerations arising out of the Peace Conference have had much to do with both the successes and the disappointments. Under an experimental plan for saving time big proposals have been dealt with in Committee "up-stairs" instead of being taken in Committee of the whole House of Commons;

speed has also been deemed essential in the stages of deliberation in the House of Commons; and the feeling that home problems were secondary to those of resettling the world's affairs has both helped and hindered progress. The absence of a strong Opposition weakened the Government in making clear-cut definitions and the circumstances of Coalition have led to compromise where sometimes bolder lines would have been more effective. The policy has been one of quick decisions—to get on or to cut out. Thus there has been trouble over some large issues—such as housing, tariffs, and labour questions—but these have involved the revival of old-standing controversies, and they are not of such close interest to the medical profession as measures of domestic concern, in the passing of which the Government shows a good record.

From our own standpoint the principal event of the session has been the passing of the Act setting up the Ministry of Health. The new Ministry absorbs the functions of the Local Government Board in health matters, and it retains the Poor Law administration until this can be dealt with differently; it takes over the insurance services, which previously formed a large and sometimes overlapping department. It has also become responsible for the medical inspection and treatment of young children, while delegating its authority in this regard to the Education Board, which has hitherto had the duty. Further, it has taken over the powers of the Privy Council under the Midwives Act, and the powers for infant life protection which were vested in the Home Secretary. The bill, moreover, was wisely framed to enable further transfers to be made by Order in Council, so that as time and opportunity allow the operations of the Ministry of Health shall be really comprehensive and complete. Dr. Addison has been prompt in setting up Consultative Councils and in reorganizing administrative machinery, but the benefits of the change cannot be expected yet to be felt. Spring time and harvest do not come together.

A measure of considerable consequence, which was passed in a day near the end of the session, is that which raises old age pensions to a maximum of 10s. a week, and extends the scope of the concession so as to enlarge the number of recipients probably by about 25 per cent. Another small bill which attracted little notice because it was essentially financial in nature, enables the Treasury to enlarge its grants to local authorities for the treatment of mental deficiency, without restriction of the amount of grant, subject only to the provision that it shall be in the same proportion of contribution as before—namely, that 50 per cent. shall be provided by the local authorities. It is hoped that much benefit may result from this change. In another category, but yet not to be regarded as insignificant in value, is the Rats and Mice Act, which will apply compulsory powers for the extermination of these disease bearers, and at the same time, it is hoped, help materially in the preservation of corn crops. A word should be said here also as to the importance of the measure which will regulate the presence of undesirable aliens in our midst; the two subjects are not so utterly remote as might at first sight appear. The restriction is of national interest in several senses.

In regard to housing the Government has been less happy than in much of its other legislation. The first bill required local authorities to act on a guaranteed subsidy which was fixed to secure these authorities against loss for a period of seven years. The second bill, which is intended to be complementary rather than to supersede the other, will give

subsidies to builders at a rate of not more than £150 a house, and subject to the limitation of the Treasury grants to somewhere about 15 million sterling. At the same time power is taken to restrict luxury building, and Dr. Addison has been careful to make arrangements with builders to secure a guarantee of priority in construction of the small dwellings so greatly needed for the life of the nation. The problem is complicated by the unsatisfactory rates of production, even with higher wages, by skilled hands, and also by difficulties of transport. There is also the handicap that the number of hands available at best is much less than in pre-war days, through the toll of casualties.

Side by side with legislative action has gone administrative development. The enlargement of the scales of pensions for men of the fighting services and their dependants has been made with great care and judgement by Sir L. Worthington-Evans, the Pensions Minister. Criticisms of detail, and indeed of principle in some matters, have been inevitable, but on the whole his work has been highly appreciated. He is one of the few Ministers who have really made good in a new position in a short time. In one matter he and Dr. Addison, as Minister of Health, have a mutual responsibility. This is in regard to the provision to be made for tuberculous discharged soldiers and sailors. The report of the inter-departmental Committee over which Sir Montague Barlow presided recommended, amongst other things that a grant of a million sterling should be made to finance village settlements of a permanent kind. How far the Treasury will go remains to be ascertained, but an immediate additional grant of £10,000 for work that can be done within the present financial year was sanctioned just before Parliament rose.

A great many other subjects have been dealt with more or less partially. The scheme for establishing ex-soldiers on the land by the purchase of farms and holdings by county councils is being proceeded with under an Act passed early in the year. Here again the housing need affects the outlook, and to a lesser degree the problem of transport also comes into the matter, for, until the circulation of commerce and the easy distribution of agricultural products can be made to run smoothly, every interest and every trade is adversely affected. Better transport conditions are essential for the relief of food prices, though, of course, they are influenced to a much larger extent by the world shortage and by the necessarily slow restoration of shipping facilities to a full extent and at reasonable freights. By co-ordinating various branches of transport service the Government expects in the course of time to promote efficiency, and it is also hoped that the Board of Trade may be able in various ways to stimulate production, and thus to assist in the restoration of prosperity. The Anti-Profiteering Act, which Sir Auckland Geddes promoted, has had some value in checking greed for commercial gain, but it needs to be supplemented, and a further measure is to be submitted to the House of Commons early in the coming session.

There is no need here to dwell upon the significance of the Government of India Act, which is framed with the object of securing conditions of greater tranquillity in the Eastern empire, nor need anything be said as to the prospects of the Irish Bill which has been put forward so bravely in the determination to place Great Britain beyond the possibility of reproach by the Irish people in regard to the form of Government for the sister isle. It is unfortunate that greater approach to the settlement of labour controversies has not been made in the session now ended, inasmuch as the unrest and uncertainty tend to prejudice production.

But it is hoped that as the grave financial situation of the country and its dependence upon exports for its stability are realized by the working classes they will more fully grasp the nature of their responsibility for the common good, and that they will respond to the call which is made upon them, certainly not less for their own interest than for the interest of those who with resources of capital have to yield such large proportions of their income to keep the country going. One encouraging sign is the increased output of coal under the new conditions, but unfortunately nearly all the labour problems which revolve round questions of nationalization, administration, and conditions of working still remain in a fluid state.

VACCINAL PROPHYLAXIS OF INFLUENZA.

As will be gathered from an announcement published elsewhere in this issue (page 19), the Ministry of Health has arranged to provide medical practitioners with anti-influenzal vaccine, and expresses its anticipation that they will be willing to keep records of their results. Since there are no present indications of a serious wave of influenza and the value of vaccines in the prophylaxis of the disease is uncertain, some may hesitate to take advantage of the offer. Actually both reasons for hesitation are the best possible grounds for recommending widespread use of the prophylaxis. One of the chief difficulties in accurately assessing the value of any prophylactic measure in combating an epidemic disease is that it is generally only used after an epidemic has begun. The consequence is that the scales are biased in favour of the prophylactic and the statistics obtained are often of no value. That this must be so is obvious on a moment's consideration. Suppose that coincidentally with the outbreak of the disease prophylactic inoculation is begun and that it is impossible—as it always will be—to inoculate the whole population within a few days; then a greater or smaller number of persons who pass through the first stages of the epidemic uninoculated, but are ultimately inoculated, will figure in the final summary of results as unattacked inoculated persons, no heed being given to the fact that during a period of possibly maximal infectivity they were exposed to risk in the uninoculated state. To allow for this bias is often difficult, so that to secure a valid control of the method it is necessary that, *before* the outbreak, a sample of the population shall have been inoculated. When, as in the present case, inoculation is unattended by personal risk, the desirability of vaccinating a large number of citizens mixing freely with the rest of the community is very great. On the other hand, to inoculate all members of an isolated community, such as a boarding school, will give no trustworthy evidence as to the efficacy of the vaccine; this can only be provided when an adequate control is secured. Naturally, if the value of the method were established, such action would be unjustifiable; but, in the present state of knowledge, a medical officer is not called upon to put pressure upon unwilling parents, and, without such pressure, the whimsicalities of the public are certain to provide an adequate control in any type of community whatsoever.

ATROPINE IN SEA-SICKNESS.

ALTHOUGH the war must have greatly increased the number of the victims of sea-sickness, there has not been any corresponding expansion of the literature on this familiar disorder. It has been said that at the commencement of his career every ship's doctor is confident of his ability to cure or prevent this *bête noire* of travellers, but that experience invariably shatters this belief. It is therefore interesting to have the experience of Dr. Pierre Cazamian,¹ of the French Navy, based on a close study of

¹ P. Cazamian, *Arch. de méd. et pharm. nav.*, Paris, 1919, cviii, 241-284.

sea-sickness for more than two years, first in a hospital ship, and then in a battleship. He first adds to the well known manifestations some that are new, and, after discussion of the pathogeny, explains the treatment by atropine which has proved successful in his hands. The systolic and diastolic blood pressures were taken in 50 cases, and it was found that at first the pressures are distinctly raised, but that after sea-sickness had lasted for twenty-four hours or more they were below normal; in both conditions the systolic and diastolic pressures varied together, so that the pulse pressure remained normal. These observations are new and important; for Naamé, relying on palpation of the pulse and the assumption that there was a fall of blood pressure, put forward the view that sea-sickness was due to a reflex inhibition of secretion of adrenalin, and accordingly treated it prophylactically and curatively by the oral administration of adrenalin, giving larger doses to remove the symptoms. He reported very good results, but Cazamian found that there were many failures and that the symptoms might even be aggravated. Another clinical observation is that the oculo-cardiac reflex is altered; normally pressure on one or both eyes causes a transient slowing of the pulse, but in sea-sick persons there is generally—in 38 out of 50 cases—a quickening of the pulse. Similarly, firm pressure in the epigastrium was followed by increase in the pulse rate instead of a fall, a reputed sign of irritation of the sympathetic. After discussing at length the various hypotheses as to the causation, Cazamian gives the following explanation: As a result of numerous impulses travelling from the sense organs, and especially from the viscera, to the medulla, both the autonomic and the sympathetic systems are upset. At first the sympathetic is overactive and the blood pressure is raised; later it becomes exhausted and the blood pressure falls; but coincidentally the autonomic system is affected, though the vagotonia is masked by effects of the disorder of the sympathetic nerves. He likens both the phenomena and explanation of sea-sickness to those of surgical shock. After mentioning most of the remedies that have been advocated, he describes his method of treatment; to cure the symptoms one hypodermic injection of atropine ($\frac{1}{10}$ to $\frac{1}{5}$ grain) is given, and it has rarely been necessary to give a second injection, but he has found it desirable in some cases to administer $\frac{1}{10}$ grain after twelve to twenty-four hours; in a late stage of sea-sickness with low blood pressure and prostration the combination of adrenalin with atropine had, he found, a very beneficial effect. As a means of preventing sea-sickness $\frac{1}{5}$ grain of atropine is injected hypodermically on embarking, and may be repeated for three days if the weather conditions are bad.

THE RIVIERA.

It is now some years since medical men were enabled to recommend their patients to visit the Riviera with any hope of their getting there without difficulty, or remaining there in comfort. English visitors are now returning in greater numbers than formerly, and have so far been rewarded by ideal weather conditions, consequent on the autumnal rainy season having duly asserted itself. Dr. D. W. Samways of Mentone, writing from his own unfortunate recent experience, tells us that it is important that travellers should see to it that their luggage accompanies them throughout their journey. It should never be registered beyond Paris. It should be seen through the Customs at Paris, taken to the hotel, and finally to the Gare de Lyon, and there registered. It then comes through promptly. If these details be not followed the luggage may be delayed for weeks. The Riviera is now free from German-speaking and German-behaving visitors, and hotel managers are catering specially for the English. Prices may seem high, but considering the exchange they are generally reasonable. Thus a room, with pension, in an hotel at 22 francs per day, is only 10s., since

the franc is worth less than 6d., and though 33 francs daily may seem a large sum, its equivalent 15s. would appear very moderate in England. It should be remembered by the medical profession that the Riviera in no way corresponds to the South of England watering places. The latter have a marine climate. The Riviera has a dry, fresh mountain climate. The air on the Riviera on practically all fine days, and almost invariably at night, sets from the land to the sea. It passes from the high background of mountains to the north southward to the sea. The textbook classification of the Riviera resorts among those having a marine climate is quite erroneous. As rivers flow to the sea so does the Riviera air, but the sea no more makes the Riviera climate on that account than it does the rivers. Hence the dryness and freshness of its mountain-born air. Hence also its influence on catarrhal conditions, whether respiratory or aural, on the appetite and debilitated states generally, and by its contrast of climate and scene on English persons requiring a change.

THE ROCKEFELLER BENEFACTIONS.

MR. JOHN D. ROCKEFELLER has added one hundred million dollars to the fund of the General Education Board and of the Rockefeller Foundation, raising the total amount of his gifts to over four hundred millions. Of the new gift, fifty million dollars are allotted to the General Education Board to increase the salaries of the teaching staffs of the colleges and universities of the United States, and the like amount to the Rockefeller Foundation. It has been recognized in America that the salaries of the teaching staffs of the universities and colleges ought to be increased to meet the great rise in the cost of living. Various universities have made special appeals to the public, and in anticipation of the result Harvard and some other universities have already nearly doubled the incomes of their professors. The General Education Board in making its allotment will proceed on the principle that an equivalent amount shall be raised by the institution. Mr. Rockefeller expressed the desire that a part of his gift should be used to promote medical education in Canada, and it is understood that the board intends to devote five million dollars to this purpose. The objects of the Rockefeller Foundation are defined to be the furtherance of the well-being of mankind throughout the world, and its report for 1918, which has just reached us, affords evidence that its activities extend from China to Brazil. Its work is mainly done through three boards—the International Health Board, the China Medical Board, and the Rockefeller Institute for Medical Research. The Health Board during 1918 has devoted its energies chiefly to yellow fever, ankylostomiasis, and malaria, but it assisted also in a campaign against tuberculosis in France, the course of which has been described in our columns from time to time. In July, 1918, a commission was sent to Guayaquil to study yellow fever and related infections likely to be confused with it. One of the members, Dr. H. Noguchi, succeeded in isolating an organism resembling the spirochaetes but presenting certain differences which led him to put it in a separate genus under the name *Leptospira icteroides*, along with the organism of infectious jaundice (*L. icterohaemorrhagiae*). The investigation¹ presented many difficulties, as the organism is very fragile and has, it is thought, a granular stage, in which it passes through filters of a certain fineness; the probability of its being the causal agent is very great. The administrative work, under the direction of Dr. White, of the U.S. Army Medical Corps, appears to have been very successful, as the disease was under control by September 19th and no cases occurred after December 2nd. A daily house-to-house inspection was made in each infected community; suspected cases

¹ BRITISH MEDICAL JOURNAL, July 12th, 1919, p. 48; August 30th, p. 283; December 13th, p. 792.

were isolated and their houses fumigated, and systematic work was carried out for the destruction or control of the breeding places of the stegomyia mosquito. Since then Dr. Connor, a member of the field staff of the International Health Board, has undertaken to direct measures for the extermination of the disease. The most extensive field work undertaken was in connexion with hookworm disease (ankylostomiasis). It was carried on in Ceylon, China, and other parts of the East, in British Guiana, St. Lucia, St. Vincent, and Trinidad, in various Central American states, and in Brazil. The disease is very prevalent in some of the southern of the United States, and stress is laid on the fact that it causes not only physical debility, but in children mental backwardness. In addition to prophylactic measures—in particular the erection of properly constructed latrines—the treatment of infested persons was carried on; the most effectual remedies were thymol and oil of chenopodium. The use of the latter has greatly increased, but its mode of action is not well understood. Very remarkable results in the control of malaria were obtained where the co-operation of the authorities and the people themselves was given. The policy of the Board in respect of both ankylostomiasis and malaria is to make a grant, start the work under the direction of trained workers, and continue an annual grant for a few years until the control has been so well established that it can be continued by local resources. We have already given accounts of the work of the China Medical Board, and conclude this short notice by reference to the work of the Rockefeller Institute for Medical Research. During 1918 its energies were entirely devoted to war work and the education of medical officers and nurses, especially in the use of the Carrel-Dakin treatment for infected wounds, a portable military hospital being set up in the grounds of the Institute for this purpose. Large quantities of serums for meningitis, pneumonia and dysentery were produced, and the method of manufacturing an anti-serum for the gas forming bacillus was far advanced when hostilities ceased. The capital fund at the disposal of the Rockefeller Foundation is now, in round numbers, 176 million dollars, the whole of which, with the exception of 26 million dollars, has been given by Mr. John D. Rockefeller. The income, including a special gift of one million dollars by Mr. Rockefeller for the American Red Cross and United War Work, was over 8½ million dollars, which was raised to 20 million dollars by the unspent balance from 1917. Altogether 15 million dollars were disbursed during the year, and another 2 million provided but not claimed. The amount allotted to the Institute for Medical Research appears to have been 265,000 dollars, but an additional sum of 350,000 dollars was disbursed for medical military work.

ANTHRAX INFECTION BY BRUSHES.

IN the summer of 1917 the Local Government Board published a report by Dr. F. Coutts on an inquiry into cases of anthrax suspected to be caused by infected shaving brushes.¹ In almost every case the lesion was situated in the shaving area of the face and neck, and in some of the brushes examined living anthrax bacilli were found. Dr. Elworthy proved that in one of the earliest cases the infection was due to the use of a recently purchased cheap shaving brush of imitation badger hair. In this, and in several unused brushes of the same kind bought from the same shop, virulent anthrax spores were found. All the brushes were traced back to one wholesale dealer, and were found to have been manufactured in a single factory. Investigations carried out by Dr. Coutts and Dr. Collis showed that the bristles used in making these brushes consisted mainly of undisinfected Chinese horsehair. The hair from the same source which had not yet been manufactured into brushes was found to be heavily infected with

anthrax spores. Four other cases of anthrax occurring about that time were traced to imported brushes of foreign make. We have now received a communication from Dr. Henry T. Maw, of the administrative committee of the National Union of Manufacturers, who wishes to draw attention to certain facts relating to the origin and prevalence of anthrax in various parts of the country at the present time. Early in 1919, he says, a consultative council was formed by the Board of Trade to advise on the restriction of imports, and a subcommittee of this council was appointed to inquire into the brush industry and the importation of foreign-made brushes. The consultative council sent up a strong recommendation to the Board of Trade against the importation of foreign-made (especially Japanese) brushes, because of the insanitary conditions under which they were manufactured; special reference being made to the brushes used for medical and toilet purposes, such as throat brushes, toothbrushes, and shaving brushes. It was pointed out that the hair used in Japan for soft brushes was pony hair, which, unless sterilized, was apt to be very infectious, and that samples of brushes then on the market which were submitted for bacteriological investigation to Professor W. Bulloch, M.D., had been reported on adversely. At a meeting of the Imports Consultative Council on June 2nd, the subcommittee recorded the opinion that it was necessary on hygienic grounds to limit the importation of the cheaper Japanese brooms and brushes, and suggested that before final settlement of this question the international agreement, so far as Japan was concerned, should be revised. Dr. Maw states that, in spite of these warnings and the recommendation of the Council not to allow medical and toilet brushes to be imported from Japan until the Ministry of Health had been consulted, the Board of Trade published, on June 5th, a decision on the importation of brushes entirely contrary to the advice of the Consultative Council. Our correspondent adds that the National Union of Manufacturers is taking up the matter with the Board of Trade, and invites members of the medical profession having information on the subject to communicate with the secretary, Mr. G. Cheesman, 6, Holborn Viaduct, London, E.C.1.

INTRAMUSCULAR INJECTIONS OF QUININE.

AS recent papers and discussions have abundantly shown, the treatment of malaria is far less satisfactory than was formerly believed, and opinion is conspicuously divided on several points; there are many methods, some complicated but all with their advocates, and the result is, to say the least, confusing. This is particularly true of intramuscular injections of quinine, which has been widely recognized to be followed in some cases by troublesome necrotic ulcers. Some who report long series without any untoward effects have confidently ascribed these ulcers to neglect of proper asepsis. It has also been stated that concentrated solutions of quinine are precipitated in the tissues, whereas very dilute solutions are rapidly and completely absorbed. In order to throw further light on the effects of intramuscular injections of quinine, Dr. L. S. Dudgeon¹ has investigated the question both in man and experimentally in cast mules, rabbits, guinea-pigs, and frogs. That necrosis of the tissues always follows intramuscular or subcutaneous injections of quinine is not sufficiently realized; within ten minutes the muscular fibres are necrosed with oedema, agglutination, and haemolysis of the red blood cells. Although concentrated solutions produce more intense necrosis than dilute solutions do, injections of solutions so dilute as to avoid necrosis and oedema are not of any practical value. Vessels may be so necrosed that severe haemorrhage ensues, and necrosis in the neighbourhood of a nerve may produce complete degeneration and paralysis. During the years 1916 to 1918 the following complications of intramuscular injections of quinine were observed:

¹ BRITISH MEDICAL JOURNAL, June 30th, 1917, p. 882.

¹ L. S. Dudgeon, *Journ. Hyg.*, 1919, xviii, 317-356.

tetanus, gangrene, abscess, pyaemia, nerve palsies, haemorrhage from large vessels, sciatica, chronic muscular pain and deficient movement, and thrombosis in varicose veins. The bad effects were not obviated by the addition of olive oil or fat or by dissolving the quinine in alcohol or ether, whether in a concentrated or a dilute solution. Although quinine is a powerful haemolytic agent, the acid used to dissolve the alkaloid is much more powerful in this respect; and it appears that the red cells and tissues generally are more readily destroyed than the malarial parasites by solutions of quinine. The bad effects of intramuscular injections of quinine were not more prominent in animals rendered experimentally anaemic than in control animals. Analyses by Captain F. S. Hele show that quinine is not fixed in the tissues immediately after injection to any appreciable extent. Intramuscular injections of quinine should therefore be given only when emergency renders them necessary, should not be made in the vicinity of large vessels or nerves, and should not be repeated in the same area. But the superiority of intramuscular injection to the oral method in malignant malaria is, as Dr. W. H. Willcox (see p. 28) points out, so undoubted that its use as a measure of urgency should not be ruled out.

REWARDS FOR MEDICAL DISCOVERY.

At the last meeting of the Joint Committee of the British Medical Association and the British Science Guild on awards for medical discoveries, a report by Sir Ronald Ross was adjusted and adopted. The report defined "medical discoveries" as "the ascertainment of new facts or theories on the human body in health, and the nature, prevention, cure, or mitigation of injuries and diseases of human beings." It was also held to include the invention of new methods or instruments for the improvement of sanitary, medical, and surgical practice, or of scientific and pathological work. The Committee intends to take steps to ensure proper rewards for medical discovery so as, on the one hand, to encourage medical investigation, and, on the other, to discharge a moral obligation incurred by the public through the advantage it takes of private effort. A sharp distinction is drawn between compensation and reward, the former being reimbursement of losses, the latter an act of grace in appreciation of services rendered. One of the principles laid down is that no medical discovery should entail financial loss upon the investigator, and it is suggested that the compensation or reward should be assessed as equal to the difference between the emoluments actually received and those that might reasonably have been expected if the investigator had devoted all his time to successful clinical practice. It is held, further, that it is proper for every civilized State, in addition to assisting investigations in progress, to remunerate those of its citizens who have already conferred upon it benefits through medical discovery. It is suggested that Parliament should revive the precedent of Edward Jenner, to whom it voted money both by way of compensation for losses incurred in achieving his discoveries, and as a reward for their value to mankind. The Committee is disposed to suggest that Parliament should provide an annual sum of, say, £15,000 for life pensions for those who have made medical discoveries, and to the widows of the discoverers after their death. It is thought that there might immediately be instituted ten pensions of £1,000 a year each, and ten of £500 a year. The intention, we understand, is to bring the views and arguments of which we have given an outline, to the notice of the Prime Minister at an early date.

THE NEW YEAR HONOURS.

In addition to the peerage granted to Sir Bertrand Dawson, to which reference is made elsewhere, the New Year list includes the honour of knighthood conferred upon Dr. J. Court of Staveley, Chesterfield, who has made important researches into certain diseases of miners,

especially miners' nystagmus and ankylostomiasis; on Dr. H. J. Gauvain, Medical Superintendent of the Hospital for Crippled Children at Alton, Hampshire, who has been active in advancing the treatment of tuberculous disease of the bones and joints, especially in children; and on Dr. Frederick Spencer Lister, Research Bacteriologist to the South African Institute for Medical Research, whose name is particularly associated with the bacteriology and vaccine treatment of pneumonia. The same honour is conferred on Mr. F. C. Danson, chairman of the Liverpool School of Tropical Medicine. The C.M.G. is conferred upon Lieut.-Colonel William Thomas Frederick Davies, M.D., D.S.O., a member of the House of Assembly, Union of South Africa. The Kaiser-i-Hind Medal (first class) is conferred upon Dr. William James Wanless, principal medical officer of the Mission Hospital at Miraj, and chief medical officer of the American Presbyterian Mission at Bombay; Dr. Kate Platt, principal of the Lady Hardinge Medical College for Women, Delhi; Dr. Margaret Ida Balfour, Joint Secretary to the Central Committee of the Countess of Dufferin's Fund; and Miss Ida Sophia Scudder, Doctor in charge of the Mary Taber Schell Hospital, Vellore, North Arcot District, Madras. The services rendered by Sir R. T. Glazebrook, F.R.S., in the organization of the National Physical Laboratory, of which, when he resigned last year, he had been director for twenty years, are acknowledged by the K.C.B., and a knighthood is conferred upon Professor Arthur Schuster, F.R.S., who recently ceased to be one of the Secretaries of the Royal Society.

THE UNIVERSITY UNIT AT ST. THOMAS'S.

We understand that Dr. E. H. Starling, C.M.G., F.R.S., Jodrell Professor of Physiology, University College, London, has accepted an invitation to become the director of the medical element at St. Thomas's Hospital, and that arrangements are in progress for the appointment of assistant directors in pathology and clinical medicine to work with him in the new element. We announced some time ago that Sir Cuthbert Wallace, K.C.M.G., surgeon to the hospital, had become director of the surgical element, so that two-thirds of a university unit has now been formed at this great hospital and medical school. Dr. Starling has been concerned for the greater part of his life with physiology as an investigator and teacher, but he has always regarded it and taught it as one of the institutes of medicine. During the war he for a time undertook clinical work in military hospitals; afterwards, with the rank of Lieutenant-Colonel R.A.M.C., he became chemical adviser to the Salonica Force, and finally scientific adviser to the Ministry of Food. He is also British delegate on the Inter-Allied Scientific Food Commission. Early last year we published a report of his Oliver-Sharpey Lectures at the Royal College of Physicians on the feeding of nations, described as a study in applied physiology. He has been an inspiring influence to others, and has himself received many honours in recognition of the importance of his researches, especially with regard to hormones and the physiology of the heart, the subject of his Linacre Lecture at Cambridge in 1915. He was Croonian Lecturer at the Royal Society, with Professor Bayliss, in 1904, and received the Royal Medal of the Royal Society in 1913. He was Croonian Lecturer in 1905 at the Royal College of Physicians, of which he is a Fellow, when he dealt with the chemical correlation of the functions of the body; he received in 1907 the Baly Medal from the same College.

We understand that arrangements are far advanced for the constitution of two elements of a hospital unit at University College Hospital and Medical School. We believe that as at present arranged Dr. T. R. Elliott, C.B.E., D.S.O., F.R.S., physician to the hospital, will become the director of the medical element, and that Mr. C. O. Choyce, C.M.G., C.B.E., F.R.C.S., will probably become the director of the surgical element.

THE ranks of the medical members of the House of Commons have been strengthened by the return of Lieut.-Colonel F. E. Fremantle, O.B.E., R.A.M.C.T., for the St. Albans Division. He received 9,621 votes as against 8,909 polled by the Labour candidate and 2,474 by the Liberal candidate. Colonel Fremantle is honorary consulting M.O.H. to the Hertford County Council and served during the war as D.A.D.M.S. Mesopotamia. He graduated at Oxford M.B., B.Ch. in 1893 and M.A. and M.Ch. in 1903, and is a Fellow both of the Royal College of Physicians of London and of the Royal College of Surgeons of England.

South Australia.

MEDICO-POLITICAL.

ONCE more our hopes are being raised by the introduction of a Medical Bill into Parliament; it is based on that which passed the Upper House six years ago, but was dropped in the Lower. If it be passed now it will remove many of the anomalies of the present Act, which has not been altered for thirty years. Meanwhile the Government will conciliate mechanical opticians by introducing a bill for their registration, and is coquetting with a very dubious attempt to control and treat venereal diseases which would impose harassing restrictions upon the victims.

THE UNIVERSITY AND MEDICAL SCHOOL.

The death of Professor Sir Edward Stirling and the resignation of Professor Archibald Watson have created vacancies in the chairs of physiology and anatomy, which have been filled, in the case of the chair of physiology, by the appointment of the son-in-law of the previous incumbent—namely, Professor Brailsford Robertson, who made a great name for himself in San Francisco and at Toronto. The new professor of anatomy is Dr. F. Wood-Jones, who is well known in London and in Manchester for his anatomical, biological, and anthropological researches. It has been decided also that the much needed chair of pathology shall be instituted at the same time, and the applications for the position are now being considered. The lamented death of Dr. Archibald Magarey, who was long the acting secretary of the South Australian Branch, caused a vacancy in the post of demonstrator of anatomy and to this a returned soldier, Dr. Malcolm Scott, F.R.C.S., has been appointed. At the Adelaide Hospital several changes have occurred in the staff. Dr. De Crespigny becomes full physician. Drs. Cavenagh-Mainwaring, F.R.C.S., and Simpson Newland, F.R.C.S., have been promoted to be surgeons, Dr. Poulton having resigned that position.

SIR JOSEPH VERCO.

The knighthood conferred upon Dr. J. C. Verco has been approved as a most fitting honour both by the laity and the profession. Over thirty years ago Dr. Verco was recognized as the head of the profession in South Australia by being elected President of the First Intercolonial Medical Congress; only this year he retired altogether from practice. He seems likely to rival Sir Joseph Banks in this respect; he has already been President of the Royal Society of South Australia for at least a dozen consecutive years, his specialty in science being conchology. Freed from the engagement of medical work Sir Joseph Verco would appear to be a busier man than ever. He was elected President of the South Australian Branch for the fourth year in succession last June, but he immediately retired to make way for Lieut.-Colonel Simpson Newland, D.S.O. The honorary secretaryship has been filled by the appointment of Colonel H. A. Powell, C.M.G.

Scotland.

THE UNIVERSITY OF EDINBURGH.

THE annual report of the University of Edinburgh for 1918-19 was issued on December 24th, 1919. It recalls and summarizes a great multitude of facts, most of them already recorded from time to time in our columns. The total number of matriculated students was 3,554—2,719 men and 835 women; this was an increase on the pre-

vious session of 1,463 students; the increase was chiefly due to the influx of those who, on the conclusion of the armistice, were released from military duty, though in the spring and summer terms a large number of soldier students from overseas attended certain courses, some of them special courses, within the university. The grand total may be analysed in various ways—for instance, into faculties. Thus, in the faculty of medicine there were 1,683 students—nearly half of the total; arts came next with 1,019, and science third with 678. The total may also be analysed according to nationality; thus, in the medical faculty the nationalities were: Scotland 948, England and Wales 298, Ireland 42, India 53, Dominions and Dependencies 296, and foreign 46. The M.B. and B.S. degrees were conferred on 95 candidates, the M.D. on 30, the M.S. on one, and the diploma in tropical medicine on two. A diploma in public health has been established.

In the faculty of medicine three new chairs were founded—that of chemistry in relation to medicine, to which Dr. George Barger was appointed last April; that of therapeutics, the first holder of which is Dr. J. C. Meakins, formerly of McGill University, Montreal; and that of psychiatry, founded through a gift of £10,000 from the Royal Edinburgh Asylum for the Insane, to which Dr. G. M. Robertson, Superintendent of the Asylum, has been appointed. The university has lost the services of Dr. Harold Pringle, appointed Professor of Physiology in Trinity College, Dublin, and of Dr. John Tait, appointed Professor of Physiology in McGill University.

The unprecedented number of applicants for admission to the university, more especially in the faculties of science and medicine (some hundreds having had to be refused admission to the latter), has emphasized the urgent need for structural developments in a number of departments. Extensions to the existing buildings are in progress, by which it will be possible to secure much-needed additional accommodation for the departments of anatomy and physiology. A very important new departure has been made in the acquisition of over 100 acres of land on the south side of the city, where building operations have already been begun, to meet, in the first instance, the long overdue needs of the department of chemistry.

COLLIERY SURGEONS' COMMITTEE.

AS a result of prolonged negotiations between the Scottish Colliery and Public Works' Surgeons' Committee and the National Union of Scottish Miners, a national agreement has been reached for a uniform flat rate in all areas. The rate has been fixed at 3½d. a week for each worker where no medicine is supplied, and 4½d. a week where medicine is supplied. It has been agreed that Joint Committees of representatives of doctors and mine workers shall be set up in each area to consider local grievances, in addition to a Central Joint Committee.

England and Wales.

THE WELSH MOBILE LABORATORY.

AT the last monthly meeting of the Cardiff Medical Society Professor Emrys-Roberts related his experience whilst in charge of the Welsh Mobile Bacteriological Laboratory presented to the Welsh Army Corps by Lady Lynn-Thomas in the beginning of 1915. The laboratory was attached to the Welsh Division during its training, and for a short time after its arrival in France, after which it was established as a unit in the First Army, having allotted to it a corps area including five casualty clearing stations. The work was varied and interesting, and Professor Emrys-Roberts described briefly what had been done, and indicated the value of a mobile laboratory not only on active service, but also as part and parcel of the equipment of a public health service. A hope has been expressed that in due time the laboratory will find its way back again to the Principality.

SCARLET FEVER AND DIPHThERIA IN LONDON.

The Minister of Health stated, just before the prorogation, that on December 18th the number of cases of scarlet fever in the hospitals of the Metropolitan Asylums Board was 2,900. He said that in 1914 the Metropolitan Asylums Board had twelve institutions containing 7,065 beds for the treatment of infectious diseases, excluding institutions

reserved for small-pox. All the institutions taken over by the War Office as military hospitals have been returned, except two; one of these will be returned at the end of February, and one additional institution has been made available for infectious cases. The number of beds at present provided is 6,162, and the bulk of the patients admitted suffer from scarlet fever or diphtheria. In addition, there is a reserve hospital with 350 beds which could be used in the absence of an epidemic of small-pox. The number of cases of scarlet fever notified in London in the week ending December 20th, 1919, was 485, and of diphtheria 325, as compared with 443 and 272 respectively in the previous week.

Correspondence.

MODE OF QUININE ADMINISTRATION,

SIR,—In reply to the kindly criticism in your last issue by Sir Ronald Ross of my letter on the treatment of malaria (BRITISH MEDICAL JOURNAL, December 13th, 1919), let me say that the object of my communication was to emphasize the importance of intravenous and intramuscular administration of quinine in certain types of malaria which do not respond readily to oral administration. The types of malaria in which this method had been found of great value were quoted. It is well known that until comparatively recently the administration of quinine by intravenous or intramuscular methods has been disapproved of by the army authorities in India; and, indeed, an Order was issued some years ago forbidding its use in those ways.

The figures quoted in my letter were intended to give some approximate idea of the comparative values from a clinical point of view of the different methods of administration, and were not meant to be mathematical expressions based on scientific experiments.

The comparison of the therapeutic value of 5 grains of quinine bilydrochloride intravenously with 100 grains given by the mouth was not meant to suggest that doses of 100 grains should be given by the mouth or that the therapeutic value increased *pari passu* with the dose, but rather that a very much greater beneficial effect (something like twenty times) resulted from this method of administration.

In Northern Persia, in September, 1918, Major F. P. Mackie, I.M.S., and myself investigated an outbreak of malignant malaria in which the oral administration of quinine proved of little value either in effecting removal of the parasites from the blood stream, or in causing an improvement in the dangerous symptoms. When quinine was administered intravenously or intramuscularly marked beneficial results at once occurred associated with the disappearance of the parasites from the blood stream. Again in October and November, 1918, when the influenza epidemic spread to Northern Persia the majority of the cases amongst the troops were complicated by relapsing or malignant malaria, a combination causing most acute and dangerous symptoms. I saw in consultation a great number of these cases, and an exactly similar experience resulted as regards the very much greater benefit following intravenous and intramuscular methods as compared with the oral administration of quinine; the difference was most striking.

The administration of large doses of quinine by the mouth was not recommended in my letter, and the only reference to oral dosage was that which Sir Ronald Ross has himself officially advised and which I entirely accept. Indeed, the last part of my letter contained a caution against the administration of large doses by the mouth.—I am, etc.,

London, W., Dec. 29th, 1919.

W. H. WILLCOX.

SIR,—The ratio of value suggested by Colonel Willcox (BRITISH MEDICAL JOURNAL, p. 792) recalls a rather dramatic demonstration which occurred in North Persia in the autumn of 1918.

The column operating in that area was assaulted by the influenza epidemic, complicated by tertian malaria (both relapsing and malignant), and a very large number of grave cases resulted. The attacks of malaria were obviously protracted by the influenzal element. The field hospital of which I had charge was staffed with a few field ambulance bearers, so it was not at first thought

possible to do more than treat the cases by oral quinine solution given after the sweating stage had appeared. Doses from 30 to 120 grains a day were given over a week or more with literally no apparent effect.

We therefore gave (both to old and to fresh cases) quinine bilydrochloride by intramuscular injection in doses varying from three to fifteen grains. Rough notes taken at the time showed sudden improvement in almost every case, sometimes amounting to abatement of the attack after one dose. The effect appeared to be proportional to the size of the dose. The fact that some of the cases were heavily "under" quinine appeared to make little difference; and although as a matter of routine most of the patients were kept on 45 grains daily by the mouth, a few control cases suggested that this might have been dispensed with.

In the cases where the pyrexia, though diminished, was not abolished, $7\frac{1}{2}$ grains of the bilydrochloride intravenously in a single dose often brought the temperature to a steady normal in the most rapid and striking fashion.

The following case may be interesting as a type of some hundreds, many of which cases were seen by Colonel Willcox in consultation with me:

Sgt. M., R.A.S.C.—Malignant tertian and influenza. Paroxysms; 105° to 106°, with remissions to about 101°. Solution by mouth for three days. Maniacal delirium; hæmolytic jaundice. Gr. x intramuscularly, given daily in addition to oral. Range about 102° to 99°. No delirium. Profound anaemia. Jaundice improved. Parasites still present. This persisted for twelve days without change. On the twelfth day gr. vii intravenously were given and repeated on the thirteenth. Temperature fell to normal on the evening of the thirteenth day, and convalescence proceeded normally with two mild relapses aborted by gr. x intramuscularly. Oral quinine gr. xxx was continued for a month at the end of which no parasites were observed, and anaemia had vanished.

I have not drawn a distinction between the relapsing and malignant cases, as clinically (with the influenzal complication) they were almost identical, and the results of treatment were exactly the same, irrespective of the type of case.—I am, etc.,

O. H. MAVOR,

Glasgow, Dec. 27th, 1919.

Late acting Major R.A.M.C.

PREVENTION OF VENEREAL DISEASE.

SIR,—On reading the correspondence relating to the prevention of venereal disease I note the stress that is being laid by some correspondents on the moral side of the question—that is, whether prophylaxis is morally right or wrong. I fail to see that as medical men we have any concern with the moral aspect of the matter. That had much better be left to others.

The medical profession has at hand certain facts, which are:

1. That gonorrhoea and syphilis are caused by two micro-organisms.
2. That certain chemical agents destroy these organisms.
3. That both diseases cause a great deal of illness and suffering.

Therefore, according to the traditions and practice of medicine, use should be made of the first two facts to diminish the third.

Some individuals—possibly the great majority, possibly a very small minority—among those exposed to venereal infection may apply the prophylaxis improperly, either owing to carelessness or owing to other circumstances, and so lose its full benefit. We shall, however, have done our duty if we impart to the public the truth that science has imparted to us.—I am, etc.,

W. HERBERT BUTCHER, M.A. Oxon.,
L.R.C.P. Lond., M.R.C.S. Eng.

Wark-on-Tyne, Dec. 24th, 1919.

SIR,—In view of the present epidemic of conflicting letters on this matter, do you not think the following quotation (from what has been written but not yet published elsewhere) presents fairly what ought to be the medical attitude towards prevention?

"All medical men, too, should be ready and willing to advise on prevention, without troubling themselves about whether action should be taken before or after the risk has been run, or whether it may be right to act in an hour's time but not now, and such-like absurd futilities. They should simply prevent, however, whenever and wherever they can and dam the consequences."

N.B. Dam does not mean damn.—I am, etc.,

December 26th, 1919.

ARTHUR COOPER.

SIR,—We are being invited to become the devil's panders by making immorality safe and—insult added to injury—the devil's proctors by proclaiming it inevitable. The way to the pit used in old days to be paved with good resolutions; it is now to be macadamized with prophylactic packets.

Let a *thinking* profession recognize that no upward step would ever have been taken by the human race if it had been generally assumed and proclaimed that the downward path was inevitable, and let an *honourable* profession refuse with deep disdain the ignominious rôle of "proctress to the lords of hell."—I am, etc.,

Streatham, Dec. 20th, 1919.

M.A., M.D.CANTAB.

THE R.A.M.C. AS A CAREER.

SIR,—I notice in the JOURNAL of December 20th a letter which, I presume, is intended to be an answer to mine of November 22nd.

It is obvious that the writer, who gives no clue to his own identity, is quite aware of mine, which, of course, I have no wish to disguise, but he appears to have overlooked the fact that "The R.A.M.C. as a Career" was supposed to be the subject under discussion and not the merits or demerits of my humble self.

Apparently I labour under the great misfortune of not being a *persona grata* to this anonymous correspondent, who, I fear, will not have the courage to come out of his shell and so give one the fair opportunity of replying in detail to a letter which is so irrelevant that it can only be concluded that its writing was prompted by personal "spleen."—I am, etc.,

Cardiff, Dec. 27th, 1919.

W. M. S.

THE DISTRESS IN VIENNA.

SIR,—Many medical men who have studied or taken out post-graduate courses in Vienna in pre-war days, will have read of the present distress in that city with much regret. Though we may be very angry with Austria for commencing the war, and though we may be strongly opposed to the action of pro-German socialists and radicals in this country, I think most of us will desire to do something, however little it may be, to help to alleviate the distress of the city, where so many of us spent such happy days thirty years ago or more recently. The opportunity to help is given this week through the special appeals made in the newspapers and by the various churches.—I am, etc.,

December 29th, 1919.

R. T. W.

THE ORDER OF ST. JOHN.

We have received the following letter of inquiry:

"SIR,—I read with much interest your leading article on Red Cross work in peace. I have been connected with the educational problem with regard to first aid and home nursing for many years. I think your suggestion to have a report of the aims and objects of the two societies—the Red Cross and St. John Ambulance Association—an excellent one. As I am under the impression that the St. John Association is granting orders and decorations for work done for that society, could you inform me under what conditions these honours are given? Is there any truth in the report that payment has to be made for them?—I am, etc.,

December 19th, 1919.

ONE INTERESTED."

We find that the Order of St. John was revived by the Knights of Malta after the fall of Napoleon and the restoration of the Bourbons in 1814. They obtained a Pontifical bull, which was issued by Pope Pius VII on August 10th, 1814. Through the exertions of Sir Robert Peat, D.D., Chaplain Extraordinary to George IV, the English *langue* was revived under the provisions of a statute of the 4th and 5th of Philip and Mary. The present order of St. John received a charter from Queen Victoria on May 14th, 1888, incorporating it under the style and title "The Grand Priory of the Order of the Hospital of St. John of Jerusalem in England." The St. John Ambulance Brigade had come into existence in 1877.

The various grades in the "Grand Priory of the Order of the Hospital of St. John of Jerusalem in England" are:

- 1. Knight of Justice.
- 2. Lady of Justice.
- 3. Chaplain.
- 4. Knight of Grace.
- 5. Lady of Grace.
- 6. Esquire.
- 7. Honorary Serving Brother.
- 8. Honorary Serving Sister.
- 9. Honorary Associate.

Honorary Associates, it would appear, are not necessarily members of the Order, but, like the members, are under the government and control of the Order, which is vested in the Chapter. This consists of the Knights of Justice, the Prelate and Sub-Prelates, certain selected members, and the executive officers (*ex officio*). The Charter lays it down that membership of the Order cannot be obtained by the mere fact of money contributions and subscriptions to hospitals or charitable work. Nor can membership be purchased by a mere monetary payment. The rules of the Order, we understand, require members down to and including the grade of Esquire to pay an entrance fee (called foundation payment) and an annual subscription (called annual oblation) as follows:

	Foundation Payment.	Annual Oblation.
Knight of Justice	£ 70	£ 5
Chaplain	15	5
Lady of Justice	20*	5
Knight of Grace	20	5
Lady of Grace	15*	5
Esquire	5	5

* Reduced in the case of a wife, sister, or daughter of a Knight. Neither admission fees nor annual subscriptions are paid by lower grades.

There are, we believe, other higher grades open only to Knights of Justice. Every member and honorary associate is required to make the following solemn declaration:

That I will ever be faithful and obedient to the Order so far as is consistent with my duty to my Sovereign and Country, doing everything in my power to contribute to its glory, prosperity, and utility; that I will combat everything prejudicial to its wellbeing; that I will never act contrary to its dignity, but that I will conduct myself always as a good Christian and a man (woman) of honour.

An application for the various grades in the Order is, in the first instance, submitted to the Finance and General Purposes Committee and then to the Council and Chapter, after which it is submitted to the Grand Prior, H.R.H. the Duke of Connaught, for approval. The name is then balloted at the next chapter. The next stage is that the name is brought again before the Grand Prior for submission to the King for final sanction.

Members of the Order wear a badge suspended from a black watered riband, but the election to any of the grades of the Order or the privilege of wearing any of the badges is not to be deemed or construed to confer any rank, style, title, dignity, or appellation or social precedence whatever.

The objects of the Order are the encouragement of works of humanity and charity, aid to the sick poor, study of the needs of the poor in time of sickness, aid to the sick and wounded in war, and maintenance of the St. John Ambulance Association, the objects of which are instruction in first aid and in the elementary principles of nursing and hygiene, the manufacture and distribution by sale or gift of ambulance material, the formation of ambulance dépôts in centres of industry and traffic, and the organization of ambulance corps, invalid transport corps, and nursing corps.

A short article describing the circumstances attending the revival of the Order was published in our columns five years ago. A good account of the origin of the first hospital of St. John at Jerusalem is given in *The Military Religious Orders of the Middle Ages* (by F. C. Woodhouse, M.A.), one of the Home Library Series of the Society for Promoting Christian Knowledge. The present Order of St. John has retained from mediæval times, in a modified form, the religious qualification required from candidates who aspire to be admitted to the various grades in the Order. One consequence would appear to be that subjects of the Crown who are not within the religious limitation laid down by the Order are not admissible, so that Unitarians, Mahommedans, and members of other religious communities within the Empire, are not eligible for admission to the Order.

So far as we are aware, the St. John is the only one of the eighteen Orders of Chivalry of the United Kingdom which retains a restriction on the ground of religion and requires payment of certain admission and annual fees.

Obituary.

SIR WILLIAM OSLER, Bt., M.D., F.R.S., F.R.C.P.,
Regius Professor of Medicine in the University of Oxford.

THE death of Sir William Osler on December 29th—within six months of the celebration of his 70th birthday—has caused a deep sense of personal sorrow throughout the medical profession of two continents. He had been ill for more than two months, but the end came quickly.

William Osler was the sixth son of the Rev. Featherstone Lake Osler and Ellen Free, daughter of Thomas Pickton, of London. One of his brothers is Sir E. B. Osler, a member of the Dominion House of Commons and a director of the Canadian Pacific Railway, and another is Judge Osler, who was a justice of appeal, Ontario. The Oslers were a Falmouth family, shipowners and merchants, and the father was born there in 1803. Subsequently he went to Canada as a missionary, and eventually became Rector of Ancaster and Dundas, Ontario (1857-93).

Early Days.

William Osler was born at Bend Head, Ontario, on July 12th, 1849. He told us in his address on Sir Thomas Browne that it was his good fortune as a boy to come under the influence of a parish priest of the Gilbert White type, who followed the seasons of nature no less ardently than those of the Church, and whose excursions into science brought him into contact with physic and physicians. Father Johnson, as his friends loved to call him, founder and Warden of the Trinity College School, Weston, near Toronto, illustrated that angelical conjunction of medicine and divinity more common in the sixteenth century than in the nineteenth. It was he who first introduced William Osler to the *Religio Medici*, a copy of which acquired then, the second book he ever bought, was always the most precious in his library. From it came subtle influences which gave stability to character and helped to a sane outlook in the complex problems of life. The thoughts of Browne, and those also of Marcus Aurelius and Epictetus grew to be his thoughts; conscientious devotion to duty and deep human interest in human beings became his master thoughts thus early in life. William Arthur Johnson was one of the three teachers—Dr. James Bovell of Toronto and Dr. Palmer Howard of Montreal being the other two—to whom he dedicated his *Principles and Practice of Medicine*, and to whom he owed his success in life, if success means getting what you want and being satisfied with it. From school he went to Trinity College School of Medicine, and in 1870 to McGill University, Montreal, where he graduated in 1872.

In the summer of 1872, after a short tour—Dublin, Glasgow, and Edinburgh—he settled at the Physiological Laboratory, University College, with Professor Burden-Sanderson, where he spent fifteen months working at histology and physiology. At the hospital he saw in full swing the "admirable" English system, with the ward work done by the student himself the essential feature, and though not a regular student of the hospital he had many opportunities of seeing William Jenner and Wilson Fox, and his notebooks contained many precepts of these "model clinicians." From Ringer, Bastian, and Tilbury Fox he learnt how attractive out-patient teaching could be made—Ringer he always felt had missed his generation, and suffered from living in advance of it. The autumn of 1873 was spent in Berlin, where he had his first introduction to the medical clinic on a large scale, on which he was to model his own clinic at Johns Hopkins Hospital. There he studied under Frerichs, Hoffmann, Riess, Ewald, and Franke. The last named made a great impression on him as an ideal physiological clinician. The first five months of 1874 were spent in Vienna in the clinics of Hebra, Bamberger, and Wlderhoffer. In Bamberger he found another ideal clinician.

Montreal.

When he returned to Montreal in September, 1874, the Chair of the Institutes of Medicine was vacant, and he found that the Faculty had, with some hardihood, appointed him, a young and untried man, to it, instead of to the demonstratorship as he hoped. With the appointment he had the "ghastly task" of delivering four systematic lectures a week for the winter session, and from this period dated his ingrained hostility to this type of

teaching. His colleagues at the Montreal General Hospital placed the *post-mortem* department at his disposal, and pathology became his chief interest. He then began that extensive experience of this subject which formed the basis of his future successful career as a physician and teacher. He was appointed physician to the small-pox wards of the Montreal General Hospital in 1875, and in 1878 honorary physician to the hospital. On the day of his election he left for London to take the Membership of the Royal College of Physicians and to work at clinical medicine. For three months he had a delightful clinical experience, attending the ward visits of several London physicians. Murchison he described as a model bedside teacher, Gee as one in whom were combined the spirit of Hippocrates and the method of Sydenham. Fred. Roberts showed how physical diagnosis could be taught. In the summer of 1879 he had his own first clinical class, working with his students through Gee's *Auscultation and Percussion*. The next five years passed in teaching physiology and pathology in the winter session and clinical medicine in the summer. In 1884 he spent four months in Germany, chiefly at Leipzig, working at pathology with Weigert and clinical medicine with Wagner.

Philadelphia.

His reputation as an inspiring, keen, and successful teacher, his character as a man, his attracting personality, and his enthusiasm for hard work, were known and appreciated far beyond Montreal, and after ten years there he was, in 1884, appointed to the chair of clinical medicine in the University of Pennsylvania, Philadelphia, then the premier medical school in the States, in succession to Dr. William Pepper. The invitation to the chair reached him whilst he was in Leipzig, and he treated it first as a practical joke, one in retaliation for similar efforts on his own part, and for a time did not reply. It was, however, serious enough, and he accepted it, leaving Montreal "a rich man, not in worldly goods, for such I have the misfortune—or the good fortune—lightly to esteem, but rich in the goods which neither rust nor moth have been able to corrupt—friendship, good fellowship, wider experience, and fuller knowledge."

Johns Hopkins.

At Philadelphia, as everywhere, teaching work was his first care, and hospitals and medical societies absorbed the greater part of his time; he lived the peaceful life of a student with students, who were the inspiration of his life and of his work. The teaching there was by lectures and the theatre clinic. Ward classes for physical diagnosis were held, but clinical clerks were unknown, and theoretical lectures occupied a large share of the student's time. Osler broke new ground there by starting a small clinical laboratory. After five years at Philadelphia he was elected to the chair of the Principles and Practice of Medicine in the Johns Hopkins University, Baltimore, and physician to the Johns Hopkins Hospital. That hospital was by the will of the founder to form part of the Medical School, and be an institution for the study as well as the cure of disease. Osler had been appointed early enough to take part in the organization of the clinical work and teaching, and thus had a leading share in establishing, for the first time in an English-speaking country, a hospital embodying the principle of hospital units, each in charge of a director. The day after he accepted office he met Dr. Gilman, President of the Johns Hopkins University, at the Fifth Avenue Hotel, New York, so that they could study the management of the hotel, there being, in Dr. Gilman's opinion, no great difference between the general management of a hotel and a hospital. They found that each department of the hotel had a responsible head, and over all a director; on this plan were modelled the arrangement and management of the hospital units. The university had not sufficient funds to open a medical school at the time, and so for several years post-graduate teaching alone was conducted there. Osler thought this a fortunate circumstance, for it gave time to complete its organization. There was nothing in his life in which he took greater pride than his connexion with the organization of the hospital, and with the introduction of English methods of practical instruction. He desired no other epitaph than the statement that he taught medical students in the wards. He firmly believed in the value to a university of the publication, even at a

Grossmann
A. Osler

monetary loss to it, of original work carried out in its schools, and he used to say that the Johns Hopkins *Reports and Bulletin*, issued in connexion with its medical school, had amply repaid the university for the money and trouble expended on them. When he went to Johns Hopkins his ambition was to build up a great clinic where the professor should have an organized body of assistants and house-physicians, and where the student should be taught not by didactic lectures, but in the wards and the laboratory.

Influence on Medical Education.

He was never a whole-time professor, and even in 1914 he was not in favour of the whole-time clinical teacher, because his life had been largely spent in association with his professional brethren, participating in the many interests they had in common. At the same time he confessed that he mistrusted his own judgement on this point, as it was a problem for young men and for the future.

He described his own method of conducting clinical teaching before the Abernethian Society, St. Bartholomew's Hospital, in 1913. The detailed ramifications of his teaching are remarkable. An essential feature of it was that students were set tasks of seeking information on any point of interest that cropped up in the class, the teacher telling them in what books to look for it, and they had to report to the class at a subsequent meeting.

Osler was an excellent clinical observer, and he attributed most of his success in this to his thorough grounding in the results of disease which he gained as pathologist at Montreal. He did a great deal of original work himself, and he had the happy faculty of inspiring others with his own enthusiasm for original investigation, and his charming personality and manner attached to him in the course of his life hundreds of young men who thought it a great honour and gain to them to be allowed to work for or with him. He always gave proper credit for work done by others, whenever and wherever it was due, and never forgot his assistants.

He had three ideals: "To do the day's work well and not bother about to-morrow; to act on the Golden Rule towards his professional brethren and patients; and to cultivate a measure of equanimity to enable him to bear success with humility, affection of friends without pride, and to be ready when the day of sorrow and grief came to meet it with courage befitting a man." The first of these ideals he elaborated in his address to Yale students, 1913, and published in small pocket-book form as *A Way of Life*.

Oxford.

When Sir John Burdon-Sanderson, the Regius Professor of Medicine at Oxford, resigned in 1904 the graduates of the University met and expressed the opinion that the new occupant of the chair should be a physician representative of medicine in its widest sense. Dr. Burdon-Sanderson had previously been Waynflete Professor of Physiology and apparently could not be described in the terms of the graduates' resolution, and when finally Dr. Osler accepted the chair (1905) it was universally agreed that Oxford had obtained such a man as it hoped for. It may be noted here that he had been elected a Fellow of the Royal College of Physicians in 1883 and a Fellow of the Royal Society in 1898.

The reasons why he gave up work into which he entered heart and soul were given by himself subsequently (BRITISH MEDICAL JOURNAL, January 3rd, 1914, p. 16):

I know how hard it is "to serve God and Mammon," to try to do one's duty as a teacher and to live up to the responsibility of a large department, and at the same time to meet the outside demands of your brethren and of the public. And if added to this you have an active interest in medical societies, and in the multifarious local and general problems, the breaking-point may be reached. I had had thirty-one years of uninterrupted hard work. William Pepper, my predecessor in Philadelphia, died of angina at 55; John Musser, my successor, of the same disease at 53! After listening to my story you may wonder how it was possible to leave a place so gratifying to the ambitions of any clinical teacher: I had had a good innings and was glad to get away without a serious breakdown.

For the following estimate of Sir William Osler's influence in Oxford we are indebted to Dr. CHARLES SINGER:

"Perhaps only those who have known the medical school at Oxford both before and after Osler's arrival can estimate fully the change wrought by his personality, not

only in the mechanism, but in the whole spirit. Among Osler's predecessors in the chair at Oxford have been men of the very highest scientific distinction, but few or none had that kind of knowledge which comes of a long life of clinical teaching and of a wide experience of a variety of medical schools. This was Osler's special asset, and it was associated in him with actual scientific attainments and humanistic sympathies that have probably not been found in combination to a like degree in any one medical teacher since the days of Boerhaave.

"When Osler first came to Oxford medicine was indeed recognized by the university both by reason of the antiquity of the endowments that existed to promote it and because it was generally allowed to be a part of the *organo*n of knowledge. But the school was exiguous in dimensions and in many ways cut off from other departments of university activity. There was thus very little temptation to select Oxford in preference to other medical schools, and a large proportion of its students—and these among the most gifted—were men who came to medicine not as a first choice but after having completed a course in some other faculty. Excellent work was done in Oxford in those days under the most difficult conditions, but it is no injustice to a bygone system to say that in the nature of the case it could attract only the few.

"With the advent of Osler all this was changed. First, his own manifold attainments provided a natural link with other departments. His enthusiasm for learning was, from his first settling in Oxford until his last public utterance, exerted in the direction of bringing the great resources of medical history, in the widest sense, into relation with the general cultural stream. This movement, he clearly saw, could not fail to react on the status and attainments of medical men as a whole. He had himself been the witness of so many changes in the practice of medicine, and his own thoughts and education had been so deeply tinged with the reflections of the past, that it was natural, in the eventide of his life, that he should turn so largely to tempering visions of what might be with musings on what had been. This extraordinary range of intellectual interests it was that chiefly marked him out and gave him his supreme quality—judgement. It is for the degree to which he possessed this quality, rather than as a pioneer or investigator, that posterity will remember him, as it remembers his great prototype Boerhaave. Not that either of these men lacked scientific powers or failed of scientific achievement. But it was their power of judgement, drawn, on the one hand, from great stores of experience and, on the other hand, from great powers of vision, that gave them their quality as teachers and as inspirers of others, and their insight as physicians. It was certainly this that was the primary source of Osler's influence at Oxford.

"As soon as Osler came to Oxford he recognized the need of bringing the academic teaching of medicine there more fully into touch with the realities of practice. He not only threw all his weight into the adequate development of the departments of pathology and physiology, but he immediately discerned the need and the possibility of an extension there of clinical teaching. He saw that Oxford, a town of between 50,000 and 60,000 inhabitants, could not be a very great clinical school, but he knew from practical experience the special value that an academic atmosphere may give to clinical instruction and the value also that comes from an intensive study of material—a method either difficult or impossible in many busier centres. He thus succeeded in linking up scientific investigation and clinical experience. Nor will this method disappear with his direct influence, for he has inspired and left behind him a number of younger and distinguished exponents who will carry on his tradition.

"Osler was gifted with those peculiar qualities of heart as well as of head that made it always seem to those in his company that their own interests were his also; but the seeming was something more than a mere appearance—it was a reality. It may have seemed that in his later years his interests moved predominantly in the direction of literary and historical pursuits. This element in his character was, however, a new thing, and was a development that comes to many as experience grows in richness and variety. It arose in him, at least, from none of that failure of the forward-looking power that goes with age, but rather from something that is almost its opposite. He seemed to have a great sense of continuity, and this

gave rise, on the one hand, to his love of antiquity, especially as expressed in the historical method, and, on the other hand, to his love of young people, and his constant desire to have active and moving minds around him. He was no mere antiquarian. It was the living past that appealed to him, the past that he traced in the present and foresaw in the future. For such a spirit Oxford was an ideal home: Oxford with its inexhaustible store of ancient memories and its young and progressive medical school, Oxford with the researches of its scholars and its scientists going on endlessly side by side. Into the heart of this complex place Osler did not creep but leapt, and became at once a part and parcel of it, influenced by it and loving it, but never losing his own rich and complex personality that had been moulded by other forces of which, as yet, Oxford knew but little.

"And so it came about that he retained in Oxford just those powers of making his surroundings react to him that had been discerned in him in other and less conservative environment. This was the secret of his power, and this it was which enabled him to raise the Medical School at Oxford to the position that it now occupies."

Mr. R. W. CHAPMAN, assistant secretary of the Clarendon Press, tells us that Sir William Osler became a Delegate of the Oxford University Press in 1905, and was recently made a Perpetual Delegate in the room of Dr. Sanday. "His immense knowledge," Mr. Chapman continues, "and great influence, his antiquarian tastes and bibliographical lore, made his help and counsel of great value to an institution which has its roots in the past and claims its place in the forefront of modern research. Osler's name will always be connected with the *Quarterly Journal of Medicine*, the publication of which by the University Press was due to his initiative. It is not so well known how much the series of Oxford Medical Publications, which began during his tenure of office, owed to his constant care and wise direction. The Press has in preparation *A Physician's Anthology*, a collection of verse made by some of his friends in his honour. All who are connected with the Press deplore that what was designed as a gift can now be no more than a memorial. His loss will be felt as a real blow, the more so as it follows immediately on the untimely death of Mr. Charles Cannon, who, as Secretary to the Delegates, had worked with Osler for many years."

Writings.

No attempt could be made here to enumerate his many writings, beginning in 1872 with reports in the *Canadian Medical and Surgical Journal* of cases in the wards of the Montreal General Hospital. The bibliography given in the July number of the *Johns Hopkins Hospital Bulletin*, which celebrated his 70th birthday, contained 730 titles of books and articles by him during the forty-nine years 1870-1919. His chief book, *The Principles and Practice of Medicine*, made its first appearance in 1892, and at once had an enormous success not only with students but with medical men in all English-speaking countries. Many editions were called for, and each was carefully revised to keep it abreast of the progress of knowledge. An eighth edition appeared in 1916. He was the editor, with Dr. Thomas McCrae, of *A System of Medicine* in several volumes. In 1889 he wrote on the cerebral palsies of children, and in 1897 on angina pectoris and allied states. In addition to his very numerous writings on clinical and pathological subjects, he from time to time delighted the profession by an address on some subject in the borderland of medicine and literature or science. In one of these he urged the student to allot a portion of each day to books not connected with medicine. "Before going to sleep read for half an hour, and in the morning have a book on your dressing table. You will be surprised to find how much can be accomplished in the course of a year." He himself found recreation in biography, and had a strong conviction of its value in education. He often chose a biography for the subject of an address, and a series were collected in the volume entitled *the Alabama Student and other Biographical Essays*, published in 1908. The subjects chosen for the biographies in this volume were nearly all medical men: John Keats, the apothecary poet, John Lock as a physician, Oliver Wendell Holmes, Sir Thomas Browne. Those who knew the boyish side

of Osler's nature can realize the zest with which he hunted out the story of the buccaneering expedition in which Thomas Dover, physician and buccaneer, was third in command, an expedition which found Robinson Crusoe in 1710, and finally realized the enormous sum of £170,000. Osler's love of history came out even in his *Principles and Practice of Medicine*, where he gave an account of the origin and growth of knowledge of the various diseases, and mentioned the men who had pieced it together. Perhaps of his occasional addresses that which best revealed his learning and sense of fun was that on "The Old Humanities and the New Science," which he delivered to a meeting of the Classical Association at Oxford in May, 1919. Its publication in our columns on July 5th, 1919, gave great and abiding pleasure to thousands of readers.

Osler loved the society of young people, and knew well how to gain their confidence. His cheery optimism appealed to them, and when he visited a large hospital he delighted to get into the common room and chat about anything and everything—and there were few matters about which Osler did not know something. He would confess that he found this association with young men very helpful to a teacher, and that he believed that it not only enabled him to understand their ideas and difficulties, but kept the teacher himself from stereotyping his mind. He was, when the subject needed it, an impressive speaker, but his lighter utterances and after-dinner speeches were full of humour, wit, and broad fun.

Honours.

He received many honours. He was made a baronet at the time of the coronation of King George V; he was honorary professor of medicine in Johns Hopkins University; he received the honorary degree of D.Sc. from the universities of Oxford, Cambridge, Dublin, Liverpool, and Leeds, that of LL.D. from the universities of McGill, Toronto, Aberdeen, Edinburgh, Yale, Harvard, and Johns Hopkins, and the D.C.L. from the universities of Durham and Trinity, Toronto. He was a foreign associate of the Academy of Medicine, Paris, and received the honorary degree of M.D. from the university of Christiania. On July 11th, 1919—the day before his 70th birthday—he was presented, in the name of a large number of subscribers, with a collection of essays in two volumes, written by some 150 representative members of the profession on both sides of the Atlantic. The presentation was made by his "brother of Cambridge," who said that the occasion was one anniversary of many years of supreme service in two kindred nations and for the world. "But while thus," Sir Clifford Allbutt continued, "we celebrate your leadership in the relief of sickness and adversity, we are far from forgetting the sunnier theme—the debt, none the less, which we owe to you in other fields of thought. In you we see the fruitfulness of the marriage of science and letters, and the long inheritance of a culture which, amid the manifold forms of life, and through many a winter and summer, has survived to inspire and adorn a civilization which so lately has narrowly escaped the fury of the barbarian." In a moving reply, Sir William Osler spoke of himself "loving our profession and believing ardently in its future; I have been content to live in it and for it," and added characteristically, "Nothing in my career has moved me more, pleased me more, than to have received letters from men at a distance; men I have never seen in the flesh, who have written to me as a friend."

Sir William Osler married in 1892 the eldest daughter of the late John Revere of Massachusetts, and great grand-daughter of Paul Revere. Their only child, a son, who was born in 1896, died in France, 1917, from wounds received in battle.

The Last Years.

To Dr. ARTHUR THOMSON, Professor of Human Anatomy at Oxford, we are indebted for the following note of Osler's life and influence in Oxford, and of his death:

"In 1905 Osler came to Oxford with a great reputation. That he has lived up to it, and given us of his best, is attested by the affection which his memory invokes. After the strenuous hustle of American life, the rest and calm of Oxford appealed to him. It is pleasant to know that the years spent here were amongst the happiest of his life. The surroundings were such as he delighted in, the society

was congenial, and the duties of his office, not overburdensome, were such as to give him ample scope for his activities, and free play for his broad outlook on life.

"Gifted with a remarkable memory, and equipped with an almost limitless experience, he never seemed to forget anything he had either seen or read. He had a marvellous power of marshalling facts and getting at the essentials. Quick to realize the ever-changing needs of the times, he was always in the forefront of progress. There was a brightness and sparkle about his views which won approval and disarmed opposition. At a meeting, whenever Osler was in the chair, the proceedings were never dull, and business was usually expeditiously transacted. He had clear views as to what he wanted, and generally got his way, and, he it here recorded, his way was usually the best way.

"Of a nature most generous and kind, he was ever mindful of the trials and sorrows of others. Many will there be this day who remember with loving affection the comforting words with which he soothed their sore tried hearts. To those engaged in the struggle of life he was full of encouragement, wise counsel, and often substantial aid. Even of the failures in life he had always something good to say. With qualities such as these can it be wondered at that he endeared himself to all who were fortunate enough to be of his acquaintance. We in Oxford know it, and now cherish the memory of his sympathetic personality.

"His delight was in books; he was never happier than when showing some recently acquired treasure. Much of his leisure was spent in the Bodleian, of which he was a curator, and his expert advice was of invaluable service to the Delegates of the Clarendon Press.

"By virtue of his office he was Master of the quaint old almshouses at Ewelme, Oxfordshire. Nothing gave him greater pleasure than to whisk off by motor car a party of American visitors, there possibly for the first time, to introduce them to the beauties of this most picturesque of English villages; it remains as a lasting memory to many who were privileged to make the visit.

"Of his work in the Medical School what need be said that is not known? He cheered us by his breezy presence, and left us all the heartier with some quaint quip or jest. None the less, he was alert and observant, and oftentimes we benefited by some shrewd remark or friendly criticism. It was around the Radcliffe Infirmary that his activities mainly centred; he was largely instrumental in getting the new Clinical Laboratory built there, and much of his time was devoted to the introduction of appropriate clinics in that institution.

"The war told badly on Sir William. Like many others, he lost his only son; it hit him hard, but he never winced. As he said to me, 'Ours is a common sorrow; we must think of others as well as ourselves.' In consequence he immersed himself in duties innumerable, particularly in connexion with the hospitals under Canadian and American control. He was always responsive to the appeal of friends from abroad who were anxious to obtain news of their wounded sons. This often entailed long and tedious journeys, and the strain told on him; he was a worn and tired man.

"When peace came, bringing with it the brighter outlook, he began to pick up; and when, this autumn, he returned from a holiday in the Channel Islands, he was a new man, with all the old vitality back again: for it appears that under the genial influence of the Jersey climate, with boyish glee, he had been indulging in all sorts of acrobatic performances, such as standing on his head and turning cartwheels on the sands—wonderful feats for a man of 70. Accordingly we were all buoyed up by the hope that our Regius had still many years of active life before him.

"Called in consultation to Glasgow, he was caught by the railway strike; he managed to get as far south as Newcastle, and there he was held up. Anxious to get home, he undertook the long motor journey to Oxford. He arrived a sick man, and, despite the care and attention of those who tended him so lovingly and long, he passed away with the fading light on the afternoon of December 29th. 'Gone west' as he would have wished, for he often talked of the land of his birth and adoption."

Sir William Osler was a student (fellow) of Christ Church, and the funeral service was to be held at Christ Church Cathedral on the afternoon of New Year's day.

CHARLES LOUIS TAYLOR.

Formerly Assistant Editor of the BRITISH MEDICAL JOURNAL.

It was a sad group that assembled at St. Mary's, Konaal Green, on the morning of Christmas Eve, when Charles Louis Taylor—who was for over thirty years on the staff of the BRITISH MEDICAL JOURNAL, and for twenty years Assistant Editor—was laid to rest. He died on Sunday, December 21st, aged 70.

He was the only child of Dr. Charles Taylor, of Peterhead, Aberdeenshire, who died at the age of 21 of cholera contracted when attending victims of the epidemic in the neighbouring village of Boddam. His widow went with her infant son to reside in France, and he first went to school at Noyon. At the age of 6, speaking only French, he returned to Scotland, and was sent as a pupil to the Reverend Dr. Kemp at Dufftown. At the age of 11 he was promoted to Blairs' College, Aberdeen, and during his four years there received a thorough grounding in the classics. He was transferred in 1864 to the Scots College, Valladolid, where he remained four or five years. He would some times speak of his experiences there—the rigid discipline, homely fare, and the continuous study of ancient learning, Latin being the colloquial language. It was during this period, however, that his acquaintance with English literature, which eventually became wide and deep, began. Finding that he had no vocation for the priesthood, he returned to this country with the intention of entering the Indian Civil Service, but when he applied was a few months over age. After a few years, during which he spent much time in France reviving his knowledge of French, he determined to follow his father's profession and entered the medical school of University College, London, in October, 1873. He was a good student, reserved, but greatly liked by his few intimates, as well as by those members of the staff who got to know him. He passed through the whole curriculum with credit, and held the usual students' appointments, but could never be induced to sit for an examination and never qualified. He acted as house surgeon to Mr. Berkeley Hill at University College Hospital for four or five months and held several other temporary appointments there. His upbringing had given him a colloquial command of French, Spanish and Latin; he had a working knowledge of Greek, Italian, and Portuguese, and later on taught himself to read German. These linguistic attainments were to serve him well.

In 1880 he became secretary to Sir Morell Mackenzie, who had just published the first volume of his *Manual of Diseases of the Nose and Throat*. Taylor gave him much assistance in the preparation of the second volume, which was acknowledged in the preface, where the author expressed his "deep obligations to Mr. C. L. Taylor for his invaluable help." The second volume was not published until 1884; it is still, we believe, highly esteemed by laryngologists, and Taylor's share in giving to it the qualities as a book of reference which have caused it to survive was large.

Louis Taylor joined the editorial staff of the BRITISH MEDICAL JOURNAL in 1886, and became Assistant Editor in 1897, retaining that position until 1917, when ill health compelled him to resign. Thus for over thirty years he served the BRITISH MEDICAL JOURNAL, accepting increasing responsibilities, and faithfully fulfilling all obligations with unremitting diligence. A great deal of the work, as is inevitable in an editorial office, was of a routine kind, but his vigilance never slept, and from how many pitfalls, for the careless or unskilled, contributors were saved, few of them were aware. It was characteristic of him to detect an error in a name or title, or, with much expenditure of time and patience, to track down a wrong reference, and yet to content himself with an inquiry, half humorous, half sad, as to the reason why scientific writers were so prone to the sin of misquotation. Should, however, an error creep in—and this may happen even with the most vigilant of editorial staffs—he would acknowledge it with his customary good humour, and, in correcting it, perchance have a quiet dig at that chief of offenders, the printer's devil. In course of time he made himself a master of certain subjects which were recurring causes of public controversy. For example, he studied the literature of vaccination and grew familiar alike with every step by which Edward Jenner established his discovery, and with every phase of the controversy provoked by its modern opponents. One result of his

researches was seen in the Jenner Centenary Number of the BRITISH MEDICAL JOURNAL, published in 1896. He also followed closely and systematically the activities of the antivivisectionists, and was ever ready to meet their champions with facts and arguments. Here again his accurate habit of mind and a style which could be both polite and caustic served him well. Satire and ridicule if necessary, were among the weapons he employed to confound his antagonists, and more than one "anti" this or "anti" that has been reduced to silence as his weapon found its mark. Later on he studied "Christian Science," and could have stood a cross-examination on the writings of Mrs. Eddy. He had the forensic faculty of getting up a case, combined with the power of retaining the story in memory and of reconstructing it in detail at short notice.

In the early days of his connexion with the BRITISH MEDICAL JOURNAL he did a certain amount of literary work in other directions. Thus, he assisted the late Mr. Marcus Beck in producing the ninth edition of Erichsen's *Science and Art of Surgery* in 1888; again, when the tenth edition was published in 1895, under the editorship of Mr. Raymond Johnson, his assistance was called in, and on both occasions its value was mentioned in the preface. He also helped in the translation of Gruber's textbook of *Diseases of the Ear* by Dr. Edward Law, who made a suitable acknowledgement in the preface. He was also for a time a frequent contributor to *Truth*, but his interest lay rather in historical research than topical discussion. His liking for biography made him accept with alacrity a request to edit a set of biographies with the general title, *Masters of Medicine*, planned by the late Mr. Ernest Hart. Eight volumes were published, and one on Vesalius by Taylor was announced. The series, however, was discontinued, and the book preparations for which had occupied much leisure time, was never written.

After his appointment to be Assistant Editor he seldom wrote except for these pages. The interest shown in some of his casual notes on historical subjects led him to suggest the establishment of the series of articles which, under the general heading "Nova et Vetera," appeared at short intervals for many years. That they were much appreciated by many readers there was ample evidence. Taylor did not write them all, but he wrote the majority. Though he never signed his name the authorship became known to some of those interested in the history of medicine, and a few years ago, on the proposal of Sir William Osler, he was elected an honorary Member of the Section of the History of Medicine of the Royal Society of Medicine. He appreciated the courtesy but did not make much use of the opportunities it afforded. His close friend the late Lord Ilkeston persuaded him to join the Reform Club, but he did not long retain his membership. This might at first seem strange; with his genial manner and fund of anecdote he might have been considered the ideal clubman. He, however, was happiest when among his books in his "den," and, above all, in his home life. Public and official functions had no attractions for him.

During the illness of the Editor, consequent on an accident in July, 1910, Mr. Taylor was responsible for the conduct of the JOURNAL during the next four or five months, which included the Annual Meeting in London that year. Amidst the pressure of other duties he found time to edit the Guide Book issued in connexion with that meeting. For this he received the thanks of the Association.

His leaning to the study of the history of medicine found an outlet in several special issues of the BRITISH MEDICAL JOURNAL, in particular in the Jubilee Number published in 1897 on the occasion of the sixtieth anniversary of Queen Victoria's reign.

Though not of robust constitution—he had intermittent glycosuria for many years—he enjoyed good general health until between six and seven years ago, when he began to suffer from symptoms which, becoming suddenly exacerbated, necessitated an abdominal operation performed by his old fellow student, Mr. Bilton Pollard. Recovery was slow, but he was eventually able to return to his post for several years. Increasing infirmities compelled him to tender his resignation, which took effect in March, 1917. Since then he had lived in retirement. His last illness, due apparently to glycosuria, began about six weeks before his death.

Mr. Taylor was a man of genial and kindly temperament which endeared him to all those with whom he worked. He was a loyal colleague, and his fund of knowledge of the past and present of medicine which he was always ready to produce in conversation made him an interesting and stimulating companion. He will long be held in kindly remembrance at the office of the Association.

Mr. Taylor married in 1882 the daughter of Mr. James Goodman of Bletchley. He is survived by his widow, two daughters, and his son, Dr. C. J. G. Taylor of Nuneaton, who served throughout the war as Surgeon R.N.V.R.

Universities and Colleges.

UNIVERSITY OF SHEFFIELD.

CLINICAL DEMONSTRATIONS.

THE Faculty of Medicine has arranged for a series of clinical demonstrations on special subjects to be given at the Royal Hospital, West Street, during the next three months of the winter session, as follows:

Mondays at 3.30 p.m.: X rays in Diagnosis and Treatment, Dr. W. H. Nutt.

Tuesdays and Fridays at 4 p.m.: Diseases of the Eye, Dr. P. J. Hay.

Wednesdays at 3.30 p.m.: Diseases of the Ear, Nose, and Throat, Dr. G. Wilkinson.

Thursdays at 3.30 p.m.: Diseases of the Skin, Dr. E. F. Skinner.

The course will begin on Monday, January 19th, and will be continued each week until the end of March. The demonstrations are open to all qualified practitioners free of charge. It will facilitate arrangements if those wishing to attend any or all of the courses will send in their names and particulars to the Registrar, the University, Sheffield, on or before January 10th. A full syllabus and time table will be forwarded on application.

UNIVERSITY OF ST. ANDREWS.

THE following candidates have completed the Final Examination for the degrees of M.B., Ch.B.:

Mildred Clark, Andrewina Laird, Florence B. Mason.

UNIVERSITY OF DUBLIN.

TRINITY COLLEGE.

THE following candidates have been approved at the examinations indicated:

FINAL M.B.—Part I, *Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene; Pathology*: *Daniel de Bruijn, *D. J. Browne, *Dorothy A. Daly, P. Jahkowitz, Rev. E. G. Campbell, J. C. Davis, Mary Horan, F. W. Pienaar, F. W. Shegor, P. Ryan, Nora Griffith, C. S. Wilson, R. R. Baker, Elior D. Stoford. *Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene*: J. D. Leahy, W. A. Murphy, R. H. J. M. Corbet, A. D. Ward, G. S. Moran, J. M. Sempie, J. R. Willis, R. W. Power, A. J. Beckett. *Pathology (in completion)*: J. C. Brennan, R. V. Dowse, H. A. Lavelle, C. W. Farr.

FINAL M.B., B.Ch., B.A.O.—Part II, *Midwifery*: *E. H. C. Allen, *Olive Baile, W. de Vos Scholtz, Essie S. Smyth, J. H. B. Crosbie, J. P. de Villiers, W. B. J. Pemberton, S. L. Feldman, J. B. Maguire, E. H. Frazer, W. B. Fox, W. T. Micks, B. F. Haythornthwaite, C. E. McQuade, J. Hirschmann. *Surgery*: *L. Abrahamson, *J. G. Holmes, T. D. Gordon, C. J. de V. Shortt, H. A. Lavelle, Doris L. Graham, W. A. Byrru, R. E. Murphy, Jessie Gilbert, Johan F. Wloht, M. Nurrook, R. W. Shaw, A. I. Steyn, S. J. Laverty, H. Cohen, A. Blagoff. *Medicine*: *L. Abrahamson, *F. W. Robertson, F. V. Small, J. G. Holmes, W. de Vos Scholtz, W. J. Hogan, T. D. Gordon, J. F. Wloht, H. A. Burridge, J. Hirschmann, R. W. Shaw, R. Connibao, Moira M. Brown, J. R. Waugh, W. A. Byrru, H. Cohen, C. J. de V. Shortt, F. W. Godbey, T. Macdill.

D.P.H.—Part I, *Chemistry, Bacteriology, Physics, and Meteorology*: V. M. Sygne, R. E. Wright, G. G. P. Beckett, N. H. H. Haskius, G. F. I. Harkness, W. H. Sutcliffe, J. S. Doekhill, G. O. F. Alley. *Part II, Sanitary Engineering, Hygiene, Epidemiology, Vital Statistics, Public Health Law, Sanitary Inspection and Reports*: V. M. Sygne, M. McKnight, R. E. Wright, G. G. P. Beckett, N. H. H. Haskius.

DIPLOMA IN GYNAECOLOGY AND OBSTETRICS.—R. W. Chambers.

* Passed on high marks.

LONDON SCHOOL OF TROPICAL MEDICINE.

THE following candidates passed the examination of this school at the termination of the sixty-first session:

*J. T. Duncan, *W. G. Seymour, *M. E. Barnes, *C. C. Chesterman, *E. C. Girling, *M. Bequaert, *R. Calleja, *A. Kidd, *E. S. Johnson, *H. Lillie, *G. F. Scudder, *W. Dawson, *W. P. Hume, *G. M. Heydon, L. N. Lee, A. N. Bose, G. Chesney, R. Chalmers, J. H. Thomson, W. R. Young, E. C. Spar, H. M. Pope, A. G. Fergus, J. Boodoosinh, P. F. Nuan, H. W. Webb, R. C. Briscoe, A. J. Galustian, T. D. Nair, P. W. Barnden, D. P. Jaisingha, J. I. A. Sorensen, N. Chena.

* With distinction.

The Services.

INDIAN MEDICAL SERVICE.

TEMPORARY COMMISSIONS.

THE Secretary of State for India makes the following announcement:

Fully qualified European medical practitioners are required for temporary service with Indian troops on special rates of pay. Applicants must be British subjects of European descent, and should not be more than thirty-five years of age. If accepted for appointment they will be required to enter into a contract to serve for two years.

The rates of pay will be Rs. 700 per mensem for a lieutenant, Rs. 750 per mensem for a captain. Three or more years' service as a medical officer in the home, colonial, or Indian forces are necessary to qualify a candidate for the higher rate. Officers will be provided with free passages both ways. Wives and families will be sent out at Government expense in the autumn of 1920, provided that shipping is available. An outfit allowance of £50 will be granted except in the case of officers who have served under the War Office or the Government of India, to whom £20 only will be issued.

Further particulars and forms of application may be obtained from the Secretary, Military Department, Room 157, India Office, Whitehall, S.W.1. Envelopes should be clearly marked in the top left-hand corner "Temporary I.M.S."

It must be remembered, first, that the price of the rupee varies and that the exchange is hardly likely to be maintained at the present rate, and, secondly, that a large part of the officer's income must be spent in India, where the rupee is worth no more, but decidedly less, than it was worth before the recent rise in the exchange. This matter is referred to in a Current Note in this week's SUPPLEMENT.

AUXILIARY ROYAL ARMY MEDICAL CORPS FUNDS.

THE usual quarterly committee meeting was held on December 19th, 1919, at 11, Chandos Street, Cavendish Square, W.1. Three grants were made in the benevolent branch for officers, amounting to £290, and fourteen grants in the relief branch for the rank and file, amounting to £624.

These funds are for the relief of widows and orphans of commissioned officers and non-commissioned officers and men of the rank and file of the Royal Army Medical Corps, Special Reserve, Territorial Force, and New Armies, and also for the relief of the children of those who have been so severely damaged in the present war that they need help for the education of children.

Requests for relief should be addressed to the Honorary Secretary, at the offices of the funds, at 11, Chandos Street, Cavendish Square, W.1.

HONOURS.

C.B.

Surgeon Commander D. W. Hewitt, C.M.G., R.N., has been appointed C.B. (Military Division) for valuable services as Senior Medical Officer on the staff of the Senior Naval Officer, White Sea.

C.B.E.

The distinction of C.B.E. (Civil Division) has been awarded to Dr. Cecil Henry Elmes, O.B.E., officiating health officer, Port of Calcutta, Bengal, in recognition of valuable services rendered in India in connexion with the war.

O.B.E.

The O.B.E. (Military Division) has been conferred upon Surgeon Lieut. Commander R. H. McGiffin, R.N., for valuable services rendered in the Archangel area of the White Sea; Surgeon Lieut. Commander A. A. Sanders, R.N., and Surgeon Lieut. Commander F. St. B. Wickham, R.N., for valuable services rendered in H.M.S. *Glory* and H.M.S. *Hyderabad* in Russia respectively.

Miss Ruth Balmer, M.B., honorary Captain R.A.F. Medical Service, and Flight Lieutenant Robert Lloyd Roe, M.B., R.A.M.C., have received the same distinction in recognition of distinguished services in North Russia and the Mediterranean area respectively during the war; and temporary Lieut. Colonel Raghobendra Row, I.M.S., and Captain Dais Raj Ranjit Singh, I.M.S., Cecil Henning Lincoln, M.B.E., assistant surgeon I.M.D., and Dr. Samuel Arthur Powell, police surgeon, Bombay, in recognition of valuable services rendered in India in connexion with the war.

M.B.E.

Captain Arthur George Brown, I.M.S., has been appointed M.B.E. (Military Division), and Khan Bahadur Mir Diwan Ali, civil surgeon, Multan, Punjab, Dr. George Noble Coombes, chief medical and sanitary officer of the Cochin State, Madras, Mr. John David O'Donnell, F.R.C.S.Ed., chief medical officer, Kolar Gold Field, Mysore, and Randhir Singh, subassistant surgeon, General Hospital, Rangoon, Burma, M.B.E. (Civil

Division), in recognition of valuable services rendered in India in connexion with the war.

Foreign Decoration.

The President of the French Republic has conferred the Croix d'Officier de la Légion d'Honneur upon Surgeon Captain O. W. Andrews, C.B.E., R.N., for distinguished services rendered during the war.

Medical News.

AN announcement appears at page 34 giving particulars of a series of clinical demonstrations on special subjects arranged by the Faculty of Medicine of the University of Sheffield. The course will be given at the Royal Hospital during the ensuing three months, beginning on January 19th. The demonstrations are open to all qualified practitioners free of charge. Those wishing to attend should communicate with the Registrar of the University, who will forward particulars.

COLONEL W. MITCHELL ROOCROFT, C.M.G., consulting surgeon to the Wigan Infirmary, and Dr. Luther Cooke, also of Wigan, have been appointed Justices of the Peace for the County Palatine of Lancaster.

DR. D. W. CARMALT-JONES, F.R.C.P., Physician to Westminster Hospital, late Colonel A.M.S. and Consulting Physician to the Egyptian Expeditionary Force, has been appointed to the Chair of Systematic Medicine in the University of Otago.

THE old students' dinner of St. Thomas's Hospital, postponed from October 1st on account of the railway strike, will take place at the Connaught Rooms, Great Queen Street, W.C.2, on Wednesday, January 14th, at 7 o'clock for 7.30, under the chairmanship of Sir George Makins, G.C.M.G., P.R.C.S.

THE annual dinner of past and present students of St. Mary's Hospital, which was postponed from October 1st, will take place at the Connaught Rooms, Great Queen Street, on Friday, January 9th, at 7 for 7.30 p.m. Sir Almoth Wright, K.B.E., C.B., will be in the chair.

THE Public and Secondary Schools' Red Cross Hospitals have handed over to the Village Centres Council, 51, Lincoln's Inn Fields, London, W.C.2, the balance of their funds, amounting to £3,500.

A COURSE of ten lectures and demonstrations has been arranged by the Royal Institute of Public Health on Thursdays, at 5 p.m., in the lecture room of the Institute, 37, Russell Square, W.C. The first lecture will be given on January 15th by Professor E. W. Hope, M.O.H. Liverpool, on schemes and methods in tuberculosis work. On January 22nd Dr. T. D. Lister will give a practical demonstration of the work of a tuberculosis department at the Poplar Dispensary for the Prevention of Consumption, 135, Bow Road, E. The course is open to medical men and women qualifying to become tuberculosis officers, and for general practitioners and others interested in the study of tuberculosis. The fee is two guineas.

THE opening address of the spring session of the North-East London Post-Graduate College—the first session since the beginning of the war—will be given by Sir Humphry Rolleston, K.C.B., M.D., chairman of the Fellowship of Medicine and Post-Graduate Medical Association, president of the Royal Society of Medicine. The subject of the address, which will be given on Tuesday, January 13th, at 4.30 p.m., at the Prince of Wales General Hospital, Tottenham, N.15, is the uses and methods of application of post-graduate teaching. Medical practitioners wishing to be present may receive a card of invitation on applying to the Dean.

A COURSE of instruction on the diseases of children will commence at the London Hospital Medical College on Saturday, January 10th. The course is open to post-graduates and students of the hospital. Dr. Hutchison will give a course of ten lectures on general diseases on Saturdays, at 10.15; and Dr. Theodore Thompson a course of eight lectures on organic and functional nervous diseases, meningitis, and mental deficiency on Mondays, at 9.15 a.m. A course of clinical demonstrations will be given in the out-patient department by Dr. Charles H. Miller, at 10 a.m. on Wednesdays.

At the meeting of the Executive Committee of the Medical Defence Union on December 22nd, 1919, the General Secretary reported that three members had forwarded donations to the funds of the Union as a mark of their appreciation of the services rendered to them by the Union in cases in which they had recently had occasion

to apply for assistance. One of the members stated that the amount of his donation (which was substantial) was really no measure of his gratitude.

SIR ROBERT HUDSON, Chairman of the Joint War Finance Committee, has reported that the total amount received by the Joint Council of the British Red Cross and Order of St. John since the outbreak of war has fallen little short of 19 millions. The balance remaining in hand is large; the primary purpose to which it must be devoted is to relieve the needs of men injured in the war, but an Act passed in 1918 provides that any surplus which, in the opinion of the Joint War Committee, cannot usefully be applied in this way, may be devoted to the general relief of sickness and suffering. Grants have already been made in this country, amounting approximately to £1,350,000, to hospitals, convalescent homes, nursing associations, and other kindred bodies capable of rendering help in the restoration to health of men injured in the war. The condition of the grants has been that wherever possible priority shall be given to the claims of ex-combatants and their dependants. Grants amounting approximately to £500,000 have been made, under similar conditions, to the Dominions, Colonies, and Protectorates. The Joint War Committee will delegate to the Joint Peace Council of the British Red Cross and the Order of St. John the duty of winding up the work of the War Committee, and it is anticipated that the new council will develop other activities proper to peace.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

RESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology, Westrand, London*; telephone, 2631, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra, Westrand, London*; telephone, 2634, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin.

QUERIES AND ANSWERS.

CELSUS seeks the statistics (in children's hospitals) of polypus recti and fistula in ano as factors causing haemorrhage from the bowels in patients under 6 years of age.

INCOME TAX.

A. V. S. is in the Government Medical Service in Uganda. He was unable to obtain his six months' furlough when it became due, with the result that he is now on furlough for six months plus four months in respect of arrears, that is, ten months in all. He has been informed by the Inland Revenue authorities that as his stay in this country will exceed six months in the financial year 1919-20 he will for that year be liable to tax on his leave pay from the date of his arrival here.

The statement is correct in point of law. A person coming to his country for a temporary purpose only does not become liable to tax as a British resident unless his stay here amounts to a period of six months in any one financial year. If the six months period is reached liability to British income tax attaches, not from the expiration of that period but as from the date of coming to the British Isles—in other words the exemption in favour of temporary residents fails *in toto*. This certainly appears to involve our correspondent in some hardship, seeing that it was due to governmental action that his furlough was delayed and gave rise to a temporary residence here of more than six months. We are not aware of any concession which would cover such a case, and the legal position seems clear. We gather that no assessment for 1919-20 has yet been made. If such cases are dealt with by means of supplementary assessments made late in the financial year—and such a course would seem to be more or less inevitable seeing that the question of liability or exemp-

tion could not be answered at the earliest until October 5th, 1919, six months from the commencement of the financial year—we are inclined to suppose that an appreciable proportion of the legal liability is inoperative, because the person assessed would probably be outside the British tax jurisdiction by the time the tax becomes exigible.

F. A. A. asks for information as to the method of obtaining repayment of income tax deducted from army gratuities.

The Commissioners of Inland Revenue made an announcement last August with regard to the arrangements for repayment of income tax in respect of war gratuities under the Finance Act, 1919, which provides for the exemption of war gratuities as from August 4th, 1914. As the present addresses of the recipients of these gratuities are not available, application for repayment is necessary; it should be addressed to the Secretary, Inland Revenue (Claims Branch), Australia House, London, W.C.2, the envelope being marked "Gratuity."

LETTERS, NOTES, ETC.

WAR NEUROSES.

We are asked by the Medical Services Division of the Ministry of Pensions to publish the following:

The advance which has been made as a result of experience gained during the war in the method of treatment for cases of neurasthenia, shell shock, and functional nervous disorders in general, is probably greater than in the case of any other form of medical disability. Moreover, medical men who have been brought directly into contact with cases of this nature, and whose duty it has been during the war to undertake the care of this class of patient, appreciate more fully than is possible to those members of the profession without similar opportunities, the dangers which attend delay in the provision of the special forms of treatment which experience has shown can alone ensure satisfactory results.

The Ministry of Pensions has established neurological hospitals for in-patients and psycho-therapy clinics for out-patients, and in both types of institution the most modern methods of treatment are applied.

The Medical Service Department of the Ministry of Pensions would be obliged if general practitioners, who have among their patients cases of war neuroses, would communicate with them at 14, Great Smith Street, Westminster, S.W.1, with regard to any case, even if the condition is not severe, which is not progressing rapidly towards recovery. In a severe case, in the interests of the patient, this should always be done. Where necessary, the Ministry will certainly arrange for treatment at one of its special institutions.

SMITH'S VISITING LIST.

We have received from the publishers, Messrs. Hazell, Watson, and Viney, Ltd., of 52, Long Acre, W.C.2, a specimen copy of one of *Smith's Medical Visiting Lists* for 1920. This well known annual publication has now reached its seventy-fourth year of issue, and its convenience has been tested by generations of medical practitioners. The visiting lists are made in two styles of binding and in five kinds of ruling and spacing. The prices range between 6s. and 12s. 6d.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 33, 39, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

THE following vacant appointments of certifying factory surgeons are announced: Canterbury (Kent), Colnbrook (Buckingham), Dewsbury (York, West Riding), Shanklin (Isle of Wight), Burnham Market (Norfolk), Gamlingay (Cambridge).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under
Each additional line
Whole single column
Whole page

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

A Clinical Lecture

ON

THE SURGICAL ASPECTS OF SPINAL TUMOURS.

DELIVERED AT THE NATIONAL HOSPITAL, QUEEN SQUARE.

BY

PERCY SARGENT, C.M.G., D.S.O., F.R.C.S.,

SURGEON TO ST. THOMAS'S HOSPITAL AND TO THE NATIONAL HOSPITAL, QUEEN SQUARE.

IN 1881 the late Mr. Frederick Page of Newcastle wrote as follows: "The operation of trephining the spine, proposed many years ago and adopted several times, has made no progress in surgery; nor is it likely to do so. It is an operation not within the range of practical surgery."¹ It was only a few years later that Sir Victor Horsley, in 1887, deliberately opened the spinal canal and removed a tumour from between the membranes and the cord. This operation gave the first effective impetus to the development of spinal surgery, and there is no single landmark in surgical history which stands out with greater distinctness.

This classical case, which marks the real beginning of the operative surgery of the spinal cord, may be briefly recalled. The patient was a man, under the care of Sir William Gowers, 42 years of age, who had suffered for three years from a peculiar pain localized to a spot beneath the lower part of the left scapula, increased by exertion and varying in severity from time to time, with intervals of freedom. Four months before the operation the left leg became weak, and a few weeks later the right leg became similarly affected. During the next two months sensation became impaired and urinary retention appeared. The condition was regarded by various physicians as aneurysm, intercostal neuralgia, or hysteria. At the time of the operation there was complete paraplegia, with loss of all forms of sensibility up to the level of the ensiform cartilage. Just above this level there was severe girdle pain, worse on the left side than on the right, and increased to agony on any movement. There was some diminution of tactile sensibility up to the fourth intercostal space. A diagnosis of tumour pressing upon the cord was made by Gowers, and in June, 1887, Horsley removed the arches of the first six thoracic vertebrae and exposed an almond-shaped tumour, of a dark bluish-red colour, resting upon and attached to the left fourth thoracic nerve, jammed between the dura mater and the spinal cord. The growth proved to be a fibromyxoma. A year later the patient was doing his full day's work, which necessitated much walking and standing about.²

Since that date not only have large numbers of similar tumours been successfully removed, but also intramedullary tumours have been enucleated, intramedullary cysts and the cavities of syringomyelia have been incised, and many other pathological conditions causing symptoms of compression of the spinal cord have been successfully dealt with through the opening afforded by the operation of laminectomy.

The following remarks are based upon a series of 27 cases which I have operated upon during the past ten years. These are all cases of true neoplasm of one sort or another associated with cord symptoms; all cases of syphilis, tuberculous disease, and cyst are excluded.

Of the various ways in which these tumours may be grouped I prefer to take the regional rather than the histological. On this basis they fall into three groups, according to whether they are (1) intrathecal but extramedullary, (2) intramedullary, and (3) extrathecal.

Intrathecal extramedullary tumours present themselves either as definitely encapsuled masses, which are almost invariably of a benign nature, or as diffuse masses of growth extending over a somewhat large area, whether of the cord itself or of the cauda equina, and histologically of a malignant character.

ENCAPSULED INTRATHECAL EXTRAMEDULLARY TUMOURS.

Fifteen of the twenty-seven cases belong to this class. They possess a certain similarity in size, appearance, encapsulation, and relationship to the cord. With a single

exception ("fibrosarcoma") the histological characteristics* of this class are those of benign tumours, namely:

Neurofibroma	4
Endothelioma	3
Psamomma...	3
Fibroma	2
Fibromyxoma	2

Such tumours may be firmly attached to the inner aspect of the dura mater or to a nerve root. On the other hand, their connexions are sometimes so flimsy that they appear to lie almost free in the arachnoid, and they can be picked out without causing any haemorrhage, and without it being possible to determine their actual point of origin. At the level of the tumour the whole thecal lumen may be so filled up that the cerebrospinal fluid above has little or no communication with that below. Hence pulsation is only to be seen above the tumour, and this may be a valuable topographical indication during an exploratory operation. When such a tumour has been removed, there remains a scaphoid depression in the cord which does not appreciably alter either in size or in depth during the time that the cord is exposed, despite the fact that the displaced cord usually moves so as to occupy more nearly its natural position. In some very long standing cases the cord appears to be flattened to a ribbon, so that one wonders how any impulses at all can be conducted through it.

The situation of these tumours in relation to the cord is most commonly postero-lateral—that is, the cord is displaced forwards and towards the opposite side (7 cases); it may be in the middle line posterior to the cord (2 cases); antero-laterally situated so as to push the cord backwards and towards the opposite side (4 cases); or anterior to the cord so as to be invisible until the cord is drawn aside (2 cases).

Segmental Level.

In neither of the fifteen cases under review was the tumour situated above the fifth cervical or below the cleventh thoracic segment. The actual situations were C.5, C.7, D.1, D.2 (3 cases), D.3, D.4, D.5 (2 cases), D.7 (2 cases), D.8, D.10, and D.11. In each case the segment quoted is the uppermost reached by the tumour.

SYMPTOMATOLOGY.

There does not appear to be any constant relationship between the position of the tumour, as regards the cord, and the incidence of the symptoms. The order in which these make their appearance is very variable.

Pain.

The most usual initial symptom is pain, referred to the area of distribution of one or more of the spinal nerve roots. This was the first symptom in eight of the fifteen cases. It may be very severe and persistent, or it may amount to nothing more than an unpleasant sense of constriction, and it may for many months or even years be the only cause of complaint.

This circumstance is sufficiently striking to suggest that in any case where severe and persistent pain, localized to the distribution of one or more nerve roots, cannot be satisfactorily accounted for, the possibility of a spinal tumour being present should be seriously considered.

Pain in the back is not a common occurrence in cases of spinal tumour of this class. When it has been present (in three of these fifteen cases) it has been the first symptom of which the patient has complained, has been unaccompanied at any time by root pain or girdle sensation, and has preceded the other symptoms by some months. In no case has any tenderness, rigidity, deformity, or abnormal radiographic appearance been noted.

A third type of pain of which these patients may complain is "pain in the legs." With tumours involving the cauda equina, such pains are naturally of the same character and causation as root pains elsewhere. But patients with tumours at a higher level sometimes complain of pain in the legs. Usually, on close questioning, it is obvious that these pains are associated with spastic involuntary contractions of the muscles, but in other instances this does not appear to be the explanation. It is possible that in some cases at least the pain is

* I am indebted to Dr. J. G. Greenfield for a recent re-examination of all these tumours.

dependent upon variations of pressure in the cerebro-spinal fluid. The thecal canal may be so fully occupied at the level of the tumour that the fluid pressures above and below may be different, and it is possible that in such circumstances a sudden exertion on the part of the patient may drive down a small quantity of fluid past the block so as suddenly to increase its tension to a point at which pain is produced. This seemed to be the explanation of the "sharp shooting pains down both hips and thighs" in one case, where the tumour was found to block the thecal canal at the level of the eighth thoracic segment.

In a recent case, not included in this series, pain in the left thigh and leg, of "sciatica" type, was for a long while the most prominent symptom, the tumour being a small hard encapsulated "psammoma" cupping the lateral aspect of the cord at the level of the eighth thoracic segment on the right side. This suggests direct pressure by the tumour upon the pain fibres in the antero-lateral column.

In a series of 33 cases of intramedullary tumour recorded by Horsley pain was the first symptom complained of in 21.

Paraesthesia.

"Numbness" in the legs is often complained of (9 cases), but always in association with weakness. Impairment of sensibility of a more definite character is sometimes noticed by the patient. Thus, one patient found that one leg was less sensitive to pain than the other; another that one leg always felt cold; another that "she could not feel the water on her legs in the bath."

Motor Symptoms.

Weakness of the legs had been present before operation in all the cases, and varied from slight impairment to complete loss of all voluntary movements. In three instances "stiffness," "jerking," or weakness was the first symptom noticed by the patient. In one of these cases the weakness preceded the onset of root pain by twelve months, and in the other two no root pain at all was complained of.

With a single exception the weak or paralysed legs were spastic, though never to an extreme degree. It is instructive to note that the one patient whose paralysed legs were stated to be "somewhat flaccid," had been unable to walk for seven years, and that no motor improvement had occurred more than five years after removal of the tumour.

Impairment of Sphincter Control.

It is a very striking fact that in eight of the fifteen cases there was no impairment of vesical function at any time, even though other symptoms had been present for periods varying from one to three years. In most of the other cases the impairment of function amounted to little more than precipitancy or hesitancy of micturition, usually the former. Very rarely is a catheter required. As would be expected, therefore, cystitis is an uncommon complication, and one that is comparatively easily dealt with if it does occur. This contrasts strongly with the gross impairment of function and the fulminating cystitis so common in cases of paraplegia of more rapid onset.

NEUROLOGICAL EXAMINATION.

The date at which sensibility first becomes affected cannot be ascertained, as the patients are often unaware of any impairment, unless it is of a particularly gross character. The greatest diversity of symptoms exists in this respect, as would naturally be expected from the variations in position of the tumours, the different degrees of pressure exerted by them, and the extreme slowness with which the compression advances. Frequently the upper limit of the sensory change is not abrupt, as it is in the case of a more sudden and severe lesion; and as in a certain proportion of cases (five out of fifteen) there are no root symptoms to afford a guide, it becomes a matter of the utmost importance, for localization, to examine carefully for the uppermost limit of even the slightest differences in appreciation of the various sensory stimuli. In this respect repeated examinations are necessary, as variations in the upper level of slight changes are met with from time to time.

The Brown-Séquard syndrome is frequently met with. In several of the cases it was well marked when the patients first came under observation. In the majority a

definite history was obtained of one leg becoming affected before the other.

When the tumour is related to one of the lower thoracic segments the abdominal reflexes may afford a more valuable localizing sign than the level of sensory change.

CLINICAL COURSE AND PROGNOSIS.

The course pursued by a case of spinal tumour is characteristic. It is slow, but remorseless. There is rarely any appreciable halting, more rarely still any temporary amelioration, and gradually the symptoms progress to the inevitably fatal termination unless relief is afforded by operation. It is in this field that the science of neurology and the art of surgery combine to achieve one of their greatest triumphs.

Horsley stated the average total duration of the symptoms in these cases of simple tumour to be three and two-thirds years. In the present series of fifteen cases it was two years, despite the fact that one patient had had symptoms for no less than nine years. It is to be hoped that the future will show a still greater improvement in this respect, as the condition becomes recognized at an earlier date.

It would be expected that the rapidity and completeness of recovery after operation would be materially affected by the length of time during which the cord had been subjected to pressure. Whilst this cannot be denied, it is true only within wide limits. Whereas in the majority of cases in which a complete or practically complete recovery occurred weakness had been present for less than twelve months, yet in one instance the legs had been weak for nearly three years. On the other hand, one patient who had been virtually paralysed for eight years showed no sign of motor recovery five and a half years after removal of the tumour. The most striking immediate result of operation is the relief of pain. This may be confidently predicted whatever may have been its previous duration, and whether or not nerve roots are divided when the tumour is removed.

Power, as a rule, begins to return before sensation. In a favourable case a definite improvement in voluntary power may be observed to take place within a week of the operation. In one patient the weakness had been coming on gradually for nine months, and at the time of the operation the legs were spastic and no voluntary movements were possible; the sensory loss was complete. In ten days power began to return and in eight weeks he was beginning to walk, but no return of sensibility to pin-prick or to cotton-wool was detected for nine weeks. In another patient with nine months' history, where spastic weakness and partial loss to all forms of sensibility were present at the time of the operation, power was rapidly returning in three weeks, but sensation was unaltered. The sensory return takes place uniformly over the affected area, the original level remaining distinguishable throughout. In two cases, examined respectively five and six years after operation, although recovery was in all respects practically perfect, the old level could still be definitely ascertained by a distinct difference to pin-prick above and below.

Four cases operated upon between five and six years ago have recently been examined with a view to ascertaining the degree of the completeness of the recovery. The chief points may be very briefly summarized as follows:

Endothelioma at Level of Fourth Thoracic Segment.

Female, aged 71 (under the care of Dr. James Collier). Fifteen months' history. Extreme spasticity; slight voluntary movements in right lower limb, none in left; profound loss to all forms of sensation; no sphincter trouble; bedsores. Tumour completely removed.

Six years after operation, in perfect health. No ascertainable weakness of legs; deep reflexes normal; plantars flexor; position sense and localization perfect; no loss to cotton-wool; pin-prick well appreciated everywhere, but it "gets sharper" when old level is reached.

Neurofibroma at Level of Tenth Thoracic Segment.

Male, aged 35 (under the care of Dr. Tooth). Twelve months' history. Severe root pain; lower limbs extremely spastic; no voluntary movements; complete loss to all forms of sensation below level. Tumour completely removed.

Five and a half years after operation was doing full work as an agricultural laborer. Says left leg feels weaker than right. No difference in power detected; powerful muscular limbs; deep reflexes normal; abdominals absent; plantars extensor; no loss detected to touch, pin-prick, or localization; position sense in left foot very defective.

Fibroma at Level of Seventh Cervical Segment.

Male, aged 32 (under the care of Dr. James Collier). Nine months' history. Before operation upper limbs weak and flaccid; intrinsic muscles of hands wasted; neuralgic pains in ulnar fingers; muscles of trunk and lower limbs very spastic; no voluntary movements in right lower limb; feeble in left; profound loss to all forms of sensation to level of C.7; dysuria. Tumour completely removed.

Five years after operation was doing full work as a letter sorter. No clumsiness or weakness in hands; no wasting; no pain; no sphincter trouble; deep reflexes somewhat brisk; abdominals present and plantars dexter; no sensory loss detected, but C.1 level can still be mapped out by a slight dulling to pin-prick below.

In contrast to the foregoing the following may be related:

Pneumonia at Level of Seventh Thoracic Segment.

Female, aged 32 (under the care of Dr. Tooth). Pain in back nine years and weakness of legs eight years before operation. On examination, complete loss to all forms of sensation; complete motor palsy with ankle clonus; plantars extensor; precipitancy of micturition.

Five and a half years after operation, no recovery of power whatever. Sphincter control normal; appreciates cotton-wool everywhere, but cannot localize; feels pin-prick and hot and cold tubes merely as unlocalizable touch.

OPERATIVE TECHNIQUE.

The procedure adopted in all cases is practically the same as that employed by Horsley, except for the method of anaesthesia. Chloroform and intravenous hedonal, which Dr. Mennell administered for me in a few cases, have been discarded in favour of ether given by the intratracheal method. I do not believe that, provided cyanosis is avoided, the haemorrhage is any greater with ether than with chloroform; whilst the abolition of the respiratory movements, and in cervical cases the being able to have the neck flexed as acutely as may be desired, is of great assistance. The amount of blood lost depends more on the surgeon's technique and resource than upon the anaesthetic.

If the first stages of the operation are conducted rapidly under a stream of normal saline solution at 113° F., and if time is not wasted in endeavouring to seize individual bleeding points with forceps, the amount of blood lost need not be great. The spinous process corresponding to the position of the tumour is first marked by a transverse scratch on the skin, and then a median vertical incision is made with this mark as its centre. The muscles are rapidly stripped from the bones, and then at least five spinous processes are cut away at their bases with strong forceps. If now the large wound is packed tightly for a few minutes with gauze, it can be rendered remarkably dry, and the rest of the operation should be almost bloodless.

The laminar arches are next removed with Horsley's laminectomy forceps, exposing the layer of fat surrounding the theca. This has to be stripped off, and the theca can then be examined. Sometimes the tumour can be easily felt at this stage, or a difference of thecal pulsation above and below may indicate its position. I always endeavour to open the dura, by a median vertical incision, without wounding the arachnoid. In this manner a beautiful view of the tumour is obtained, seen through the transparent arachnoid, and its relations to the cord and nerve roots accurately ascertained. If the cerebro-spinal fluid is allowed to escape the posterior nerve roots, which normally float free, fall against the cord, so that their real relationship to it and to the tumour cannot be determined. I have several times seen the tumour, through the unopened arachnoid, moving up and down for a short distance, like a shuttle, with the pulsations of the cerebro-spinal fluid.

The arachnoid is next torn through and the tumour can then be gently lifted out of its bed with some small blunt instrument. If necessary a nerve root or a tooth of the ligamentum denticulatum must be divided. It should hardly be necessary to state that this part of the operation must be conducted slowly and with the utmost gentleness.

The theca should be sutured and the muscles brought accurately together, preferably in two separate layers, in order to avoid any chance of leakage.

POST-OPERATIVE DANGERS.

Leakage of cerebro-spinal fluid is a dangerous complication. It introduces the possibility of meningitis, and, apart from that, the patients usually suffer a good deal in general health, for the total amount of fluid lost may be enormous.

Two of my patients have died suddenly within forty-eight hours of the operation, the tumours having been removed from alongside the upper thoracic part of the cord.

Other occasional causes of serious symptoms, which may terminate fatally, are acute dilatation of the stomach, and paralytic ileus.

RESULTS.

Of the 15 cases in this series, 11 may be described as in all respects satisfactory. Of these patients 6 are (or when last heard of were) doing their full ordinary work; another, 77 years of age, is in perfect health and vigour, and the other 4 are so far recovered that they may reasonably be regarded as successful cases. Of the 4 unsuccessful results 1 (whose paralysis had existed for nine years before operation) remains virtually *in statu quo* five and a half years after removal of the tumour. The remaining 3 patients died. They are instructive cases, and may be very briefly quoted:

CASE I.

W. L., male, aged 47. After having suffered pain in the back for fifteen months, and increasing weakness in the legs for ten months, was admitted to the National Hospital under Dr. James Taylor. On admission he had spastic paraplegia, almost complete, with impairment of sphincter control, and almost total loss to all forms of sensibility up to the level of the eleventh thoracic segment.

A laminectomy was performed, and the cord exposed from the sixth thoracic to the first lumbar segments. No sign whatever of a tumour could be found. Seven weeks after this unsuccessful exploration he had voluntary movements at all joints of the lower limbs, less involuntary spasm, and much less complete sensory loss, together with considerable improvement in sphincter control. He left hospital much improved, but was readmitted two years later in practically the same condition as he had been prior to the first operation. It was decided to attempt to relieve the distressing muscular spasms, and accordingly another laminectomy was performed, and the posterior roots of the second, third, and fifth lumbar and the second sacral nerves were divided on both sides. Five days later he died from paralytic distension of the bowel.

Post mortem an ependymoma $2\frac{1}{2}$ by $1\frac{1}{2}$ cm. was found, attached firmly to the dura, lying wholly in front of the eleventh thoracic segment, which was flattened to a ribbon over it. The particularly interesting points in the case are (1) that the tumour was in an unusual position and completely out of sight, (2) that at no time were any root pains experienced, (3) that pain in the back had existed for six months before the onset of any other symptoms, (4) that death after the second operation was due to paralytic ileus, and (5) that the mere relief of pressure afforded by the first operation was followed by a considerable degree of temporary improvement.

CASE II.

Male, aged 59 (under the care of Dr. Risien Russell). When first admitted to the National Hospital he had suffered from girdle pain at the twelfth thoracic level for five months, and dragging first of one leg and then of the other for four months. He had no sphincter trouble; both legs were weak and spastic, the right more so than the left. The sensory loss was almost complete to all forms up to the twelfth thoracic level on the left side. Three weeks later, whilst the girdle sensation persisted at the same level, the level of sensory loss had moved upwards and spread to the opposite limb. Three months later there was sensory loss up to a definite level—that of the third thoracic segment. The legs were much worse and very spastic; slight hesitancy of micturition had appeared.

A fibroma, the size of a small marble, was removed from in front of the cord at the level of the third thoracic segment. The operation was easy and without untoward incident, and all went well until thirty hours later, when he died quite suddenly and without warning.

Post mortem nothing was found to account for his death.

CASE III.

Female, aged 34 (under the care of Dr. James Taylor). Two years' history of stiffness and weakness in the legs, abdominal girdle pains, and loss of feeling in the legs. No sphincter trouble.

A firm tumour, attached to the right eighth cervical posterior root, was easily removed. It was pronounced microscopically to be a fibrosarcoma. All went well for nine days, when removal of the stitches was followed by leakage of cerebro-spinal fluid. This continued, and a month after the first operation the muscles were re-sutured. Meanwhile a considerable degree of improvement had occurred both as regards power and sensation, and the general condition had remained excellent. Some thirty hours after the closure of the wound she died quite suddenly.

Post mortem nothing was discovered to account for the death.

OTHER FORMS OF SPINAL TUMOUR.

Twelve cases of tumour causing cord symptoms, other than the encapsulated intrathecal extramedullary type, were encountered during the same period. They contrast strongly in many ways with the others. In the first place the tumours were, without exception, of a malignant

character, though their degree of malignancy, judged clinically, was extremely variable.

I classify these tumours, according to their probable point of origin with relation to the cord, into three groups: (1) Intrathecal extramedullary. (2) intramedullary, (3) extrathecal.

The membranes constitute an almost if not absolutely impermeable barrier to the spread of these growths, so that we rarely find any overlapping between these three groups. All tend to spread upwards or downwards in a direction parallel with the cord, confined within the limits of the pia or dura as the case may be. In only one case did an intradural tumour gain the exterior of the theca, and that was through the operative incision.

With the upward spread of the tumour mass there develops a gradual compression of the cord, which progressively reaches a higher level. Hence we find that with malignant tumours there is often a varying upper limit of sensory change, together with root pains spread over many segmental areas. These are important points in the diagnosis between diffuse malignant tumours on the one hand and the more definitely localized encapsulated tumours on the other.

LEVEL AND SYMPTOMS.

In the three cases of non-encapsulated extramedullary intrathecal tumours, all sarcomatous, the tumour involved the cauda equina, and the nerve roots were surrounded by growth. Nevertheless, radiating pain was absent in two of them; in these two pain in the back was noticed early. Loss of sphincter control was an early and prominent symptom in two instances; in both of these the growth surrounded the conus medullaris.

The cases of intramedullary tumour contrast strongly with these extramedullary malignant ones, for in the former weakness and numbness in the limbs is the earliest symptom, though in one of the four radiating pains had occurred before any other symptom. Again, sphincter disturbance is slight or absent as a rule in the intramedullary cases.

If we compare the incidence of the symptoms in cases of extrathecal tumour due to malignant disease of the bones, whether primary or secondary, we find pain, either local or radiating, to be the first symptom, and usually it is of an extremely severe character and is increased on movement. Sphincter disturbances are not much in evidence in these cases.

Whilst *x*-ray examination has so far been uniformly negative in other forms of tumour, it usually gives valuable help in the cases of tumour arising in the bones. We cannot, however, in this manner distinguish between malignant disease and tuberculous caries; and even when exposed by operation the granulation mass, in some cases of tuberculosis, has so closely resembled tumour that only by microscopical examination has the true nature of the case been ascertained.

In none of the 12 cases of malignant growth in this series was the exact nature of the case diagnosed before operation. The fact that the cord was being subjected to an increasing degree of compression led in each instance to the performance of an exploratory laminectomy, and in all but one the diagnosis of "tumour" was made before operation (one was thought to be tuberculous caries); in all, too, the segmental level of the compression was correctly ascertained before operation. But in no instance could the exact position with relation to the cord and membranes, or the nature of the tumour be foretold. The operations were therefore primarily of an exploratory character.

RESULTS.

Two patients—one with a high cervical intramedullary tumour, and the other with a sarcoma of bone in the upper dorsal region—died within a few hours of the operation. The rest may be briefly set out as follows:

A. Diffuse Intrathecal Extramedullary Growths.

Male, aged 42. Died, unimproved, ten months after exploratory laminectomy.

Female, aged 22. Left hospital, unimproved, two months after removal of tumour, and was lost sight of.

Male, aged 61. Improved so much after partial removal as to be able to return to business, but after six months relapsed, and died ten months after the operation.

B. Intramedullary Tumours.

Male, aged 33. Incision of cord over tumour. Improved considerably and lived six and a half years.

Male, aged 59. Enucleation of tumour. Improved greatly, then relapsed and died two years and two months later.

Female, aged 45. Incision of cord over tumour. Some improvement at the end of three months.

C. Extrathecal Tumours.

Male, aged 33. Decompression of theca and cord. Improved very greatly and lived seven years.

Female, aged 53. Decompression. No improvement after two months; lost sight of.

Female, aged 63. Decompression. Greatly improved at the end of ten months; lost sight of afterwards.

Male, aged 41. Decompression. Slight improvement after four months.

It might seem from a cursory glance at these facts that surgery has little to offer in such cases. It is not easy to put into words, still less into tabular form, what these patients do gain by surgical intervention. The most striking benefit is the relief of pain, a benefit which in most cases is in itself sufficiently great to justify the operation. This is a palliative measure of the first importance. In some cases sphincter control has been improved, but I would not lay much stress upon this point seeing that in general the cases which have done best have been those in which there was little or no disturbance of sphincter function before the operation.

In several cases power and sensation have so far been restored as to enable a bedridden patient to get about and even for a few months to attend to his business. But in estimating the value of operative treatment, the subject of compression paraplegia must be considered as a whole. The causes, other than tumour, are many, and the differential diagnosis is difficult. Loculated collections of fluid (the "meningitis circumscripta serosa" of Horsley), post-gummatous stricture, simple encapsulated tumours, and cold abscess, are conditions which can often be diagnosed with certainty by operation alone, and all these are lesions after removal of which, if the cord has not been too long subjected to pressure, recovery is to be expected.

CONCLUSION.

The chief lesson to be learnt from the study of a series of cases of compression of the cord is that early exploratory operation should be more frequently undertaken. Neither should a clear history of syphilis nor the existence of a positive Wassermann reaction be considered as a contra-indication for operation should improvement not rapidly follow the administration of antisyphilitic remedies. For persons with active syphilis may suffer from spinal neoplasms (three out of fifteen of my cases of simple extramedullary tumour), whilst a constriction of the cord by fibrosis following gummatous meningitis, incapable of being influenced by drugs, may be successfully dealt with by operation.

PUBLIC HEALTH VERSUS THE STATE.

BY

BERTRAM G. M. BASKETT, M.B., B.Ch. Oxon.,

RAYLEIGH.

Nearly seven years ago I spoke at a meeting of this Division and prophesied that the sequel of the Insurance Act would inevitably be an increase in deaths from tubercle. I was called to order; it was ruled that any other aspect was irrelevant than that which had reference solely to the interests of medical men. I am here to-day not to say that my prophecy was true, for you all know that as well as I, but first to show the grounds on which my prophecy was founded, and secondly, to ask you to say that the ruling that such a topic was irrelevant was wrong, inasmuch as to have insisted from the first that the Act could not be in the interests of the public health would have averted the confusion of to-day, and completely frustrated the menace which now confronts the profession.

I may take it for granted that everyone will agree that it is a reproach to a civilized community that a preventable

¹ An address delivered before the South Essex Division, British Medical Association, October, 1913.

infective disease should be on the increase. It is bad enough if it is a newly discovered disease; the reproach becomes far worse in the case of an old disease, the way to check which has been discovered, and when the disease is increased by deliberate reversal of the process by which it has been checked. And when it is a disease which causes the death of some 1,500 persons per million, causes the disability of two or three for every one who dies in a given year, and is a disease whose cause is known, the reproach becomes a scandal.

This is what we have to say of tuberculosis in Great Britain. Its cause has long been known; it is an infective and preventable complaint; for fifty years it steadily and progressively decreased; and the decrease should have

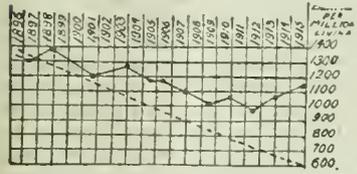

CHART I.—Tuberculosis, England and Wales: yearly rates. The broken line indicates the point which should have been reached if the old rate of fall had been continued.

grown still more rapidly, so that by 1896 we had a right to expect, and did expect, the approaching extinction of tubercle as a serious factor in the national statistics. Instead of this we find that in 1896 the rate of decline reached its acme; that after this it became sensibly slower; that later it became stationary; and that in the end it began to rise again. Thus a rapid decline was interrupted by an increase, at first relative, then absolute; so that by 1915 the divergence between the two curves, namely, the actual curve, and that which continues the direction of the fall to 18.6, amounted to 25,000 lives.

I have designedly limited the inquiry to the end of 1915 because down to that date the war could have made little or no difference in the death rate of a disease lasting generally at least two and often three or more years. To test my theory I worked out as far as I could in 1916 what should be the result of the economic conditions then prevailing and promising to prevail. It was clear to me that among the civil population the artificial demand for labour was enabling, and would continue to enable, money wages to overtake the rise in prices; it seemed clear that the momentum of the previous increase before 1916 would only gradually cease to be operative, but that so the rise in the rate would cease. I felt indeed, and committed myself to the prophecy in writing, that there would probably be even a slight decrease in the rise in 1916, 1917, and 1918. About 1918 I do not yet know, but as to 1916 and 1917 I was right. The question is complicated after that time by the return of a number of soldiers to civil life, men of all ranks who have been exposed on service to the conditions which in less severe degree are the result of poverty in civil life, such as underfeeding, or feeding on materials lacking in vitamins, overcrowding, exposure to bad weather, depressing nervous strain, and the like. If that part of the population can be separated still, the result for a year or two more should probably be a still further but slight decrease. The question is highly complicated; one has to recollect that certain valuable foods were lacking in quantity, so that even raised wages could not purchase them towards the end. Probably no prophecy can be made with any confidence again till three or four years more have passed. If this theory is right, the rate must then necessarily increase again; or, if not the death rate, still tuberculosis must increase, and the more if expensive State measures continue to be passed. But we must note this very striking fact, that, on any orthodox theory, the tuberculous death rate should have been highest at the end of the war, as in Germany, Austria, France; what did happen here was that the increase was greatest at the beginning.

Of the official explanations of the rise, it is sufficient to state that all are different and none are satisfactory. The Registrar-General's explanation will not hold water for a minute. He insists that a rise in mortality of 12 per cent.—in women only—by the end of 1915 was the result of the rush to factory life before factory conditions were reasonably sanitary. But the rush did not begin until well on in that same year, and the mortality must have been due to disease contracted, on the average, two years previously. The Local Government Board explanation of influenza may be true for 1914 and 1915, but does not

explain the fall before and after. And the worst epidemic of influenza in my experience was that in the early nineties, which conspicuously raised the tuberculous death rate for the time, but allowed the five yearly average to fall without apparent check. Such isolated facts as influenza will not explain a fall which, taken in five-yearly averages to avoid ephemeral phenomena, was constant for fifty years, and was succeeded for twenty more by a rise partly relative, partly absolute. Some common factor must be found which varies as the death rate has varied, or nothing has been explained. If such a factor is found; if nothing else will explain the mortality curve; if in addition to explaining the past, it makes it possible to forecast the future, then the conditions of a scientific proof have been fulfilled.

It is unfortunate that there is only one country, Great Britain, which has preserved quite reliable figures—with one break only early in the period—over so long a time as seventy years. Sweden has figures, with one important break from 1831-1860, reaching back to the decade

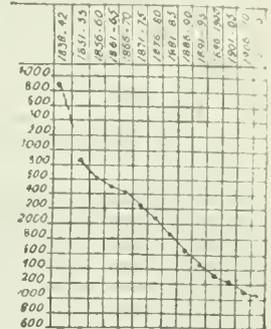

CHART II.—Tuberculosis, England and Wales, 1831-1915: five-yearly averages.

1751-1760; but as they were collected by the clergy I do not know how far they may be relied on. We have to find a theory which will account for the astonishing fall in the tuberculosis death-rate all over Europe, beginning in the forties with Great Britain; and extending till well on in the present century everywhere in Europe, with the exception of Ireland and Norway; and beyond the confines of Europe with the exception of Japan. We have to explain why a sparsely populated paradise like New Zealand, or a continent with a handful of population, the majority of whom lead the outdoor life, like Australia, should have higher death rates than a well populated country like Denmark; why a country like the German empire, with a most thorough state organization for stamping out tubercle, should have such disgraceful tuberculosis rates as 55 per 10,000 for Düsseldorf, 59 for Elberfeld, over 50 for Osna-brück and Cologne, and 50 for Munich; and why a continent like the United States, starting recently with a clean slate, and taking extraordinary precautions to exclude foreign-born tubercle, should now be involved in a desperate fight against the disease.

The conclusion that the more municipalities and the state have extended their sphere of benevolence the worse matters have become, is so contrary to our preconceived notions as to seem at first incredible. But if it be admitted, as I think it must, that poverty is the chief of many adverse factors, embracing nearly all these factors, producing national morbidity; and if it be recognized, as is the fact, that the distribution of wealth was steadily becoming more equable down to 1896, and that from 1896 to 1914 it steadily became less equable, then it must be allowed that my theory demands respectful consideration.

There is much to confirm it from foreign statistics. They are neither so long dated nor so trustworthy as ours; and of course it is exceedingly difficult to be sure of one's ground unless one can have the intimate knowledge of alien social conditions which one can have of one's own country. But from Koch's last paper on the subject I have been able to get several interesting charts which throw some confirmatory light on the question. He touches on most of the points to which I have referred, but oddly enough, though he repeatedly asks why there was the universal drop all over Europe (save in Ireland and Norway), and though he repeatedly emphasizes the importance of the environment of poverty, he never stops to ask whether economics have anything to do with it. As is natural with a German, the only solution which occurs to him is that more police are needed, though he is fain to confess that the best record comes from days before the disease was known to be infectious. Great Britain, he says, began in the race for improvement. A very little inquiry would have told him of the enormous improvement in real wages due to the introduction of free trade. The rest of Europe followed; he might easily have found

ont that every considerable community in Europe lowered its tariff in response to Cobden's crusade. He might easily have found out that the wealth of Europe was enormously increased, partly through the development of steam and electricity, partly by reason of State policy, and found that the typical environment of poverty had been modified. As an object lesson of first magnitude he might have

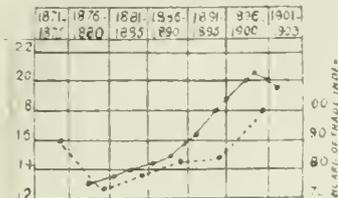

CHART III.—Tuberculosis, Norway. Death rate, after Koch

first altogether checked and then lowered the rate of fall. Comparing New York and Berlin, where in both the rate had fallen rapidly for some time and then slackened down, he might have remembered that similarly the Wilson tariff had been followed by the Dingley and then by a still higher tariff. In the same way in Massachusetts the fall under the Wilson tariff is distinctly checked after the higher Dingley tariff.

I lay stress on the tariff as a factor because it is the one ready guide which a foreigner can have, except in such cases as the Massachusetts chart, where I was struck by a check to the fall in 1876 onwards, and looked up the history, to find that it was four years after the disastrous Boston fire, which was followed by a commercial crisis spreading over the whole state.

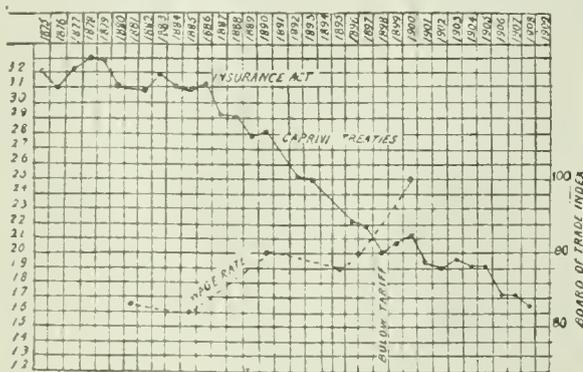

CHART IV.—Tuberculosis, Prussia. After Koch as regards death rate.

Clearly the fall all over Europe from the forties onward cannot be due to variable phenomena. It cannot be due to a biological or spontaneous variation such as occurs in other infective diseases, producing an autogenous immunity, or leading, now to a virulent, now to a trifling, epidemic. On the contrary, we are all mournfully aware that in the individual case tubercle is as lethal as ever. Though probably far more cases are cured than used to be cured, we still have the residual cases and the more acute cases which seem at the end to have been hopeless from the start. It cannot be due to the increase of knowledge or of facilities for treatment, for the most startling diminution occurred before the cause was known or any politic means of treatment existed; and in Great Britain it remained for the most momentous increase in our records to occur after there had been a huge addition to both. Nor can it be simply that the tuberculous death rate has fallen because the general death rate has fallen; for the whole fall of the latter has been much slower than that of the former. It is plain that some common factor must exist.

When, in devoting myself to free trade work, I had to study wage rates in various countries, and came to recognize the remarkable relation between a high tuberculous rate and a high tariff, it seemed to me that a flood of light had been thrown on the subject, and that poverty was at the root of the mischief on a national scale. Outside of

military life during a war there is only one condition which connotes all the evils of bad environment, as insufficient or unfitting food, overcrowding, bad sanitary conditions, airless houses—namely, poverty. Every one who mentions the question of environment insists on the importance of poverty; and the Insurance Act took its stand, even in the case of so lukewarm a supporter as Mr. John Burns, on the importance of poverty.

Now, as all know, or should know, the "golden age" of the British working class was the fifty odd years from 1842-1896. The rise in money wages was enormous; there has been nothing quite like it in history, except once, for a shorter period, under the similar régime of Robert Walpole. From 1843 to 1834 the average income of a working-class family had risen in money from some £40 a year to £85 or £90; middle-class incomes under £1,000 had risen by a somewhat less, and large incomes over £1,000 by a very considerably less, percentage. All the time money was gradually purchasing more. But after 1896 the process began to be reversed. In money, wages have perhaps been rising, just as they are rising now. But prices have risen still more; so that "real" wages, as distinguished from "money" wages, had been falling from 1896 right up to the war. This fact was mournfully admitted by Radical ministers on every platform, although they were doing all they seemed to know to remedy the defect. The more they tried, the worse matters became.

The coincidence of the height of resistance to tubercle and the height of real wages must at once strike attention. If the yearly chart be closely looked into, indications will be noticed of the extraordinary sensitiveness of the tuberculous death rate as a gauge of real wages. The average case of phthisis may be taken as lasting two or three years; three or four years after political conditions which necessitate higher taxation, or cause distress and raised prices, it may be observed that the number of deaths, if not the death rate, rises for a time proportionate in length to the severity of the causative conditions. For instance, the revolutionary era in Europe is followed by a rise lasting till 1853; the Crimean war and the Indian mutiny are followed after three or four years by a rise in the number of deaths, though negligible in the rate. The American civil war is followed by a rise in the number of deaths which makes a perceptible difference in the rate. The Boer war is similarly followed by a rise.

But all these causes are trivial in degree compared with the rise in municipal rates and municipal debt which began in the nineties, to be followed later by the wildest extravagance on the part of the State; the excuse in both cases was the amelioration of the condition of the poor. By 1905 the municipal debt of Great Britain had come to rival the National Debt, and before the war the State revenue had come to exceed £200,000,000. The larger part of the money is obtained from the pockets of the poor, who, through higher prices, have to pay for State and municipal extravagances, not more in the shape of a protective tariff than in the shape of Workmen's Compensation, or of Old Age Pensions, or last, but not least, of Insurance Acts. In their blighting influence on the poor there is no difference between protection and State paternalism. It is indeed a significant fact that the very name in Australia for the highly developed system of the latter which it enjoys is "the new protection." The excuse in either case is that by benefiting chosen individuals at the cost of the community at large the community derives a benefit which more than compensates the cost. In Mr. Lloyd George's own phrases—to associations of employers—"Of course the consumer will pay; the producer will no more pay than he does under Mr. Chamberlain's Act. Where the consumer will gain is increased efficiency." The effect, however, in either case is indirect taxation, which always hits the community, and hits hardest the poorest and most helpless portion. It does so by lowering "real" wages.

It will thus be seen that the inverse ratio of real wages and death rate is preserved right through the whole period. As wages rise—or, what is the same thing, as prices fall—the death rate falls; as wages fall off the fall in the death rate slackens; and the relation is so constant that the rise due to other causes—for example, epidemics of influenza—is absorbed and concealed by the five-yearly average of the falling rate prior to 1896. The momentum of the fall due to previous wages rise continues some time

after the cause has ceased to be operative in the previous degree. But after a time the new conditions show the effect clearly, and the Insurance Acts had an effect precisely similar to a big war or any other such economic calamity. This effect necessarily will be abiding; and if the Act remains on the Statute Book in its compulsory form its effect must slowly increase. As the result of increased taxation due to the war the death rate must necessarily increase again, the more so if expensive State measures continue to be passed. Out of many things which are doubtful one fact stands out indisputably and beyond cavil—namely, that the more municipalities and the State have extended their sphere of benevolence the worse matters have become. The conclusion is irresistible that the tuberculosis death rate ultimately depends on the cost of living to the poor more than on any other single factor. There are many others, but the one which has to be considered by the State is the problem of raising the "real" wage rate—in other words of lowering prices. And let us be under no illusion. Economic *laissez faire* benefits all classes but it benefits the poor most.

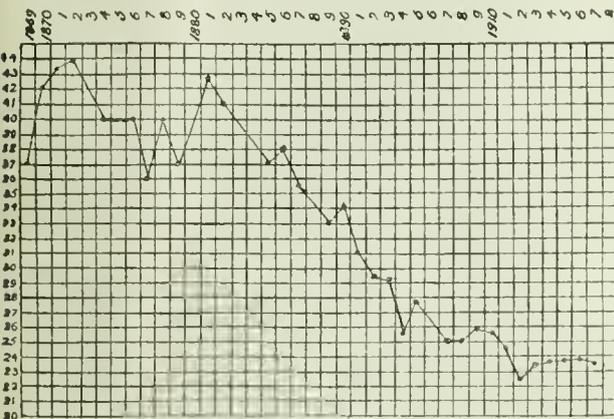

CHART V.—Tuberculosis, New York. After Koch. President Cleveland's Administration, 1885-90; McKinley Tariff, 1890; Wilson Tariff, 1895; Dingley Tariff, 1897.

To sum up: I have not found a case which contradicts the suggestion that if a government concentrates on the question of raising real wages it does more to eliminate tubercle than it can do by any other means. On the other hand, there are very distinct indications that when it sets itself by direct means, involving expense, to improve the conditions of the poor, the usual result is to encourage tuberculosis and raise its death rate, relatively if not absolutely. The Insurance Act enhances, and will go on enhancing increasingly, the cost of living to the very poor, and in this way will increase disease. A capital illustration of the absurdity of State regulation of wages was recorded in the press early in September. A master baker was forced to add 5s. a head a week to his five men's wages. He was allowed to charge $\frac{1}{4}$ d. a lb. extra for his bread. He made £18 7s. 6d., and his men 5s. each, as the result of State interference. So it is always when you attempt to override natural law. Every statute to lower the rate of interest in usury has raised it. Governments tried deliberately for one hundred years after the Black Death to lower wages; they only succeeded in raising them. For six years before the war they tried directly to raise wages. They only succeeded in lowering them. They have passed laws to prevent the private employer paying in truck; and justly. But they are perpetually passing laws to pay men in Government truck, and Government truck has nothing to recommend it as against private truck. As a prominent Forester said at the friendly societies' meeting the other day: "We can give for 1d. what the State charges 1 $\frac{1}{2}$ d. for."

I submit that there is no possible doubt that the Insurance Act operates to lower the value of wages. I submit that the grounds on which a rise in the death rate from tubercle was predicted as a result of the Act were just, and that there is a strong *prima facie* case for an inquiry. Now I want to say a few words as to why an inquiry should be instituted by the British Medical Association.

In the first place, in the frenzy now raging for the

extension of State activities, which has lately been the invariable sequel of a war, it will be long before you will prevail on any Government to inquire whether its activity is not in itself a mischief. The recent extensions of the franchise, however desirable in themselves, cannot but have the effect of attaching a factitious importance to Parliaments and Governments for a period, depending on the time it takes to disillusionize the great body of the electorate. For example, working men rarely use the telephone or telegraph for themselves; they are paying in raised prices in order that these conveniences may be at the call of people better off than themselves, yet I have never heard of a working man raising his voice for the resale of either to private hands. Government is a fetish with them, and, as they are the driving force for the moment, there is little chance of such an inquiry at the instance of the State.

Moreover, for such an investigation it is imperative to have men of science who have no prejudices, no preconceptions, who care only for truth. There should be no party politics in such a committee. Many men among our ranks, especially in high places, have been smitten by the prevailing mania for officialdom, but it would be easy to find medical men without bias who would decide for scientific truth, and that only.

Another decisive reason for an inquiry by medical men is that we best know the facts and could start free from the embarrassment of a load of fallacies which the layman would have to learn painfully to discard. It would, for example, be no use to tell medical men that the Act brings treatment within reach of the poor, in any way where the old individualist method failed to supply it. You and I know that it was not poverty *per se* that was the bar. I can say for myself—and I am sure for everyone here—that never in my life have I refused to attend any person on that ground; the few times I have refused have been where I had reason to know that he *would* not pay if he *could*, not because he could not pay. Nor will Mr. George's pathetic illusion that the admittedly too great cost to the poor will be compensated by greater efficiency on the part of the service bear a moment's scrutiny. It is obvious to us, and should be to the public, that a system which makes the pay the lower the more diligently you attend, and the higher the less, cannot tend to promote efficiency.

Again, we know better than any other class the moral deterioration which has begun to work. Is there any man here who has not more than once heard the remark: "Well, they make me pay; I shall take care to get my own back"? It is perhaps a pardonable, certainly a natural, feeling; as towards a State undertaking it is surely an appalling one. But it is there; and at this juncture it is a dreadful menace to have people feeling and saying, as a woman said to me the other day: "Well, the State is rich."

There are many other facts of this kind, of the utmost value in the appreciation of such a scheme, best known, perhaps solely known, to us. There is no other class, except perhaps the district nurse, which enjoys so intimate a knowledge, or the confidence in so full measure, of the poor.

But more than all is the fact that it is *right* to inquire. These overgrown children in Parliament and in Government offices are deciding the fate of a nation without thought, without caution, with a single eye to the benefit, not of the nation, but of individuals in the nation.

Under the old conditions it was often painful to insist on payment from the poor. But every thoughtful man knows that in the long run it was good for the community to do so, except, of course, in special cases. Just as Octavia Hill, by rigorous insistence on her rents and friendly intimacy with her tenants, showed the solution of the housing problem for all time, and transformed some of the worst characters in London into respectable hard-working people who never, in the worst winter on record, amid general clamours for State relief all over England, went without a day's work, so we know that we were raising the standard of living of the poor, and ultimately raising the market rate of wages. But under the insurance scheme and the extensions proposed that burden is transferred to the community in general, which means that ultimately the poor will pay relatively most. Can you bear that the cost of the raising should come out of the suffering

of those who are least able to bear it? You remember what Brutus says:

By heaven, I would rather coin my heart to gold,
And drop my blood in drachmas than to wring
From the hard hands of peasants their vile trash
By any indirection.

The railway strike might have been devised on purpose to drive the fact home. Individuals in the pay of the State were to suffer, perhaps are suffering, and the demand arises from their fellows that at the cost of the State their suffering should be relieved. Our latest convert, and a most valuable one, Mr. Lloyd George, pleads that he is trustee for the public funds and cannot accede to the demand without grave injury to the public. He has at last learnt that to relieve poverty out of the taxes is but to increase poverty; that so to relieve a handful of railwaymen would be to impose a heavy burden on every other poor man in the kingdom; and that it is the bounden duty of a Government to resist with all its power the imposition of every additional penny of taxation. The principle, if not the amount, is exactly the same in our case. We ought to have, and must have, more; Government ought not to give more. The position is an impossible one. There is only one course open honestly to the State—namely, to abandon interference and to return to the old system which cost the community nothing—that is, because it was paid by the individual.

In that great book of Sir H. Maine's, in which every man should pass a rigorous examination before he sits in Parliament, he lays down an axiom which has attained instant and permanent acknowledgement—namely, that the history of progress has been the history of advance from status to contract. No human being can deny that the Insurance Act abolishes contract in favour of status or a very large portion of the community. A man who by law cannot contract freely is in status, and the status is that of a slave or a child.

And so we come back to the old motto—

All constraint,
Except what wisdom lays on evil men,
Is evil.

To find it is not a mere political platitude, but a natural law, a profound political truth. Compulsion is not good even for children, except very naughty children. For honest grown men it is not only a crime, but a blunder. Leave it for criminals.

At the conclusion of the address the following resolution was unanimously adopted:

This meeting calls attention to the slackening of the fall in tuberculosis mortality from 1896 onwards, culminating in an actual rise in the death rate after the Insurance Act; and resenting its enforced association with a measure which prima facie seems, and on strict investigation may be proved to be, prejudicial to the national health, urges the Council of the Association to institute an inquiry into the effect of the Act upon the nutrition of the poor.

THE Reports of the Borough of Poplar Dispensary for the Prevention of Consumption for the years 1916, 1917, and 1918 have been received. Statistical analyses of cases attending, arranged under different heads, open each report. Attendances at the dispensary for the three years totalled 28,217. Of 539 contacts examined, 71 were regarded as tuberculous. Patients discharged as cured numbered 165. New features include the adoption of "a dried milk of high nutritive value" in lieu of the more expensive ordinary milk. The need of an open-air school is emphasized. Another requirement—a new x-ray installation—has been met.

THE calendar of the Faculty of Medicine of the University of Toronto for the year 1919-1920, besides containing the lists of names and information as to examinations customary in such calendars, contains in the issue for 1919-1920 a special notice to the effect that "The senate of the university has determined that the increase in the length of the undergraduate course in medicine from five to six years will go into effect in the autumn of 1919." This notice will apply to all students entering on and after that date, with the exception of those who have been prevented from entering their course during the war on account of their having been on military service.

REMARKS ON SCLERODERMIA.*

BY

FRANK H. BARENDT, M.D.LOND., F.R.C.S.ENG.,
PHYSICIAN TO THE DEPARTMENT FOR DISEASES OF THE SKIN, SENIOR
MEDICAL OFFICER, V.D. CLINIC, ROYAL SOUTHERN HOSPITAL,
LIVERPOOL.

UNLIKE the names of many skin diseases, the word sclerodermia is not of ancient lineage; its introduction is, indeed, well within the recollection of most of my hearers. The insertion of the "i" before the last letter is to emphasize the fact that we have a definite disease of the skin and not merely a change in structure and texture, which the word "scleroderma" implies. A similar alteration is illustrated in the terms "pachydermia," or elephantiasis, and in "xerodermia," and for exactly the same reason. Parenthetically, I may observe that these descriptive terms ending in "ia" are feminine substantives, whereas the original ones are neuter.

The earliest account of this disease was given by Dr. Curcio of Naples, who apparently did not even bestow a name upon it. Willan, the English dermatologist and great terminologist, called it "ichthyosis cornea." Later Thibial of Paris introduced the term "sclerema adultorum" to describe the disease, and variants—for example, dermato-sclerosis, scleriosis cutis, scleroderma—soon made their appearance in the writings of subsequent observers in different countries. Popularly it is known as the "hide-bound disease," and this Anglo-Saxon term alone and of itself is sufficient to proclaim its existence from time immemorial, even though the first medical record only dates back to 1752.

It is rather curious to note that many of the earlier observers, after the fashion of the schoolmen, seemed to be more intent upon linking up this disease sclerodermia with elephantiasis arabum—pachydermia—and seeking some subtle connexion between the two, than in endeavouring to elucidate its nature. Indeed, it is only in comparatively recent times that we have freed ourselves from the thralldom of tradition in medicine. It is well that it should be so; on the other hand, although, owing to our progress in science, we may justly differ from our forefathers in their views of disease, yet there is a real danger that in coining new terms we may be misled to regard them as new knowledge. A great advantage would accrue to us if a short course on the history of medicine were instituted in our university. Nosological nomenclature alone would play an interesting, not to say fascinating, part in such a subject.

Under sclerodermia two types are described, the diffuse and the circumscribed. One of the cases now reported shows both types, and the other illustrates the circumscribed type only. The circumscribed type was formerly known as, and is still called, morphea. It has been well described by Erasmus Wilson, who regarded the disease "as a faint trace of a woru-out disease, leprosy," once endemic in these islands. Later Addison described this circumscribed type as "keloid," deriving his term from the Greek *κελός*, a mark such as left by a burn. Hence the combination "Addison's keloid." Addison was at pains to show that the disease he depicted was the true keloid, and quite different from Alibert's keloid. Addison was right, but apparently overlooked the fundamental terminological confusion introduced by the two words with the same initial letter. Alibert, owing to the exigencies of French pronunciation, transliterated the Greek "κ" as a "k." The name was derived from the Greek *χρῆνη*, signifying a crab's claw, to which a fancied resemblance can be detected. Certainly if we are to dispense with the French dermatologist's name, cheloid should be so written—with "ch." This terminological confusion is now a matter of historic interest, especially as Addison's keloid has been definitely recognized by modern writers as a localized type of sclerodermia, and the term keloid is passing into desuetude. Sclerodermia is not a frequent disease. I can call to mind only four examples that have come under my direct observation, and two of these are here this evening for your inspection. It is more often seen in females (nearly 75 per cent.), but no abnormality of the sexual organs has been brought into causal relation.

* A paper read at the Liverpool Medical Institution.

† Cancroid, from the Latin "cancer," was also used as a synonym by French writers.

CASE I.

A schoolgirl, aged 12½, came to the Skin Department of the Royal Southern Hospital in February, 1919. She displayed at that time a white glistening ivory-like patch situated in the lower third of the left arm on its extensor surface. It was hard, and the skin could not be raised in folds; there was no itching, no pain, and no disturbance of sensation. There was impaired movement of the elbow, but the wrists and digits were freely movable and the skin in these regions apparently normal. A similar change in the skin was noticed in the left foot implicating the two outer toes and extending along the dorsum pedis to some four to five inches above the external malleolus.

Her mother stated that the child first noticed this condition during the summer holidays, July and August, 1918. She thought she had sprained her arm when playing with the may-pole. The condition of the toes and outer margin of the foot and ankle was not noticed until November, 1918; but neither the patient nor mother can definitely state when or how the disease began, and these data are not therefore quite trustworthy. From February, 1919, to the present time sclerodermia has slowly extended, implicating the whole of the extensor region of the upper extremity. The flexor aspect of the limb is not involved, and over the biceps and flexors of the wrist and hand the skin is supple and apparently normal. The hand itself shows typical sclerodactyly. The scapular region is also involved, and here appeared slight ulceration, of which the cause could not be ascertained. This is now healed, leaving a scar like that of a burn. In April, 1919, two circumscribed patches, one in the left hypochondrium and the second in the umbilical region, were discovered, and have since undergone a certain degree of involution. This fact has been noted by various observers in the circumscribed type.

The present redness of the skin of the hand and fingers is referable to the cold weather, and does not suggest any connexion with Raynaud's disease, which some writers would appear to support. The morbid histology is briefly that of atrophy of the fibrous elements of the true skin and subcutaneous tissue. The elastic element is not involved. The blood vessels are atrophied, the result of interstitial inflammation of the walls. The glandular apparatus, as well as the hair follicles, show secondary atrophic changes. The epidermis is diminished in depth, but otherwise normal. I hope to show a microscopic specimen of these changes at a forthcoming pathological meeting.

The pathology of sclerodermia is unknown, and equally so its etiology. Of course, hypotheses are forthcoming, but no facts to support their validity. There is an angioneurotic hypothesis, a central nervous hypothesis, and an autotoxic hypothesis. I have no extra one to offer, and cannot explain sclerodermia. It cannot be referred to malnutrition, although the parents think that the food rationing in the early part of 1918 may have had something to do with its appearance. I have not read of any increase in sclerodermia among the inhabitants of Central Europe who have suffered immeasurably more from malnutrition than we.

Treatment locally and constitutionally has signally failed. It has not prevented the progress of the disease. Locally, linimentum potassii iodidi *c* sapone, beloved of the surgeons, has been vigorously rubbed into the affected region for a month or so. This was followed by more stimulating liniments—turpentine and ammonia equal parts—for another month. Then successively the following ointments were used, but with no benefit: Unguentum acidi salicylici, unguentum hydrargyri compositum. At present, more from a massage standpoint of view, olive oil is being vigorously rubbed into the withered limb.

Internally fibrolysin was given hypodermically every week for three months. It made not the slightest impression. Fibrolysin is another name for thiosinamine, which is an organic derivative from oleum sinapis. It was introduced as a solvent or discutient of fibrous, and especially cicatricial, tissue in tubercular and hypertrophic scars as a result of burns. In these cases, used as a plaster, I have noted great benefit. Since August, 1919, thyroid extract has been administered, 2½ grains thrice daily, and she is still taking this, but with no benefit as far as I can judge. The only point I can make is that during the last six months the disease has not extended. The withered condition of the left arm has become more striking owing to the atrophy of the muscles.

The blood has not been examined by the Wassermann test for syphilis; there is not the slightest clinical indication of inherited or acquired syphilis. Colonel Harrison returned the blood of a case of sclerodermia as positive; three other bacteriologists returned the same case as negative. According to Drs. Browning and Kennaway (bacterio-

logical experts) the blood of every patient, no matter what the nature of the disease may be, should be submitted as a matter of routine to the Wassermann test. If this be a correct method of handling suffering humanity, then I plead guilty to this sin of omission. I have, however, serious intention of repairing the fault, for who of us knows nowadays that on a serological test he may not be declared to be possessed of latent syphilis which a Wassermann test has rendered patent! And, moreover, are not "606" and "914" potent remedies, and fit to be tried in diseases in which hitherto we have been impotent to cure? [A Wassermann test has since been made and reported negative.]

CASE II.

A woman aged 35, married twelve years, who has no children but gave birth to a premature child at seven months which died shortly after birth, shows a patch of circumscribed sclerodermia in the middle of the bicipital groove of the right arm, from which a band extends along the ulnar margin of the forearm. She has had it for six years, and has only recently complained of weakness and impaired movement. She was sent to the Royal Southern Hospital by Dr. Humphreys in October, 1919. I ordered compound mercurial ointment to be rubbed well into the affected region, and probably it is due to the vigorous rubbing that she states she is much better, and has freer movement. The disease, at any rate, has made no progress during the last six weeks as far as I can judge.

In conclusion, I can but regret the futility of every medicament that has been used. It would have added greatly to the interest had I been in a position to say how the disease can be ameliorated, let alone cured.

MENINGITIS TREATED BY INTRATHECAL INJECTIONS OF THE PATIENT'S BLOOD SERUM.*

BY

RUPERT WATERHOUSE, M.D., M.R.C.P.LOND.,

CONSULTING PATHOLOGIST TO THE ROYAL UNITED HOSPITAL, BATH;
PHYSICIAN TO THE ROYAL MINERAL WATER AND
ROYAL UNITED HOSPITALS, BATH.

THE clinical features and the characters of the cerebro-spinal fluid in the following case leave little room for doubt that the patient was suffering from cerebro-spinal fever. The cerebro-spinal fluid was not examined until the eighth day of illness, and absence of meningococci so late in the disease does not, I think, invalidate the diagnosis.

The patient, a man aged 30, had always enjoyed good health except that two years ago, whilst serving with the heavy artillery in France, he suffered from "boils." In his last camp before demobilization many of his comrades suffered from influenza, but he escaped. He was demobilized about the middle of April, and on April 28th entered a gentleman's service as valet. At this time he seemed somewhat dull and lacking in energy compared with his former self, but had no definite illness until May 30th, when he shivered and complained of headache. The headache was accompanied by fever (103° F.) and photophobia, and for the next few days was so severe as to require morphine for its relief. On June 4th he complained of stiffness of the neck, and on June 6th a crop of herpes appeared about the nose and lips.

On the following day he was admitted to the Royal United Hospital. At this time there was slight retraction of the head, the posterior cervical muscles were very stiff, and the head could not be bent forward. With the thighs flexed at a right angle to the trunk the legs could be extended only to an angle of 135 degrees with the thighs. All the reflexes were normal except that the right abdominal reflex was much brisker than the left. The plantar reflexes were of the flexor type. The temperature was 102.2° F., the pulse 100, and the respirations 22. There was no optic neuritis, and the membrana tympani were normal.

The cerebro-spinal fluid was under considerably increased pressure and about 50 c.cm. were removed by lumbar puncture without difficulty. The fluid was turbid, clotted on standing, and contained 3,000 leucocytes (91 per cent. polymorphonuclear) to the cubic millimetre. Exhaustive search failed to detect any micro-organisms in stained smears. The urine was alkaline, turbid from the presence of bacteria, and showed a white deposit consisting of phosphatic crystals, leucocytes, epithelial cells, and a few erythrocytes; the bacteria present comprised Gram-negative coliform bacilli, encapsulated Gram-positive diplococci, and a short Gram-positive bacillus.

On the following day culture tubes of human blood serum agar and of Loeffler's blood serum inoculated the day previous with the cerebro-spinal fluid were found to have remained sterile, and as the patient's condition showed no sign of

* A paper read to the Bath and Bristol Branch of the British Medical Association.

amelioration but rather the reverse, the headache, Kernig's sign, and retraction of the head all being more pronounced, it was decided to try the effect of intrathecal injections of the man's own blood serum, in the hope that antibacterial substances might be pre-ent in sufficient quantity favourably to influence the supposed infection of the meninges.

Accordingly about 50 c.c.m. of blood were removed from a vein in the arm into a bottle which was then allowed to stand overnight in ice-cold water; 20 c.c.m. of the resulting serum, after being warmed by placing the container in warm water, were then slowly injected into the subarachnoid space by lumbar puncture after removal of the same quantity of cerebro-spinal fluid. This proceeding was repeated on the three following days; only 12 c.c.m. of serum, however, was injected each day as the cerebro-spinal fluid was under less tension and no more could be conveniently abstracted. A further 5 c.c.m. were injected two days later (June 14th). From June 9th 10 grains of helmitol were given every four hours until June 14th, when the appearance of a considerable quantity of blood in the urine led to its being reduced to 5 grains every four hours. This haematuria quickly cleared up, and though the urine contained a trace of albumin until June 21st it was subsequently free; there was no evidence to the naked eye of bacteriuria, and the reaction was acid.

On admission to hospital the patient gave the impression of being desperately ill, and for the next two days the symptoms increased in severity. Headache was intense, there was delirium at night, the retraction of the head and Kernig's sign became more pronounced, and flesh was lost at a truly astounding rate. Improvement set in from the time of the first intrathecal injection, though headache was still sufficiently severe to require morphine hypodermically on the nights of June 9th, 11th, and 13th, and he continued to lose flesh. On June 15th and 16th there was incontinence of urine. From this time a striking feature of the case was the rapidity of convalescence.

After admission to hospital the temperature kept between about 100° and 102° until June 14th, when it fell by lysis, becoming normal on June 18th. There was a rise the following day June 19th, to 101°, but subsequently, except for an evening rise to 99° on June 25th, 26th, and 27th, it remained normal till his discharge from hospital on August 3rd. In September he resumed work as a valet and has since remained perfectly well.

The failure to find micro-organisms in the fluid withdrawn by the first lumbar puncture was repeated in examinations, both by smears and cultures, of that withdrawn on subsequent occasions.

Had cultures been available of the four different groups into which the meningococci most commonly met with have been divided by Gordon, it would, perhaps, have been possible by the agglutinative reactions of the patient's blood serum to have determined which particular group was responsible for his illness and to have administered the appropriate antiserum. As they were not available, it was decided to proceed as above, and though it may be urged that the mere removal of the cerebro-spinal fluid or the administration of helmitol, which by some is claimed to exert a bactericidal action in the cerebro-spinal fluid when given by the mouth, may be factors in producing the favourable result, the recovery—and perhaps one might add the rapid recovery—of a case which at one time appeared to be hopeless is recorded in the hope that the measures adopted may be of use in similar cases where the exact nature of the infecting organism cannot be ascertained.

McKenzie and Martin¹ in 1908 reported twenty cases of cerebro-spinal fever treated by intrathecal injections of the patient's own serum or of serum from other patients convalescent from the disease. Of these four were chronic cases and all died. Of the sixteen acute cases ten recovered, and of these two were treated by injections of their own serum, though in what quantity is not stated.

In conclusion, my thanks are due to our president, Dr. King Martyn, for kindly supplying me with the details of the earlier period of the patient's illness.

REFERENCE.

¹ *Journ. Path. and Bact.*, 1908, xii, 539.

ACCORDING to the *Boston Medical and Surgical Journal*, it has been established that the sum of 15 million dollars must be raised throughout the country in order to carry out the work already begun in supplying food, clothing, and medical aid in countries devastated by the war and for continuing the health campaign.

Mrs. H. M. PLAYER, of Redland Park, Bristol, who died in October last, has bequeathed £500 to the Bristol General Hospital and £250 each to the Bristol Eye Hospital and the Bristol Royal Hospital for Sick Women and Children. The Bristol Royal Infirmary is to receive the remainder of her estate after the various bequests enumerated in the will have been distributed.

FORGETTING: PSYCHOLOGICAL REPRESSION.

BY

ALFRED CARVER, M.A., M.D., D.P.M. CANTAB.,
DIRECTOR OF THE BIRMINGHAM PSYCHONEUROSES CLINIC.

Those who devote themselves to the treatment of functional nervous disorders, especially so-called neurasthenia—which term as used by the services and the pensions boards really conceals various hysterical manifestations among which anxiety states predominate—are constantly confronted by the patient with the statement that doctors have advised him to pull himself together, exercise his will power, and forget all about the incidents which proved his undoing. Such an attitude was taken up by Sir William Hale-White,¹ who stated explicitly that "talk should never be about past war experiences," but the patient should be helped to forget them by the aid of easy games of cards, light reading, croquet playing, etc. It is unfortunate that, in spite of the experience gained during the war in the special military neurological hospitals, this attitude should be so prevalent. The forgetfulness thus advised is nothing other than repression, and psychological analysis invariably reveals the fact that the patient's anxiety condition is directly attributable to it. This is due to dissociation and displacement of the affect, which then tends to attach itself to suitably associated presentations.

The more successful he is in repressing the memory of his unbearable experiences the more severe become his symptoms. Roughly, one may note three grades of repression or forgetfulness.

First, there is the degree in which the idea of the original incident is so unbearable to the ego as to be immediately and completely repressed. In this case the patient attempts to defend himself by complete amnesia for the event, which amnesia often includes, as an additional security, a considerable lapse of time in which the unbearable event is contained. For example, a patient may remember nothing after an explosion until he "comes to life again" in hospital a month or so later. Such a patient has most effectively practised the method of forgetfulness, but his condition is pitiable in the extreme.

One such case recently under my care was discharged from the army in 1916 as permanently unfit. Instead, however, of improving with lapse of time, he became progressively worse and had to give up work altogether. Recovery of the amnesia showed the unbearable incident to be that while lying semi-conscious upon a stretcher he had been robbed, and when he had offered such feeble resistance as he was capable of had been struck on the jaw and told to lie still. The recovery of the amnesia—in August, 1919—produced a remarkably steady effect upon the patient. Other apparently forgotten events were subsequently in a similar way revived and the patient's attitude towards them readjusted, with the result that he lost his anxiety symptoms and has been comfortably back on full work for the past two months.

The second degree of repression is that in which a patient remembers and is able to talk about most of the events in his military life, but has incompletely repressed certain of them on account of their highly disagreeable nature. Cases of this sort are particularly apt to deceive one and thus run a protracted course.

As an example I might mention the case of a man who had seen three years' service in France and to all outward appearance carried on satisfactorily until slightly wounded just before the armistice, after which he had to be invalided home with "neurasthenia." With a little encouragement the patient could discuss his military history apparently in detail. A good deal of perseverance was required to bring to light the pathogenic event. This proved to be the death by shooting, under tragic circumstances, of a close friend with whom he was constantly associated as a sniper.

The resistance which the analyst experiences in bringing such a repressed incident to light is considerable, as is also the emotional reaction of the patient at the moment, but the rapid recovery which follows is equally gratifying to both parties.

The third degree of repression is found among pensioners to be the most common and the most troublesome to deal with. In it there is no event of particular moment; the subjects of it deliberately try to exclude the whole of their military service from their minds, and desire to live as though the experiences contained in it had never been. In this group of patients especially one may notice a latent period intervening between the disagreeable experiences and the onset of the symptoms. Thus, a considerable

number of the men in this group make no claim upon demobilization, their symptoms having developed later and after they had resumed civilian employment. Analysis of these patients generally shows that their powers of adaptation were never good, and that prior to military life they had a marked tendency to expect external conditions to be made comfortable for them rather than strive to adjust themselves and to dominate their environment. As their environment naturally refuses to comply they endeavour to ignore everything which does not suit them. When confronted with their failures, they tend to explain these as due to lack of physical strength on their part or as due to the injustice of a system or of persons with whom they were brought in contact. Here again treatment resolves itself into getting the patient to face external reality, to remember and assess his past failures, disagreeable experiences, etc., at their true value. The success or otherwise of treatment depends very largely upon the intelligence of the patient.

It should be borne in mind that the making conscious of the forgotten—repressed—material is only a necessary first step, our ultimate aim being to readjust and re-educate the patient. This cannot be accomplished while his mind is refusing either consciously or unconsciously to deal with past unpleasant experiences, for these tend to cast a baneful influence over all the reactions of his subsequent life; hence the necessity for the removal of the resistance.

Limitation of space forbids my entering into the psychic mechanism involved in these cases, but I have dealt with this more fully elsewhere.²

In conclusion, I would say that the remarks here made apply with equal force to civilian psychoneurotics, though the latter are as a rule more difficult to deal with, and require of the doctor a greater experience in the preliminary bringing to light of the repressed material. I feel that, at the present time, when so large a number of these cases are demanding treatment, it would be a great advantage if the profession as a whole realized the pathogenic effects of repression. The task of those who are engaged in the treatment of the conditions above referred to is rendered all the more difficult if the patient is fortified by medical advice in his efforts to forget.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

GASTRIC ULCER AFTER GASTRO-
JEJUNOSTOMY.

IN THE BRITISH MEDICAL JOURNAL of November 29th, 1902, I made a brief reference, among other cases of gastric ulcer, to that of a man, aged 51, from Lancaster upon whom I performed pyloroplasty and gastro-jejunosomy on December 12th, 1901, on account of two ulcers; one near the pylorus I excised, and did pyloroplasty to widen the narrowed pylorus. The other ulcer, deep in the pylorus, could not be excised owing to complicated adhesions, but as an additional safeguard gastro-jejunosomy was performed at the large curvature of the stomach. A very good report was made in my hospital case-book by the dresser, Mr. A. B. Sykes, now of Formby, near Liverpool. The man made a good recovery and continued in good health and vigour nearly three years.

However, a report was made to me by Mr. C. W. Dean of Lancaster that the man had died on August 14th, 1904, having been admitted moribund into the (now Royal) Infirmary of that town. *Post-mortem* examination showed perforation of a fresh ulcer of the jejunum, where attached to the stomach. This last illness had lasted a couple of days, and the man might have had a chance if he had applied at first, when an operation would have been done, with good prospect of success, by the Lancaster surgeon.

The remarkable thing about this occurrence was the ulceration of the jejunum at its point of attachment to the stomach, and entirely away from the two gastric ulcers previously relieved.

Liverpool.

RUSHTON PARKER.

TREATMENT OF DELIRIUM TREMENS.

DR. F. WYATT-SMITH'S note in the BRITISH MEDICAL JOURNAL of December 6th, 1919, raises several interesting points. Before the war it was my lot in twenty years of asylum work to treat many cases of this disease, and I cannot recollect one that did not respond to the old mixture of potassium bromide 30 grains, chloral hydrate 20 grains, and tincture of digitalis 10 minims, every four hours, with a calomel and saline purge to start with; nor do I remember losing a case, unless complicated by pneumonia. But since whisky drinking has become expensive the disease has practically vanished.

Dr. Wyatt-Smith's remarks on hyoscine and sulphonal should not be allowed to pass without a warning. Hyoscine hydrobromide is the most reliable sedative in states of acute excitement, and in doses of $\frac{1}{5}$ grain, combined with $\frac{1}{3}$ to $\frac{1}{2}$ grain of morphine, is my sheet anchor in such cases. But I have notes of three cases in which hyoscine given over extended periods had a cumulative effect, ending fatally.

Dr. Wyatt-Smith says he never met anyone who had seen a case of haematoporphyria the result of sulphonal. I have had three cases in my own experience, two ending fatally. One was in the early days of sulphonal, when it was beamed as an absolutely safe hypnotic, and occurred in the case of a strongly built girl the subject of chronic mania. She had sulphonal in 20 grain doses night and morning for some weeks, developed haematoporphyria and died. The other fatal case arose in a young man after only two doses of 20 grains each, and was obviously due to an idiosyncrasy to the drug. I have also seen alarming coma result from a single dose of 20 grains in a woman. She was unconscious for twenty-four hours and needed strong stimulation with caffeine, etc., to bring her round.

I find veronal in doses of 7 to 10 grains preferable in every way to sulphonal and now rarely employ the latter drug. It is of the utmost importance, when prescribing any of these drugs over extended periods, to keep the bowels well open.

W. STARKEY, M.B., B.Ch.,
Medical Superintendent, Plymouth
Borough Asylum.

Ivybridge, S. Devon.

CALCIUM CHLORIDE AS A HAEMOSTATIC.

A SHORT time ago (November 8th, 1919, p. 597) Dr. Gwillim Davies related a case in which he had used calcium chloride with success as a haemostatic. On the first occasion he injected from eight to ten grains of the salt in solution into the gluteus, and on the second four grains. He mentioned that he was indebted to Dr. W. R. Grove of St. Ives for a knowledge of the value of the drug in this respect. We have received a communication from Dr. Grove expressing the opinion that the doses given by Dr. Davies were unnecessarily large, and, in fact, bordering on the unsafe.

Dr. Grove described his method in the *Guy's Hospital Gazette* of May 18th, 1918. He uses a solution of fused calcium chloride made up 1 in 4. If, as is the case when hard water is used, there is a precipitate, this is shaken up. Four minims of the fluid are drawn into the syringe, and boiled hot water is drawn up afterwards to the 20 minim mark; this is injected deeply into the gluteal muscles. The injection is painless. Dr. Grove has sometimes made the injection in patients who have been going about; these got slight stiffness afterwards down the leg. No external signs remained. He states that some years ago, at a meeting of the Cambridge Medical Society, Professor Dixon pointed out that while the value of salts of lime for increasing the coagulability of the blood was well known, their absorption from the intestine was practically nil. He therefore suggested a hypodermic injection, and recommended a dose of 1 grain. The hypodermic injection, however, produced sloughing of the skin, and therefore it must be given intramuscularly. Dr. Grove states that he has used the drug in the dose and in the manner described not only in haemoptysis, but also in haematemesis, in a case which presented signs of peritoneal haemorrhage after abdominal hysterectomy, and has found it useful also in certain cases of metro-rhagia. He states that it will be found of value in ruptured extrauterine pregnancy, before operation, and in typhoid haemorrhage. He also mentions having used it in a case of aortic aneurysm with apparent benefit. He points out that evidence as to the rate at which the salt is

excreted would be helpful; from clinical evidence he thinks that the blood soon returns to normal. Again, he asks whether, in old people with roughened arteries and a liability to thrombosis, it is safe to use the method. He also raises the point whether it would be better to use a still weaker solution.

Reports of Societies.

UTERINE CANCER.

At the last meeting in 1919 of the Section of Obstetrics of the Royal Academy of Medicine in Ireland, Dr. BETHEL SOLOMONS showed two specimens: (1) a carcinoma of the cervix; (2) a sarcoma of the uterus.

The uterus in the first case was removed by Wertheim's method from a woman of 31. She consulted him because of sterility. On examination he found a nodule in the cervix; he removed this, and the pathologist reported it to be an epithelioma. It was then necessary to decide between vaginal hysterectomy and Wertheim's operation. The disadvantage in the former was that the vagina was extremely narrow; the disadvantage in the latter was that the woman was very fat. After due consideration the abdominal operation was determined on, and after a Pfannenstiel's incision the operation was speedily accomplished. He dwelt on the advantage of this incision in fat women, as the fat area was avoided.

The second specimen removed was from a woman of 60 who complained of a stinking discharge, wasting and cachexia. On examination a tumour about the size of a six months foetal head was found in the vagina. This was removed by morcellation, and on reaching the cervix it was found that the os uteri admitted two fingers and the uterus was filled with a fetid tumour. The latter was removed with the spoon forceps and the uterus curetted. There were several pounds of the tumour, and the pathological report was giant-celled sarcoma. On examination of the patient after the removal of the tumour it was found that the uterus was fixed and that the growth extended to the right pelvic wall and evidently involved the intestines. The disease was so advanced that no further operation was possible. The patient was greatly relieved and there was no discharge.

Sir WILLIAM SMYLY agreed that in cases where cancer of the cervix had been diagnosed with certainty, even where the disease was very limited in extent, the most radical method possible should be employed.

Ovarian Insufficiency.

Dr. ASHE read a paper on ovarian insufficiency as a probable cause of epilepsy. He advocated the administration of glandular extracts in suitable cases.

Dr. SOLOMONS said he thought hypodermic medication of glandular extracts was probably an improvement on oral administration. He had had great success with corpus luteum extract, also with some of the combined extracts—for example, hormotone and ovo mammoid. He still felt that endocrine therapy was rather "a shot in the dark," and he hoped investigation would soon put endocrinology on a sounder basis. He had met many cases of epilepsy in connexion with menstruation, and he had found that some were benefited by glandular extracts, others by ergot, and others by anti-anaemic and anti-constipation remedies.

Sir W. SMYLY remarked on the importance, in young women, of preserving both ovaries if possible, because though it might appear that one would suffice, yet subsequently, as in one of the cases mentioned, it also might have to be removed. As to treatment by glandular extracts, he thought there was more likelihood of obtaining definite knowledge by the hypodermic injection of one than by the simultaneous introduction of half a dozen into the stomach.

Schultze's Forceps.

Sir W. SMYLY gave an exhibit of Schultze's forceps. He maintained that Schultze's spoon forceps, though not now such an important instrument as it was when first introduced into practice upwards of a quarter of a century ago, was still one of the best means of removing submucous myomata, whether pedunculated or not.

Dr. BETHEL SOLOMONS said that he found the original Schultze's forceps a most useful instrument. The absence of the lock made morcellation, which was sometimes a tedious operation, a quick one. He saw the advantages in the increased weight and in the lock devised by Sir William Smyly, but so far he was satisfied with the lighter instrument without the lock.

Reviews.

THE GREAT WAR AND THE R.A.M.C.

THE first volume of the popular medical history of the war, or *The Great War and the R.A.M.C.*, by Lieut.-Colonel F. S. BRERETON,¹ deals with the narrative of events during the first two months of the war. As pointed out in a short preface by Lieut.-General Sir John Goodwin, the author has had access to official documents and diaries so as to ensure accuracy.

The first two chapters give a general account of the Army Medical Service, and show the improvements, such as the sanitary sections with specialists in the destruction of flies, that produced the phenomenal contrast between the toll of disease, especially enteric fever, in the South African war and in the years 1914-19. The organization and various units of the R.A.M.C. are described and illustrated by a diagram, and by tracing the sick or wounded man from the front trenches to England. The failure of horse transport, which rendered the field ambulances immobile in the retreat from Mons, led to the substitution of the motor ambulance with incalculable benefit to the wounded. It is sad that the parsimony of the Government and the narrow outlook of ignorant individuals had blocked the Director-General's recommendation for motor ambulances before the war. The casualty clearing station—a new unit—to which the field ambulances passed the sick and wounded, proved to be a vital link in the medical arrangements, and again and again justified its establishment. The great debt of gratitude to the British Red Cross Society under the guidance of Sir Arthur Stanley and to the Order of St. John of Jerusalem is graciously acknowledged.

After a brief but graphic description of mobilization in August, 1914, the detailed narrative starts. The cavalry field ambulances were naturally the first of the medical units to smel powder, about August 22nd, but the first casualty in the British Expeditionary Force was four days earlier, when two flying officers suffered disaster at Peronne on the Somme. The story of the terribly exhausting retreat from Mons gives a pathetic interest to an account of the hard and conscientious work of the R.A.M.C., crippled by the need for motor ambulances, which led to the capture of a number of medical officers who remained with the wounded; whereas the Germans, whose transport was similarly deficient, left their wounded exposed and unattended in the action of the Marne.

The reader passes with relief from the account of the retreat from Mons to the advance over the Marne after von Buelow and von Klück had been obliged to retrace their steps. The advance over the Marne showed practically for the first time the excellence of the British Field Ambulance, and during this week of rapid movement the scheme of evacuation so often practised on peace manoeuvres was carried out successfully. The description of the operations of the Second Division at the crossing of the Aisne contains an account of the heroic deaths of Lieut.-Colonel O. Dalton, Captain H. S. Rankin, and Lieutenant Huggan. The appendices give the staff of Surgeon-General Sir T. P. Woodhouse, the D.M.S. in France, who sailed with the Expeditionary Force in August, 1914, and the official report to the British Government on the horrors of Wittenberg.

In conclusion, a running summary of the military events accompanies the account of the movements of the R.A.M.C., and provides a most interesting and clear description on which Lieut.-Colonel Brereton may be heartily congratulated.

GENITO-URINARY SURGERY.

DURING the last six months or so a great number of books on venereal disease have been published, but the majority, it must be said, have added little to our knowledge of that important subject. In Major N. P. L. LUMB's book, *The Urethroscope in the Diagnosis and Treatment of Urethritis*,²

¹ *The Great War and the R.A.M.C.* By Brevet Lieut.-Colonel F. S. Brereton, R.A.M.C. London: Constable and Co. 1919. (Pp. 300; 9 maps and 2 appendices. Price 12s. 6d.)

² *The Urethroscope in the Diagnosis and Treatment of Urethritis: A Contribution to Urology.* By Major N. P. L. Lumb, O.B.E., R.A.M.C.(T.C.). London: J. Bale, Sons, and Danielsson, Ltd. 1919. (Demy 8vo, pp. 63; 40 illustrations. 10s. 6d. net.)

we are glad to welcome a work that should prove of real use to those engaged in the treatment of gonorrhoea. It achieves its purpose, which is to furnish a practical guide to urethroscopy, and more especially a guide to the use of the urethroscope in the control of treatment. Instead of emphasizing, as has too often happened in previous works, the rarities encountered in the urethra, the author wisely directs attention to the lesions found in everyday practice. He also shows the changes in the appearance of these lesions after appropriate treatment, such as dilatation. The merit of a work on urethroscopy lies in the illustrations rather than in the letterpress, and both Major Lumb and his publishers are to be congratulated on the quality of the coloured plates in this work. One smaller criticism may, however, be made. While engaged in studying the letterpress the reader is compelled to do a considerable amount of turning over of pages in search of the appropriate illustration: some of this trouble might possibly have been avoided by a different method of arrangement. However, the interspacing of coloured plates is always a difficult task, and this minor inconvenience will not divert attention from the general excellence of Major Lumb's work. It may be commended to all who are on the look out for a practical guide to the diagnosis and treatment of urethritis by means of the urethroscope.

In writing his book, *An Outline of Genito-Urinary Surgery*,⁵ Dr. G. G. SMITH has aimed at presenting to students and general practitioners a clear and concise summary of symptomatology, pathology, and treatment. Genito-urinary surgery has made such great advances during the past two decades that it can have been no easy matter to have kept such a work within narrow limits. Nevertheless the author has covered the ground with remarkable completeness, and has brought together within a comparatively few pages a vast amount of useful information. A handbook of this kind, if it is to be kept within prescribed limits, must of necessity be written in a somewhat dogmatic style; the author cannot afford space for the presentation of alternative theories and views of treatment. It would be easy, therefore, in reviewing such a work to pick out statements that are open to criticism, but this would scarcely be fair when the object of the author is kept in mind. Although genito-urinary surgery as it affects the general practitioner is the main topic, enough detail has been given concerning the major surgery of this region to allow the reader to gain a very fair knowledge of its indications, its aims, and its dangers. For those who desire further information on any of the subjects under discussion the author has appended to each chapter a useful list of references. The illustrations and plates are of the high quality maintained by so many of the better American textbooks, and contribute in no small way to the value of the work. Altogether it should be most useful to all practitioners in search of a compact and readable outline of genito-urinary surgery.

NOTES ON BOOKS.

ANNUALS.

THE 1919 edition of that most useful reference book, *Burdett's Hospitals and Charities*,⁴ appeared towards the close of the year; it contains some 250 pages more than its immediate predecessor, though the price is the same. The thirtieth year of issue of the work has been full of anxiety for the managers of voluntary hospitals and kindred institutions, and it is therefore natural that Sir HENRY BURDETT should devote a good deal of the introductory matter to the present and future of the voluntary system. He recognizes that in the period now approaching the field of charity must expect much reorganization and many modifications and changes. The first chapter discusses the volume of charity in the British Isles, with tables showing the income and expenditure for 1916 and 1917 of the hospitals, dispensaries, homes, and so forth, of which particulars are given in the subsequent sections. The opening chapters taken together give a full account of the financial position of the voluntary institutions in the British Isles, and of the general effect upon them of the

war. The editor remains full of hope and confidence for the future of voluntary hospitals, but he is very contemptuous of the way in which the sponsors of the National Insurance Act failed to provide for the hospital requirements of the insured population. "British men and women entitled as insured persons to medical benefits under the Acts were thus placed in the humiliating position, which Germans of both sexes had refused to occupy, of being recipients of charitable relief, if and when they could obtain it, which in practice was seldom or never." This is a hard saying, and not quite easy to reconcile with his praise of the voluntary hospital system. The main body of the work—some 800 pages—provides the customary detailed directory of institutions, both at home and abroad. The volume, as a whole, is a mine of accurate yet condensed information.

That section of *Whitaker's Almanack* for 1920⁵ which deals with foreign countries reflects the changes brought about by the Versailles Peace Congress, and also, as was inevitable, the confusions and uncertainties which still remain, especially with reference to Russia and Arabia. The information, however, is very complete and for the moment accurate, so far as we are able to judge, save that the maps with which it is most usefully illustrated do not appear to be in all cases quite consistent. The article on France has been revised and brought up to date, and we find new articles on Czecho-Slovakia and on Serbia, which appears with extended territory and under a new name as Yugo-Slavia. There is a new section on questions of the day touching on a great variety of subjects; they range from the Channel tunnel to the Trade Union Congress, and from the movement for the prohibition of alcohol to research associations, although we fail to find the Medical Research Committee either here or under the Ministry of Health, to which it is at present attached, nor under the Department of Scientific and Industrial Research, where we thought we might find it in a temporary resting place. The earlier part of the volume is arranged in the same way as before, and is as comprehensive and accurate as daily experience leads us to expect. We feel bound, however, once more to say that the table of medical fees is misleading, and has now become less accurate than ever it was. Nevertheless, the Almanack, taking it altogether, is an indispensable desk companion.

*The New Hazell Annual and Almanack*⁶ for 1920 contains a great deal of current general information, clearly printed, and well arranged, though it is a little disconcerting to find the last page of the section on religious denominations rounded off with a tabular list of bankruptcies in 1918. The year-book is now edited by Mr. T. A. INGRAM, M.A., LL.D., and appears as one of the Oxford University Press Publications. The particulars with regard to education, pensions, honours, and aviation are especially full. The new articles in this edition include a summary of the peace treaties with Germany, Austria, and Bulgaria, and the text of the covenant of the League of Nations, and of Labour's charter under the League; sketch maps are given of the new Germany and the new Austria as fixed at Versailles. The volume forms a useful reference book and record of events.

We have received from the Incorporated National Union of Manufacturers a copy of their *Directory*,⁷ in which will be found descriptive and classified lists of purely British manufacturers of commodities of every class. The book contains much information that should be of service to those who wish to promote British trade.

⁵ *Whitaker's Almanack for 1920*. By J. Whitaker, F.S.A. Lond. 1920. Fifty-second annual issue. (6s. net.)

⁶ London: H. Frowde, and Hodder and Stoughton. 1920. Thirty-fifth year of publication. (Cr. 8vo, pp. 925. 6s. net.)

⁷ *National Union of Manufacturers (Incorporated) Descriptive and Classified Directory of Members*. Compiled to July 1st, 1919. London: National Union of Manufacturers. (Cr. 8vo, pp. xii + 241. 5s. net.)

In a report compiled by Jordan and Sons (Chancery Lane) of companies registered during the half-year just ended, it is stated that "patent remedies . . . do not appear to be in great request"; nevertheless, fifteen patent medicine companies, with an aggregated capital of nearly half a million, were registered. The activity of the publishing trade is shown by the fact that 115 companies were registered in London and twelve in Edinburgh or Dublin, with an aggregated capital of over two and three-quarter millions. Chemical companies registered—consisting, no doubt, chiefly of chemical manufacturing concerns—numbered 186, with a capital of nearly five millions.

⁸ *An Outline of Genito-Urinary Surgery*. By G. G. Smith, M.D., F.R.C.S. Philadelphia and London: W. B. Saunders Co., Ltd. 1919. (Post 8vo, pp. 301; 71 figures. 12s. 6d. net.)

⁴ *Burdett's Hospitals and Charities, 1919, being the Year Book of Philanthropy and the Hospital Annual*. By Sir Henry Burdett, K.C.B., K.C.V.O. Thirtieth year. London: The Scientific Press, Ltd. 1919. (Cr. 8vo, pp. 1073. 12s. 6d.)

British Medical Journal.

SATURDAY, JANUARY 10TH, 1920.

LONDON'S OPPORTUNITY.

IN discussing, a few weeks ago, the grievance which exists for the majority of London medical students in that they cannot obtain a medical degree, we recalled that Sir Alfred Keogh, in the article he wrote for the *Proceedings*¹ of the Special Clinical and Scientific Meeting of the British Medical Association held in London last April, claimed that the Imperial College of Science and Technology in South Kensington was in fact a three-faculty university, and asked whether there was not in the history of the Kensington movement an example which might well be followed by the London medical schools.

The Kensington movement went a little further forward when a deputation from the Imperial College had an interview with Mr. Balfour and Mr. H. A. L. Fisher last month, to point out the position of the students of the College with regard to university degrees. Lord Crewe, who headed the deputation, said that the students of the College suffered in competition with those holding degrees, and pointed out that there were three courses open. The one was that the Imperial College should be constituted a university, with faculties in science and technology but without other faculties usually found in a university; the second, that it should be empowered to grant its own degrees as a college; the third, that it should be enabled to award degrees of some other university, presumably the University of London, on the sole testimony of the College professors. Adoption of the third course would mean either that the College would cease to have the independence and elasticity with regard to the curriculum which it regarded as fundamentally important, or that the same degrees would be given for two entirely separate examinations; that course, therefore, it was hoped would not be adopted. He urged, on the other hand, that though the limitation of faculties in a university or the grant to a college of power to award degrees were novel in this country, they were not unprecedented. The College was not actuated by jealousy of the University of London, but was convinced that the present position was hampering the higher form of education with which it was entrusted. Greater London, with a population of $7\frac{1}{4}$ millions, was, he argued, as much entitled to two universities as Lancashire with $4\frac{3}{4}$ millions or the West Riding of Yorkshire with 3 millions. Mr. Balfour, as was to be expected, made a non-committal reply, but promised that both he and Mr. Fisher would give the fullest and most serious consideration to the matter.

Mr. Balfour was concerned in the matter because, as Lord President of the Council, he is the Minister responsible to Parliament not only for the grant of charters to universities, but also for the work and expenditure of the Department of Scientific and Industrial Research, and will, we hope, before long be similarly responsible for the Medical Research Committee. It is a happy circumstance that at this time Mr. Balfour should be the Minister on whom these responsibilities rest, for the bent of his mind enables

him to appreciate the needs of science; his long experience in the greatest offices of the State has provided him with many instances of the immense services science can render to the nation, and there is no man in public life whose guidance in such matters will be more confidently accepted by public opinion—

Statesman, yet friend of truth
 of soul sincere,
 In action faithful, and in honour clear,
 Who broke no promise, serv'd no private end,
 Who gained no title, and who lost no friend.²

Already during the few weeks he has held his present office Mr. Balfour has taken several opportunities to show his sympathy with the aspirations of scientific men with regard to education and research.

Clearly there is a close parallelism between the position of the institutions which have combined to form the Imperial College and of their students on the one hand, and the position of the medical schools in London and their students on the other. The difference lies in the complete absence until quite recently of any financial support by Parliament for the medical schools. Even now the financial support given is on a very small scale. As early as 1858 the demand for scientific education had gathered force enough to induce the Government to establish a School of Mines; gradually there grew up in association with its special work, scientific teaching in other subjects: this was consolidated and systematized in the Normal School of Science, which eventually, in 1890, became the Royal College of Science, and was incorporated with the Royal School of Mines. Meanwhile the corporation and guilds of the City of London had established their Technical College; so that at South Kensington there existed three colleges—the Royal School of Mines, concerned to give a scientific and technical education to those intending to engage in the mining industry; the Royal College of Science, providing systematic instruction in the various parts of pure science; and the City and Guilds College, devoting its energies to applied science and technology, especially in relation to civil and electrical engineering. The charter of the Imperial College of Science and Technology was granted in July, 1907, and it has developed its activities in various directions. There are in the department of biology alone five professors, with staffs and laboratories, dealing respectively with botany, zoology, applied physiology and pathology, the technology of woods and fibres, and entomology. Arrangements have been made in all departments for special courses of advanced lectures of a post-graduate character, as well as for the extension of research facilities.³ There is therefore a great deal of justice in the Rector's plea that the College is virtually a science university, since it provides the vocational training of men intended for the professions of chemistry, engineering, economic biology, and so on; and, as he said also, there is in the story of the history of the Imperial College a lesson and perhaps a model for medicine. "Combination, discipline, establishment of principles have carried Kensington as far as it has yet gone. Similar efforts in London medicine should lead to similar results." The Imperial College would, we make no doubt, prefer the first alternative Lord Crewe mentioned—namely, to be constituted a university. There are objections to such a plan, and they will no doubt have considerable weight with the Privy Council and

² Said by Pope of the younger Cæsars, and applied by Joseph Chamberlain to Mr. Balfour, October 15th, 1902.

³ *Calendar of the Imperial College of Science and Technology, London, for 1919-20.* London: Eyre and Spottiswoode, or through any bookseller, 1s.

the Board of Education. Their force would be diminished if the medical schools in London were quickly to come together and put forward an appeal that, under the new conditions brought about by the establishment of university hospital units with the help of money voted by Parliament, they should be formed into the medical faculty of the university the Imperial College desires.

THE TOXIC EFFECTS OF ARSENO-BENZOL PREPARATIONS.

In a recent publication of the Medical Research Committee's Special Report Series, Surgeon Lieutenant-Commander R. J. G. Parnell and P. Fildes give a clinical study of the toxic reactions following the intravenous injection of novarsenobillon, or neokharsivan, into 1,250 men at the Royal Naval Hospital, Haslar, between October 18th, 1917, and June 30th, 1918.¹ The great majority of the men were suffering from the early stages of syphilis, and they were practically all treated on the same plan—that is to say, six doses of 0.45 gram were given by intravenous injection, with two clear days' interval between the doses. Toxic results ascribed to the drug alone occurred in 55, or 4 per cent., of the 1,250 men, of whom 23 had more than one reaction, so that there were 78 reactions, or about 1 per cent., among 6,588 injections. It appeared that these toxic symptoms were specially likely to occur with the administration of the third dose, and that if no reaction occurred then the probability of a subsequent reaction was considerably reduced; in other words, if the first three doses do not contain sufficient toxic material to produce symptoms, it is unlikely that the man will be susceptible to further doses. This observation militates against the commonly expressed view that the toxic reactions are due to accumulation of arsenic in the body from a too rapid succession of doses, for, if this were true, the later doses should be increasingly often followed by reactions.

The authors point out that two groups of symptoms following the intravenous injection of salvarsan preparations must be distinguished from those caused solely by the arsenic; these are the endotoxic reaction and "water fever." The first is almost certainly due to the sudden liberation of endotoxin from the spirochaemes by the destructive action of the drug; they are to a greater or less extent constant after the first, and are occasionally seen after the second, injection in cases of early untreated syphilis; there is pyrexia, usually starting six to ten hours after the injection, and there may be a chill or nausea or vomiting; but the temperature becomes normal in a few hours and there are not any further bad effects. The other form of reaction, known as "water fever," which at one time constantly occurred, is ascribed to the presence of protein derivatives from the bodies of bacteria in the water before sterilization. This reaction can be avoided by sterilizing the water immediately after distillation and using it within a short time of opening the sterile flask. The water fever starts very soon after the injection, often within half an hour, and when a large injection has been given there is often a rigor and there may be cyanosis and severe general symptoms. Analysis of the toxic symptoms due to the arsenic showed that fever occurred most frequently (in 85 per cent.), and varied in its onset and course; in one instance it persisted for fifteen days. Skin lesions, usually erythematous or macular, were noted

in 69 per cent., headache in 60 per cent., suffusion of the eyes in 47 per cent., vomiting (usually associated with skin lesions) in 27 per cent., oedema and pains in various parts of the body each in 16 per cent., jaundice and albuminuria each in 3.6 per cent. No fatal case is recorded.

Before the introduction of salvarsan remedies benign jaundice was known to occur in the early stages of syphilis and had been estimated to supervene in 0.3 per cent. Recently the incidence of this jaundice has attracted more attention; thus, among 30,377 military cases of syphilis treated by salvarsan preparations, it was reported in 0.56 per cent. Jaundice appearing after intravenous injections of salvarsan is usually ascribed to the effect of arsenic on the liver, but Milian² insists that the real cause is syphilitic hepatitis, and that for its cure the administration of mercury by the mouth, so that it may be absorbed from the alimentary canal and conveyed in considerable quantities to the liver, is much more satisfactory than intravenous injection of salvarsan. In the pre-salvarsan era acute atrophy of the liver was known to supervene on the early stage of syphilis, but it was extremely rare; in 1909 Dr. Parkes Weber collected 53 cases, and in some of these cases the condition was subacute rather than acute. Since the introduction of salvarsan remedies these fatalities have become less rare, and during 1918 a number of cases were reported by MacDonald, by Fenwick, Sweet and Lowe, by Veal and Wedd. More cases were recorded in 1919; thus Strathy and Gilchrist³ observed seven cases confirmed by necropsy, and described a characteristic x-ray picture, the upper surface of the liver being more dome-shaped than normal, so that the organ becomes pudding-shaped or helmet-shaped, and the angle formed by the junction of the shadows of the upper surface of the liver and the vertebral column acute instead of the normal right or obtuse angle. A case presenting some special features and giving rise to some interesting comments has recently been recorded by Stewart, Vining, and Bibby.⁴ The patient, a young woman aged 21, received four injections of 0.45 gram each of galyl (tetraoxydiphosphaminodiarsenobenzene), and rather more than two weeks after the fourth dose was jaundiced for two days, looked ill, and was tremulous. Three months after the last dose of galyl she was given a general anaesthetic (ether) for the removal of labial condylomata, and died an hour later without recovering consciousness. The necropsy showed a large fleshy thymus weighing 17 grams, and, though this suggests that death may have been really due to lymphatism and not to the grave changes in the liver, the authors, while mentioning the notable enlargement of the Malpighian bodies in the spleen, state that no conspicuous lymphatic glandular enlargement was present, and, possibly wisely, do not adopt this view. The liver was small, weighed 38 oz., and showed typical red and yellow atrophy, the latter greatly predominating. There was evidence of much new formation of bile ducts, but none of regenerative hyperplasia of the liver cells. Chemically the liver contained an insignificant trace only of arsenic. The appearances closely resembled those seen in the fatal toxic jaundice due to trinitrotoluene, except that the

fatty degeneration of the existing liver tissue was much more prominent and that there was no evidence of biliary stasis. The hepatic changes were regarded as directly due to the galyl, but it is noteworthy that jaundice was transient and that clinically there was no suspicion of hepatic disease. The authors incline to the view that the patient was on the way to recovery when the general anaesthetic produced such an effect on the already injured organ that death immediately ensued.

In connexion with the hepatotoxic action of galyl and other arseno-benzene preparations, emphasis is laid by Stewart, Vining, and Bibby on the clinical and pathological resemblance of these cases to the toxic jaundice due to poisoning by trinitrotoluene, dinitrobenzene, and trinitrophenol (picric acid); and, as the chemical group common to all these substances is benzene or one of its derivatives (toluene or phenol), it is suggested that this group is the essentially toxic factor as far as the liver is concerned.

PATERNALISM OR LAISSER FAIRE?

THE doctrine of "laissez faire" dates from Colbert, one of the greatest financiers who ever controlled the affairs of a big nation. Dr. Arthur Shadwell has recently given the reference to Colbert's words; they were: "La liberté est l'âme du commerce. Il faut laisser faire les hommes qui s'appliquent sans peine à ce qui convient le mieux."

The address given by Dr. Baskett, of Rayleigh, to the South Essex Division of the British Medical Association, published at page 40, is a disquisition on the application of Colbert's dictum to a particular case. His argument may be stated as follows: To ensure internal peace and prosperity in a nation real wages should be high. They are high under conditions of "laissez faire." Government paternalism is the antithesis of "laissez faire," and increases taxation, which is always passed on to the masses of the people. Thus any increase of taxation reduces real wages, for however much nominal wages are increased they are always in the position of trying to catch up the increase in the cost of living, which increase is magnified by any rise in taxation. Dr. Baskett then goes on to argue—supporting his argument by reference to history—that real wages are lowered by corn laws, by protection, and by Government schemes for bettering the lot of the poorer industrial classes, because all such legislation involves extra taxation. He believes that the Insurance Act was an example of such legislation, and that the bulk of the cost of the National Insurance scheme comes ultimately out of the pockets of the poorer industrial classes, and therefore lowers real wages. He takes tuberculosis as a typical "disease of poverty," which in one sense it is, since underfeeding undoubtedly appears to increase its incidence. His contention is that the statistics prove that tuberculosis mortality varies inversely with real wages. He shows that for the fifty years before 1896 the mortality from tuberculosis in this country fell steadily and progressively, and we think he is right in saying that it was expected that after 1896 the rate of decline would continue even more rapidly, and that the hope that tuberculosis would disappear as a serious factor in the national statistics did not then seem altogether unreasonable. This hope has not been fulfilled: the rate of decline was interrupted by an increase, at first relative, then absolute.

Dr. Baskett limits his inquiry to the end of 1915, so that the effect of the war, whatever

it may prove to have been, is not a disturbing influence. It must, of course, be remembered that the effect of the increased incidence of tuberculosis is only seen in mortality statistics two years or so, on the average, after the rise in incidence really begins. Those persons who died of tuberculosis in 1915 must on the average have contracted the disease in 1913—that is to say, before the war. At the same time it must be remembered that those who died in 1913 must, on this showing, have contracted the disease in 1911—that is to say, before the Insurance Act was passed. Dr. Baskett, however, does not maintain that the Insurance Act was more than one of the causes of the diminution in the rate of decline of tuberculosis. He associates it with increased taxation generally, due to increase of State and municipal expenditure, of which part is traceable to Workmen's Compensation, Old Age Pensions, and the Insurance Acts. This paternal policy, he holds, has lowered real wages, depressed the standard of living, and thereby raised the incidence of tuberculosis, which is a "disease of poverty." He finds much to support his view in the experience of other countries, and arrives at the general conclusion that when the fiscal policy of a Government includes protection, or when it sets itself by direct means, involving expense, to improve the conditions of the poor, the usual result is to encourage tuberculosis and raise its death rate relatively, if not absolutely; he deduces the particular result that as the Insurance Act enhances the cost of living to the poor it must take a share in the increase of tuberculosis due to the lowering of real wages.

Dr. Baskett, it will be seen, has the courage of his opinions, and it is to be noted that in discussing economic questions he speaks as an expert. He was at one time secretary of the Cobden Club, which is the great defender of free trade principles. With some readers this circumstance may prejudice the argument he presents, but it must be treated with respect, for it is the result of lifelong study. He had no difficulty in convincing his fellow members, and the South Essex Division of the British Medical Association, before which the address was delivered, adopted a resolution to the effect that there was a *prima facie* case justifying the institution of an inquiry into the effect of the Insurance Act upon the nutrition of the poor.

MEDICINE AND GOVERNMENT.

THE article published at page 56 tells briefly, but for the first time, we believe, in a consecutive manner and with sufficient fullness, the truth about the early history of the Medical Department of the Local Government Board. It makes plain the handicap with which the department started, owing to the subordinate position into which it was thrust. It is perhaps unnecessary to point the moral of the story, which puts our boasted capacity for efficient administration in a rather melancholy light. We hope with confidence that a new spirit inspires the Ministry of Health, and that within it the broader needs of health will not be placed in an inferior position through the growth of any particular subdepartment, such as that now concerned with housing. The forty-eighth and last annual report of the Local Government Board calls attention to certain resemblances between the position now, and in 1871. The Act which established the Local Government Board was designed "to concentrate in one department of the Government . . . the supervision of the law relating to the public health, the relief of the poor, and local government." It is pertinently remarked that "an observer unacquainted with the domestic history of the intervening

period might have heard with surprise the speech in which a Ministry of Health Bill was commended to the House of Commons in February, 1919. The main object of this bill, the House was told, was to concentrate the more important responsibilities of central government in matters affecting the health of the people in the hands of a single Minister, and by doing so to create 'a necessary instrument,' 'a vital and essential instrument' for improving the health services of the country. Had not the same main object, it might have been asked, underlain the legislation of 1871? and what were the reasons, in spite of all that had been achieved since the central authority was then created, which necessitated the proposal of 1919? The circumstances, it is said, do not afford an example of the circular motion of history, but "illustrate the tendency of English institutions to persist in growing with a freedom which necessitates periodical pruning and adjustment." It is this free growth that has made it necessary to recast the central administrative machinery so as to enable it to carry out the conceptions of 1871 in accordance with the rapidly growing needs and standards of to-day. The first Minister of Health is not likely to repeat the mistake of the first President of the Local Government Board; but we must hold fast to the principle that in a Ministry of Health medical opinion, founded on research, investigation, and experience, must have the determining influence. Medicine must be free to develop its powers for the benefit of the nation, not forgetting that "the price of liberty is eternal vigilance."

THE ORIGIN OF TUMOURS.

In an earlier discussion on the constitution of mankind Professor Hugo Ribbert had propounded the view that, while no certain knowledge can be obtained of the mode of origin of inherited characters, we have no grounds for supposing that a hereditary abnormality could appear *de novo* in any single ancestor of a family group. From the nature of the process we are compelled rather to refer its origin back to still earlier progenitors. Pursuing this line of thought, he came to the conclusion that transmitted abnormalities, like normal properties, are a latent legacy to mankind in general, and that though recessive in most individuals, they are dominant in a few. Ribbert now (*Deut. med. Woch.*, November 13th, 1919, p. 1255) applies this view to the consideration of neoplastic growths. It is admitted that the extent to which tumours may be recognized to be hereditary varies greatly in different instances. In some—for example, neurofibromatosis or multiple chondromata—heredity is frequent and obvious: while with other types—ovarian cystoma and even carcinoma—it appears from time to time. Apart from such evidence of transmissibility, however, it appears certain that, of simple tumours, a large number can be derived only from a congenital abnormality. It is difficult to believe that a delimited, autonomous growth, composed of apparently normal fat cells, blood vessels, striated muscle fibres, or chromaffin cells of the suprarenal, can be produced by any form of irritant in the widest sense of the term, acting during adult or even during embryonic life. These tumours must find their origin in a germ composed of cells which during early development have become separated structurally and functionally from their natural sphere. Ribbert evidently believes that the isolation of these tumour germs is a hereditarily transmissible character which may be expressed to a greater or less degree by all tissues. In the application of this view he goes further than has generally been accepted regarding the relation of embryonic rests to tumour growth, as he maintains that unless an embryonic rest has been present in a part no tumour can develop. Even in relation to the carcinomata the same proposition is maintained, although it is admitted that frequently its applicability in this form of tumour is less obvious. In some carcinomas—for example,

rodent ulcer or carcinoma developing from papilloma—it is a sufficiently probable view. A difficulty for the theory is presented particularly by carcinomas which arise at the site of action of some known irritant, such as x rays or in Sweep's cancer; but it is pointed out that carcinoma is not an invariable sequel to these special forms of irritation, and that when it does develop it is generally from a single focus, and never as a general carcinomatosis of the whole affected area. The contention, therefore, is that it is only in certain spots that cells are present which have the faculty of cancerous growth in response to the irritant, and that in absence of such cell-groups no tumour appears. Possibly failure hitherto to produce cancers by continued irritation may thus be explained. The article crystallizes into a very definite and complete form a hypothesis which must have been entertained at one time or another, and in more or less fully developed fashion, by many investigators of the subject since the time of Cohnheim, and it must be admitted that it contains at least as much probability as any other hypothesis that has been made regarding the etiology of tumours. As Ribbert himself points out, this view, if correct, leaves us no hope of being able to control or prevent tumour growth, except in so far as we can diminish the incidence of recognizably dangerous forms of irritation, and these, unfortunately, seem to account for the few and not for the majority of morbid growths.

ANTHRAX INFECTION BY BRUSHES.

WE published last week (p. 25) some information supplied to us by Dr. Henry T. Maw with regard to the origin and prevalence of anthrax in this country at the present time. Dr. Maw referred particularly to the danger due to the importation of foreign-made—especially Japanese—brushes used for medical and toilet purposes, such as throat brushes, toothbrushes, and shaving brushes. The Ministry of Health now announces that in the last few weeks several cases of anthrax have occurred in this country, two of which have been fatal, and that in a substantial proportion of these it has been found on inquiry that the infection was from new shaving brushes recently imported from Japan. In consequence of this, samples have been taken by the Ministry from several consignments of Japanese shaving brushes which have been found to be infected with anthrax germs. As several consignments of these brushes have now been distributed throughout the country, it is impossible for steps to be taken to discover them all, and no test of samples would provide adequate safeguards. Retailers and individual purchasers of shaving brushes are therefore advised to consult wholesalers or dealers as to whether an assurance can be given that the purchase is not one of a batch recently imported from Japan; without this assurance such brushes must be viewed with suspicion. The Government, it is added, is taking steps with regard to the further importation of shaving brushes.

UNIVERSITY GRANTS COMMITTEE.

It will be remembered that last June the Treasury, in consultation with the President of the Board of Education, the Secretary for Scotland, and the Chief Secretary for Ireland, appointed a University Grants Committee "to inquire into the financial needs of university education in the United Kingdom and to advise the Government as to the application of any grants that may be made by Parliament towards meeting them." Sir William Osler accepted nomination to the Committee, but after further consideration resolved some months ago to retire. His place has been taken by Sir Wilmot Herringham, K.C.M.G., consulting physician to St. Bartholomew's Hospital. While the war was still in progress the Government had come to the conclusion that the existing provision for aiding university education must be increased and consolidated. A survey of the needs of the universities showed that a

considerable increase in the parliamentary grants was urgent, and that the allocation of the grants could best be determined on the advice of a single body which could consider the needs of university education throughout the United Kingdom. The intention is that the method of distribution shall be such as to give the individuality of each institution free play and safeguard the legitimate interests of university autonomy. In the estimates for this financial year—April, 1919, to March, 1920—the annual recurring vote for universities and colleges in the United Kingdom was raised to £1,000,000,¹ and a special non-recurring vote of £500,000 was made "for special grants in aid of certain universities, colleges, medical schools, etc., to assist them to re-establish their work on a basis of unimpaired efficiency" after the war. In these amounts the grants for agriculture and training of teachers are not included; they will continue to be made by the Board of Agriculture and the Board of Education respectively. The annual sums allocated to the different institutions will take the form of inclusive block grants to be expended at the discretion of the governing bodies, will remain fixed for a prescribed period of years, and will be reviewed at the end of those periods. The University Grants Committee, which will maintain contact with the other Government bodies concerned, will be directly responsible to the Treasury as the authority with financial jurisdiction extending over the whole of the United Kingdom. The grants will be paid by the Treasury. The Committee now consists of Sir William McCormick, LL.D., chairman; Dr. William Bateson, F.R.S., formerly Professor of Biology at Cambridge; Sir Dugald Clerk, K.B.E., F.R.S., until recently Director of Engineering Research to the Admiralty; Sir J. J. Dobbie, F.R.S., Principal of the Government Laboratories, London; Miss S. M. Fry; Sir Wilmot Herringham, K.C.M.G.; Sir F. G. Kenyon, K.C.B., Director and Principal Librarian of the British Museum; Sir Stanley Leathes, K.C.B., a Civil Service Commissioner; and Sir J. J. Thomson, O.M., F.R.S. President of the Royal Society.

THE LONDON SCHOOL OF TROPICAL MEDICINE.

THE London School of Tropical Medicine will, it is hoped, be able to begin work in its new central premises before the end of this week. The house is a lofty building of eight stories, at the south-west corner of Euston Square, and abuts at the back on a part of the buildings of University College. It is a new building, but it has already been used at various times as a nursing home, a hotel, and during the war as an officers' hospital. The upper stories are being arranged as wards, and a large number of small wards will be provided, which, it is believed, will be found very convenient for the special class of cases the hospital will receive. On the middle floors laboratories are being provided for the several departments of the School, and offices for the Tropical Diseases Bureau, which will shortly be removed there. The joint library of the Bureau and the School will be placed on the ground floor, with a book store in the basement, where also will be a common room.

MEDICINE IN BOLSHEVIST RUSSIA.

A CORRESPONDENT has published in the *Medizinische Klinik*, Berlin, for October 26th, an account of conditions in Russia as they affect the medical profession. It appears that, with other cultured classes, the doctors of Russia have suffered greatly since the outbreak of the Bolshevist revolution. They were numbered among the "bourgeois," and of the various accusations hurled at them the chief was that only the rich benefited by their treatment. The first doctors to suffer under the Bolshevist Government were those in public departments, such as prisons and factories. They lost their positions, and were supplanted

by so called medical assistants, or by army surgeons; between these there was naturally much friction. In private sanatoriums the lower members of the staff only demanded higher salaries, but in the Government hospitals, or in such military hospitals as still survived, more serious conflicts often arose, and doctors were daily attacked and imprisoned. The position of the doctors in military hospitals became dependent on the goodwill of their subordinates. The medical administration department ceased to act, and its office was usurped by a special medical commission in the local Soviet. The private practitioner suffered also; his fees were not raised, and the number of private patients grew very small. In the winter of 1918, for instance, doctors were found who still received only from two to three roubles for a visit. Well known professors were spared this distress, as they retained their high fees; later they were numbered by the Bolsheviks as among the "grand bourgeoisie." The cultured classes as well as artisans refused to recognize any necessity for higher remuneration for medical work. With the gradual rise in the wages of workmen and officials came an increase of salary for the medical officers employed in public positions. This, together with increased food rations for medical men in official posts, attracted many doctors, including older members of the profession, to the Bolshevist government. In the spring of 1918 many of the cultured classes took part in communal affairs, and many doctors entered the newly formed Red army, in which no special declaration of solidarity was demanded of them. They were obliged only to declare themselves neutrals. The doctors were exempted from the wholesale arrests of the summer of 1918. The outbreak of cholera at this time obliged the Government to take various sanitary precautions, and these included an increase in the number of State medical officials. But the terrible scarcity of food, which drove the poor and hungry to search for something eatable even in the dust heaps, hindered and retarded any effective control of the disease. The Bolsheviks and the doctors were able to combine peaceably in purely medical work; but disagreed when obliged to form joint committees. When the inhabitants of every town were classified, the Government placed the doctors in the third class, among such as were of little use to the community. They were thus placed on the same footing with lawyers and artists. The persons in this third class received a weekly food ration barely sufficient for one day. On this account the doctors were most thankful when allowed to receive their fees in kind. When, in October, 1918, the measure for lodging the proletariat in the houses of the rich was enforced, two rooms were allotted to each doctor for the pursuit of his calling.

HISTORICAL SURGICAL INSTRUMENT CASES.

AS was announced in the *JOURNAL* of December 6th, 1919, Professor A. Keith has displayed in the museum of the College of Surgeons Dr. Livingstone's surgical instrument case brought back with his body from Africa; it will be on view till the end of January. Mr. Alban Doran, at Dr. Keith's suggestion, has arranged by its side several similar boxes of instruments, that have been on their travels with more or less illustrious surgeons and spent many years in inglorious retirement, forgotten, in the instrument room. Dr. Robert H. A. Hunter's army surgeon's case was used by him all through the first Afghan war; he marched in 1838-39 through the Bolan Pass to Cabul, returning by Quetta and Kelat. The case was recently presented to the College by its late owner's daughter, Miss Hunter. There is also in this group a navy amputating case once belonging to Joseph Bellot, who first saw service in H.M.S. *Pegasus* in 1789; his nephew gave it to the College in 1873. Beside it is the case of a French army surgeon who was killed in Egypt in 1801. It was presented to the College in 1811 by Surgeon-General Thomas Kent; Mr.

¹ The total includes £29,700 for intermediate education in Wales.

Clift, then Conservator, clearly suffered from the insular prejudices of his day, as in his note in the catalogue he speaks scornfully of the instruments, which show "the miserable state of hardware manufacture in Paris." Experts in surgeons' cutlery, however, have examined them recently and found that the steel is good and the workmanship excellent. Mungo Park's surgical pocket case is also on view; he lost his life in Africa in 1806, but before leaving England in the course of the previous year he gave the case to Sir Anthony Carlisle "for a professional memento"; Carlisle gave it in 1816 to Mr. Bartley, of Mitcham, Surrey, for his kind attentions to a sick relative. Mr. Bartley's daughter presented it to the College. Lastly comes a case containing a saw, knife, and catlin set in agate handles, and an ivory tourniquet, a beautiful sample of old-fashioned surgical cutlery; unfortunately, the name of neither its owner nor donor is recorded.

SCANDINAVIAN MEDICAL JOURNALS.

THE well known *Nordiskt medicinskt Arkiv*, first published by Axel Key of Stockholm in 1869, is appearing in a new guise. Henceforward the journal is to be divided into two parts, known respectively as *Acta medica Scandinavica* and as *Acta chirurgica Scandinavica*. The editors hope that by giving their papers a neutral, Latin, name they will make a wider appeal. Under the old title would-be readers have been put off by taking it for granted that the contents would be in a language quite unknown to them. They have thus missed a number of scientific contributions of the greatest value. The contents are in English, French, or German, according to the author's predilection or choice. The editors of *Acta* hope to be able to publish papers from foreigners in all countries, according as room may be found for them. The journals are therefore of interest to everyone, and, judging by the numbers which we have already seen, the standard of scientific work published is likely to be high. Norway, Sweden, Denmark, and Finland furnish assistant editors and committees. It is to be hoped that their desire to overcome their geographical isolation from the great English and French speaking nations will meet with the warm response which it deserves. Anyone who has travelled in Scandinavia will agree with us when we say that we have many temperamental characteristics in common with the peoples of those countries, and that nothing but good to all concerned can come from a closer scientific liaison between us. The editor of *Acta medica Scandinavica* is Professor I. Holmgren of Stockholm, of *Acta chirurgica Scandinavica* Professor Einar Key, also of Stockholm. The journals are published by P. A. Norstedt and Son of the same city in an attractive format; price 20 Swedish crowns, six numbers to the volume.

THE FRENCH ARMY MEDICAL SCHOOL.

THE French Army Medical School at Val de Grâce, the regular educational functions of which were suspended during the war, recently resumed its ordinary work. The returning students were welcomed by the director, Dr. Jacob, in the presence of a large assembly of distinguished members of the Paris Faculty. M. Jacob said that the medical service had lost between 4 and 5 per cent. of its personnel but it had achieved success. Typhoid fever, which was severe in 1914, was overcome during the early months of 1915 through antityphoid vaccination. The net result was that in this war the number of deaths from wounds was very much larger than the number of deaths from disease. M. Toubert related the history of the Abbaye of Val de Grâce, which was transformed into a military hospital in 1793, when France was menaced by enemies on all frontiers. The Military Governor of Paris, in bringing the ceremony to an end, said that the Army Medical Service had deserved well of the country by maintaining the number of effectives and keeping constantly in repair the weapon with which victory was achieved.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

THE growing importance of physical methods of treatment especially electro-therapeutics and the remedial use of x rays, is now generally recognized. This is shown by the movement to give full staff rank to the medical officer in charge of this department of hospitals. The subject indeed becomes more complex every day, and calls for the whole-time services of the worker. It is important, therefore, that this branch of medicine should be kept only in trained and competent hands. *The Archives of Radiology and Electro-therapy* for December, 1919, in describing the results of the work of the British Association of Radiology and Physiotherapy, announces the now accomplished fact that the University of Cambridge has instituted a diploma in medical radiology and electrology, the first examination for which will be held in July, 1920. The regulations for the diploma are printed in full, as is also the required course of study, the syllabus of subjects, the fees payable, etc. A course of instruction in physics and electro-technics begins at Cambridge on January 20th, and in electrology on the previous day, to be followed by a course of lectures on radiology beginning on April 26th. Most of the well known workers on these subjects are to take part in the teaching, at any rate during the first course of instruction, and arrangements are made for lectures to be given both at Cambridge and in London. The importance of this new departure is evident; it means that the whole subject of physical medicine shall take rank fitting to its importance in the domain of medicine, and appropriate to the research which has been made on the effect of radiations and of electric currents upon living things. It should also ensure a supply of well-equipped specialists for various hospital posts, and prevent men practising this branch of medicine without ample previous training. Full particulars can be obtained from the secretary to the university committee for the diploma, Dr. Shillington Seales, Medical Schools, Cambridge, and from Dr. Robert Knox, 38, Harley Street, London, W.1. The University of Cambridge is to be congratulated upon its foresight in instituting this diploma.

POST-GRADUATE COURSE IN VENEREAL DISEASE.

WE are asked by Mr. E. B. Turner, F.R.C.S., chairman of the Medical Committee of the National Council for Combating Venereal Diseases, to state that a post-graduate course of instruction in the diagnosis and treatment of venereal disease is being arranged by Mr. Kenneth Walker, F.R.C.S., officer in charge of the venereal department of St. Bartholomew's Hospital. The course will be given at the venereal centre established by the Corporation of the City of London, in Golden Lane, and medical men who wish to take advantage of the scheme are asked to forward their names to the Medical Secretary, National Council for Combating Venereal Diseases, 81, Avenue Chambers, Southampton Row, London, W.C.1. It is proposed to hold the course on Thursday afternoons, at 5.30, and to limit the number of those attending to fifteen. Should the scheme induce more practitioners to apply, the course will be repeated; thus the first fifteen names will be accepted, and other applicants will be referred to a future course. Illustrative cases from the various clinics will be shown. The first course, to be limited to male practitioners, will probably start towards the end of this month.

WE regret to learn that Sir Thomas Fraser, F.R.S., Emeritus Professor of Materia Medica and Clinical Medicine in the University of Edinburgh, died on January 4th. Sir Thomas Fraser, who would have attained the age of 79 next February, retired from the active work of his chair in the spring of 1918.

THE EARLY HISTORY OF THE MEDICAL DEPARTMENT OF THE LOCAL GOVERNMENT BOARD.

In the recently issued forty-eighth and last annual report of the late Local Government Board is given a short account of the circumstances which led to the establishment of that Board in 1871. In this connexion it may be useful to recall some of the facts relating to the early days of the Medical Department of that body, and how the intention of those responsible for setting up a new Central Health Authority was defeated by the Board itself, and a great opportunity thus lost for improving the national health.

It is undeniable that this unhappy result was, to a large extent, due to the unfortunate combination of public health with the relief of the poor in the work assigned to the new Board. The old Poor Law Board furnished the Local Government Board's first president, secretary, and assistant secretaries; moreover, almost the whole clerical staff, along with the Poor Law inspectors, were transferred from the old to the new Board. The Local Government Board was thus, practically, the old Poor Law Board under a new name. The latter Board had had no medical department or medical adviser of its own, though it had been obvious for some time to competent observers that such a department was urgently required, if the interests of the sick poor were to receive due attention. The medical staff of the Privy Council, from 1858 to 1871 the central health authority for England and Wales, was transferred to the Local Government Board under Mr. (afterwards Sir John) Simon, its chief medical officer, of whom it may with truth be said that he did more than any other worker of the Victorian era to prevent disease and to prolong life. He had been medical officer of health for the City of London, and had been appointed later medical officer to the Central Board of Health, and, still later, to the Privy Council. For more than twenty years, therefore, before he came to the Local Government Board he had been busily engaged in sanitary administration and had acquired an unrivalled experience in preventive medicine. He brought with him to the Board in 1871 a brilliant group of nine devoted workers, each a specialist in some branch of public health. Among the best known were Seaton, Buchanan, Netten Radcliffe, Thorne, Ballard, Blaxall, and Dr. (afterwards Sir) Anthony Home, V.C. A little later William Henry Power joined them.

Simon himself was an F.R.S., and four others of his small band of medical inspectors subsequently received this blue riband of science. Three of them also ultimately succeeded, one after the other, to the office of medical officer to the Board, one receiving a knighthood and the other two the K.C.B. These facts show the high quality of the men who were the first members of the Board's Medical Department, and how deserving they were of confidence.

As far back as 1854 Simon had drawn up a scheme for the formation of a "Ministry of Health" in which investigation of industrial diseases and the supervision and regulation of unwholesome conditions of employment found a place along with other matters for improving the health of the nation. When the Local Government Board was established, the more thoughtful sanitary reformers of the time had misgivings as to the effects that might follow upon the conjunction of public health with the administration of the Poor Law. It was confidently expected, however, that separate secretaries would be appointed for each of the two branches of the work, that therefore the two interests would not clash, and that Mr. Simon would have the same liberty of action and powers of initiation in regard to the medical policy and work of the Board as he had when at the Privy

Council. Unfortunately for public health the president concentrated the duties in the hands of one secretary, the previous Secretary of the Poor Law Board. By statute the new Board was empowered to delegate the exercise of its powers to its secretariat, and Mr. Simon was informed that his department was only to be used for consultation for special inquiries, and that in all cases these inquiries would have first to be sanctioned by the secretary or by an assistant secretary. The effect of this was, practically, that Simon could take no action without the written permission of the secretariat. The groundwork of his plan for immediately improving the sanitary condition of the country was to make, by his medical staff, a survey of every district in England and Wales, and he asked for sanction to carry this out; also, in order to do the work without undue delay, he proposed the appointment of four or five additional medical inspectors. Most unfortunately for the country his proposals were rejected. All that he secured was permission to inspect, as occasion arose, certain districts in which a scandalous amount of disease was present, or where complaints had been made as to grave insanitary conditions. But the districts thus inspected formed but a fraction of the number that should have been visited, and the beneficial results were therefore comparatively small for the whole country. How great was the need at the time for this survey is shown by the following facts: There were no medical officers of health in office except in a few large cities such as London and Liverpool; what sanitary legislation existed was largely of the adoptive kind and seldom adopted; filth nuisances of the grossest sort were almost universal; the subsoil of many towns and villages was sodden with human excrement; midden privies stood in close proximity to shallow wells sunk in porous soil; sewerage and drainage were often defective or absent altogether; housing conditions were bad, and overcrowding was common; the so-called tenement houses of the poorer classes were "hotbeds of nuisance and disease"; the general death rate and the infantile mortality were excessive; statisticians of the day calculated that of about 500,000 deaths annually reported at least 125,000 were due to preventable causes. It may be added that in 1871 nearly 14,000 persons died of enteric fever and over 23,000 of small-pox; typhus and malignant scarlet fever were prevalent in many parts of England, and relapsing fever was appearing in London. At the same time cholera was epidemic on the Continent and had spread to ports in the Baltic, from which it had reached Hamburg, a place that often in the past had supplied the infection to England by means of shipping.

It is evident from all this that there was urgent need for a sanitary survey, but the Board's secretariat, obsessed apparently with the idea that the administration of the laws for the relief of the poor was the one thing needed, refused to listen to Simon or to allow his medical inspectors to rescue the nation from insanitation and filth diseases. This refusal was a bitter blow to Simon, with his great record of hitherto continuous progress. Unhappily another humiliation was awaiting him. In 1872 an Act had been passed making the appointment of medical officers of health and inspectors of nuisances compulsory in every sanitary district in England and Wales. In 1875 the Board decided to ascertain the sanitary state of the country and to advise local authorities as to these new appointments. It seems now incredible, but it is the fact that the Poor Law inspectors, now called "general" inspectors, were entrusted with this duty! These inspectors were gentlemen of good average education, well versed in the laws for the relief of the poor, but quite ignorant of public health or of sanitary administration. Simon had the humiliation of witnessing the harm these men were doing in dealing without expert advice with the formation of sanitary districts—mischief, it may be observed, from the results of which the sanitary service of the country is still suffering. The action of the Board can hardly be

explained by ignorance of the problems involved; it is more probable it was an aggravated instance of the antagonism which then prevailed among lay officials of the Board against the medical profession, an antagonism which is said still to linger in some Government departments. Other medical investigations which Simon wished to carry out were cut down or restricted, the Medical Department becoming more and more subordinate to the Poor Law work. Any medical inspector instructed to make an investigation was directed by the Board to write, before he began the work, to the Poor Law inspector of the district, intimating to him that it was proposed to make inquiry on such and such a date into epidemic disease or insanitary conditions, as the case might be. It was, we believe, very rare—at any rate in the earlier days—for any acknowledgement to be made of the medical inspector's letter, or for the Poor Law inspector to assist him in the investigation. There is no doubt the latter official resented what he regarded as the intrusion of a medical inspector into his district.

Another point which galled Simon was that correspondence with sanitary authorities, regarding matters arising, for instance, out of a medical inspection, had to be conducted by the clerks of the Board and the letters signed by a secretary. Letters drafted by the clerks of the Board often missed the point at issue, though the letters had passed through three or four hands. The obvious way to save time and labour would have been for the medical officer or his deputy to dictate in his own department the letter, which would then have been signed by him. Referring to this "circumlocution" method of the Board, Simon remarked in his *English Sanitary Institutions*: "Where medical officers of health were supposed to be advised on their official reports and on points of sanitary practice involved in them, not only does the signature of the secretary fail to add weight to the advice in the letter, but the advice may to some extent have had to adapt itself to the signature; for the common usages of professional life would hardly allow the central medical officer to express himself through a non-medical secretariat as freely as if he were writing in his own name. There would be difficulty in medical consultation correspondence on the treatment of disease if it were made similarly circuitous; if, for instance, a foremost London consultant, having to suggest to his professional brother in the country some different treatment for the squire's asthma or the lady's megrim, were not in direct correspondence with his fellow practitioner, but must have his medical suggestions adopted by the family solicitor and expressed to the distant doctor in the form of a lawyer's letter." Simon's position gradually became more and more untenable; and to him it was intolerably bitter to see great opportunities wasted or mismanaged by a hostile and sanitarily incompetent lay staff. He struggled on for five years, from 1871 to 1876, when he retired, a discouraged and disappointed man.

Considering the course of subsequent events it is impossible not to realize how much higher would be the present position of our national health, and how much higher also would be the status of the sanitary service of the country, if Simon's statesmanlike and practical proposals had received the attention they merited. It is a matter of notoriety that the brilliant work which he and his successors did at the Local Government Board was achieved in the face of official hostility and petty interferences; nevertheless many of the reports of the Medical Department under Simon are still regarded as classics in sanitary literature. Though somewhat late, Simon received ultimately some acknowledgement of his unselfish efforts on behalf of public health, for in 1887 he was decorated with the K.C.B. He died in 1904 at the age of 88. He was succeeded as Medical Officer of the Board by Dr. Seaton, whose name will always be honourably associated with the passing of various Vaccination Acts, and who will be remembered for his organization of public vaccination throughout this country. He, however, remained in office for only

three years. His health was bad most of the time, and he died a month after his resignation in 1879. His successor was Dr. (afterwards Sir George) Buchanan, who continued the struggles of the Medical Department against the oppression of the Board's secretariat, striving for a proper recognition of the importance of the medical work, and for a freer hand in taking steps to improve the public health. He carried on, with varying success, until 1884, when cholera again became epidemic on the Continent and threatened to invade England. By this time public opinion as to the prevention of disease had so far developed as to hold the central health authority responsible for taking proper steps to protect the country. For this or some other reason, a proposal by Buchanan to start a sanitary survey of the country was favourably considered by the Board and finally sanctioned, permission being given to engage six temporary medical inspectors to assist the permanent staff. This survey led to most gratifying results. Many badly administered districts were placed in a proper condition, many scandalous nuisances suppressed, water supplies improved and protected, proper sewerage and drainage provided, and other conditions made wholesome and sanitary. The district councils as well as their officials were deeply grateful for the help and advice they had received from the medical inspectors during the survey. Even the unsympathetic officials of the Board could not deny the good work that had been done, and later agreed to a fresh sanitary survey and the appointment of additional medical inspectors in 1892, when cholera actually invaded England. In 1892 Buchanan, whose health was now unsatisfactory, resigned, but his death did not occur until 1894. Upon Buchanan, as well as upon Simon, fell the heaviest part of the great struggle against the injustice inflicted on the Board's Medical Department.

Sir Richard Thorne succeeded Buchanan in 1892, and under him the Medical Department came in time gradually to receive better treatment from the lay officials of the Board, and in consequence much excellent work was then accomplished. The improvement of the relations of the Medical Department with the Board after 1892 was due to a great extent, to the firm attitude assumed by Sir Richard Thorne, and to the exercise of his diplomatic abilities and tact, which helped to smooth over some of the difficulties that had previously existed. We have not space to discuss further events in the life of the Medical Department under the leadership of Thorne and his successor, Sir William Power, and later under Sir Arthur Newsholme. The attitude of the secretariat towards the Medical Department in the Board's latter period was greatly improved and their relations were more or less cordial; but it may be said that the seeds of evil planted in the early days of the Board left their inhibitory influence on the national health to the very end of that authority's existence.

THE annual congress of the Ophthalmological Society of the United Kingdom will be opened at the Royal Society of Medicine on the morning of Thursday, April 29th, when the president, Mr. J. B. Story, president of the Royal College of Surgeons of Ireland, will deliver an address. In the afternoon there will be a clinical meeting at Moorfields Hospital, and books, museum specimens, drawings, and portraits belonging to the hospital will be exhibited. On the morning of April 30th a discussion on diabetes in relation to diseases of the eye will be opened by Sir Archibald Garrod, Mr. R. Foster Moore, and Dr. E. Spriggs. Papers will be read in the afternoon. On the morning of Saturday, May 1st, a visit will be paid to the special hospital of the Metropolitan Asylums Board for cases of ophthalmia neonatorum, and a discussion on the prevention and treatment of that disease will be opened by Dr. Gibbon FitzGibbon, Master of the Rotunda Hospital, Dublin, and Mr. M. S. Mayou. The openers of discussions and the readers of papers are allowed twenty minutes, and subsequent speakers ten minutes. Further particulars can be obtained from Mr. F. A. Juler, 24, Cavendish Square, London, W.1. Notice is given that all communications must be typewritten.

Scotland.

WESTERN INFIRMARY, GLASGOW.

CHRISTMAS was celebrated at the Western Infirmary, Glasgow, by an informal meeting of its supporters. Lord Glenarthur, Chairman of the Board of Management, spoke of the great responsibility that fell on the medical superintendent, Colonel D. J. Mackintosh, C.B., and the matron, Miss Gregory Smith, in carrying on the work during the war, and heartily welcomed back those members of the staff who had been on naval and military service. The Scottish Branch of the Red Cross Society, he said, had made a grant of £10,000 to provide and equip a building for massage, medical electricity, and remedial exercises, and friends had given the university £5,000 to establish a lectureship in electrical diagnosis and therapeutics in connexion with the infirmary. It had been possible to give the nurses on day duty a fifty-six-hour week, but to make further progress the public must provide funds for an addition to the Nurses' Home. The Countess of Glasgow then presented the prizes to nurses successful at the half-yearly examinations. In moving a vote of thanks, Sir Hector Cameron expressed the hope that the whole body of the medical profession and of the nursing profession would resolutely set their faces against any perpetuation of amateur nurses, an opinion which was received with applause. Congratulating the nurses on the fact that they were within sight of a statutory register, he warned them that it would not guard and protect them like a trade union; it would protect the public just as the Medical Acts protected the public, by enabling them to distinguish between qualified and unqualified practitioners.

England and Wales.

COUNTY HEALTH ADMINISTRATION.

A REVIEW of health administration in Cheshire with reference to the Ministry of Health Act, 1919, communicated to the Cheshire Insurance Committee by its clerk, Mr. F. T. West, has been published in a pamphlet. It is stated that in the county of Cheshire there are now nearly 300 separate organizations, including public, voluntary and charitable bodies, and others carried on by private enterprise, all interested in health administration, but working for the most part without co-ordination. It is admitted that the desired co-ordination must be built up little by little, but it is suggested that the first step should be the establishment for each area, whether it be county or county borough, of a central health authority on which every interest shall be represented and which shall be directly responsible to the Ministry, with subordinate health authorities for subareas where required. On this authority ratepayers, insured and non-insured, the medical profession and pharmacists should have direct representatives. Among other matters with which this authority should deal are specially mentioned housing and town planning, food inspection, instruction in cookery, extended supervision of shops, warehouses, and offices, as well as of factories, infant mortality, medical examination and feeding of school children, sick nursing, education in personal hygiene, additional institutional provision for tuberculosis including after-care, training and convalescent colonies, and physical and recreational training. It is suggested that the whole financial burden of health administration should be directly borne by the Exchequer, and that the constitution proposed for the health authority would render it capable of preventing wasteful expenditure. This suggestion runs counter to general experience in this country, and may be expected to excite opposition. A detailed list of the various health organizations operating in Cheshire is given, and an elaborate chart of a proposed scheme of organization and co-ordination, starting from the Ministry of Health as the supreme authority, and allocating the relative positions which should be taken by each of the present organizations.

CENTRAL MIDWIVES BOARD.

A meeting of the Board was held on December 18th, with Sir Francis Champneys in the chair. Out of the

four fresh cases heard three midwives were removed from the roll and the resignation of the other was accepted.

It was decided to comply with the request of the Ministry of Health to attend a conference on the question of approval as teaching centres of maternity homes established under the schemes of the Ministry of Health; the Chairman, Lady Mabelle Egerton, Dr. Fairbairn, Miss Paget, and Mr. Sangster to be the Board's representatives.

Dr. Fairbairn having drawn the attention of the Board to a case of difficulty on the part of a midwife in obtaining medical assistance at the fees allowed by the London County Council, it was decided that copies of the letter be forwarded to the London County Council and the British Medical Association.

Correspondence.

FORERUNNERS OF HARVEY IN ANTIQUITY.

SIR,—In his learned Harveian Oration Dr. Raymond Crawford makes no allusion to the contribution of the ancient Egyptians to medical knowledge. Of course, a great deal of nonsense is written from time to time concerning these people and their mythical medical proficiency; indeed, it has been gravely asserted recently by an acknowledged authority that we are but "poor imitators" of them, and that in Egypt, 3000 B.C., doctors had very much the same knowledge as we have, and "that one is really obliged to ask oneself whether the world has progressed since the days of Sesostris to those of Pasteur, or if humanity goes back a pace in one direction, when she advances in another."

However, as regards their anatomical knowledge, especially as concerns the circulation, I think they "suspected" a great deal, which probably at a much later period has been assigned to others. Anatomy was chiefly studied on animals, and human dissections were only allowed for a short period, about 300 B.C. in Alexandria. Anatomy occupies a small space in the pages of the Ebers papyrus and is confined to two very small and very ancient treatises, which are painfully obscure. One has the pretension to impart full knowledge of the heart, including its functions, and it is interesting to notice that the same word—*moret*—designated both arteries and veins. According to this ancient anatomist, there is, in the heart, the vessels that supply all the members. The physician, the magician, or the enchanter, who puts the fingers on the head, on the nape of the neck, on the hands, on the region of the heart, on the arms and legs, everywhere the motion of the heart touches him, coming through the vessels which permeates all the members. The pulse is evidently alluded to, and it appears to me that the action of the heart as a pump is here recognized. There are, it is stated, four vessels in the nostrils, of which two give the mucus and two give the blood. There are four in the interior of the temples which furnish the blood to the eyes and afterwards supply all the humours which lubricate the eyes. There are four vessels to the two ears, two to the right side and two to the left. There are six vessels to the legs, three to the right and three to the left, which reaches to the sole of the feet. There are two vessels to the testicles, which supply the sperm, two for the thighs, and four for the liver, which supply the water and spirit producing all the humours that purify the blood, and two the kidneys, producing the urine. When the heart is diseased its work is imperfectly performed, the vessels coming from it are inactive, so that they cannot be felt; they are full of air and water. When the heart is dilated the vessels proceeding from it contain effete matter. If a suppurative disease occurs in the body abscesses are formed in various parts, the heart causing (evidently the septic matter) to traverse the blood vessels, producing fever and inflammation of various kinds in the body. The heart is in a morbid state while the fever lasts. It is quite evident that the facts underlying the circulation were known, and that the action of the heart as a pump was recognized.

Incidentally, in the small treatise alluded to thoracic aneurysm (then very common, doubtless from the nature of the employment of the majority of the inhabitants) is accurately described.

If the aorta is made to project, to protrude, all the members degenerate, or become affected on account of the strain put on

the heart. If aneurysm is produced in the heart there is a sac at the confluens of the stomach and liver. The orifices of the heart and its vessels are protruded, and after they become inflamed the sac bursts.

Some of the anatomical information quoted can be referred to a period about 6,000 years ago, while the greater part was written about 1600 B.C. During the intervening period it must be admitted that but little progress was made in anatomical knowledge.—I am, etc.,

T. GERALD GARRY, M.D.

Consulting British Physician, Pístany (Postyún),

LOCAL CLINICAL LABORATORIES.

SIR,—I believe I shared the honour (together with Dr. Hugh Miller) of beginning the discussion on local clinical laboratories, so perhaps I may be allowed of your hospitality to reply.

All the evidence hitherto adduced has been in favour of many local laboratories and few central ones. The commercial laboratory has been shown to be undesirable for many reasons, the greatest of which is the absence of the pathologist at the bedside. "Clinical Pathologist" is a whole-hogger for the central laboratory, partly because there are only eight reliable histologists extant. I cannot resist a sly dig: Does he include himself? "Clinician" would have the pathologist out of the way as a competitor in practice. A pathologist might as fairly deprecate the handiwork of those general practitioners who do a little private pathology of their own. Abduction of patients, deplorable though it be, is not a peculiar attribute of the pathologist. I agree that if a patient is sent for an autogenous vaccine the doctor who sends him or her has the right to give the vaccine, but I am not by any means sure that this is always sound from the scientific point of view. Strictly speaking, the person with the greatest experience of vaccine therapy should administer vaccines.

It may be of interest to state that here in Eastbourne we have recently established a local clinical laboratory by our own initiative. The laboratory itself, with certain apparatus (about one-third), was provided by the generous foresight of the hospital authorities at my suggestion, backed by the Medical Committee. The rest of the apparatus, all materials and maintenance, are found by the pathologist who does therein both hospital and private work. Cleaning is done by a hospital servant, and the pathologist provides his assistant (one is at present sufficient). This scheme works well, and is fairer perhaps than when private work is allowed, assistants, salary, materials and maintenance are provided, as in some London hospitals. I think the Ministry of Health might easily adopt some even standard between these two extremes. If this were done, the problem of the local laboratory would be solved, for it need cost but little; it could be made self-supporting, and sound pathology could be made to cost less to the private patient.—I am, etc.,

Eastbourne, Dec. 29th, 1919.

A. G. SHERA.

"NEW LAMPS FOR OLD" IN OBSTETRICS.

SIR,—Dr. Shirlaw is under an entire misapprehension as to the objects and results of the system I am advocating. It is not a question whether the patient will not do well if she is left to nature. She may do so, but she will suffer a great deal of wholly unnecessary pain—pain, well described in the Old Testament as the "pains of hell,"—this suffering will be prolonged for hours, and she will often be left in a state of exhaustion and generally with a ruptured perineum.

All these evils are entirely obviated by the skilful use of forceps and chloroform. Since I have used Wagstaffe's instrument, I have never had a laceration of any kind; the time consumed, by the passage of the head, has been about five minutes, and the patient makes a rapid recovery.

In a consecutive series of a thousand labours there have been three cases of septicaemia.

The first had been left entirely to nature—not even an examination being made. She recovered.

The second had no lacerations of any kind. I was informed by a distinguished gynaecologist that she would certainly die. She made a complete recovery, and I subsequently found that she had attempted to procure abortion with a piece of wood.

The third case died, apparently of pulmonary embolism, on the fourth day of the fever. She had undergone a difficult craniotomy.

This gives a case incidence of 0.3 and a death rate of 0.1 per cent. There are hundreds of men in England who employ the same methods as I do whose experience is very much greater than mine and whose results are just as good.

To stigmatize such procedure as "a reign of force," or to draw comparisons with it and craniotomy or Caesarean section is, to say the least of it, ridiculous. Nor is it reasonable for anyone to condemn a system of which he has had no practical experience.

After all, this discussion is of little more than academic interest, for the future practice of midwifery depends neither on the theories of gynaecologists nor on the methods of general practitioners, but on the attitude of the general public. It is the expectant mother and her friends who will decide for us what line of treatment shall be adopted. The modern young woman is an enigma, but she knows her own mind on many things, and when she has to choose between being left to nature—already outraged by many thousand years of civilization—and the safe and speedy relief offered her by a skilful obstetrician, there can be little doubt what her decision will be.—I am, etc.,

London, E., Dec. 27th, 1919.

A. CAMPBELL STARK.

SIR,—I have read with interest Dr. Mears's reply to my letter in your issue of December 27th, 1919. While completely agreeing with him that the teaching of hospital obstetric physicians is not always sound, I see nothing in his arguments to make me alter my contention that watchful expectancy is sound midwifery and early interference on the slightest provocation is not—a contention in which, though only a general practitioner, I feel confident that I will be upheld by the majority of consultant obstetricians.

If we accept, as he evidently does, the modern view that labour is a pathological process, at least amongst civilized women, we must also accept the fact that any internal interference with its course is in the nature of a surgical operation. Given, for instance, a case of acute appendicitis, the surgeon will only operate in the patient's home when it is impossible to do otherwise. How much the more would he hesitate to remove an appendix under home conditions at the first sign of trouble in that region, or merely to prevent the development of such trouble! Yet an uncomplicated appendicectomy is no more difficult than forceps delivery or placental removal.

My reply to Dr. Mears's remark regarding the application of forceps twenty four hours after the child should have been born is contained in Barnes's adage: "We should wait to see what a woman can accomplish, not what she can endure." The italics are mine.

Dr. Mears first of all advocates prophylactic surgery, and then, to render his position tenable, would see us all specialists before being allowed to handle our instruments: which is a condition of things only to be hoped for at the millennium.—I am, etc.,

Blackheath, S.E., Dec. 27th, 1919.

WILLIAM CORBET.

SIR,—I notice that the chief argument brought by some of your correspondents against the frequent use of forceps in labour is the increased risk to the patient from (1) laceration of cervix, vagina, and perineum; (2) haemorrhage; (3) sepsis.

(1) I think every one agrees that forceps should not be applied until the cervix is completely dilated. With reasonable skill and care, therefore, laceration of the cervix should never be caused by forceps. My own experience is that tears of the vagina and perineum are more easily avoided when the head is completely under the operator's control, as it is when grasped by the forceps.

(2) Forceps should, of course, never be applied during secondary uterine inertia. If this rule be adhered to, I see no reason why haemorrhage should be more common with forceps than without. On the contrary, *post-partum* haemorrhage is more likely to occur in a case where the uterus is over-tired after a prolonged labour without assistance.

(3) With regard to sepsis; it should surely be possible nowadays to make reasonably certain of avoiding serious infection by hands or instruments.

Another argument we hear is that there is great risk of injury to the child's head when forceps are used. With reasonable care and skill there should be no risk of serious injury except in those very bad cases in which every one would agree that delivery could not take place without assistance. Personally I have used forceps in four or five hundred cases (40 to 50 per cent.), and do not remember among them any case of serious post-partum hæmorrhage, sepsis, or injury to the child (beyond a few bruises and abrasions in some cases).

I apply forceps in every case when the second stage is unduly prolonged if the head is presenting. Of course, occipito-posterior presentations should be allowed a longer time than occipito-anterior, so that reduction may, if possible, take place. To my mind, everything depends upon the skill of the operator. With reasonable skill the use of forceps should not increase the risk either to mother or child—quite the contrary. Skill can only come from frequent practice. The man who only uses forceps in extreme cases—say, two or three times a year—cannot acquire the skill and self-confidence which are necessary in a difficult forceps case. Dr. Mears mentions Dr. Park, who attended 3,900 confinements and only used forceps twice. He speaks of the avoidable agony which must have been endured by at least half of these cases. I agree with him; but my sympathy goes out even more to the two unfortunate women (probably very difficult cases) who were delivered with forceps by a man with that amount of practice in their use.—I am, etc.,

Leicester, Dec. 28th, 1919.

JOHN A. BARNES.

SIR,—The old controversy regarding the question of interference or non-interference in confinements which run a normal course—in other words, natural parturition—has again exhibited all the virulence of the past. I believe the last war of words upon this theme raged for several months in 1906, and since then I have heard or read nothing more confusing or enlightening.

The truth is, I believe, that it is quite impossible to lay down arbitrary rules that will suit all circumstances. Everyone attending an obstetric case should have a thorough knowledge of the technique underlying all operations and manipulations in the delivery of a woman, otherwise there is sure to be a certain percentage of bad results. And it is my opinion that the average medical practitioner who has been in practice for some years has acquired almost perfect skill and dexterity in the management of most obstetric cases. The maxims taught in the schools and laid down in textbooks are chiefly of value in guiding the tiro; after that much depends upon the experience, observation, and resolution of the practitioner. One of the oldest obstetric aphorisms is the soundest: "Meddlesome midwifery is bad midwifery." One correspondent advises us not to "stay with the patient until the cervix is dilated," even should "the baby be born before your next visit." That writer evidently has never practised in a wide country district like mine.

The percentage of operative interference of all kinds depends upon many factors. Possibly in dense industrial districts, with overworked women of poor physique, a conscientious practitioner may be compelled to use forceps and anaesthetics more frequently than I in a country district, where the women lead a healthy outdoor life and show few pelvic or other abnormalities. In towns the proportion of highly nervous women is much higher than here. These neurotic creatures frequently have their alarms increased by poring over trashy literature of the "silent sleep" parveyor, who is out to harrow their feelings with vivid descriptions of tortures suffered by women at the hands of callous doctors of the old school. Scopolamine-morphine treatment has a certain value in such cases, and is a great boon to the practitioner, its chief disadvantage being the close and constant attendance it demands. I have used it in nearly fifty cases, and I consider it more suitable for institutional treatment than in general practice.

I may be utterly wrong, but I think many town practitioners, and possibly some country ones, resort to the use of forceps upon very slight provocation, chiefly for reasons of comfort or convenience. With a skilful manipulator no harm may be done; but it is not good practice to undertake a needless operation, no matter how skilfully performed. If a case is progressing steadily and favourably,

even if slowly, and the patient's strength is well maintained, I consider it is taking an unjustifiable, if somewhat remote, risk to expedite or, worse still, hurry delivery; it is almost always bad treatment to attempt it before the end of the first stage of labour. With a little tact, or perhaps an assumed sternness, one can work wonders with most women. Fortunately most cases are quite normal, and patience, next to absolute cleanliness, is of the greatest importance.

I suppose all of us, early in our obstetric practice, employ forceps oftener than we do later after a more extended experience. The temptation comes most forcibly when we have acquired some skill in their use. Greater certainty in diagnosing the presenting part leads, in my opinion, to a less frequent resort to hastening delivery. The practice of examining women during pregnancy is an excellent safeguard, and it obviates many obstetrical catastrophes. A great deal of unnecessary traction is the result of ignorance; an occipito-posterior presentation detected early loses half its terrors, and, indeed, becomes as easy, in many cases, as a L.O.A. Let it get impacted in the cavity and the case is then of quite another complexion!

Much of the bad teaching of the schools has been responsible for bad midwifery. We can all remember the douching mania, not to mention the giving of ergot before the birth of the child, and the silly practice of completing the third stage in a panic of squeezing and kneading, with the inevitable danger of post-partum hæmorrhage due to pieces of retained placenta. Even writers of textbooks taken different views. Whitridge Williams instructs us to search always for the posterior ear when applying the left blade of the forceps; Webster, another American writer, stigmatizes such teaching as being "unscientific and ridiculous," and states that the blades lie safely only in one position—namely, right and left as regards the pelvis.

The only percentages we should be anxious to maintain are the percentages of good results, with healthy mothers and vigorous babies. That sounds like a platitude; but it is not always kept steadily in view. Midwifery being to many of us the sole department of our profession where we are called upon to do "major" work, we should take every means in our power to excel in it. A rise in temperature should cause us seriously to overhaul our methods and review our technique, and a dead fully developed baby should be accounted a disaster.—I am, etc.,

Helmsley, Yorks, Jan. 4th.

ALEXANDER BLAIR, M.D.

MODE OF QUININE ADMINISTRATION.

SIR,—In his letter in your issue of December 27th Sir Ronald Ross expresses a doubt "whether the therapeutic value of quinine always increases *pari passu* with the dosage," and in support of this view he states that in a series of cases 2 grains four times a day caused the parasites to disappear as quickly as 30 grains a day.

But is there not a fallacy working in the background of such reasoning? The amount of quinine which will cause the disappearance of parasites from the peripheral circulation is not an index-coefficient of cure, for a similar and as complete a disappearance will sometimes take place after an attack of untreated malaria. This fact serves to remind us that in administering quinine we are not curing the disease but only helping Nature to do so. The personal factor in each individual case is an "unknown x ," and it is vain to imagine that we can lay down any hard and fast rules as to dosage. Many people have died as a result of having had too little quinine, but for myself I have never seen one who suffered from having had too much. Since whatever we do we may err, let it always be in the safe, and therefore right, direction.

In my humble opinion, experiments on dosage conducted in England have little practical value, for those who make them are necessarily dealing with the disease at a stage when it is too late to think of cure. He who would cure malaria must act quickly and drastically, for when once the relapsing stage has supervened Nature, with her hand-maiden Time, alone can, and will, bring about the desired end. True we can still assist her with quinine, but the amount we give no longer affects the ultimate issue as it may in the first attacks. In this respect the analogy between malaria and syphilis is both interesting and instructive.—I am, etc.,

Farnham, Dec. 26th, 1919.

R. U. MOFFAT, M.D.

SIR,—I hesitate to add to a lengthy correspondence, but there is a point which has not been mentioned by your correspondents. In many cases of malaria, whether benign tertian, malignant tertian, or quartan, quinine given by the mouth fails to affect the temperature. In a few cases, even when intercurrent disease can be excluded, intramuscular or intravenous injections of quinine have little effect upon the temperature. In the latter cases the drug should be administered both orally and by injection.

Colonel W. H. Willcox (BRITISH MEDICAL JOURNAL, December 13th, 1919, p. 796) states that in certain cases "courses of treatment should commence with from three to six intravenous or intramuscular injections of quinine, and treatment carried on afterwards by oral administration." My point is that in these cases quinine should be given by the mouth during the courses of injections as well as afterwards. The result is even more striking.

Quinine in malaria furnishes by no means the only example of the beneficial result of the administration of a drug by a dual method.—I am, etc.,

Maidstone, Jan. 3rd.

S. G. ASKEY, M.A., M.D.,
Late temporary Captain R.A.M.C.

CONTRACTION AND RETRACTION RINGS.

SIR,—The question of the contraction and retraction rings is one to be decided by experience, and it is perhaps fortunate that experience has not been sufficient to establish their precise relations.

The evidence we have tends, in my opinion, to show that the uterine muscle is apt to contract—in obstructive cases to retract—wherever there is a sulcus or room for a thickened piece of musculature to find a locus.

My object in writing, stimulated by Dr. Lochrane's article in the BRITISH MEDICAL JOURNAL of January 3rd, is to maintain that in labour one may meet with a contraction ring where there is no evidence of obstruction or exhaustion. I came to this conclusion in a case where a patient (multipara) gave birth to a fetus in the seventh month. There was no obstruction in the pelvis, there was a breech presentation, and in due course the membranes were ruptured. I expected delivery to follow rapidly, but it did not, and traction on the legs failed to cause any progress. Exploration of the uterus revealed a contraction ring round the neck, and under chloroform anaesthesia dilatation was sufficient to enable the head to be scooped out of the uterus, and so the labour was easily terminated. A contraction ring of this sort is obviously differentiated from a retraction ring, inasmuch as there was no obstruction, and, being a breech case, it was situated quite high up in the uterine cavity.—I am, etc.,

London, W., Jan. 6th.

O. ECCLES.

PREVENTION OF VENEREAL DISEASE.

SIR,—Our attention has been called to a letter in your number of December 27th, 1919, from Mr. E. B. Turner and Dr. Otto May, making some comments on a pamphlet issued by this society. These gentlemen are at perfect liberty to place any construction on this pamphlet they think proper. The names of those who are associated with our society furnish sufficient contradiction to the imputation that we are animated by a desire to promote promiscuous sexual intercourse.

Our policy was clearly expressed in an address given by our treasurer, Sir William Arbuthnot Lane, at a meeting held at the Central Hall, Westminster, on December 16th, copies of which can be obtained on application to the honorary secretary.

For the information of your readers we enclose a general statement of our aims and objects, which we should be obliged if you would publish.—We are, etc.,

WILLOUGHBY DE BROKE,
President.

H. WANSEY BAYLY,
Honorary Secretary.

143, Harley Street, W. 1, Jan. 7th.

* * * The document enclosed states the aims and objects of the society as follows :

It is obvious that the best way of avoiding venereal disease is to abstain from promiscuous sexual intercourse. It is, however, certain that a large number of persons continue, in spite of moral teaching, to expose themselves to risk, and so to incur and spread disease among the community, the chief sufferers being women and children. Venereal disease is accountable for

a large proportion of cases of insanity, nervous diseases, loss of sight, and sterility. These diseases have become a menace to national health and prosperity, and infection can be prevented by means of self-disinfection, if properly applied, immediately after exposure to risk. It is therefore necessary :

- I. To instruct the public as to (a) the vital importance of self-disinfection at the time of exposure to risk as a preventive of venereal disease; and (b) the methods of application.
- II. To advocate such further steps for the prevention and ultimate eradication of venereal disease as may be deemed advisable.

SIR,—I was surprised to read the objections of "Surgeon Commander R.N." to the letter of Drs. Mary D. Sturge and Rose Lynch Molloy, which was a valuable reminder that the prophylactic scheme has its limitations, especially with women. It is indeed a serious error to state that "such diseases are very easily prevented." The world was not made for man alone, but also for woman, and the latter will be very seriously misled if she accepts the statement at its face value.

Moreover "Surgeon Commander R.N." will not find all his colleagues of his opinion. As a temporary surgeon lieutenant during the war I made it my business to collect opinions on the results of prophylactic treatment in the navy from as many "permanent" senior medical officers as possible. Their opinions varied, and none were as dogmatic as his. Most of them "thought it did a good deal of good," but would go no further than that. One stated that he could vouch for an instance where he knew definitely that prophylactic nargol and mercury ointment had been thoroughly applied at the time, and nevertheless failed.

What is "Surgeon Commander's" method of ascertaining if prophylaxis has been properly carried out? In many cases how can he know? Any one inclined to be dogmatic can easily say that because the prophylaxis has failed it cannot have been carried out properly. The psychology of the patient enters largely into the character of the reply he will give when asked whether he used prophylactic measures. He may falsely answer "Yes" merely to put himself in the right, especially if he knows that the medical officer holds strong opinions on the subject. Again, he may falsely answer "No," fearing to prejudice the diagnosis.

Lastly, "Surgeon Commander" apparently attributes any failure of the men to adopt effective prophylaxis to the medical officers "largely drawn from civil life." I and many other temporary medical officers have explained the benefits and methods of prophylaxis to the men many times, and supervised the supply of the necessary disinfectants, but have been handicapped in some instances by the lukewarm support or even apathy shown by some of our senior medical officers. The last surgeon commander under whom I worked was in charge of a big naval shore station, but he did not have one address given to the men, nor see that the necessary arrangements were made for them to obtain disinfectants.—I am, etc.,

December 22nd, 1919.

HEAR BOTH SIDES.

SIR,—In your issue of December 20th, 1919, there is a letter under this heading signed by "Surgeon Commander R.N." Much as we appreciate the motives of the writer in promulgating his experiences for the public good, we, on the contrary, greatly deprecate his insolent attitude towards temporary medical officers to whose negligence and stupidity he attributes many of the failures in venereal prophylaxis in the services. These medical officers are alleged to "damn what he and others consider the invaluable and almost certain benefit of prophylaxis." Truly a most remarkable observation!

We would humbly suggest that these sweeping remarks are scarcely accurate when including the large body of men who turned out to supplement the medical services; we protest against the low morale assigned to temporary officers by this critic.

Many of us were experienced in the science of venereal prophylaxis, many were actually "eminent," the remainder were surely sufficiently well versed in modern hygienic science to appreciate and to advise against this venereal scourge. We would be loath to think that we were the demoralized faddists that this correspondent suggests. As "Surgeon Commander" now informs us, the correct way to preach venereal prophylaxis is "by stealth." I fear that the measure of "stealth" employed by a large

proportion of permanent officers of the rank of "Surgeon Commander R.N." is too insignificant to be appreciated. Should they first attempt to put their own house in order probably they might allot some of their failures to their own permanent officers, who maybe are "too tired" to preach the doctrines of preventive medicine, or who may conveniently call to their aid the other formulated excuses with which "Surgeon Commander R.N." seems familiar.

As late temporary medical officers we have preached and practised prophylactic medicine to much advantage before joining the services and in the services, and so have a great many more of us who were "drawn from civil life." We maintain that the percentage is small of those temporary officers to whom it is imputed that they damn the progress of venereal prophylaxis by holding such views as "the punishment fits the crime" or "who have little faith from lack of experience, or conscientious objections to lecturing on the subject," or are even "too tired."

It was imprudent on the part of "Surgeon Commander" to assume so much, and improper of him to cast such aspersions upon a worthy section of an honourable profession.—I am, etc.,

December 31st, 1919.

"LATE TEMPORARY SURGEON."

SIR,—Dr. Herbert Butcher (January 3rd, p. 28) makes the following statement: "I fail to see that as medical men we have any concern with the moral aspect of the matter. That had much better be left to others."

This is a comfortable but entirely false doctrine, look at it from what point of view we will, whether moral or medical. It is as though one said of the treatment of tuberculosis: "We as medical men have no concern with the causes of the disease—bad housing, overcrowding, insufficient and unsuitable food, etc.; the treatment of the causes had much better be left to others; our business is to treat the disease as it arises."

In the matter of venereal disease we are faced with a symptom of a moral disorder, and we shall be guilty of malpractice if we are content merely to attack the symptom and do not "treat the cause." It would seem that the only effectual method of treating the cause lies in giving our children a better sex education than we ourselves received. Now, it is a firm belief among those who lay stress on the moral side of this question that the distribution of literature on prophylaxis and the issuing of "preventive packets" is going to neutralize that better education we so urgently desire for our children.

If there is any truth in this belief, is it not our duty to give to the views propounded by the "moralists" our most careful attention?—I am, etc.,

WILFRED A. RUSSELL.

Surrey County Asylum, Brookwood, Jan. 5th.

* * We have received a number of letters from readers in various parts of the country, repeating in different words the argument, already put forward by other correspondents, that the moral aspect of this question is one that closely concerns the medical profession.

CHRONIC PANCREATITIS.

SIR,—The letters on chronic pancreatitis concern my daily work, and I should like to ask for myself and others that the discussion should be brought within the reach of the general practitioner, who certainly would rarely make a section of the pancreas for microscopical inspection even if he suspected pancreatic disease. We come, then, to the urine, and most of those who examine urine regularly have noticed, when using the copper test, the greenish-yellow reaction, which thirty years ago was regarded as of sinister prognosis.

Those who have examined urine carefully and found no sugar have yet been obliged to conclude 4 per cent. sugar shortly afterwards. This occurred to a patient quite recently. Feeling ill, and suffering from epiphora, the tears coming to her lips she found were sweet instead of salt. Such facts as have been brought forward by your correspondents force upon us the necessity of recognizing the dextrinous precession of diabetes. How far, then, is dextrose in the urine of the same importance as microscopical examination of the pancreas? Again, what is the exact character and differentiation of the dextrose? For the dextrines I have examined are sensitive to the iodine test—say 1 gram to 4 litres. Neither Professor

Cushny's *The Secretion of Urine* nor the recent edition of *Practical Physiological Chemistry* of Professor Cole give us data. In the test which I have called the "carbohydrate test"—saturated permanganate solution 4 c.cm., dilute sulphuric acid 1 c.cm., and 1 c.cm. urine; elevation of temperature during ten minutes or more—would, I showed in the *BRITISH MEDICAL JOURNAL* some years ago, estimate lactic acid. I find that the oxidizables are in ratio to the specific gravity, the same as other constituents. So, taking 100 samples of non-diabetic urine, multiplying the temperature from 1° to 2.2° F. by 100, and dividing by the two last terminals of the specific gravity, we obtain a number of, say, 8. Although I suspect that dextrose, like alcohol, glucose, mannite, lactose, would alter that number, I am unable to say in the absence of experiment. If we could get dextrose amongst the suspects of the carbohydrates, or oxidizables, it would be a gain secured by this simple test. The carbohydrates offer wide divergencies as regards time of action, and dextrose, like the others, might be marked by its gravamen. Certainly the importance of the dextrose period of diabetes is urgent. Does the absence of dextrose precede the advent of sugar? Does the urine which normally converts or destroys small quantities of cane sugar, when recently passed, proved by my carbohydrate test, indicate similar conditions as the dextrose when this power is increased? Who can tell us?—I am, etc.,

Loudou, S.E., Dec. 14th, 1919.

J. BARKER SMITH.

FRACTURE DISLOCATIONS OF THE ANKLE.

SIR,—It Sir Arbuthnot Lane's views on the best methods of treating these fractures needed any further support, it could be obtained by a consideration of the difficulties met with by Mr. Rowlands¹ in using any other method. The case upon which Mr. Rowlands operated (Fig. 2) was an "abduction" fracture, and the easy way to get a perfect result would have been to expose the inter al malleolus, the bone displaced towards the centre of the foot, disengage it from its position under the lower end of the tibia, adduct the foot and bring the fragment into correct apposition with the surface of the tibia from which it had been torn, and finally fix it there with a small plate.

But Mr. Rowlands operated on the fibula, on the bone displaced away from the centre of the foot, and in spite of dividing the tendo Achillis and peroneus brevis, seems to have met with very considerable difficulty before he was able, by introducing a long screw, to reduce the deformity and fix the bones in perfect position. The cause of his difficulty is at once seen on examining the radiogram (Fig. 2). What is keeping the external malleolus and astragalus from slipping back into position is not the tendo Achillis or the peroneus brevis, or anything inherent in the first named bone, but the presence of the fractured internal malleolus jammed beneath the tibia, and occupying the space which should be filled by the astragalus. In the easy operation of Lane this fragment is got out of the way at once and back the astragalus slips, bearing with it the attached portion of fibula. Indeed, Mr. Rowlands was lucky to get the parts back without any further injury, for if the misplaced internal malleolus had proved obstinate, it is probable that the onward thrust of his screw, penetrating deeper and deeper into the tibia and failing to draw after it the fibula fragment, would have snapped the latter in two. Fortunately, this did not occur, and he obtained an excellent cure.

To some of us the attempt to fix the lower ends of the tibia and fibula together by a rigid screw and subsequent bony ankylosis may appear a questionable proceeding, but Mr. Rowlands is able to tell us of a case perfectly well after seven years, so probably everything is quite all right.

Perhaps a word may be permitted on the nomenclature. Mr. Rowlands quotes Pott, but fails to quote Dupuytren. An inquiry at the library of the Royal Society of Medicine revealed that there were three copies of Dupuytren's works, but all muted! On turning to his lecture on Fracture of the Fibula,² we find a perfectly clear definition of the rare fracture which is called by his name. "It involves not only fracture of the fibula, but also laceration of the strong tibio-peroneal ligaments, which generally

¹ *BRITISH MEDICAL JOURNAL*, December 6th, 1919, pp. 735-737.

² *Injuries and Diseases of Bones*. By Baron Dupuytren. Translated and edited by F. De Gros Clark. London: Sydenham Society, 1847. Part I, p. 282.

resist a force to which the osseous tissue yields." This is followed by an account of the only case he had met with "in nearly 200 cases of fractured fibula," entitled "Fracture of the fibula and rupture of ligaments, with dislocation of the foot outwards and upwards."

It follows from this that Mr. Rowlands's definition of Dupuytren's fracture as one in which "there are the lesions already described under Pott's fracture, and in addition either the inferior tibio-fibular ligaments are torn or there is a vertical fracture in the tibia just mesial to the tibio-fibular articulation," is not the true one.

After all, what matters in treatment is to make a clear division of all fracture-dislocations of the ankle into two, depending on their manner of production—namely, "abduction" fractures and "adduction" fractures. In the former, if an operation is required, the tibia is the bone to operate on, and in the latter the fibula; then, in recent cases, it will be rare indeed to meet with any difficulty. The later cases form a special class, and Mr. Rowlands is to be sincerely congratulated on the splendid result he obtained by transverse osteotomy in the case shown in Figs. 8, 9, and 10.—I am, etc.,

PAUL BERNARD ROTH.

London, W., Dec. 11th, 1919.

APPARENT SPONTANEOUS RUPTURE OF A NORMAL SPLEEN.

SIR,—In Major Shorten's interesting account of rupture of a normal spleen (*BRITISH MEDICAL JOURNAL*, December 27th, 1919, p. 844), two points call for comment:

1. Is spontaneous rupture (that is, without the application of force external to the organ) of the spleen possible, except as the result of effusion of blood or other fluid into the spleen itself? I should say "No." Some force is required, and there is none available. It is true that the fall was a slight one to rupture a normal spleen, but the organ may have been displaced by the previous accident, and so rendered more vulnerable. Here we have to choose between an improbability and an impossibility, so need not hesitate which view to take.

2. The state of the gall bladder was quite consistent with an attack of biliary colic.

It is time textbooks taught, what most surgeons know, namely, that the great majority of gall stone attacks are due to plugging of the neck of the gall bladder, and not to the passage of a stone along the ducts.—I am, etc.,

R. D. MOTHERSOLE.

Bolton, Dec. 28th, 1919.

THE MACHINERY OF THE ASSOCIATION.

SIR,—I note in the SUPPLEMENT for December 13th an invitation to members of the Association to submit to a special committee, which is considering the subject, suggestions as to desirable modifications in the machinery of the Association. Doubtless many suggestions will be submitted. I hope to send some myself. But serious consideration should be given by the committee and those sending suggestions as to the essential functions which the Association is intended to perform by means of its modified and, we will hope, perfected machinery.

It would be well, I think, if those interested would carefully study a series of supplements to the *New Statesman*, issued a year or so ago on professional organization. I do not suppose that all medical men would agree as to the accuracy of the history of organization of the medical profession set out in the special supplement dealing with our profession. But there are valuable lessons to be learnt from it and from the particulars given of efforts made by other professions to secure adequate organization. Particularly valuable, I thought, was the classification of the objects to be obtained by professional organization. The writer or writers of these supplements seemed to incline to the ideal of a single body constructed so as to be able to secure the fulfilment of all the objects that should properly be aimed at by professional organization.

My own personal experience of organization as applied to the medical profession leads me to doubt the feasibility of any attempt to reach this ideal so far as medicine is concerned, and nothing that I read at the time in the various supplements convinced me that it was any more likely to be successful in other professions. If I am wrong and it is possible and desirable for a single body to do the necessary work, and the Association decides to endeavour to occupy this position of great responsibility, its machinery must be adapted to this end. But if, as I hope, the Association intends to play a less ambitious part, it must define either the work it wishes to do or the work it wishes to leave to other bodies, and secure a constitution adapted to its task limited in this positive or negative manner.

The three divisions of the work of professional organization, if I remember aright, laid down in the article to which I have referred above are as follows:

- (1) The control of admission into, and continuance within, the profession.
- (2) The development of the knowledge which forms the basis of the profession's work.
- (3) The maintenance of the standard of professional work and conduct, and the safeguarding of the social and economic interests of its members.

If this classification is accepted it will be for the committee to advise the Association as to the changes, if any, in its machinery which are desirable to enable it to carry out all or any of these classes of work.

Personally I believe it would be wise for the Association to confine its energies to (3), leaving (1) and (2) to the General Medical Council and the Royal Society of Medicine respectively. For this limited though still considerable and highly important work the Association would be best equipped by completing the good work begun chiefly by Horsley of democratizing its constitution, in the light of the experience now being gained with some pain and difficulty in respect to representative government in industry.

I hope that any members who may agree with me that more complete democratization of the Association is desirable will send to the committee suggestions as to the best means of carrying it out.—I am, etc.,

London, W., Dec. 15th, 1919.

LAURISTON E. SHAW.

Universities and Colleges.

UNIVERSITY OF LONDON.

A MEETING of the Senate was held on December 17th, 1919.

The following were recognized as teachers of the university in the subjects at the institutions indicated:

Guy's Hospital Medical School.—Mr. T. B. Layton (Anal Surgery), Mr. William M. Mollison (Laryngology), Dr. Nathan Murch (Clinical Medicine).

London School of Medicine for Women.—Mrs. Mary F. L. Keene (Anatomy).

Hospital for Sick Children.—Mr. L. E. Barrington-Ward (Diseases of Children).

Professor A. E. Boycott, F.R.S., having relinquished his military duties, has resumed the appointment of Director of Research under the Graham Legacy Committee.

The Vice-Chancellor, Sir Cooper Perry, in view of his appointment to be Principal Officer, has from February 1st, 1920, resigned his office, and Dr. Sydney Russell Wells was elected Vice-Chancellor for the remainder of the year 1920: Dr. Russell Wells was also elected chairman of the Brown Animal Sanatory Institution Committee.

An additional first examination for medical degrees will begin on March 22nd. Forms of entry, to be obtained on application to the Academic Registrar, must be returned, accompanied by the proper fee, by February 23rd.

Dr. W. L. Symes will give a course of eight lectures in the Physiological Laboratory of the university on physiological balanced solutions on Tuesdays at 5 p.m., beginning on January 27th. Dr. J. W. Trevan will deliver at St. Bartholomew's Hospital a course of eight lectures on the reaction of the blood and acidosis on Wednesdays at 4.30 p.m., beginning on January 28th. Dr. Pembrey and Mr. J. H. Ryffel are giving a course of eight lectures at Guy's Hospital on the regulation of respiration on Thursdays at 4.30 p.m., beginning on January 8th. These courses, which are free, are recognized as advanced lectures which a candidate at the B.Sc. Honours examination may name for part of his examination.

Medico-Legal.

UNQUALIFIED TREATMENT OF VENEREAL DISEASE.

HEAVY fines were imposed at the Newcastle-on-Tyne Police Court on December 16th for infractions of Section 1 of the Venereal Disease Act, 1917; the charges were of having (not being duly qualified medical practitioners) unlawfully for reward prescribed a remedy for venereal disease and given certain advice. Mr. V. B. Bateson, the deputy town clerk, who conducted the prosecution, stated that the Act was directed to getting rid of backstairs shops, where persons suffering from the disease received inexpert and inadequate treatment. He mentioned that in Newcastle a scheme had been established whereby any person suffering, or believed to be suffering, from such disease might have the highest measure of medical skill free of charge, and with absolute secrecy. In one of the cases heard, in which there were four informants, the bench imposed a penalty of £50 in each (£200 in all). In another case there were two informants against each of two defendants, and the penalty in each case was £50 on each summons. In a third case the bench imposed a penalty of £50 in respect of each of two summonses, or £100 in all.

SIR WILLIAM OSLER.

WE published last week a biography of Sir William Osler in which the main incidents of his career were briefly set out. We are now able to publish tributes from many of the University medical schools in the United Kingdom, written in response to our request.

The two Regius Professors of Oxford and Cambridge worked together in union and with constant exchange of ideas. "I was," Sir Clifford Allbutt tells us, "rarely a week without a little affectionate postcard or a letter." Much good has come to English medicine during the last fifteen years through this close union of two great leaders. When Osler's pupils and friends on both sides of the Atlantic determined to offer him a Collection of Essays in celebration of his seventieth birthday, it was natural that his "brother Regius" should make the presentation. In doing so Sir Clifford Allbutt expressed in a few sympathetic sentences the feelings of respect and affection by which all the givers were inspired. His words were reported at the time,¹ but we have permission to reproduce here a dedicatory letter written last March:

My dear Colleague,

The stealthy foot of time carries us from youth to age so imperceptibly that we are hardly aware of the change; insensibly we shorten our arms, husband our strength, and are willing to think our prowess undiminished. Yet men have not refrained from marking the lapse of time by signal days, and months, and years: often by celebration of those whose lives have been devoted to the good of their kind, often by memorials of joy and achievement, or again of bitter and unforgotten sorrow.

And, as for the nation or the race, so in his own life, are there for each of us memorable days of sympathy in joy and sorrow. One day of sympathy in joy was that in the summer of 1904 when some of us were gathered around the hospitable hearth of Sir John and Lady Burdon-Sanderson, and, as suddenly, I believe, to you as to the others of us, like a flash of light the thought was born, how one scarcely knew, that you might surrender your great functions at Baltimore to enter upon a new life at Oxford.

Ever in the heart of the folk of the New World lies warm and deep the kinship with the old home; thus, almost with the rapidity of thought, between Canada, the United States, and Great Britain, an academic link threefold was forged. In no person so well as in your own could this unity have been so happily consummated; you arrived indeed from overseas, but as a pilgrim child of Oxford. In you the literary and historical tradition of the beautiful city was united with the zeal and adventure of the New World; so that in winning you for Oxford, and for Cambridge and Great Britain, we did no robbery to Baltimore and Montreal.

Since that day we have shared, in our degrees, your happiness and your sadness; we have rejoiced in your honours, and on this day when you reach the limit that the men of old regarded as the last ripeness of a man's life, I, your brother Regius Professor, am permitted to offer you as a tribute of our admiration and affection from both worlds, our little horn, if not of plenty, yet the best of our garden. Your "radical humours contain more than sufficient Oyl for seventy years"; oyl enough to keep your lamp trimmed and bright till the Old World, now tardily procreant, be brought again to the birth. Meanwhile in good days or evil you can thankfully say after our great example, "My Father works hitherto and I work."

Affectionately yours,

C. A.

The volumes arrived in Oxford two days before Osler's death—he never saw them.

Sir Clifford Allbutt has, as President of the British Medical Association, expressed the feeling of all its members in an appreciation contributed to the larger world of science through the columns of our contemporary, *Nature*. In it he speaks of Osler going to Oxford, "bring-

ing with him, as gifts from the New World, an openness and simplicity of mind and conversation, a frankness and generosity of temper, a freedom from the frost and weight of custom, and a pioneer's command of affairs which made him as delightful a fellow worker as he was clear-sighted and effectual. . . . Oxford took him to her heart as her own; there as one of her own he rested. And if Osler had not also to capture Great Britain, as he captured Oxford, it was because Great Britain was already his mistress. Indeed, there was not a school of medicine in the Old World where his presence was not almost as well known, and his friendship as precious, as in the New. It was characteristic of him that a few years later he obtained leave from Oxford to spend some months in Paris, during which period he regularly attended the clinics of the great hospitals at 7.30 a.m., like an ordinary student."

Sir Clifford Allbutt continues:

A quality which made Osler so fascinating a companion, his teaching so vivid and telling, and his parts in debate often so lively, was his wit and humour; the sharpness of the wit tempered by the sweetness of the humour. Indeed, much of his playfulness and whimsical mystifications were, in naturalist's phrase, a protective colouring to cover deep sensibilities.

Of Osler's contributions to knowledge it is as hard to make a list as it would be for Socrates. They were many, no doubt, but consisted even more in his dissemination of other minds, in personal teaching and influence upon his disciples. His great textbook, for many years, and still, the guide of every English-speaking student, had many and almost singular merits. Although within its compass no particular subject could be dealt with at large—for every subject had to be kept in subordination to the whole—yet in the successive editions it was always helpful in any quest to turn to "Osler," because, if it were but in a word, or the turn of a sentence, one perceived that the latest and best researches, if not presented in detail, were known to the author. Thus the work was not a provider only, but also to the wise an indicator. The reader feels as he reads that both whole and parts were being continually readapted to the developing phases of knowledge. Perhaps the author's most original and valuable researches were in the field of the diseases of the spleen and blood; but he made eminent contributions also to the study of infections of the heart, of angina pectoris, of malaria, and of many minor maladies. But, the most modest of men, his conversation was always of the good work of others, silent on his own.

Osler's work for others was so incessant, and his hospitality so unbounded, that one always wondered when and where he amassed and made use of his learning; learning which, in particular, would discover itself, as it were, by accident, unless, indeed, his companions were expert enough to see it under the surface of his talk. Somehow or other he put himself not only in sympathy with various subjects of study other than medicine, especially with literary pursuits, but he was able also to converse on something like equal terms with the masters of them.

OXFORD.

THE DEAN OF CHRIST CHURCH:

In a private letter from which he permits us to quote the Dean of Christ Church (the Very Reverend Sir Thomas Strong, G.B.E.) recalls that the first time he met Osler was during the annual meeting of the British Medical Association in Oxford in July, 1904, when Osler was still professor of medicine at Johns Hopkins. "He was to have been my guest, but at the last moment went to Sir John Burdon-Sanderson. In the course of the proceedings he called to apologize for having broken from my party. When, a little later, he was made Regius Professor of Medicine, having made his acquaintance and heard something of his fame, I took counsel with other members of the governing body here, with the result that I was instructed to cable out to him and offer him a Studentship (that is, a place on our governing body). I remember that when he called in 1904 he talked to me about John Locke and Richard Burton; but I did not know how great a devotion he had to these great men. In his letter accepting our offer, he told me that nothing could have pleased him more than to hold the position of Student here, which had been held by both his

¹ BRITISH MEDICAL JOURNAL, July 16th, 1919, p. 80.

prophets, Locke and Burton. It is interesting that on the night, in the interval between the service on Thursday afternoon (January 1st) and the journey to London on the morning of January 2nd, his body rested in the Cathedral close by the monument of Richard Burton. The article in the last issue of the JOURNAL has helped me to understand what always rather puzzled me, and that was the enormous range of Osler's knowledge. After he had been here a little time he sent me a copy of his big book, *The Practice of Medicine*, saying he thought the head of his college ought to know the sort of things he was after. Of course, it was not a thing I should read through; but I turned over the pages, and my eye was caught from time to time by phrases such as this: 'In a case which I saw in such-and-such a place'; and it seemed to me that he must have had extraordinary opportunities of seeing cases of various ailments, and that his book really depended upon this very wide experience. But I did not know at all how he had got it, and this your article to a large extent explains.

"It was a very great gain to us to have him as a member of the governing body. Socially, of course, no one could have been more delightful. But apart from that, though he was rather irregular at our meetings, he took a real interest in the business of the college; and he had so many varied subjects of interest that he could help us in a variety of unexpected ways. I remember that very shortly after he came here there was a question of accommodation in our library; our books were increasing upon us and we were anxious to find space. The question was raised whether we should move, or perhaps get rid of a part of, an old collection of scientific books, all long since out of date. We asked Osler to go through them. There were, of course, some that were of no importance, but a large number of them had come to us as a single collection from the library of Lord Orrery; and though they were now of no use from the point of view of scientific teaching, Osler was enormously impressed to find a more or less complete library of a man interested in science in the early eighteenth century. He made a careful statement at a subsequent meeting about them and their value from the point of view of the history of science. From the same source we have a collection of scientific instruments, of which Mr. Gauthier of Magdalen has been writing recently; and these were a great interest to Osler. I think that one of the great grounds of distinction in his outlook was his habit of co-ordinating the present and the past without, so far as I can understand, being behind in the movement of science at the present time. It will easily be understood what a power in a university, where literature occupies such a large place, this characteristic gave him of mutual understanding and friendship. I came across him also on the delegacy of the University Press and in the management of the Bodleian, of which I was a curator during my time as Vice-Chancellor. He had the greatest interest in the Bodleian and always was forward in promoting its interests—the Bodleian Record owes almost its existence to him."

Dr. C. S. SHERRINGTON, F.R.S., Waynflete Professor of Physiology, Oxford:

Many traits of Osler will be adverted to, and by those better competent than I to do them justice. To my own thinking, among the characteristics which endeared Osler to his friends none was perhaps more striking than his combination of an intense affection for the past, and not least for the antique past, with an enthusiastic receptivity for the new, a sort of open-arms embracing of the future. To run his eye backward and forward along the historic continuity of Medicine seemed with him a daily and hourly habit. No man, I think, was ever less open to the misconception of the present as a moment apart, a thing that was stopping still to be looked into, and was intelligible by itself alone. Akin to his optimistic welcome of the new was his genial sympathy with the young; there was never a greater believer in the young generation than Osler, or a more generous encourager of it.

LONDON.

Sir HUMPHRY ROLLESTON, President of the Royal Society of Medicine:

It is difficult to find the right words to describe such a many-sided man, the like of whom we shall not look upon

again. It is the more difficult because so many others must feel that the guide, philosopher, and true friend, to whom in the event of trouble they could confidently look for help, has been taken. It is indeed hard to believe that never again shall we see that familiar figure and that the voice of that blithe spirit with its humorous and kindly touches is for ever silent.

Perhaps the most remarkable of his many gifts was that of rapidly making and then permanently retaining friendships. To see, speak to, and place at his ease as naturally his equal a young man, somewhat in awe of a famous leader of his profession, seemed an easy matter in his hands, and no doubt was the outcome of a wonderful sympathy that never failed, and at the same time was never obtrusive or other than natural in a very human man. This made him the same age as his companion, and indeed much as he loved old men, he delighted in meeting the young; with children he was a romping companion; to a mother in terrible distress for a son lost in the war the gentlest of comforters; and it was inevitable that in spite of his bravery he was never quite the same after his only son was killed on August 30th, 1917. There was no trace of the wall between the generations that the years so often build up, and probably few ever realized how strange this really was. His encouraging and stimulating attitude to young men made Oxford a Mecca to which there was a constant flow of pilgrims, especially from Canada and the United States, all certain of a welcome. Annoyance, irritability, or personal feeling of any kind was impossible to imagine in connexion with his sunny temperament; that this was part of his philosophy of life is obvious in his charming address "Aequanimitas," and his attitude to his professional brethren finds expression in another address in the same volume on "Unity, Peace, and Concord." Though a shrewd judge of character, neither his opinion nor the reason for it, if unfavourable, was given unless there was some urgent reason, and then the man's surroundings were blamed or a semi-humorous phrase settled the question without further affecting reputation; what he did not say in such circumstances was often very significant of his charity to poor human nature. There was a close resemblance between his personality and the written message conveyed in his charming addresses; the serious *motif* was always clear, but it was worked in with such a light hand that there was none of the solemnity or tedium almost inseparable from even a lay sermon. All his life he had been a lover of old authors and old books, Sir Thomas Browne being undoubtedly his favourite and his prototype in life's philosophy; thus it was that he did much to attract others to medical history and bibliography by weekly meetings during term at his house, at which the advances in medicine were sketched and early editions of the corresponding epoch-making works passed round. His literary style was epigrammatic, with apt illustrations, attractive from its classical flavour, and with the distinction conferred by his easily discernible personal touch. This was a feature of his popular textbook, so remarkable for its up-to-date picture of our science; a new edition was busily occupying his thoughts when his fatal illness began. His output was enormous, and it was a puzzle how, with innumerable engagements outside and an open house very rarely without its complement of visitors, he found time to read and work. To see him examine a case was a lesson in thorough clinical observation, and not least because the patient's interest was not forgotten in that of the case. His energies were freely given to campaigns in the public interest, such as tuberculosis, venereal disease, medical education, and the financial needs of the universities. As a result of an unrivalled clinical experience, a peculiarly retentive memory, and a habit of systematic work, his name will be always connected with a number of clinical syndromes, such as chronic splenic anaemia, polycythaemia rubra (Osler-Vaquez's disease), and the painful erythematous swellings in the skin of the hands and feet in malignant endocarditis (Osler's sign). But these are of comparatively little importance in comparison with the rest of his work in general medicine.

To those who knew Osler well the simple lines written by Sorley about a V.C. who fell in the war, will not appear unsuitable:

We know the glory that is his,
A glory that can never die.

Dr. ARNOLD CHAPLIN, Harveian Librarian, Royal College of Physicians, London:

Although full justice has been done to the great merits of Sir William Osler as a man and as a physician, there is one aspect of his influence in medicine upon which insistence should be laid. It may be doubted if the annals of medical history contain another example of a physician uniting so completely in his intellect a wholehearted veneration for the past in medicine and the keenest enthusiasm for modern medical methods and knowledge. The history of our profession teems with the names of those who initiated new ideas, developed new theories, and forced the advance of medical knowledge against all opposition. It also contains the names of many who feared to embrace new doctrines because they clashed with the traditions of a departed age, and were contrary to the teaching of so-called authority. Both classes of thinkers had their limitations, and each would have accomplished more could it have borrowed from the other. But Sir William Osler's intellect was so fashioned that, while essentially modern in thought and action, it possessed, nevertheless, a deep and abiding sympathy with the past. When approaching any problem connected with medicine he invariably used the historical method, and while he was bold in deduction, his conclusions were all the more reliable, since they had been checked and tested by an appeal to the work of those who had gone before. Eager to advance along the untrodden path, he never neglected to scan the road left behind for any indications as to the course to be pursued. These were the methods employed by the great clinicians, and in the hands of Sir William Osler they produced those results which raised him to such a commanding position in the art of medicine.

The introduction of the knowledge of Greek in the last years of the fifteenth century, the so-called "new learning," gave the death-blow to the intellectual monstrosities produced by centuries of scholasticism. It softened the hard intellectual processes; it widened human sympathy, and acted on knowledge generally in the same way that the principles of equity adjusted the rigours of the common law. Sir William Osler applied the same principles to medicine. Widely read, with deep human sympathies, his conception of the ideal physician was not merely that of a man fully equipped with medical and scientific knowledge to contend with the problems of his art, but one possessed of a wide culture designed to increase his influence in the practice of his profession. He was fully conscious of the fact that while every day more and more time is being bestowed upon the superstructure of special medical knowledge, less and less time can be devoted to the foundation, and he threw all the weight of his influence into the appeal for a wider knowledge in the medical man, and, therefore, a wider sympathy with thought and action in human affairs. He knew full well that time sets a limit to the acquirement of general knowledge, and that a medical student is peculiarly handicapped in this respect. But he gave splendid encouragement to the study of the history of medicine, a subject easily within the reach of the medical man, and closely allied to the serious purpose of his life. Probably he would have agreed that no better subject could engage the attention of the busy practitioner during the few leisure hours at his disposal, for it embraces considerations of history, biography, philosophy, mediævalism, and the classics—in fact, most of the activities that have occupied the human mind. No better monument to his efforts in this direction can be found than the new school for the study of the history of medicine and science at Oxford, which owes its inspiration almost entirely to Sir William Osler's powerful advocacy. He did not expect or desire to see medical men devoting much of their time to the study of the humanities, for he knew the arduous nature of a life devoted to medicine, but he felt that, by broadening the mental range, clearer and wiser perceptions would be sure to follow. The physician cannot afford to neglect the "humanities," and while it is not to be expected that all can take rank with Arbutnot, Preind, Mead, and Baker, yet their cultivation will bring to all increased influence and usefulness. To these principles Sir William Osler was faithful to the end of his life.

MANCHESTER.

Dr. GEORGE R. MURRAY, Professor of Medicine in the University of Manchester:

While we are still in the shadow of so great a loss to medicine it is difficult to express at all adequately a proper appreciation of Sir William Osler's great qualities. Two of the most remarkable features of his genius were his ability to take a wide outlook and to form a sound judgement in all departments of medicine. Possessed of a unique experience of medical men and affairs in two continents, he was able to take a lofty and impartial view of medicine, not only of the present but also of the past and of the future, and to impart to others the results of his survey in clear and striking language. He was always in touch with the growing borders of medicine, and took the warmest interest in the endeavours of younger and less experienced men to expand them by observation and research. He had the capacity of assessing the true value of new developments and was able to recognize the gold and reject the dross more rapidly than others. This power rendered his teaching valuable to both students and graduates and enabled him to produce and maintain his *Principles and Practice of Medicine*, which has been so helpful to students and teachers alike. In these times of unrest and reconstruction we shall greatly miss his wisdom and guidance, which would have been of such inestimable worth to all who are interested in the development of medical education in the immediate future.

BRISTOL.

Dr. J. A. NIXON, C.M.G., lately consulting physician with the British armies in France and on the Rhine; physician to the Bristol Royal Infirmary:

Sir William Osler's public appearances in Bristol were all too few. He was present at the British Medical Association meeting in 1894, when he took part in a discussion on the use of antipyretic drugs. His attitude made a considerable impression, since he condemned freely the use of the drugs which were then almost universally in vogue in the treatment of fevers, and spoke as the staunch advocate of cold baths, especially in the routine treatment of typhoid fever. In 1905 Osler distributed the prizes to the students in the Faculty of Medicine at the University College. His speech on that occasion acted as a great stimulus to the foundation of a university in Bristol. Before his visit a few voices had been raised, almost timidly, hinting that a university was an ideal to be aimed at. His speech put courage into the pioneers, and carried the proposal at one bound from a pious hope to an insistent demand. This was another example of his marvellous gift of encouragement and emboldenment of innovators. On the same occasion he attended the annual dinner of the Bristol Medical School as the guest of the evening, when he made a memorable speech. One phrase from that speech still lingers in our minds, where he described himself as having been "born with the woolly side out," and hence had always been able to rub along with his fellow-practitioners. His enthusiastic admiration for some of the Bristol men of medicine almost surprised his audience, many of whom were less aware than he of the achievements of Pritchard (in jurisprudence), Budd (in hygiene), and Symonds (in medicine). But when all was said and done, his chief interest in Bristol was focussed on Thomas Dover, buccaneer, inventor of "Dover's powder," and finder of Alexander Selkirk. Osler followed with eager attention every fresh discovery of Dover's life and parentage. In 1911 Osler again came to Bristol to attend the inaugural meeting of the Bristol Medical History Club. Here he gave no formal address, but wished the club all success, with many wise hints as to lines of progress. He showed his incomparable collection of Sir Thomas Browne's works, and talked of the old Norwich physician almost as a personal friend. On this visit he made the acquaintance of the City Library, principally to do homage to the Duke of Bedford's MS. of Guy de Chauliac. Characteristically he found other treasures to admire; all the *incunabula* had to be brought for his inspection before he could drag himself away. His love of books surely came next after his love of men.

Perhaps the following anecdote, which he related to the writer in 1912, may be new; it is at any rate illustrative of these two aspects of his character finely blended.

Osler was once called from Baltimore to see one of his students ill with typhoid fever. He found his way to a

planter's house in Virginia. It was an old derelict shadow of its former splendour, with broken shutters and gates off their hinges. The grandfather (for the boy was an orphan) turned every convertible thing into drink. After seeing the lad Osler had to wait all day for the night train back to Baltimore. So he found his way to the library and browsed round the shelves. Presently the granddaughter, a charming intelligent girl of eighteen, came in and said: "If you're interested in old books, we've got some much older than these in the attics." There he found stuffed into barrels priceless first editions, including Byron, Shelley, and Keats (*Endymion* and *Lamia* "in blue wrappers"). The volumes comprised practically the whole early history of the house of John Murray. These were the yearly consignments of books which wealthy planters were wont to order from England. Osler told the girl of their great value. She, with tears in her eyes, begged him to say nothing to the grandfather, as he would sell them for drink. Eventually, through Osler's good offices, Putnam's bought the books at so fair a price that the old home was restored and the family fortunes comfortably re-established.

EDINBURGH.

Dr. G. LOVELL GULLAND, Professor of Medicine in the University of Edinburgh:

Osler has been for so many years, the outstanding figure in British medicine that we feel lost and fatherless without him. I leave it to others to talk of his medical and literary triumphs, for to me the man has been even greater than his work, fine and enduring though that is. I saw him just before his last illness, when he was full of life and energy and of plans for his own work and for others and full of hope—plans and hope, alas! not to be realized. He was greatly interested in all that we are doing and aiming at in the University of Edinburgh, because so much of it is along the lines which he regarded as the ideal in medical education, and he greatly encouraged us. When, indeed, did he ever fail to encourage anyone who was trying to do good work? There must be thousands who have been helped along a thorny path by his words of cheer. Many years ago, at our first meeting, he gave me criticism, encouragement, and advice which were invaluable, and from that day I loved and revered him. To countless others his helping hand has brought success when failure seemed imminent, and with me to-day they mourn the man and not the great physician and teacher. He loved youth for itself and young people for the promise that is in them, and was far happier when playing with a child than when discussing serious questions with his peers. He would always have young people about him, and his keen sympathy and affection enabled him to enter into their joys and sorrows, and kept him young in defiance of his years. In every man he saw and desired to see only what was best, and so brought out the best in those with whom he had to deal. One left him with a sense of moral uplift, and a desire to be more worthy of his confidence and esteem. To his friends he was always the same. I don't know what he was to his enemies—I doubt if he ever had one.

It is now an old regret that he did not take the Chair of Medicine in Edinburgh. The calmer air of Oxford was perhaps better suited to the full ripening of his genius, and there he had the time and leisure for his literary tastes and work, which would have been denied to him among the strenuous Scots. But what a fount of inspiration he would have been, and to how many more of the young men whom he loved! He gained, and Oxford gained, but I think medicine lost. Valuable though his writings are, one would rather have had an hour's talk with Osler than all his books. It was his personality and his personal radiation which gave him the immense power for good which he possessed. He seemed to exercise his only half-consciously; he was too humble-minded to value himself as we valued him. Welcomed wherever he went, he walked among us giving help and kindness with both hands, and the example of a blameless and worthy life.

ABERDEEN.

Dr. ASHLEY W. MACKINTOSH, Professor of Medicine in the University of Aberdeen:

It is significant that, when one read of the death of Sir William Osler, one thought mainly not of the loss to scientific medicine—although this is great and almost irre-

parable; one felt stunned as by the sense of a great personal sorrow. His was indeed a wonderful personality—full of charm as of compelling power, lovable, unselfish, ever kind and helpful. I met him first at the Oxford meeting of the British Medical Association, and as a secretary of a section I was much impressed by the quiet courtesy and kindness shown by him in our official relations. Later, his letter to me—personally unknown to him—on my appointment to a chair of medicine, addressed to "Dear Brother Regius," was characteristic of the man, and has always been a real inspiration and encouragement to try to be worthy of such a "brother." How many must have had a similar experience! During the annual meeting of the British Medical Association at Aberdeen in 1914—so nearly clashing with the outbreak of the Great War, which was to bring him such a terrible sorrow—I had the privilege and honour of having him as my guest: the happy memory of those days will remain for ever. Great as is our debt to Osler for his contributions to the progress of medicine, the man himself was greater than his works, and I learnt to love him as I have loved few men.

WALES.

Dr. W. MITCHELL STEVENS, senior physician to King Edward VII Hospital, Cardiff:

By the passing of Sir William Osler gallant little Wales loses one of her best friends. When Osler first visited Cardiff, many years ago, his reputation had, of course, preceded him, and many expected to see a more or less typical American of the Anglo-Saxon type, but we were delighted to find him a true and warm-hearted Celt, and in a very short time he was a great favourite among medical men and others in all parts of the principality. On his first visit to Cardiff he noted our incomplete medical school, and also our large rapidly growing hospital, and he expressed his surprise that Wales should be obliged to send her medical students to other parts of the United Kingdom to complete their education, seeing that she had no lack of splendid clinical material.

Osler recognized that there were no better medical students than the Welsh, and that even the poorest Welsh parents were only too pleased to deny themselves in order to educate their sons to a profession. It is therefore not surprising that a man with such warm sympathies as Osler took a very keen interest in the proposed establishment of a Welsh National School of Medicine. He met in the late Colonel Bruce Vaughan a man with ideals similar to his own, and in every effort these two were closely associated, and we have to regret that both these workers for humanity have been taken from us; but their influence will remain.

Osler perceived that our medical school would not be hampered by preconceived ideas or old traditions, and that a virgin soil was presented for establishing a great medical school on the newest lines. In May, 1903, he opened the new out-patient department of the King Edward VII Hospital in Cardiff, and the address he gave on that occasion made a deep impression upon every one present, and served to stimulate both medical and lay interest in the proposed completion of the medical school. In August, 1905, he was present at the laying of the foundation stone of the new medical school buildings, the cost of the erection of which, amounting to £100,000, was to be defrayed by the princely gift of Sir W. J. Thomas. On account of the war these buildings have been delayed to such an extent as to cause great dissatisfaction in Wales, and it is much to be deplored that Osler should not have been able to open them.

In June, 1916, a Royal Commission, of which Osler was a most distinguished member, was appointed to inquire into the subject of Welsh University education in general, and this Commission made certain recommendations regarding the proposed medical school. In March, 1918, Osler came with other visitors to Cardiff under the conditions of the trust deed of the Mansel-Talbot Chair of Preventive Medicine; he inspired such confidence that he was asked to nominate a committee of experts to submit a scheme to the trustees, and when the scheme was approved, to proceed at once to the appointment of a professor. He visited Cardiff and other parts of Wales on many occasions, and was always most willing to give us his advice, and to use his influence on our behalf.

As he has passed away, but his memory will ever be held dear, his example will always be a daily stimulus, and his love for his fellow men a lesson to us all.

IRELAND.

Sir JOHN W. MOORE, Representative of the Royal College of Physicians of Ireland on the General Medical Council:

The President of the Royal College of Physicians of Ireland (Dr. James Craig) has intimated to me that you would welcome a tribute to the memory of a great man, the late Sir William Osler, Bt., F.R.S.—a tribute in this case from one who had the privilege of counting Sir William among his close personal friends for wellnigh thirty years.

It was shortly after the appearance of the first edition of his classical work on the *Principles and Practice of Medicine* that Dr. Osler entered into communication with me relative to the subject of fevers and their prevalence in Ireland. As the years passed by he corresponded with me from time to time on that and cognate subjects. The formal superscription in his letters gradually gave way, titles were dropped, and the letters began "Dear Moore," "My dear Moore," and at last, under date September 14th, 1917, came this touching note: "Thanks, dear Moore, for your kind message of sympathy in our sorrow. You know how hard it is—but one must bear these blows bravely. Sincerely yours, Wm. Osler." Five short weeks before, on August 7th, 1917, he had written: "I am grieved to hear that you have lost the boy. How terribly the profession has suffered in this war! Our boy is in the thick of it in France in the R.F.A. Ever yours, Wm. Osler." Many years before, in 1905, Sir William had been asked to open the winter session of the Meath Hospital and County Dublin Infirmary. Owing to press of work he was obliged to decline. He wrote: "It is really a great regret to me to feel that I could not comply with your request, as both Graves and Stokes are among my special professional 'friends.'"

Of Osler's outstanding attainments as an orator, a classical writer, and an accomplished man of affairs there is no need for me to write. His great talents—and they were very many—were at all times and in all circumstances devoted to the benefit of mankind and to the relief of the sick and suffering. His humility, devotion to duty, and the sympathetic spell with which he attracted friends to his side gained for him the title, worn by his forerunner, St. Luke, of the "Beloved Physician."

WILLIAM OSLER had a genius for friendship. The congregation in Christ Church Cathedral on the afternoon of New Year's Day was witness to it. He was a senior to whom had come all the honours, but those who went to do him the last honour were of all ages and ranks, and of many callings. It was a cool grey afternoon, and Oxford was in a mood of sadness as the great bell tolled, and the soft wintry light fell on the towers and spires he had learnt to love for their tranquil beauty and for all that they symbolized—the continuity of thought, the life of the spirit reaching back beyond Erasmus, with whom in temperament and width of learning and in a certain cosmopolitan way of thought, covering serious purpose in light even mocking words, he had affinity.

The Editor of this JOURNAL recalls, still vividly, the first meeting with him many crowded years ago, in the old laboratory in University College, London, where he was at work with Sir E. Sharpey-Schafer—the small wiry frame, the quick gesture, the steady eyes that seemed to read one's inmost thoughts, the swift smile, and hearty friendly greeting—from the first intimate; and, with many incidents between, the last and happy memory of him on a not far past summer afternoon, in the garden of Exeter College, under the great window of the Bodleian Library, as he passed from group to group, a little quieter, perhaps, as though the past were casting its shadow on the future, but saying the right word to each, entering into each man's thoughts, and friendly, always friendly, for he had a genius for friendship. How many of us feel that we have indeed lost not a teacher and a guide only, but a friend.

Here is a little picture of how he struck one member of our profession whose particular vocation might seem far as the poles apart from Osler's:

The leaders of thought in medical science and literature will hasten to pay their last homage to the memory of the late Sir William Osler. Their words of appreciation and farewell will be read with heartfelt interest by the countless admirers of a very great man.

May I venture to add a few words on the personal side, because I think they will appeal to not a few of his friends? Many of us have had reason to think with gratitude of Sir William in times of sorrow, but it is remarkable that his magnetic personality often intruded itself on our thoughts in moments of great happiness, when his bodily presence was far distant. Particularly I think was this the case in lonely but lovely surroundings in the country. Personally, I have thought of him often in times of great enjoyment—watching the sun set on the banks of Loch Lomond, whilst waiting for the evening flight of wildfowl; fishing on the river Spey, and on lonely Highland lochs; admiring the sunset effects on the lovely Cromdale hills and the beautiful shores of Loch Ard. I think his open, generous, kindly disposition, transparent goodness, and unaffected manners created a sort of atmosphere about him that reminded one of the country, so that thoughts of him came without volition in happy scenes such as those I have ventured to describe. Two other great men of equally attractive personality—the late Sir William Power and Sir William Ramsay—produced in me the same effect. The world has lost a wonderful man, but even death cannot rob his friends of their memories of a personality so magnetic as to be almost without parallel. I should not have ventured to write these few halting words did I not feel that I am voicing, however imperfectly, the sentiments of many of those who were fortunate enough to know him, and who have felt, as I have, the undefinable charm which could steal into our happiest moments at the mere thought of him.

To the feeling here expressed others might give different expression, but the impression A. C. H. conveys—the sense of the vivid, sympathetic, friendly soul in Osler—is the impression all who knew him retain. Those who were grateful were a great multitude, some of whom did not know him save by his writings. He said in acknowledging the presentation on his seventieth birthday last July: "To a larger circle of men with whom my contact has been through the written word—to the general practitioners of the English-speaking world—I should like to say how deeply their loyal support has been appreciated. Nothing in my career has moved me more, pleased me more, than to have received letters from men at a distance—men I have never seen in the flesh—who have written to me as a friend."

The funeral service on January 1st was conducted by the Dean of Christ Church, and among the congregation were representatives of Oxford, of medicine, and of the many other interests which entered into Sir William Osler's life.

University of Cambridge: Professor G. H. F. Nuttall, F.R.S.; University of Edinburgh: Professor J. Arthur Thomson; University of London: Professor W. M. Bayliss, F.R.S.; University of Liverpool: Dr. J. G. Adams, F.R.S. (Vice-Chancellor). University of Oxford: The Vice-Chancellor, the Senior and Junior Proctors, the Master of Balliol, the Warden of All Souls, the Director of Exeter, the Principal of Mansfield, Professor H. H. Turner and Mr. F. A. Bellamy (Radcliffe Observatory). Rev. G. B. Croushaw (Radcliffe Infirmary, Oxford). Royal College of Physicians of London: Sir Norman Moore, Bt., President, and Dr. J. A. Ormerod, Registrar. Royal College of Surgeons of England: Sir George Makins, G.C.M.G., C.B., President. The British Medical Association: Sir T. Clifford Allbutt, F.R.S., President (who also represented the Faculty of Medicine of the University of Cambridge); Dr. William Collier, ex-President; Dr. Dawson Williams (Editor of the JOURNAL), and Dr. A. W. Neil (Oxford and Reading Branch). Royal Society of Medicine: Sir Humphry Rolleston, K.C.B., President; and its Section of the History of Medicine, Sir D'Arcy Power, K.B.E. Medical Research Committee: Sir Walter Fletcher, K.B.E. Ministry of Health: Dr. A. S. MacNalty. Lister Institute of Preventive Medicine: Professor C. J. Martin, F.R.S. Canada: Sir George Perley, High Commissioner, and Colonel Chisholm, C.A.M.C. Association of American Physicians: Dr. E. J. Wood, Toronto. Lieut.-Colonel G. W. Badgerow (Trinity University, University of Toronto, and Academy of Medicine). Fellowship of Medicine and Post-Graduate Association: Dr. A. F. Hurst and Mr. C. H. Fagge. Oxford Graduates Medical Club: Dr. R. C. Jewsbury. London School of Medicine for Women: Dr. Aldrich-Blake. Classical Association: Professor G. Murray. Director-General Army Medical Service: Colonel D. Harvey, C.M.G. Among others present were Lord and Lady Harcourt, Sir Frederick Treves, Bt., G.C.V.O., Sir William Church, Bt., K.C.B., Sir Archibald Garrod, Sir William Hale-White, and Sir Charles Ballance.

The cremation took place privately at Golders Green on January 2nd.

Obituary.

JOSEPH QUIRKE, M.D.,
Birmingham.

By the death of Dr. Joseph Quirke, of Endwood Court, Handsworth Wood, the profession in Birmingham has lost one of its oldest and most respected members.

Dr. Quirke was born in 1846, the fifth son of the late Dr. John Quirke, of Tullamore, King's County, and it was as a pupil of his father that he laid the foundations of the shrewd clinical judgement and sound knowledge of pharmacology and therapeutics which distinguished his after-career. He received a sound classical education at Tullabeg and Clongowes, and completed his medical studies at the Catholic University School, Dublin, where he gained many honours. At the early age of 21 he qualified, married, and settled in the Handsworth district.

Although an entire stranger and handicapped (in those days) by the circumstances of nationality and religion, his attainments were quickly recognized, and he soon built up a most successful general practice, which was relinquished only some few months before his death, after more than fifty years of strenuous work.

Dr. Quirke was an accomplished obstetrician, and owed a good deal of his success in practice to his skill in that branch of his profession. In addition, his unflinching cheerfulness invariably inspired his patients with hope and confidence, and it was a common saying among them that his presence in the sick room was in itself a guarantee of recovery. In lighter moments his ready wit and inexhaustible fund of anecdote and quotation did much to brighten the patient's outlook.

Leading so busy a professional life—for one period of eleven years he took no holiday—and with the responsibility of a large family on his shoulders, Dr. Quirke found little time for interests outside his work, and took no active part in political or municipal affairs. In 1879 he became a member of the Royal College of Physicians, Edinburgh, by examination, and in 1915 the National University of Ireland conferred on him the degree of M.D. (*honoris causa*) as a distinguished student of the old Catholic University School, which had not the power of granting degrees in the days when Dr. Quirke qualified.

He was an old member of the British Medical Association, a Fellow of the Royal Society of Medicine (Obstetrical Section), and had filled the offices of President of the Midland Medical Society in 1905-6 and Vice-President of the Birmingham Medical Benevolent Society. In 1887 he was Examiner for the Ingleby Prize in Midwifery at Queen's College, Birmingham. Dr. Quirke was made a Justice of the Peace for the county of Stafford in 1894, being the first Irish Catholic so appointed since the Reformation, and on the absorption of Handsworth into Greater Birmingham was included amongst the city magistracy also.

As in so many other instances among the older members of the profession, the war was primarily responsible for Dr. Quirke's breakdown in health. For a time he carried on unaided his own practice and most of that of his son, Dr. H. C. Quirke, while the latter was serving with the forces abroad, but he was terribly overworked during the influenza epidemic of 1918, when he could not bring himself to refuse to see his old patients. The strain proved too great, his heart failed, and though for some months he appeared to improve, he became gradually worse during the summer and died on August 19th, in his seventy-fourth year.

Dr. Quirke is survived by his widow (whose health unfortunately broke down completely shortly before his death) and a family of four sons and five daughters. Three sons are in the practice of the medical profession, as also is one of his sons-in-law, Dr. F. Rowland, who was released from military service after the armistice to relieve Dr. Quirke in the practice, but, unfortunately, the mischief was already done. Major M. J. Quirke, I.M.S., arrived home from India a few days after the burial, which took place in the grounds of St. Thomas's Abbey, Erdington, after a very largely attended Requiem Mass at the Church of St. Francis, Handsworth, which the deceased had attended since its completion.

ARTHUR RIEUSSETT LITTELJOHN, M.R.C.S.,
L.R.C.P., D.P.H.,

Medical Officer in the Ministry of Health.

WE regret to have to record the death of Arthur Rieussett Littelljohn, M.R.C.S., L.R.C.P., D.P.H., M.R.C.V.S., Medical Officer in the Ministry of Health, which took place at a nursing home in London on December 8th at the early age of 38. He was a son of the late Dr. Sa tern George Littelljohn and was educated at St. Paul's School and at the Royal Veterinary College and St. Mary's Hospital. He was for some time tutor in veterinary medicine at the Royal Veterinary College and made a number of contributions to scientific journals on veterinary matters of special medical interest. He was the author of a well arranged and very useful handbook on meat and its inspection. In 1911, when Dr. Littelljohn was appointed to the medical staff of the Local Government Board, he had already made a close study of the many important points at which veterinary and human medicine touch in their bearing on public health. He had added to these a sound knowledge and practical experience of public health administration gained in the course of several municipal appointments which he had held, and with this somewhat rare and valuable equipment he speedily found scope in the Food Department of the Local Government Board for the practical application of his knowledge and fine judgement. The war interrupted progress in the special work in which he was engaged and the Food Department immediately became immersed in the task which it undertook for the War Office, of organizing and controlling arrangements for securing that the army's food supplies were manufactured and prepared under proper sanitary conditions.

With those of his colleagues to whom military service was denied, he threw himself with characteristic zeal into this work. Early in 1915 the Local Government Board was asked by the War Office to provide inspectors to undertake supervision of the preparation and packing of the vast quantities of food materials which were being manufactured in North and South America for our armies. Littelljohn was entrusted with this mission in the United States and Canada, and laboured without a break in his extremely arduous and responsible task from the spring of 1915 till the autumn of 1918, when he returned to England much impaired in health, but with the satisfaction of knowing that his work in America had contributed in no small degree to the welfare and efficiency of our troops in the field. His correspondence during this time shows how capable he was of dealing with a big problem in a big way. In spite of the great distances which he had to cover in the United States and Canada, his arrangements enabled him to maintain effective control in all the packing houses engaged on British contracts. The reputation which he had gained at home for sound knowledge of his subject, reliable judgement, and prompt and fair decision was quickly established amongst the American and Canadian packing firms. Many representatives of these firms have since testified their respect and admiration for his gifts in this direction, and the helpful and stimulating spirit in which he invariably dealt with the many difficult problems with which they were faced. It is no exaggeration to say that one of the chief factors which went towards securing the extraordinarily uniform and consistently good quality of the food supplied to our troops during this unprecedented war was the high character of Littelljohn's work, and the respect which his courage and ability inspired in those with whom he had to deal.

After a brief rest in England, during which his health seemed to improve somewhat, he undertook a mission of a similar kind for the War Office in Australia, where he remained for a few months. He had barely completed his work there when his health broke down and he returned to England in July last. Since then he gradually became worse, but his fortitude never deserted him throughout his long and painful illness. For his services and sacrifices during these strenuous years he was mentioned in War Office dispatches.

"A. R." Littelljohn was well known generally as a fine athlete and first-class right-hand slow bowler. He played cricket for Middlesex for a number of years, and he and his brother, "E. S.," also a medical man, on many occasions did brilliant things for the county eleven. His loss will be keenly felt by all his numerous friends, both in the Ministry

of Health, where his ability and high character were fully recognized, and in the world of sport, where he was so well known and loved.

We regret to record the death on December 2nd, 1919, at the age of 59, of Dr. WILLIAM CAMPBELL DOWNS of Motherwell, after an operation for duodenal ulcer. In 1888 he graduated M.B., C.M. at Glasgow University, and after some experience as assistant in Hamilton he started general practice at Uddingston. During the two years he was there he took the D.P.H. at Cambridge and then bought a practice in Motherwell, where during the last twenty-five years he established a large connexion, ultimately having two partners. In the early stage of this practice he was lecturer on public health at Anderson's College, Glasgow. Although over the age limit, when the war broke out he would, had he been allowed, have devoted his whole time to the army, and actually did serve a year with the R.A.M.C. Dr. Downs had many qualities which attracted and held his friends. Not only was he fond of music and literature, but he had much grit, a quaint turn of humour, and at all times an unaffected manner, which was but the reflex of a genuine and sincere character.

Dr. WALTER B. HASTINGS, medical officer Parish of Sleat, Isle of Skye, was accidentally killed on Sunday, December 21st, 1919, owing to the overturning of his car while going to attend a patient. He graduated M.B., C.M. Glasg. in 1892, and settled at Sleat nineteen years ago. Owing to the scarcity of medical men caused by the war he undertook the work of medical officer for the parish of Strath in addition to his work in Sleat, and carried on the duties of medical officer of health for the whole of the island of Skye as well. Dr. Hastings was of the very best type of Highland medical practitioner, capable, and thoroughly reliable. No matter the hour, day or night, he never failed to answer a call, and cheerfully faced often very long journeys under very trying weather conditions. His kindness and courtesy endeared him to all, and he is greatly mourned, especially in the parishes of Sleat and Strath, where his work mostly lay.

Dr. ALEXANDER DAVID CRAWFORD, of Stanton Hill, Skegby, Notts, died recently, at the age of 60. He studied medicine at the University of Glasgow, and graduated M.B., C.M. in 1886. He was medical officer of the Marston Green Cottage Home, and served as a lieutenant in the R.A.M.C. during the war. He had long practised at Skegby, and was held in high esteem by his patients and colleagues. He was a member of the Nottingham Division of the British Medical Association. Dr. Crawford was at work on December 15th, and appeared to be in his usual health, but the next day he had an attack of cerebral haemorrhage. He was attended by his friend Dr. Tweedie, of Sutton, but died in the early morning of December 18th. He was buried at Stanton Hill, where the miners who followed the remains and carried them to their last resting place filled the church. Dr. Crawford had three sons, one of whom was killed in France during the war.

Dr. CHARLES ROBERT LEADER died from syncope on December 14th, 1919, aged 57 years, at the Old Hall, Wem, Salop. He had been at work up to late the night before his death. He was the son of Henry Leader of Clonmoyle, co. Cork, and was educated at Repton and Queen's College, Cork. He had been in practice at Wem for over twenty years, and was very popular there with all classes of people.

MAJOR-GENERAL JAMES GAUSSEN MACNEECE, C.B., Army Medical Staff (retired), died suddenly at Southsea on December 13th, 1919, aged 63. He was born at Arboe, County Tyrone, on February 27th, 1856, the son of the Rev. James MacNeece, M.A., of Clonfeacle Rectory, Moy, and of Mulnagar Lodge, Dungannon, County Tyrone. After taking the diplomas of L.R.C.S.I. and L.K.Q.C.P.I. in 1877, he entered the army as surgeon on August 4th, 1878, becoming surgeon-major on August 4th, 1890, lieutenant-colonel on August 4th, 1898, colonel on June 4th, 1905, and surgeon general on April 23rd, 1910, and

retiring on December 28th, 1917. He served as P.M.O. at Malta in 1905-9, of the Lucknow Division in 1910-11, and of the Southern Command, England, in 1912-14, till appointed Director of Medical Services in India in 1915. His war services comprise the Afghan war of 1878-80, the siege of Kandahar, and battle of September 1st, for which he received the medal; the Bozdar campaign of 1881, and the Zhob Valley expedition of 1884, on the North-West Frontier of India. In South Africa, 1900-1, he was in charge of a general hospital, with temporary rank of colonel, from January, 1900, to November, 1901, and took part in operations in Natal, March to June, 1900, and in the Transvaal, January to November, 1901. He was mentioned in dispatches, and received the Queen's medal with three clasps. In 1908 the King of Italy bestowed on him the decoration of Commander of the Order of St. Maurice and St. Lazarus for services in connexion with the Messina earthquake of that year, and he received the C.B. at the Coronation on June 19th, 1911.

LIEUT.-COLONEL M. MACGREGOR RATTRAY, D.S.O., died suddenly at Basra, Mesopotamia, on November 27th. He was born at Portobello, Midlothian, in 1869, being the second son of the late A. M. T. Rattray, M.D. He graduated M.B. and C.M. at the University of Edinburgh in 1893, and four years afterwards entered the R.A.M.C. as surgeon-lieutenant. He became lieutenant-colonel in 1915 and temporary colonel the following year. He took part in the South African war of 1900-2, receiving the Queen's medal with three clasps, and the King's medal with two clasps. He served for over four years in the late war, until he was invalided home early in 1919. He received the D.S.O. in 1917, and was twice mentioned in dispatches. Colonel Rattray leaves a sister and two brothers, one of whom is a brigadier-general in the Indian Army and the other Dr. A. M. Rattray of Treharris, Glamorgan.

LIEUTENANT-COLONEL GRENVILLE EDWIN MOFFET, R.A.M.C. (ret.), died at Brechin, Forfarshire, on December 14th, 1919, aged 63. He was born on December 10th, 1856, and educated at the Universities of Calcutta, where he was Duff scholar in 1874, and Aberdeen, where he graduated M.B. and C.M. in 1883. Entering the R.A.M.C. as surgeon in January, 1885, he became lieutenant-colonel on January 31st, 1905, retiring on October 21st, 1905. After retirement he was employed at Perth as medical inspector of recruits from 1905 to 1910, and was also inspecting medical officer of school children. He served in South Africa from 1899 to 1901, took part in operations in the Orange River Colony, and received the Queen's medal with a clasp; he rejoined for service in the recent war, from March 23rd, 1915, and served under the Ministry of National Service until the present year.

MAJOR RICHARD JAMES BRADLEY, Indian Medical Service, was reported as having died on service, in a casualty list published on December 31st, 1919, aged 43. He was educated at Edinburgh University, where he graduated M.B. and Ch.B. in 1901. He entered the I.M.S. in 1902, and attained the rank of major in 1913. He was medical officer of the 14th Gurkha Rifles, with which he served in the North-West Frontier of India campaign of 1908, receiving the Frontier medal with a clasp; he served also in the late war. He was decorated with the White Eagle of Serbia, Fourth Class, in February, 1917.

STAFF SURGEON SAMUEL GROSE, R.N. (ret.), died at Bishop's Teignton, on December 12th, 1919. He was educated at St. Thomas's Hospital, and took the diplomas of M.R.C.S. and L.S.A. in 1859, entering the navy soon after, and retiring with the rank of staff surgeon, which he reached on August 19th, 1870. He also took the diploma of F.R.C.S. Eng. in 1868, and the degree of M.D. St. Andrews in 1878. After retirement he held the post of honorary medical officer of Melksbam Cottage Hospital for twenty-two years. He was a member of the Torquay Natural History Society, of the Devon Association for the Advancement of Science, and of the Wiltshire Archaeological Society.

BRIGADE SURGEON WILLIAM GEORGE ROSS, R.A.M.C. (retired), died at Thornton Heath, Surrey, on December 25th, 1919, aged 79. He was educated at Edinburgh University, where he graduated M.D. in 1862, and entered the army as assistant surgeon on October 1st, 1862. He retired with the rank of brigade-surgeon in 1885. In the regimental days he served in the King's Liverpool Regiment (the 8th Foot).

SURGEON-MAJOR GEORGE KENNETH POOLE, Bengal Medical Service (retired), died at Upper Norwood on December 19th, 1919. He was born in March, 1832, the son of the Rev. John Poole of Kensington. He received his medical education at the London Hospital, and took the diploma of M.R.C.S. in 1855 and the degree of M.D. at Erlangen in 1863. He entered the I.M.S. as assistant surgeon on March 14th, 1855, being nominated by Mr. W. T. Priese, and was one of the last to receive his commission by nomination, after the introduction of competitive examination in January, 1855, getting a vacancy caused by Assistant Surgeon T. E. Clarke, nominated in December, 1854, not joining. He became surgeon in 1867, and surgeon-major in 1873, retiring on May 7th, 1876, forty-three years ago. After his retirement he was consulting surgeon to the Dalrymple Home for Inebriates, and surgeon-major of the Lambeth National Reserve.

CAPTAIN GEORGE ALAN MITCHELL, R.A.M.C. S.R., was reported as having died on service, in a casualty list published on December 23rd, 1919. He was educated at Liverpool University, where he graduated M.B. and Ch.B. in 1912, took a commission as lieutenant in the Special Reserve of the R.A.M.C. the same year, and was promoted to captain after a year's service.

Medical News.

A POST-GRADUATE course in neurology will be given at the National Hospital for the Paralyzed and Epileptic, Queen Square, W.C.2, during January, February, and March, beginning on Monday, January 18th. The fee for the course is seven guineas; further particulars can be obtained from the Dean of the Medical School. A course of practical pathology, the fee for which will be five guineas, will be given by Dr. J. G. Greenfield if there is a sufficient number of entries.

A COURSE in the diagnosis and treatment of the nervous disorders due to war will be given in the clinique of Professor Gilbert at the Hôpital-Dieu, Paris, beginning on January 26th. It has been organized by Professor Maurice Villaret with the co-operation of ten other lecturers who have given particular attention to neurology, and will include demonstrations on orthopaedics and treatment by exercises. The course will extend over three weeks and will occupy both mornings and afternoons. It will be essentially practical and clinical. The fee for the course, which is open to foreign doctors, is 150 francs, payable to the Secrétariat de la Faculté de Médecine, Paris.

THE NATIONAL Association for the Prevention of Infant Mortality and for the Welfare of Infancy has arranged for two courses of advanced lectures on infant care. One is intended for crèche nurses and probationers, and the other for teachers, infant welfare workers, mothers, etc. The first course is being given at the Essex Hall, Essex Street, Strand, W.C., on Thursdays, from 7.30 to 8.30 p.m., commencing on January 23rd; the fee is 10s. for the course, or 1s. for any individual lecture. The second course will be given at the Morley Hall, George Street, Hanover Square, W.1, on Mondays, from 5.30 to 6.30 p.m., commencing on January 12th, the fee for which is 5s. for the course, or 1s. for any particular lecture.

PROFESSOR ARTHUR KEITH will give six lectures on John Hunter's observations and discoveries in anatomy and surgery, at the Royal College of Surgeons of England, on Mondays, Wednesdays, and Fridays during the last two weeks of this month. The lectures will be given at 5 p.m., and the first, on January 15th, will deal with Hunter's contributions to our knowledge of the heart and blood vessels.

PROFESSOR G. ELLIOT SMITH will begin a course of lectures on the art anatomy at University College, London, on January 15th, at 5 p.m.

The address by Sir H. H. Fowler on the uses and methods of application of post-graduate teaching will be given on Tuesday next, at 4.30 p.m. at the Prince of Wales's General Hospital. Members of the profession are invited to attend.

MR. JOSEPH WATSON of Wetherby has presented the sum of £50,000 to the Leeds General Infirmary as a new year's gift, stipulating that £10,000 shall be invested for the benefit of a nurses' pension fund.

THE offices of Epsom College have been transferred from 37, Soho Square, W., to 49, Bedford Square, W.C.1.

AN order has been issued by the Ministry of Health, continuing the regulations for the compulsory notification of acute encephalitis lethargica and acute haemorrhagic leucencephalitis until further notice.

DR. ROBERT DONALDSON, M.A., F.R.C.S., D.P.H.L., has been appointed Pathologist and Curator of the museum at St. George's Hospital. The appointment was held by the late Dr. R. Salisbury Trevor, since he died the work of the curator has been carried on by Miss Helen Ingilby, M.B.C.P., and Sir Humphry Rolleston, K.C.B., has been supervising the pathological laboratory honorarily.

THE League of Red Cross Societies has informed the presidents of the twenty-eight National Red Cross Societies, members of the League, that a meeting of the General Council will be held at Geneva on March 2nd, 1920. The business of the meeting will be the appointment of additional governors, the discussion of the progress of the League on the lines indicated at the Cannes conference, and of future development in general.

DR. GEIKIE CORB's book, *The Origin of Internal Secretion*, of which the second edition was notified in our columns last March, has been translated into Spanish by Drs. De La Poza and Toutain and into Italian by Professors Belfanti and Valagnosa.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 423, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 423, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Autology*, Westrand, London, telephone, 2531, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London, telephone, 2530, Gerrard.
3. MEDICAL SECRETARY, *Melusera* Westrand London, telephone, 2534 Gerrard. The address of the Irish Office of the British Medical Association is 18, South Frederick Street, Dublin.

QUERIES AND ANSWERS.

FETAL MOVEMENTS.

A CORRESPONDENT raises the question whether it is possible to deduce any facts as to a child's future size, physical development, and sex from the violence of the fetal movements in utero at the seventh month.

* The answer, so far as we are aware or can ascertain, is a general negative. It would not be unreasonable to expect that a child that was particularly "live" in utero at the seventh month and consequently, would prove at birth to be healthy and well developed; but nothing could with any safety be deduced as to sex or other particulars. There are other factors to be considered besides the fetus—for example, the nervous susceptibility of the mother, the thickness or thinness of the uterus and abdominal walls, the presence or absence of the placenta anteriorly, the quantity of liquor amnii and so forth.

INCOME TAX.

E. F. F. inquires whether a local assessment charging 1s. 9d. in the £ on his military pay for service in the Egyptian Expeditionary Force is correct.

* The rate, 1s. 9d. in the £, is the correct rate for six years mentioned provided that the amount of the total income

for each year exceeded £500 but did not exceed £1,000. Normally the tax is deducted by the army pay agents, but we understand that local assessments have been made in some cases where an insufficient amount of tax was deducted by the agents. We suggest that "E. E. F." ascertain from Holt and Co. exactly what tax was deducted by them, and that he then compares those figures plus the amount of tax charged locally with the tax calculated at Is. 9d. in the £ on the amount of the pay for each year. If our surmise as to the origin of the local charge is correct, the local inspector of taxes should be able to explain the matter in detail.

LETTERS, NOTES, ETC.

THE PREVENTION OF BERI-BERI.

DR. ALFRED S. GUBB (Algiers) writes: The cause of beri-beri having been traced to the use of polished or over-milled rice as food, we are comforted by the assurance that the disease can be cured by administering an extract of rice polishings to the sufferers. But why in the name of logic and common sense do the authorities not prohibit the placing of polished rice in the market—at any rate, in the market whence the afflicted populations derive their supplies? It may be, of course, that for some inscrutable reason this measure does not fall within the compass of practical politics, but if not, why not? It has been drummed into our ears so long that "prevention is better than cure," that the above suggestion obtrudes itself on one's attention.

SEVERE ANAPHYLAXIS: RECOVERY.

DR. G. C. GARRATT (Chichester) writes: I am sure we shall all be ready, with Dr. A. Escourt-Oswald (December 27th, 1919, p. 868), to congratulate Captain Munro on his "prompt and plucky treatment" which achieved such success *BRITISH MEDICAL JOURNAL*, November 22nd, 1919, p. 668). Nevertheless one is tempted to wonder whether the remedies used were the best possible. He injected adrenalin, used chloroform inhalation under conditions which for a time precluded satisfactory anaesthesia, and forcibly compressed the chest. Was there not grave risk of inducing fatal ventricular fibrillation? It would be very useful to know whether the good results obtained could have been achieved by the chloroform without the adrenalin, or the latter without the chloroform, or whether the atropine also given prevented injurious action by a combination generally regarded as so risky as adrenalin and chloroform. As such a case might occur in the practice of any one, the answer to these questions assumes real importance, and I hope it may be forthcoming from some source or other.

OCULAR CONDITIONS IN INFLUENZA.

MR. SYDNEY TIBBLES (London, W.) writes with reference to paragraph 242, p. 41, of *Epitome*, December 13th, 1919: A doctor's sister asked me, on visiting, in 1913, to see her cat, which had had influenza, and was being treated by a veterinary surgeon. It had mydriasis of both eyes and some limitation of movement of the external ocular muscles, and also, apparently, peripheral neuritis of one leg. A week later violent iridocyclitis set in with much keratitis profunda. In spite of atropine locally, extensive iritic adhesions formed, and the cat became half blind, and was destroyed. It was impossible to obtain an eye for sectioning, but so long as it was possible to see the fundus there were no further complications. Veterinary surgeons have told me that iridocyclitis is fairly common after influenza in cats, but I do not know whether that is so or not.

THE FOUNDER OF CHINESE MEDICINE.

SHEN NUNG (B.C. 2733-2697) is generally regarded as the founder, or rather the first patron, of medicine in China. He ruled as an emperor first in Shensi and later in Shantung, with Yenchowfu as his capital. His name has been handed down by tradition as the founder of agriculture, trade by exchange of commodities, and medicine by the use of various kinds of herbs for the relief of pain, and by distinguishing medicinal from poisonous plants. The image of Shen Nung is often found in temples dedicated to agriculture. The *National Medical Journal of China* for June publishes a photograph taken from a figure shrined in a special temple in the famous Imperial Granary established at Peking by the Ming emperors, where for centuries the tribute rice from various provinces was stored. This granary has now been demolished, and its site is occupied by the new Army Medical College, transferred from Tientsin, and now under the direction of Surgeon-General Chuan Shao Ching.

THE TALIA-COTIAN DOCTRINE.

A CORRESPONDENT writes with reference to Sir J. O. Skevington's note on "Separation of the tip of the nose with complete primary adhesion" (*BRITISH MEDICAL JOURNAL*, September 27th, 1919) to recall certain passages in John Bell's *Principles of Surgery*, vol. 1, published in 1801. In discussing the "Talia-cotian doctrine of adhesion," Bell says that the vulnerability of Garbage is responsible for the following: "A young fellow, as a soldier, reeling out of a tavern drunk along with some of his companions, got into a quarrel

in which one of them bit his nose off, threw it into the gutter and trod it under foot. He picked up his nose, flung it into Mr. Gallin's, an apothecary's shop, ran after the fellow who had done it, and when he returned Mr. Gallin washed the nose at the well, stuck it with plaster in its place, and in two days after it was firmly united; and Mr. Garengot four days after dressed the nose with his own hands." The Talia-cotian doctrine of adhesion, says Bell, is unquestionably true but not to this extent; "I hold it possible to preserve every flap of skin, though almost entirely insulated (though left hanging by a tag merely) but those parts which are entirely separated are entirely and irreversibly dead."

Bell emphasizes his scepticism by quoting Rabelais's burlesque story of the setting on of a head: "Having gone out to search the field for Epistemon, they found him stark dead, with his head between his arms all bloody. But Panurge said, my dear buddies all, weep not one drop more, for he being yet all hot I will make him as sound as ever he was. In saying this he took the head, and held it warm fore-against his cod-piece, that the air might not enter into it, and other two carried the body. Leave off crying, quoth Panurge and help me. Then cleansed he the neck very thoroughly with white wine, afterwards he anointed it with I know not what ointment, and set it on very just, vein against vein, sinew against sinew, and apodyne against spodyne, that he might not be wry necked. This done he gave it round about, some fifteen or sixteen stitches with the needle. Suddenly Epistemon began to breathe, then opened his eyes, yawned, squeezed . . . ; now certainly quoth Panurge, he is healed, and so he was finely, only that he was somewhat hoarse for about three weeks together." Rabelais may have had in mind the story of the Laconian woman named Avata who suffered from a dropsy. Her mother made a pilgrimage for her to the sanctuary of Aesculapius at Epidaurus, and there dreamed that the god cut off Avata's head, and bung the body up neck downwards till all the water had run out; he then took down the body and clapped on the head. On the mother's return to Lacedaemon she found her daughter perfectly cured (*Frazer's Folk Lore in the Old Testament*, vol. ii, p. 48.)

A SOFT ANSWER.

SIR SAMUEL WILKS was severe in his judgement of contemporaries and was apt occasionally to express his opinion in caustic phrases his victim did not easily forget. It may have been a resolution to be more careful in an official position that led him unexpectedly to get up at an informal dinner on the evening of the day of his election to be President of the Royal College of Physicians and make a little speech on the text, "A soft answer turneth away wrath." As an illustration of the advantage of acting in this spirit he told a story of Addison, who had been his teacher at Guy's. The story, so far as we are aware, has not hitherto appeared in print, although it may be well known, since we were reminded of it some years ago by a correspondent. When Addison was establishing the nature of the disease which bears his name Dr. George Harley, who lived in a house near Addison's, took to meetings of the Pathological Society cats which had apparently remained in good health after removal of the adrenals, proving, as Harley contended, that these organs were of no vital importance and that disease of them did not cause the symptoms described by Addison. At one meeting of the Society he brought a dissection of a cat apparently perfectly healthy, which nevertheless had diseased adrenals. Addison did not argue the matter, but asked Harley what was the colour of the cat. "An ordinary tortoiseshell cat," Harley replied. "Ah!" said Addison, "I knew that cat. Six months ago it was a white cat."

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 42, 45, 46, 47, 48, and 49 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 43, 44, and 45.

THE following appointments of certifying factory surgeons are vacant: Kidwelly (Carmarthen), Kirkliston (Linlithgow), Lerwick (Shetland), Moll (Flint).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0 6 0
Each additional line	0 0 9
Whole single column	4 0 0
Whole page	12 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

THE TREATMENT AND MANAGEMENT OF DISEASES DUE TO DEFICIENCY OF DIET:

SCURVY AND BERI-BERI.*

BY

W. H. WILLCOX, C.B., C.M.G., M.D., F.R.C.P.,
COLONEL A.M.S.,

CONSULTING PHYSICIAN TO THE MESOPOTAMIAN EXPEDITIONARY FORCE (1916-1919).

AMONG the many fascinating and interesting medical problems which presented themselves during the campaign in Mesopotamia those connected with scurvy and beri-beri occupied the foremost place. These two deficiency diseases occurred to a greater extent in Mesopotamia than in any theatre of war.

The enormous wastage caused by scurvy in that campaign can be realized from the statistics available; thus, 11,445 cases occurred in the last six months of 1916. These cases were almost all evacuated to India, since they were quite unfit to undergo the hardships of active service in the field.

The careful investigations made in connexion with these diseases in Mesopotamia, and the results of the management—that is, the scientific rationing—of the troops, have most conclusively established that both scurvy and beri-beri are essentially deficiency diseases and are due to a deficiency in the respective vitamins in the dietary associated with their causation.

From the beginning of May, 1916, until the end of January, 1919, as senior consulting physician to the Mesopotamian Expeditionary Force, I made a special study of scurvy and beri-beri from their clinical aspects and from the point of view of prevention and treatment, and acted as special adviser with regard to deficiency diseases. I would take this opportunity of expressing my thanks to the Directors of the Medical Service, Major-General Sir Francis Treherne, K.C.M.G., and Major-General A. P. Blenkinsop, C.B., C.M.G., for the help and encouragement always given me in this work.

In order to understand clearly the problems which presented themselves in the Mesopotamian campaign in connexion with the management of scurvy and beri-beri it is necessary to pass in review the circumstances which effected the rationing of the troops in so far as they related to the occurrence of scurvy and beri-beri.

The Mesopotamian campaign commenced on November 6th, 1914, when troops under General Delamain landed at Fao; on November 22nd, 1914, when General Sir Arthur Barrett was in command, Basrah was occupied. The force pushed its way up the Tigris, and after a series of brilliant military successes Kut was captured on September 28th, 1915.

From the beginning of the operations until 1916 the Mesopotamian Force was under the control of the Indian Government, and the system of rationing troops was based on the field service scale of rations laid down in War Establishments, India.†

It may be stated now that scurvy in Mesopotamia was practically limited to Indian troops. A few isolated cases occurred amongst British troops; their causation could be traced to inadequate dietary owing to some other diseases occurring in the individual patient.

TABLE I.—Field Ration of British Troops.

Bread	1 lb.	Sugar	2½ oz.
Fresh meat	1 lb.	Salt... ..	½ oz.
Bacon	3 oz.	Pepper	5/8 oz.
Potatoes	1 lb.	Fuel	5 lb.
Tea	1 oz.		

TABLE II.—Field Ration of Indian Troops and Followers.

Atta	1½ lb.	Ginger	¼ oz.
Fresh meat	4 oz.	Chillies	½ oz.
Dhall	4 oz.	Turmeric	½ oz.
Ghi... ..	2 oz.	Garlic	¼ oz.
Gur	1 oz.	Salt... ..	½ oz.
Potatoes	2 oz.	Fuel	1½ lb.
Tea	½ oz.		

Beri-beri, on the other hand, was limited to British troops; practically no cases occurred amongst Indians.

Some cases occurred amongst the Chinese Labour Corps at Basrah in 1918, and also amongst the crews on board ships arriving at Basrah. Both of these epidemics were traceable to polished rice as the etiological factor.

A review of the ration scales shows that as regards deficiency disease the ration for British troops was fairly satisfactory. Attention will be called later to the deficiency as regards the anti-beri-beri factor under the conditions of service at the front. For Indian troops the field service ration was very deficient as regards anti-scorbutic vitamins, the only anti-scorbutics being 2 oz. of potatoes and 4 oz. of fresh meat. This deficiency became much accentuated owing to the conditions of service at the front.

The great cause of the wastage in the Indian troops of the Mesopotamian force up to the end of 1916 was scurvy. To understand this thoroughly it is necessary to explain the system of rationing of Indian troops in India prior to 1917. An allowance was made to each soldier equivalent to the cost of the items in the field service ration. He bought his ration from the bunniah or food contractor of his unit. The Indian has the instinct of saving money for his family very firmly implanted in his mind, and under the old system of rationing Indian troops in India there was no guarantee that the Indian soldier bought and consumed even the field service ration. He no doubt often starved himself to save a few annas.

As a consequence of this system the Indian troops arriving from India in Mesopotamia in many cases showed a considerable percentage of men anaemic and debilitated, and suffering from pyorrhoea; they had little balance in the bank, so to say, against the onset of the deficiency disease scurvy, and their latent period would be short were dietetic hardships imposed on them. My colleague the late Colonel H. C. Melville, I.M.S., paid special attention to the examination of Indian troops arriving from India during the latter half of 1916, and he found at this time a considerable percentage of men on arrival to be anaemic, debilitated, and suffering from pyorrhoea. These men were not actually suffering from scurvy, but they were in a condition which strongly predisposed them to it.

The British soldier, on the other hand, came out to Mesopotamia well nourished and with a good balance in his bank against deficiency disease, and if he developed this his latent period would be a long one.

A glance at the map of Mesopotamia shows the military situation up to February 23rd, 1917, when the Tigris was crossed at Shumram and the Turks retreated towards Baghdad. From December 11th, 1915, down to this date the operations of the Mesopotamian Force were directed towards the relief of Kut and the advance onwards to Baghdad.

Basrah and Amara were centres of local production of fresh fruit and vegetables and the incidence of scurvy was very slight amongst the troops stationed there. Beyond Amara there were no centres of local production of fruit or vegetables and troops had to rely entirely on the river transport for supplies of these articles.

Attempts were made by the army to grow vegetables for the troops, but it was impossible to do this in sufficient quantity since in Mesopotamia irrigation is essential for cultivation and a scheme for growing vegetables for the army on a large scale would have taken a very long time to carry out. To grow fruit and vegetables successfully involved a long and intimate experience of local conditions, and it was found that this could be much more economically and satisfactorily carried out by the native Arabs under our supervision; the produce was purchased from them by the army.

During 1915 and 1916 the river transport was taxed to its utmost in conveying troops and supplies and in carrying sick and wounded downstream. No special provision for the transport of fresh fruit or vegetables or fresh meat was available until towards the end of 1916. The climatic conditions of Mesopotamia were such that vegetables and fruit sent by river from Basrah arrived generally in a damaged condition unsuitable for issue.

It is thus obvious that the troops in the front area from December, 1915, to February, 1917, obtained few supplies of fresh vegetables or fruit; this explains the fact that up to February, 1917, there was an enormous incidence of scurvy amongst Indian troops in the front area in Mesopotamia.

* A paper read before the Section of Therapeutics and Pharmacology of the Royal Society of Medicine.

† Pages 10 and 11: Table 1, British rations; Table 2, Indian rations.

Alterations of Rations.

The incidence and causation of deficiency diseases in Mesopotamia was thoroughly appreciated, and steps were taken to put the ration scales on a scientific basis in this respect. The army commander, Sir Percy Lake, in 1916 with this object sanctioned the ration scales of July 4th, 1916, which were a great improvement as regards the protection from deficiency diseases.

TABLE III.—RATIONS, JULY 4TH, 1916.

A. Field Rations of British Troops.			
Bread	... 1 lb.	Condensed milk...	2 oz.
Fresh meat	... ½ lb.	Salt	... ½ oz.
Bacon	... 3 oz.	Pepper	... 3/8 oz.
Potatoes	... 1 lb.	Wood	... 3 lb.
Tea	... 1 oz.	Oatmeal	... 4 oz.
Sugar	... 2½ oz.	Condensed milk	... 2 oz.
Cheese	... 3 oz.	Tobacco (weekly)	... 2 oz.
Rice	... 3 oz.	Matches (boxes weekly)	2
Jam	... 3 oz.		

Extras.

Chocolate	... 1 oz.	Dates	... 4 oz.
Bread	... 4 oz.	Fresh fruit	... 4 oz.
Lime juice	... ½ fl. oz.	Dry lentils	... 2 oz.
Rum	... ½ oz.	Curry powder	... 3/8 oz.
Sugar	... 4 fl. oz.	Limes (per man)	3

B. Field Rations of Indian Troops.

Atta	... 1½ lb.	Tea	... ½ oz.
Fresh meat	... 4 oz.	Ginger	... ½ oz.
Dhall	... 4 oz.	Chillies	... ½ oz.
Ghi	... 2 oz.	Turmeric	... ½ oz.
Gur	... 2 oz.	Garlic	... ½ oz.
Potatoes	... 2 oz.	Salt	... ½ oz.
Fresh fruit	... 2 oz.	Fuel	... 1½ lb.
Tobacco (weekly)	... 2 oz.	(Substitutes same as per British troops.)	
Matches (boxes weekly)	2		
Condensed milk	... 2 oz.		

Extras.

Atta	... ½ lb.	Fresh fruit	... 4 oz.
Ghi, 1 oz., or Gur	... 2 oz.	Tamarind	... 2 oz.
Fresh meat	... 2 oz.	Rum (25 per cent. under proof)	... 2 fl. oz.
Fresh vegetables	... 4 oz.		

Later the rations were further improved, and the army commander, General Sir Stanley Maude, who took a very great interest in the prevention of scurvy and beri-beri, sanctioned the ration scales of October 31st, 1916.

TABLE IV.—RATIONS, OCTOBER 31ST, 1916.

A. British Troops.

Daily:	Weekly:
Bread ... 1 lb.	Pepper ... ½ oz.
Or biscuit when bread not available... 12 oz.	Mustard ... ½ oz.
Fresh meat ... 1 lb.	Tobacco ... 2 oz.
Or preserved when fresh not available... 12 oz.	Or cigarettes No. 40, or sweets ... 4 oz.
Pickles when preserved meat is issued ... 1 oz.	Matches (boxes) ... 2
Bacon ... 3 oz.	Twice weekly:
Potatoes or fresh vegetables ... 12 oz.	Marmite (Monday and Thursdays; not in summer) ... ½ oz.
Or dried vegetables when fresh not available ... 3 oz.	Thrice weekly:
Tea ... 3/8 oz.	Oatmeal (Mondays, Wednesdays and Fridays) ... 3 oz.
Cheese (not in summer) ... 3 oz.	Tinned milk (Mondays, Wednesdays, and Fridays) ... 1 oz.
Sugar ... 3 oz.	Rice (Tuesdays, Thursdays, and Saturdays) ... 2 oz.
Jam or golden syrup ... 3 oz.	Curry powder (Tuesdays, Thursdays, and Saturdays) ... ½ oz.
Tinned milk ... 2 oz.	Butter (Mondays, Wednesdays, Fridays; not in summer) ... 2 oz.
Salt ... ½ oz.	Lime juice (Tuesdays, Thursdays, Saturdays; not in winter) ... ½ oz.
Fresh fruit ... 2 oz.	
Or tinned fruit 2 oz., or dried fruit 1 oz., when fresh fruit not available	
Soup or oxo (not in summer) ... 2 oz.	
Fuel (coal 1 lb., wood 1 lb.) ... 2 lb.	

B. Indian Troops.

Daily:	Daily (cont.):
Atta or rice ... 1½ lb.	Condiments (ginger, chillies, garlic, turmeric) ... 3 oz.
Fresh meat ... 6 oz.	Salt ... ½ oz.
Gur when fresh meat not available ... 2 oz.	Tamarind or cocum ... 2 oz.
Dhall ... 4 oz.	Fuel (wood) ... 2 lb.
Gur ... 2 oz.	Thrice weekly:
Ghi ... 2 oz.	Ghi (Mondays, Wednesdays, Fridays) ... 2 oz.
Potatoes or fresh vegetables ... 6 oz.	Lime juice (Tuesdays, Thursdays and Saturdays; not in winter) ... ½ fl. oz.
Dried vegetables when fresh not available ... 2 oz.	Weekly:
Fresh fruit ... 2 oz.	Tobacco (Sundays) ... 2 oz.
Tinned fruit 2 oz., or dried fruit 1 oz., when fresh fruit not available	Or cigarettes No. 40, or sweets ... 4 oz.
Tea ... ½ oz.	Matches (boxes) ... 2
Milk, tinned ... 2 oz.	

Reviewing the ration scales of October 31st, 1916, we find that as regards protection against scurvy the Indian ration contained:

Potatoes or fresh vegetables—for example, onions	... 6 oz.
Fresh fruit (limes, etc.)	... 2 oz.
Fresh meat	... 6 oz.
Tamarind or cocum	... 2 oz.
Lime juice (three times a week)	... ½ oz.

The only difficulty was to convey this ration to the troops. The fierce heat of Mesopotamia rendered it impossible to carry perishable articles, such as vegetables, fruit, and fresh meat, up the 300 mile journey on the Tigris without special provision as regards transport. Down to the later part of 1916 transport was inadequate both on river and land to cope with this great problem. Towards the end of 1916 the transport was much improved, and the refrigerator barges which arrived, with cold storage chambers for fresh meat, were of great value.

Major-General Sir G. MacMunn, K.C.B., Inspector-General of Communications, took a great interest in the problem of conveying antiscorbutics to the troops on the front, and devised crates for the carrying of fresh vegetables and fruit which were of great value in protecting them from damage during transport.

Fresh Meat.

The evidence from the Mesopotamian campaign proved that fresh meat has important antiscorbutic value. During 1916, when the troops at the front, both British and Indian, were unable to get fresh vegetables or fruit for long periods, the only protection that the British had above that of the Indians was the fresh meat allowance of 1 lb. daily. Usually two or three issues were obtained from local supplies of Arab sheep; on other days tinned beef was issued. The Indian troops did not care for meat, and usually had only one or two rations of 6 oz. a week. On other days, owing to their class prejudices, tinned meat could not be issued.

Further evidence of the value of fresh meat was obtained by investigations carried out by Major Marjoribanks, I.M.S., on Indian patients suffering from scurvy, in 1916, at Nos. 9 and 10 Indian General Hospitals. Two parallel groups of scurvy cases were treated on identical lines as regards diet, except that one group was given a daily ration of fresh meat juice; they improved much more rapidly than the other patients. I saw these patients several times in consultation, and can testify to the striking antiscorbutic value of raw meat juice.

The climatic condition of Mesopotamia and the risk of parasitic infection prohibited the general use of raw meat juice in the treatment and prophylaxis of scurvy, but in the treatment of cases of scurvy in hospital the beneficial effect of a liberal allowance of fresh meat was very striking.

Tamarind.

In all probability the tamarind has antiscorbutic properties. It was taken by the Indian troops either as a chutney with stewed meat or, as an infusion with sugar, formed a palatable acid drink. Cocum is a sort of dried plum, which appeared to have no antiscorbutic value. It has had a reputation in India as an antiscorbutic, but it was not liked by the Indian troops, and was little used in Mesopotamia.

Lime Juice.

The ration lime juice up to the end of 1916 had no antiscorbutic value, and produced no beneficial effect on patients suffering from scurvy. It usually arrived in Mesopotamia after a long journey overseas, and was probably six months or more old before issued. At my suggestion, in August, 1916, fresh lime juice was prepared in India from fresh limes, a small quantity of alcohol (5 per cent.) and salicylic acid (2 grains to the pint) being added as a preservative. This was sent to Mesopotamia in special casks with the date of preparation marked on it, and gave better results as regards antiscorbutic properties; it was used in the treatment of patients suffering from scurvy as well as for issue to troops.

Lime juice as a prophylactic against scurvy is of uncertain value, since it is difficult to ensure its delivery to an army in the field within three months of its preparation, and after that time much of its antiscorbutic value is lost. Undoubtedly when fresh it has important antiscorbutic properties, as I saw demonstrated on many occasions in patients suffering from scurvy. After the occupation of

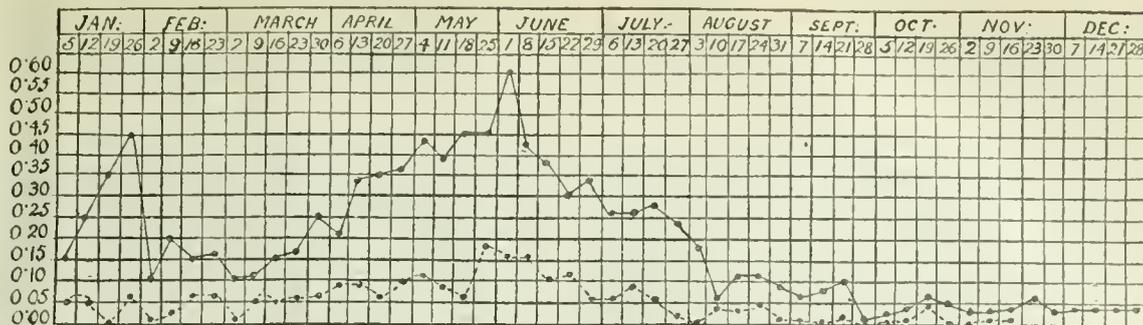

Chart showing admission rate to hospital per mille of Indian strength. Upper curve = 1917. Lower curve = 1918.

Baghdad lime juice was prepared from limes and bitter oranges obtained locally; preservative was added as above described. It was issued to troops with as little delay as possible, and had undoubted value as an antiscorbutic. The recent work of Miss Chick and Miss Hume showing the superior value of lemon juice to lime juice is of great value and interest.

During the deficiency of fresh vegetables and fruit in 1916, owing to the great incidence of scurvy among Indian troops, an order was issued that they should have the first call on the fresh vegetables and fruit available.

Beri-beri in Relation to the Ration Scales.

Indian.—This ration is highly protective as regards antiscorbutic vitamins. Atta, the usual issue to Indian troops, although rice was an alternative, is a wheat flour containing the germ and some of the aleurone layer of the grain, so that it is rich in anti-beri-beri vitamins. Dhall contains the coat and germ of the lentil, and is also rich in anti-beri-beri vitamins.

British.—In 1915 over 300 cases of beri-beri occurred amongst British troops. The India field service British ration was protective against beri-beri, but owing to the inadequacy of transport and the long distances from the base, fresh meat and vegetables were not available for the troops at the front, so that the basis of the ration was tinned beef, bread or biscuits, jam and tea. The British bread and biscuits were made of white flour from which the germ and aleurone layer had been removed, thus depriving them entirely of anti-beri-beri vitamins. The British soldier as regards this became liable to beri-beri, and in many cases became a victim to the disease.

In the July, 1916, ration, oatmeal 4 oz. and dhall 2 oz. were added to the British ration to supplement the British vitamin deficiency. In October, 1916, marmite ¼ oz. three times weekly was added to the ration.

Beri-beri cases occurred in the Dardanelles; I saw practically all of them, and at the suggestion of Colonel C. J. Martin advised the treatment with yeast, which gave satisfactory results.

In February, 1916, I suggested to the Sanitary Committee of the War Office the advisability of an extract of yeast being issued to the troops as a prophylactic against beri-beri. Experiments instituted by Major-General Sir William Horrocks, K.C.M.G., were carried out by Professor Starling, F.R.S., Dr. S. M. Copeman, and their co-workers, who showed that extract of yeast was a prophylactic against beri-beri, and a preparation known as marmite was issued to British troops in Mesopotamia in October, 1916. Marmite can be mixed with warm water and taken like bovril or be added to a stew after cooking. It was undoubtedly of great value as a prophylactic against beri-beri in Mesopotamia, and it was a valuable remedy in the treatment of cases that occurred. It kept well in Mesopotamia, and no difficulty was experienced in its issue as a ration to troops.

In February, 1917, at my request experiments were carried out at Amara to determine the practicability of issuing to British troops bread made with a certain proportion of atta in the flour. Loaves were made with flour containing 100 per cent., 75 per cent., 50 per cent., and 25 per cent. respectively of atta. The bread was very palatable, but the addition of much atta caused some difficulty in the rising of the dough so that the bread was somewhat heavy. Bread made with 25 per cent. of atta

was quite as palatable, and differed little except in the slightly brownish colour from ordinary bread. It was issued to several units at Amara with satisfactory results, and later on a general issue to the army on three days a week was sanctioned by the General Officer Commanding in Chief. The issue to British troops of bread rich in anti-beri-beri vitamins was undoubtedly an important factor in the reduction of beri-beri among them.

Rice.

As a causal factor of beri-beri amongst the troops rice did not attract much attention, because atta was almost entirely issued in its place to Indian troops. But in 1918 a Chinese Labour Corps arrived at Basrah, and the men of this unit refused to eat any rice except the polished variety; in consequence a number of cases of beri-beri occurred amongst them. The difficulty was overcome by the issue of atta in place of a portion of the rice ration; the outbreak of beri-beri then subsided.

After the occupation of Baghdad on March 11th, 1917, local supplies of fresh vegetables and fruit and fresh meat became available in ample quantity. General Dickson, C.M.G., C.B.E., Director of the Department of Local Resources, took the greatest pains in ensuring the issue of these articles to the troops throughout the advanced area. It was owing to the adequate supply of fresh vegetables, fruit, and fresh meat that deficiency diseases were stamped out from the Mesopotamian Expeditionary Force after March, 1917.

Statistics.

Scurvy in Indian troops and beri-beri in British troops were very prevalent up to July 1st, 1916, but correct statistics were not available. From July 1st, 1916, scurvy and beri-beri were made notifiable diseases in the army. From July 1st to December 31st, 1916, 11,445 cases of scurvy occurred in Indian troops. In 1917, 2,199 cases occurred, and in 1918 only 825, although the force in 1917 and 1918 had been largely increased.

TABLE V.—Scurvy in Indian Troops, and Beri-beri in British Troops.

Year.	Scurvy (Indians).	Beri-beri (British).
1916 (July 1st to December 31st) ...	11,445	104
1917	2,199	84
1918	825	51

The chart shows for 1917 and 1918 the incidence of scurvy, the maximum being in May and June.

As regards beri-beri, records are available showing that 335 cases occurred among British troops to the end of February, 1916, and 104 in the last six months of 1916. In 1917 only 84 cases occurred, and in 1918 only 51 occurred.

ETIOLOGY.

Undoubtedly the prime causes of scurvy and beri-beri are vitamin deficiencies; other factors, however, play a part as predisposing causes.

The Climatic Influences.

The maximum incidence of scurvy was in the hot months of May, June, and July, while beri-beri attained its maximum in November and December.

Mental Depression.

This is mentioned by Osler as a predisposing cause in scurvy, and undoubtedly in Mesopotamia the depressing influences associated with the campaign in 1916 were factors in the causation of the high incidence.

Intercurrent Diseases.

Patients suffering from such diseases as dysentery, those of the enteric group, and epidemic jaundice, which required careful dieting, would rapidly develop scurvy unless care were taken that antiscorbutics formed a part of the dietary. It was remarkable how quickly scorbutic symptoms would develop in Mesopotamia in patients on a dietary devoid of antiscorbutics. I have seen several cases develop typical scorbutic gums within six weeks of admission to hospital. It became a rule, therefore, to add to the diet of all patients in hospital a sufficiency of antiscorbutics—for example, lemons, limes, oranges, etc.—to prevent the development of scurvy.

In the Dardanelles campaign I called attention to the occurrence of beri-beri in patients recovering from an attack of epidemic jaundice. The absence of anti-beri-beri vitamins in the dietary proscribed for the jaundice was undoubtedly the cause.

A few cases of scurvy occurred among British troops in Mesopotamia in men with very carious teeth, who, on account of the difficulty of mastication, avoided eating any fresh fruit or vegetables. I saw one case in a man who had an intense dislike to fruit or vegetables of any kind.

Starvation *per se* does not cause scurvy or beri-beri. In May, 1916, I examined a large number of sick who had been in Kut during the period of its siege (December 11th, 1915, to April 29th, 1917). Many of them showed signs of acute starvation, but symptoms of beri-beri and scurvy were not usually manifest.

TREATMENT.

In order to obtain effective control of the diseases special hospitals for scurvy and beri-beri were established in June, 1917, at Baghdad, Amara, and Basrah—an Indian hospital for scurvy and a British hospital for beri-beri. A special medical officer was attached to each of these hospitals, and special registers were kept in which all the cases of scurvy and beri-beri were fully recorded. In this way the occurrence of either in any unit was at once recognized, and moreover uniformity of diagnosis and treatment was ensured.

Scurvy.

The symptoms of scurvy exhibited by the individual called for special lines of treatment. Anaemia and debility were the early symptoms.

Mouth.—The hyperplastic condition of the gums with characteristic red buds between the teeth, often shown best on the buccal aspect, was the most common symptom. In some cases the gums were so swollen as to present an appearance resembling a new growth. Pyorrhoea, which is quite a distinct disease from scurvy, often accompanied it, and no doubt by its presence tended to accentuate the symptoms of scurvy. Petechiae or patches of haemorrhage occurred in the soft and hard palate; if old they had a pigmented appearance, also a characteristic dark crimson or purplish area of discoloration commonly extended from the inner aspect of the molar teeth upwards towards the palate. This sign was very common, and a very valuable early indication of scurvy. The palate itself was usually pale, owing to the marked anaemia present.

Muscle haemorrhages occurred in about 30 per cent. of the cases, usually in the calf or thigh muscles or around the popliteal spaces or anterior tibial region, forming a hard brawny swelling hot to the touch and tender on pressure.

Oedema.—Scorbutic oedema of a firm brawny type occurred in the legs and feet and around the tendo Achillis; it was of quite a different type from cardiac or renal dropsy, and was often tender. It was too firm to pit readily.

Subperiosteal swellings for example, along the ulna or tibia—were fairly common.

Effusion into the joints of a haemorrhagic type sometimes occurred

Skin.—In Indians skin manifestations were very difficult to determine owing to the natural pigmentation of the skin. In white races purpuric patches were very common, and frequently the skin had a general earthy or bluish appearance.

Subconjunctival haemorrhages occurred in a few cases. *Haemorrhagic pleural effusion* was seen by me in six cases.

Bowel.—In some cases haemorrhage from the bowel required careful differentiation from dysentery.

Dilatation of the heart, usually accompanied by haemic murmurs, was generally present in severe cases, and was an important indication for a period of rest in bed.

Rules for Treatment of Scurvy.

Captain A. J. Stevenson, M.C., R.A.M.C., who was appointed M.O. in charge of the scurvy wards in the special scurvy hospital at Baghdad, did valuable work. The following scheme of treatment for scurvy in Indians was drawn up by us:

Rest in bed was essential as long as the anaemia or cardiac dilatation persisted; also the presence of muscle haemorrhage, oedema, periosteal or joint haemorrhages, or other severe haemorrhagic symptoms, demanded complete rest in bed.

Local Treatment of the Mouth and Gums.—A solution of $\frac{1}{2}$ per cent. salicylic acid in alcohol was applied to the gums twice daily. A mouth wash of alum and carbolic acid was used frequently; also dental treatment, such as scraping the teeth to remove tartar and removal of carious teeth, was carried out.

Anaemia.—A mixture of iron and arsenic was given for this in addition to the other measures.

Diet.—The diet table was:

6 a.m.	Tea and biscuits and 2 oz. fruit.
8 a.m.	$\frac{1}{2}$ oz. fresh lime juice.
10.30 a.m.	Chappatie or rice with: 8 oz. vegetables and two pints fresh milk.
12 a.m.	$\frac{1}{2}$ oz. fresh lime juice.
2 p.m.	10 oz. fresh fruit.
7 p.m.	Meat 14 oz., vegetables 8 oz.

Tomatoes, cucumbers, and onions were given raw; other vegetables were boiled for twenty minutes.

The accompanying tables show the selection of fruit and vegetables obtainable in the Baghdad area.

TABLE VI.—*Vegetables obtainable in Baghdad Area.*

A. Summer planting commencing from the month of February.		B. Winter planting commencing from the month of September.	
Onions	Tomatoes	Cabbage	Turnips
French beans	Cucumber	Beans	Radish
Haricot beans	Pumpkin	Spinach	Cauliflower
Brinjals	Melons	Beetroot	Lettuce
Lady's finger	Water melons	Carrots	Purslane

TABLE VII.—*Fresh Fruits obtainable in the Baghdad Area.*

A. Fruit produced during the summer locally.		B. Fruit produced during the winter locally.	
Apricots	Figs	Oranges	Limes
Apples	Dates	Tangerine	Quince
Peaches	Pears	oranges	Pomegranates
Plums	Mulberry	Sour oranges	Citron
Grapes		Lemons	

One of the most effectual remedies for scurvy is a salad made by cutting raw potatoes into very fine slices, and adding slices of onion and a little vinegar. Captain A. L. Shepherd, I.M.S., at my suggestion tested this in 1916 on cases in the scurvy camp at the front area. He found that it gave a better result than any of the antiscorbutics he was then using.

Physical exercises were given for twenty minutes twice a day to those patients who were sufficiently well.

In a few isolated cases the muscle haemorrhages suppurated and required surgical treatment, incision, etc. The cases of scorbutic haemothorax required treatment by aspiration, in addition to the other treatment of scurvy.

Germinated Dhall.—The discovery in 1917 by Miss Chick and Miss Hume of the value of germinated dhall as an antiscorbutic gives to forces in the field where no fresh vegetables or fruit are available a very valuable antiscorbutic prophylactic. Unfortunately during the trying periods of 1915 and 1916 in Mesopotamia, when antiscorbutics were not available for the troops at the front, this discovery had not been made. After May, 1917, germinated dhall was used in outlying districts in Mesopotamia as a ration when fresh vegetables or fruit could not be supplied. It was used also in hospitals for the treatment of scurvy, but it had no advantage over the use

of fresh fruit and vegetables, and was less palatable. The great value of germinated dhal is that it can be used as a good substitute for fresh fruit and vegetables when these are not available; it is not meant to take their place.

Beri-beri.

In a country like Mesopotamia where toxic influences causing multiple neuritis were present most careful examination was necessary to exclude such causes of multiple neuritis as dysentery, enteric or paratyphoid fever, heat, malaria, sand-fly fever, and diphtheria.

The early signs of beri-beri were those of cardiac weakness accompanied by symptoms of multiple neuritis. A valuable early diagnostic test for troops was the squatting test which I described in 1916.¹ In Mesopotamia the cases were treated on similar lines to those described, the only difference being that marmite was used in place of yeast; it was given thrice a day.

CONCLUSION.

The experiences of the war, specially in distant countries such as Mesopotamia, called for special attention to the scientific rationing of troops. The old idea of sufficiency of calories, or of proteins, fat, and carbohydrates, is quite inadequate. A dietary to be satisfactory must contain proteins, fat, and carbohydrates in the proper amount, and must satisfy the calorie requirements, but it is essential that, in addition, it should be adequate as regards vitamin content—for example, it must be protective against scurvy, beri-beri, and other deficiency diseases.

Too often financial considerations predominate, and I cannot let this opportunity pass without calling attention to the action of the Indian Government in the matter of the rationing of the Indian soldiers serving in India. On February 17th, 1917, a ration was sanctioned by the Indian Government for Indian troops in India. This ration repeats the field service ration which was responsible for the enormous outbreak of scurvy in the Indian troops in Mesopotamia; and, indeed, it is inferior as regards antiscorbutic value, for it entirely lacks any fresh meat allowance. Under a ration of this kind scurvy is likely to be prevalent amongst Indian troops in India, and if at any time they are called upon for active service there is bound to be a great wastage owing to the incidence of scurvy. Rationing of this kind may appear to those without special knowledge economical, but to those who have studied the subject it is a false economy. It seems incomprehensible that after the tragic experiences of Mesopotamia the same mistakes should be repeated.

Since the rationing of troops or of a civil population is carried out usually by the laity not possessing special medical knowledge, the education of the lay mind in the scientific principles which form the basis of a sound dietary is of the utmost importance. For this purpose in Mesopotamia the "Official Memoranda" on scurvy and beri-beri which had been carefully drawn up were circulated not only to all the medical units, but to the commanding officers of all combatant units in the force. The education of the fighting forces in the principles of rationing as regards protection from the deficiency diseases—scurvy and beri-beri—was of great value, for the commanding officers took the greatest care to see that their troops received those articles of dietary which were essential for their protection.

REFERENCES.

- ¹ *Lancet*, March 11th, 1916. ² *Ibid.*

THE Board of Education has issued a new edition of the *Syllabus of Physical Training*. The general suitability of the syllabus issued in 1909 has been established, but experience has shown that certain modifications and developments are desirable. They have been made on the advice of a committee, after hearing suggestions made by a number of experienced gymnastic teachers. The syllabus has been made less formal; the arrangement of the lessons has been retained, but a considerable amount of free movement has been introduced and "breaks," rather than rests, between the exercises have been recommended, and also that half the lessons should be given to general activity exercises, including games. The exercises and games are classified according to age, and there are appendices dealing with school dress, general activity exercises and games, dancing and swimming.

THE AIMS AND METHODS OF GRADUATE STUDY.

By SIR HUMPHRY ROLLESTON, K.C.B.,

M.D., F.R.C.P.

PRESIDENT OF THE ROYAL SOCIETY OF MEDICINE; EMERITUS PHYSICIAN, ST. GEORGE'S HOSPITAL.

The universal process of reconstruction has led to much discussion on medical education, as the writings of Sir Clifford Allbutt, Dr. Fortescue-Brickdale, Sir James Mackenzie, Sir George Makins, Mr. Thelwall Thomas, Sir George Newman, and others testify, and the present moment affords an opportunity to review some of the problems in connexion with graduate, usually and perhaps unnecessarily called post-graduate, education and teaching.

It is often said, especially in introductory addresses, that we remain students all our days, and this of course should be true; but, in assuming that we are industrious students, possibly some of us flatter ourselves—as an unconscious compensation for the apparently modest admission—for in the face of many distractions it is not so easy to carry this ideal into practical effect as it may seem at first sight. It is natural, by glancing at the weekly journals, to keep more or less in the fashion, so as to be familiar with new names and thus avoid being too obviously out of date, but more than this may be difficult for want of a definite stimulus; the bogey of examination has been safely left behind, and it is only in the naval and military services that the earlier steps of promotion are accompanied by study leave and an examination test. Without some such incentive it is only too easy to stagnate in a gradually narrowing groove, and to remain satisfied with the same outlook and the methods that held the field at the time of qualification, but have become obsolete. The advance of medical science is so rapid that without knowing it—and he seldom does—a man easily becomes a medical Rip Van Winkle. In 1911 the late Dr. J. B. Murphy¹ of Chicago suggested that the licence to practise should be granted only for a certain number of years, five or ten, and that at the expiration of this period practitioners should be required to pass an examination or take a prescribed course of study. The idea of a temporary diploma with a renewal contingent on an examination is not likely to meet with an enthusiastic reception.

But a less drastic step towards the same end would be the grant of some kind of a higher diploma, or even of a degree after a series of yearly courses or after a single prolonged course. This addition would perhaps be analogous to the bar to the D.S.O. or the Military Cross. It might be suggested that whereas an M.B. degree is the crown of undergraduate work, the M.D. now awarded for a thesis or by examination should be given after proof of graduate education. If such a scheme were general the habit of graduate education would in time become almost obligatory instead of optional, and would enable the graduate course to be standardized just as that demanded for qualification has long been. At first sight this may seem a revolutionary proposal, but the principle has long been acted upon in the diplomas in public health and other special branches; and in America certificates, which vary in their value and the standard required, because many post-graduate institutions are proprietary, are given after a course. Certificates were, indeed, given after the Emergency Post-graduate Course of the Fellowship of Medicine. At Harvard, where the minimum time qualifying for a certificate is four months of work occupying the whole day, the question of these degrees was under discussion as long ago as 1913; and though the matter was postponed, the personal opinion of the Dean of the Graduate School² was in favour of their ultimate establishment, and to the effect that a systematic course of at least eight months should be required.

Immediate Need of Organization.

The need for organization of graduate teaching on a large scale is urgent because, owing to the reluctance of English-speaking nations and their allies to go to Berlin, Vienna, Munich, and other medical centres of the Central Empires, there is a great opening for efficient and complete

¹ The opening address of the session at the North-East London Post-Graduate College, Prince of Wales's Hospital, Tottenham.

graduate facilities in this country, and especially in London. That the need exists has been thoroughly realized both in America and in France, where extensive preparations are being made to obviate the necessity formerly felt for a journey elsewhere to acquire the desired facilities. London's unrivalled wealth in clinical material obviously indicates that it should be the leading centre of graduate teaching. Yet though there have been various post-graduate colleges since 1890, when the first scheme under the late Sir Jonathan Hutchinson was inaugurated, it must be admitted that they have not successfully competed with those abroad. During 1919 the Fellowship of Medicine, a body originally formed to promote friendly relations among our brethren of the Dominions and Allies, organized emergency courses, mainly attended by the medical officers of the Dominion Forces and the U.S.A. Medical Corps, who were authorized by their Governments to avail themselves of graduate instruction before they returned home. Similar courses were held elsewhere—for example, in Edinburgh, Glasgow, Manchester, and Birmingham. Courses on the same lines are now going on under the amalgamated Fellowship of Medicine and the London Post-Graduate Association; Edinburgh, Glasgow, Bristol, and Norwich are also engaged in this work. It is sincerely to be hoped that this scheme will be so expanded that a permanent Imperial graduate institution will be organized in London to attract men from the Dominions, India, Egypt, America, and abroad, as well as from this country, in the same way as Berlin and Vienna used to attract them in the past. This matter will be referred to later.

The Organization Needed.

Organized graduate instruction may be divided into three distinct forms from the point of view of time:

FORMS OF GRADUATE INSTRUCTION REQUIRED.

- I. The continuation of education immediately after qualification:
 - A. Classes for higher examinations and special diplomas.
 - B. Training for general practice.
 - C. Training for clinical and pathological research.
- II. The continuous education of the general practitioner: local hospitals and clinics.
- III. Periodic refresher courses.

I. The continuation of education directly after qualification; this again is of various kinds, and to some extent depends on what branch of the profession the newly qualified man intends to adopt—general practice, public health, the naval, military, or colonial services, specialist or consultant practice, or laboratory research. In any event a resident post as house-physician or house-surgeon is advisable, and in most branches absolutely essential. Quite recently I heard a very distinguished physician ask the pertinent question, "Have you ever known a man recover from the handicap of not having held a resident appointment?"

(A) A brief reference should be made to advanced classes for higher examinations, such as the M.D., M.S., M.Ch., F.R.C.S., and the diplomas of Public Health, Tropical Medicine, Ophthalmology, and other special branches. The first four have usually been taken at the graduate's original hospital comparatively soon after qualification; but the character of the instruction in all of them is obviously so different from that of undergraduate schools that it might with advantage be included in a well organized graduate scheme, and this specially applies in the case of older men who, after some years in practice, are anxious to take a higher degree. The work for the diplomas of Ophthalmology, Psychiatry, and Tropical Medicine can obviously be most efficiently carried out at special hospitals; and instruction in industrial medicine—namely, the care of the health of factory workers, a branch of public health and preventive medicine destined to be of the greatest importance—must be given in the neighbourhood of manufacturing centres.

(B) Before qualification few men realize that there will be much more to learn when once the portal is safely passed; when, however, this has been negotiated, they soon begin to see that, like the preliminary subjects of the so-called ancillary sciences, the hospital knowledge of their professional subjects is only a further though more complete preliminary to the efficient practice of the healing art. Hospital and ordinary practice essentially deal with different aspects and stages of disease; hospital patients

are usually acutely ill or well advanced in chronic disease, and mainly require curative or merely palliative treatment, whereas ordinary practice is largely concerned with minor ailments, especially dyspepsia, and the early stages of disease, and should, accordingly, be largely preventive. There is therefore a new aspect of medicine before the recently qualified medical man, even after he has had the great advantage of a resident appointment. When launched into practice he finds that he is at sea, and often the landmarks of definite organic disease on which he has been accustomed to rely in hospital work fail him. This is much more marked now than in the old days of apprenticeship, when a medical student began his career as an unqualified assistant and then did his hospital work before going up for his examinations. A return to this plan is impossible; is there any substitute? Possibly Sir James Mackenzie's idea of the appointment to teaching hospitals of one or more physicians who have spent ten or more years of their professional life in general practice might in some degree meet this need, especially if in connexion with the out-patient department there was an outdoor visiting department, as in some dispensaries, under the supervision of this new type of hospital physician.

(C) Graduates who after holding resident appointments have decided to aim at a consulting and hospital career require further opportunities for clinico-pathological work; a certain number in the past have managed to obtain it, largely on their own initiative, by holding posts such as registrars at hospitals or assistants in the pathological or physiological laboratories, or university studentships. Beit fellowships and grants from various scientific bodies have also enabled men to devote themselves to various lines of research. More opportunities for this line of work will, it may be expected, now become available in connexion with the whole-time directors of clinical units, where help and inspiration might also be given to men from a distance. This is the period for the training in systematic investigation of the future teacher in medicine, who should thereby learn how to direct others in his turn, and with them to advance the science of medicine.

II.

The continuous education of the general practitioner. A continuous process of self-education depending on reading the medical periodicals and textbooks and by keeping careful notes of cases, aided to some extent by attendance at the local medical society, is, of course, possible. Many men no doubt carry out the ideal so appropriate to England, which has been called "the land of individual effort," but the difficulties are great, and it is not to be wondered at that the good resolutions made at the outset fail in the face of adverse circumstances, such as overwork and want of urgent stimulus, to maintain this high ideal. Some men, more fortunately placed by being able to use opportunities in connexion with a local hospital, find the way easier. Local hospitals are a comparatively untapped source for organized graduate instruction, and there should not be any difficulty in arranging demonstrations and a more extended system of clinical assistantships; and in the future the Ministry of Health may multiply these facilities, among which attendance at venereal, tuberculous, psychiatric, and other clinics may play a part. The benefit to the teachers would also be considerable; this was well put more than a hundred years ago by Lyman Spalding³ to a colleague who proposed to resign his professorship: "Look at the Princes or rather the Fathers of Physic. . . . What has put them at the head of the profession? Nothing but their being compelled to labour, and annually to review their profession, and incorporate with their old stock all the new improvements. Show me a man in private practice who does this annually. He is not to be found. But your friends say that you can do this, yet stay at home. I acknowledge this, but tell me honourably, will you do it? No, Sir, you have no inducement."

III.

Periodic courses of instruction so as to keep practitioners, particularly those isolated in country districts, up to date in recent methods of diagnosis and treatment. They thus learn what can be expected from expert pathological investigation, and gain a broader outlook from contact with other minds and men. These refresher courses should be taken every five years or oftener, and should be

both general and special in character, dealing with clinical medicine, surgery, and gynaecology, and also with the special branches, such as ophthalmology, laryngology, orthopaedics, and radiology. The latter should be so arranged in series that a man could either get a good elementary course in a comparatively short time or by taking more elaborate courses and devoting himself entirely to the subject could eventually become qualified for this special branch of work. The instruction should be essentially practical rather than didactic, with demonstrations in preference to set lectures. Too much stress can hardly be laid on the importance of providing ample facilities for clinical work, particularly in the special courses in which clinical assistantships should when possible be available, so that the technique of diagnosis and treatment can be thoroughly mastered.

A Graduate Hospital School.

The graduate instruction should be centred in a large hospital with which neighbouring special hospitals may be affiliated, and the organization of the extensive facilities available in London should be carried on at a central bureau. The graduate schools in the provinces should also be co-ordinated with the central organization, which may most conveniently have its home in London. Centralization, especially in London, where much time is necessarily spent in going from one hospital to another, is important. The hospital should be entirely devoted to graduate teaching, for general experience proves that undergraduate and graduate instruction cannot be satisfactorily carried out at the same time and in the same institution. Such a hospital, fully equipped with modern laboratories, would take a long time to build under present conditions; and as it is most important that such a hospital should be in working order at the earliest possible moment, it has been suggested that some teaching undergraduate hospital should be given up to graduate instruction. The teaching staff of the graduate hospital and school raises some difficult points; its members should be well known for their teaching ability and in the full tide of their energies. Such men would of course be engaged elsewhere, and in order to obtain their services some plan by which they could be seconded from their existing chairs without losing them would be necessary. A period of years—five or more—has been suggested, but this would make it very difficult to keep their permanent posts open, and it would be better that they should take service at the graduate hospital for short terms of a few months in each year. If the graduate hospital is started *de novo* there would be much less difficulty than in the event of a teaching hospital with its staff being taken over for graduate instruction. In the latter case some of the original staff would necessarily have to make room for the temporary service of outside teachers, and, unless an alternating service, such as obtains in some American hospitals, be adopted, the question of providing an equivalent position would have to be faced.

The duration of these courses also requires consideration, as a man can rarely spend many weeks away from his practice and is then naturally disinclined to sacrifice the whole of his hard-earned holiday. Time is money, and though time thus expended is a good investment, the available capital is too often small. As a result the courses in this country for general practitioners have usually been short and intensive—lasting two or three weeks—such as those at St. Bartholomew's Hospital before the war, which were held in the summer vacation as most convenient both for the general practitioners and from the point of view of the undergraduate school. In 1909, at the International Congress at Buda-Pesth, the opinion was definitely expressed that the State should provide these courses free of charge, and, according to Abraham Flexner,² the Central Committee for post-graduate education, with its head quarters in Berlin, had in 1912 organized gratuitous courses for practitioners in forty-eight of the larger cities of the German empire. In this country as the State, through the University Grants Committee with the concurrence of the Board of Education, now subsidizes undergraduate teaching, it is only logical that it should also assist in graduate instruction, and there is reason to believe that it would adopt a sympathetic attitude to this proposal. If in the future a general medical service subsidized by the State comes into being, as seems not improbable, the duty of the Government to provide

medical men engaged in such work with periodic study leave would be a natural corollary, so as to correspond to the condition of service in the navy and army. In such conditions a course of three or more months would be practicable and appropriate, especially if some step in promotion, a higher diploma or degree, depended upon attending and showing evidence of having benefited by a somewhat prolonged course.

THE USES OF FREE TRANSPLANTS OF THE FASCIA LATA IN SURGERY.

BY

G. GREY TURNER, M.S.DURH., F.R.C.S.ENG.,

F.A.C.S.(HON.),

ROYAL INFIRMARY, NEWCASTLE-ON-TYNE.

IN using the term "free transplants" I refer to a portion of fascia lata removed from the thigh of the patient for use in some remote part of his own body. I am not able to state with certainty who first introduced this valuable method to the notice of surgeons, but I believe that it is to Murphy of Chicago that we owe its more general application, for he popularized its use in his work on arthroplasty.

I have personally used this method in arthroplasty in the elbow and in the jaw joint with very satisfactory results, but I want to briefly draw attention to its uses under other circumstances which are perhaps less well known.

I.

It is valuable for protecting the deeper structures, such as sutured nerves or tendons during the slow healing of a wound by granulation, or when the superficial tissues are so much damaged that their recovery after suture is likely to be attended with sloughing. For instance, in a man who had a lacerated wound over the dorsum of the right thumb, with complete division of the tendons, it was necessary to protect the latter after suture, because the skin was so much damaged that it was difficult to get it together, and the likelihood of subsequent sloughing rendered sepsis and healing by granulation extremely probable. Under these circumstances, I carefully repaired the tendons with catgut, and then laid a piece of fascia lata about 1½ in. long by 1 in. broad over the line of union, and fixed it in such a way that it extended beyond the area of damaged tissue, thus forming a covering for the tendons, and an effective barrier between them and the skin. The latter was carefully sutured, but part of it was so much crushed that, as was anticipated, sloughing occurred, leaving an area ¾ in. by ½ in. directly over the site of tendon suture to heal by granulation. The floor of this area was formed by the fascia lata which at the first dressing was seen looking white and lifeless, as though it also was about to slough. However, it was not interfered with, and healing by granulation proceeded satisfactorily and completely, with no evidence that the transplant was disturbed. The man made a perfect recovery, and within three months was able to use the tendons, the complete usefulness of the thumb being restored.

Fascial transplants can similarly be used for the protection of sutured nerves, and I have seen it applied in a case of aneurysm of a large artery, where rupture of the sac, following ligation of the main trunk, appeared to be a possibility to be especially guarded against.

II.

It is also exceedingly useful for the replacement of lost tendons, and I have used it with success in war surgery under these circumstances. One patient lost a considerable length of the extensor tendons of his right forefinger. After the wound had soundly healed and had been tested against latent sepsis by exposure to radiant heat, the retracted ends of the tendon were exposed and separated from the scar tissue in which they lay, leaving a gap of about 1½ inches. No attempt was made to deal separately with the extensor communis and extensor indicis, but it might have been done with the expenditure of a good deal

more time and care." A transplant of the fascia lata was cut $\frac{1}{2}$ in. longer than the gap which was to be bridged, and sufficiently broad to allow of its being rolled into a tube. It was laid beneath the ends of the tendon, to which it was carefully sutured with fine catgut, and the sides of the transplant were then wrapped round the tendon ends, and so held by further sutures that it had the appearance of a rolled cigarette, with the remains of the tendon at either end resembling the tobacco. In this case a skin covering could not be provided, and the area had to be covered by a pedicled flap cut from the thigh. The pedicle was divided at the end of a fortnight, and a week later the patient was allowed to make a little movement, but this was not encouraged until six weeks following operation. The usefulness of the finger was completely restored.

III.

Transplants are also useful to cover the exposed brain, where the membranes are deficient, thus preventing it becoming adherent to the scalp.

In one case a patient suffered from severe Jacksonian epilepsy, with almost daily fits, following a gunshot wound of the head, which had already been trephined. On turning back the skin flap it was found to be adherent to the unprotected brain over an area as large as half a crown, and after separation this area presented the appearance of lacerated brain tissue, with a small old blood clot in the centre. The trephine opening was $2\frac{1}{2}$ in. in diameter. A flap of fascia lata was cut $\frac{1}{2}$ in. larger than this opening, and, after separation of the dura from the margins of the bony aperture, the edges of the fascial flap were tucked in so as to form a complete covering for the exposed brain, and a light curtain over the aperture in the skull. The skin flap was then reapplied and carefully sutured without drainage. The patient made a complete recovery, and had no further fits up to the time that I last saw him, some three or four months after operation. It is intended at a later date to close the opening in the skull by bone grafting, now that an efficient background has been provided.

IV.

Similarly, fascia lata may be used for repairing the urethra. I used it in the case of a large fistula which had been operated upon four times without success. I found a rounded opening in the penis, just in front of the scrotum, which would admit the end of a lead pencil. The skin was tucked in, and was adherent to the edges of the urethral mucous membrane. The parts were carefully exposed, using a median incision, and the skin and the urethra were very thoroughly separated. By using a flap cut from the side of the channel which had been established between the urethra and the surface I was able to close the latter without appreciably narrowing its lumen. This looked as if it might of itself have been efficient, but previous operations on these lines having failed, I felt that I must reinforce the union if success was to follow. I therefore covered the area with a flap of fascia lata about 1 $\frac{1}{2}$ in. long by $\frac{3}{4}$ in. broad. This was closely fixed over the sutured urethra with fine catgut, and the skin was very carefully drawn together over the fascia and sutured. At the same time a perineal drain was introduced and kept *in situ* for a fortnight. This patient made a complete recovery. There was never any leakage or any suggestion of subsequent stricture, and seven months after the operation I was able to pass a No. 10 rubber catheter without the slightest difficulty.

I have been surprised at the behaviour of the transplants in the presence of active infection. In one case of arthroplasty of the elbow, which I recorded in the *Edinburgh Medical Journal* (May, 1914), there was a severe outburst of suppuration, but in spite of that the large flap of fascia lata which had been used did not slough, and the result as regards movement was excellent.

Similarly, in one of the cases in which the fascia was used to repair a tendon, there was the recrudescence of sepsis which is so familiar in connexion with war wounds. After the discharge of pus the edges of the skin wound separated, exposing what looked like a big yellow slough, but actually the fascial tendon. It was not interfered with, and in a remarkably short time the wound healed by granulation, and the process of repair of the tendon was evidently not interrupted, for the patient regained movement in the terminal joint of the thumb.

These are illustrations of a few of the uses of fascial transplants. Ingenuity and necessity will suggest many more, and my experience leads me to believe that it can be freely used wherever it will fulfil the indications in view.

I have had no trouble associated with the area from which the flap is cut. I always expose it through a vertical incision on the outer side of the thigh, and, except where the transplant has been a very small one, I do not resuture the fascia, and I have seen no trouble from the break in the covering of the thigh muscles, though the patients sometimes complain of soreness and aching in that area for a time.

THREE ACUTE ABDOMINAL CASES.

BY

J. LIONEL STRETTON,

SENIOR SURGEON, KIDDERMINSTER INFIRMARY AND CHILDREN'S HOSPITAL.

THE three cases here reported have occurred since July, 1919, and are all of sufficient rarity to justify their publication. I have never seen a polypus of the stomach before, and I have never found an extensive haemorrhage between the walls of the intestine. The ovarian tumour is rare because of its size. The largest one I had removed previously contained four gallons. In these days it is seldom indeed that they are allowed to reach such dimensions.

CASE I.—*Polypus of Stomach.*

In July, 1919, I was asked to see a man aged 59, in consultation with Dr. Emrys-Jones, who was acting as locum tenens for Dr. Askey Wood. The patient had been suffering for six months from intermittent pains in the abdomen, which were thought to be biliary or renal colic. I ascertained that the pain came on about fifteen minutes after food of any description, but it was more severe after solid than liquid food. If the patient was lying in bed upon his back the pain did not occur, but if he was sitting up it always came on. There was no vomiting. The bowels were constipated. He had lost flesh (1st.). The conjunctivae had an icteric tinge and he appeared to be ill. The abdomen was too rigid to make a full examination, but there was tenderness two inches above and to the right of the umbilicus.

Operation.—I advised an exploratory operation, and the patient was admitted to the infirmary on July 21st, 1919. On July 22nd, under ether and chloroform administered by Dr. W. Miles, the abdomen was opened by a vertical incision through the right rectus muscle. The liver and gall bladder seemed to be normal. There was no dilatation of the stomach, and its appearance was natural. On manipulating the pylorus with my fingers and thumbs I could feel a substance which slipped from side to side within the stomach, and which appeared to be pedunculated. A transverse incision was made over this "substance." On exposure it proved to be a pedunculated polypus about $1\frac{1}{2}$ in. long and $\frac{3}{4}$ in. broad. The pedicle was attached to the posterior wall of the stomach about an inch inside the pyloric orifice. It was ligatured and removed. The stomach and abdominal wounds were closed in layers.

Description of Polypus.—The specimen removed was sent to Birmingham University for examination. Dr. Balt reported as follows:

"*Polypus of Stomach.* The growth is a simple adenoma consisting of gland spaces lined by a columnar epithelium. The epithelium shows degenerative and proliferative changes, and is frequently desquamated into the lumen of the acinus, but is everywhere contained within the basement membrane, and is, I think, without malignancy. Some of the acini are enlarged to form cysts, the contents being derived from degeneration of the lining cells."

After-History.—The patient made an uneventful recovery. The abdominal wound was healed on July 30th and the sutures were removed from it. He was able to take food without pain, and was discharged from the infirmary on August 18th. I saw him on October 2nd. He was then well, had gained 6 lb. in weight, and could take solid food without discomfort.

The diagnosis in this case appeared doubtful, but had we appreciated the importance of the history we might have suspected such a condition. The fact that the patient was free from pain when lying on his back was certainly significant when considered with the condition revealed at the operation—namely, "a pedunculated polypus . . . attached to the posterior wall of the stomach about an inch inside the pyloric orifice."

CASE II.—*Large Haemorrhage into Wall of Caecum.*

On October 4th, 1919, I was asked to see, with Dr. Brocket of Stourport, an unmarried lady, aged 22. She had been seized with sudden pain in the right iliac region the previous evening, when she vomited. The temperature was 101° and the pulse

120. The abdomen was too tender to palpate. There appeared to be a mass in the right iliac fossa. She was removed to my nursing home.

Operation.—Ether and chloroform were administered by Dr. Craig, and Dr. Brocket assisted me. The abdomen was opened by a vertical incision through the right rectus muscle. Some serous fluid escaped, and a large cystic mass was seen. It was about eight inches by four inches, and extended down into the pelvis. When it was delivered it was found to be the caput caeci. The appendix was inflamed. It was removed and the stump inverted with a purse-string suture. During the manipulation the cyst burst, and a pint and a half to two pints of blood escaped. The collapsed cyst wall appeared to be composed of peritoneum and the muscular wall of the caecum. There had, in fact, been a haemorrhage between the muscular and mucous coats of the caecum. The bowel was returned to the abdomen and a drainage tube left in the lower angle of the abdominal wound.

After-History.—The following day the patient's condition was unsatisfactory; her pulse and temperature were still up, and there was some abdominal distension. She was again placed under chloroform and ether by Dr. Craig, and I opened up the wound. Nothing further was discovered: the caecum had a more normal appearance, as the collapsed sac wall had contracted. The drainage tube was left in. The patient gradually improved. The tube was removed on October 10th; the stitches were taken out on October 15th. The wound had healed, except the sinus where the tube had been. She was discharged on November 8th.

I do not think the inflammation of the appendix was sufficient to account for this haemorrhage. It appears to me more probable that it was due to a strain received by the patient during the afternoon of October 3rd, when, in her capacity of lady gardener, she was moving a number of chrysanthemums in pots.

CASE III.—Large Ovarian Cyst.

A married woman, aged 61, was sent to me by Dr. Crawford Newland, suffering from a large abdominal tumour. She stated that she had been aware of it for three years, but that it had increased in size more rapidly during the last six months. The girth at the umbilicus was 56 in. From the ensiform cartilage to the pubes was 25 in. The tumour was freely movable and fluctuating. On November 4th, 1919, under chloroform and ether administered by Dr. W. Miles, the abdomen was opened by a vertical incision through the right rectus. The cyst was tapped and the fluid withdrawn. The cyst wall was ligatured and removed. It was a cyst of the right ovary. The fluid measured 6½ gallons, and the solid weighed 3 lb. 2 oz.

The patient made an uneventful recovery. The wound was healed and the stitches were taken out on November 12th.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

A NEEDLE IN THE ALIMENTARY CANAL.

At a meeting of the Midland Medical Society held at Birmingham on November 12th, 1919, Mr. Christopher Martin showed a specimen of a concretion formed around a pin in the appendix. I think the narration of the following case may prove interesting.

After a rather long walk (August, 1913) a lady complained of severe pain in the region of the anus. I saw her soon after, and on examination felt what I at first took to be a hairpin fixed across the bowel close to the anus. After some difficulty I managed to remove it. It proved to be a darning needle 1½ in. long, quite black and dull. The patient had no idea how it came there. It must presumably have been swallowed, possibly in soup.

The history of the case as given by the patient herself is remarkable, indicating that, in the course of perhaps nearly twenty years, the needle travelled the whole length of the alimentary tract without producing a fatal result, although it apparently came near doing so. In 1897 the patient suffered from indigestion and what was diagnosed as gastritis, and was allowed only fluid food. In 1907 she had a violent attack of haematemesis, bringing up about 2 pints of pure blood, and she nearly died; the haemorrhage ceased within forty-eight hours, after treatment including rectal feeding, ice, and albumin water. Subsequently she suffered from occasional recurrences of acute epigastric pain. In July, 1913, about a month before the needle was found, she had an attack of acute pain in the region of the duodenum, which a medical man whom she consulted in London thought might be appendicitis, but when he heard the story of the needle he concluded it was due to that. With regard to the severe

haemorrhage in 1907, it is probable that the needle pierced some blood vessel in the neighbourhood of the stomach. Altogether I consider the passage of the needle during all those years through the whole alimentary tract very remarkable, and the patient is to be congratulated on its successful termination. She has had no recurrence of any symptom of gastritis since the discovery of the needle.

Chichester.

HEYWOOD SMITH.

MAMMARY SARCOMA IN OLD AGE.

An interesting pathological curiosity is presented in the following case:

Mary N., admitted May 7th, 1902, for senile dementia, died on October 11th, 1919, at the age of 98, from sarcoma of the breast with pulmonary metastases.

Three and a half months earlier attention was drawn to the right breast by the fact that during routine bathing she shielded the organ with her hand. There was no sign of trauma nor had there been any history of injury or previous indication of any new growth.

The breast did not appear to be enlarged, but seemed to be painful, as she resented the slightest interference. The nipple was not displaced; several hard small masses were scattered through the substance of the gland; their outlines were indefinite, and they did not appear to be attached to the skin, the nipple, or the pectoral muscle. The axillary lymphatic glands were not enlarged; owing to her senile state operation was not undertaken.

The breast rapidly increased in volume and soon attained the size of a football. The skin became stretched and shiny, the veins enlarged in size, and increased in number. The whole organ pulsated visibly and palpably, and in places appeared to be cystic. The skin eventually gave way over the upper and outer part of the mass, but the patient died before a fungating mass could form. On one occasion during the last month the patient coughed up a small clot of blood, but apart from this the symptoms and signs were localized to the right breast.

Pathological Characters.

The right breast with some remnants of pectoral muscle weighed 11 lb. 14 oz. The growth had infiltrated the pectoralis major but had not extended to the chest wall. Beneath the skin were plexuses of dilated veins and numerous haemorrhages. On section an irregularly shaped central cavity holding about half a pint of dark brown fluid and blood clot was found. The surface of the walls of the cyst were roughened by clot deposit and tissue torn by haemorrhages. The tumour cut toughly and varied in appearance, in some parts white, in others intensely vascular and spotted with numerous haemorrhages of varying size. The associated axillary and clavicular lymphatic glands were not enlarged. The left breast showed no abnormality. The right lung weighed 21 oz., the left 18 oz. Scattered through the substance of both lungs, but more particularly just below and on the surface of the visceral pleura, were numerous metastases, varying in size from small well defined pea-like nodules to one the size of a turkey's egg, forming a sessile tumour at the base of the right lung in the mid-axillary line, its pleural surface having contracted recent adhesions with the parietal pleura. The smaller nodules on the pleural surface had a white smooth button-like appearance, their sessile character being due to collapse of the adjoining lung tissue. The metastases on section presented a similar appearance and density to the original growth, the smaller were white and fleshy and the larger strewn with numerous haemorrhagic points. The pulmonary tissue intervening between the metastases showed no gross abnormality. The pleural cavity and parietal pleura were otherwise normal. The heart and liver showed senile degenerative changes. The brain was atrophied, especially the frontal convolutions where the thickness of grey matter was much reduced.

The kidneys weighed, right 4 oz., and left 3 oz.; on section the cortex was indistinguishable from medulla; both were paler and tougher than normal, and the capsules stripped with difficulty, tearing away portions of the adherent renal tissue. The vessels were arterio-sclerotic.

Microscopic sections were made from the breast growth and from one of the pulmonary metastases by the paraffin method. Both showed similar microscopic characters, the only difference being that the section from the secondary deposit appeared more vascular than that from the parent growth. The cells were large spindles; the intervening matrix was slightly fibrillated, and the vessels lined by cells similar to those of the rest of the tumour. Glandular acini were not observed in the section either of the parent growth or the secondary deposit.

T. C. GRAVES, M.D., B.Sc.Lond., F.R.C.S.Eng.,
Medical Superintendent, the Hereford County
and City Mental Hospital.

THE late Mr. William Carnelley, of Fallowfield, has bequeathed £2,000 to the Beckett Hospital and Dispensary, Barnsley, for the endowment of two William Carnelley beds, £1,000 to the Manchester Royal Infirmary and Dispensary, £400 to St. Bartholomew's Hospital, London, and £300 to Guy's Hospital, London.

Reports of Societies.

DIVERTICULITIS.

A DISCUSSION on diverticulitis was held on January 7th by the Subsection of Proctology of the Royal Society of Medicine. Mr. LOCKHART-MUMMERY, president of the subsection, was in the chair. An excellent collection of pathological specimens, drawings, and radiograms illustrative of the subject under discussion was on view before the meeting, and was available for inspection at the Royal Society of Medicine until the conclusion of the adjourned discussion on Wednesday, January 14th.

INTRODUCTION.

The discussion was opened by Dr. W. H. MAXWELL TELLING (Leeds), who directed his remarks to the broad lines of the subject, and mainly to its clinical aspects. The situation to-day, he said, was the same as in 1917, when in reviewing the subject, he wrote:¹

Diverticulitis is a condition which has now passed out of the realm of doubt and uncertainty into that of proved and accepted fact. It has an important place in medical literature, and in the experience of every operating surgeon of large practice. This last statement is not as yet true of all clinicians, some of whom are still apparently unaware of the condition, and not a few of its frequency and clinical importance. Not until a morbid condition is described in all the ordinary students' textbooks² of medicine and surgery can it be said to have attained complete recognition, and this is not yet the case with diverticulitis.

He continued:

Diverticulitis means any inflammatory change in any diverticulum or series of diverticula. In practice, however, usage has restricted the term to the inflammatory changes and secondary pathologic processes generally occurring in or in connexion with a certain type of diverticulum. This type is the secondary, acquired, multiple, false diverticula of the large bowel, particularly and nearly always found in the sigmoid flexure. The diverticula occur mainly in the lower part of this structure, in small or great numbers, but may be found elsewhere, as in the descending colon, the other flexures, the caecum, the rectum, or throughout the entire large bowel. They may be limited to these special positions, though when in them are more usually associated with sigmoid lesions as well; if so limited they may give rise to puzzling and anomalous symptoms. The caecal cases especially are of considerable interest, and merit much more attention and investigation than they have hitherto received. Occasionally there is a widespread tendency to diverticulum formation throughout the whole intestine. For convenience, however, I shall confine my remarks to the typical lesion as it occurs in the sigmoid flexure.

Historically, diverticulitis may fairly be said to be a new subject. Odd specimens had been described from time to time during last century, but such descriptions were "buried" and isolated, and the clinical aspects of the lesion were for all practical purposes unknown.

Peridiverticulitis.—In 1898 Graser³ described examples associated with fibrous hyperplasia, causing stenosing tumour formation—peridiverticulitis. Similar cases were then described in America, and Patel,⁴ in France, drew particular attention to the more acute inflammatory lesions—sigmoiditis and peritonitis. I observed my first case in 1899, and finding nothing about it in the literature, or even anyone who was familiar with the condition, I thence onwards made it a practice to examine almost every sigmoid flexure personally at the autopsies I made. The result was the accumulation of a considerable amount of material.

Classification of Cases.

In 1907 Moynihan⁵ published the first case in England of the Graser-tumour type, and this induced me to analyse and classify my cases. This I did in 1908,⁶ and this was the first time the subject had been treated as

a whole and the various pathological findings and clinical symptoms correlated, or that any complete arrangement and classification had been attempted. That classification has been in essentials accepted by almost all subsequent writers and observers, and writing now twelve years later, when a very considerable number of cases has been observed and recorded, I have no important modification to offer.

The reason that this early "stabilization" of the subject was possible is this—given the occurrence of a tendency to the formation of multiple, hernial outpushings of the mucosa in the sigmoid flexure, every secondary process that does in fact occur may be logically deduced *a priori* by general pathological comparison and study. I am not proposing to deal with the vexed question of *why* these diverticula occur in the first place, except that there is no doubt that they are largely, if not entirely, due to increased pressure from within the bowel. Constipation, therefore, plays an important part, but I feel convinced that flatulent distension, often, of course, coexisting, plays a part that cannot be overlooked and needs more study.

Pathological Anatomy.

A knowledge of the anatomy of these diverticula is of the first importance in understanding the secondary pathologic processes, and also in detecting them at all, either in the deadhouse or at operation. At this point the inquiry is pertinent as to how it comes about that the condition has for so long escaped practical recognition, having regard to the large number of cases recorded—not a tithe of those observed—since 1898. The answer is, I think, to be found in three facts: Firstly, the majority of demonstrators of morbid anatomy fail to devote special and personal attention to the sigmoid flexure and perhaps to those surgical autopsies in which, from their point of view, the surgeon has "spoiled" the abdomen generally, and a specimen in particular, by his manipulations, particularly when the structures operated on have been more or less inflamed, adherent, and "mixed up." Secondly, the diverticula themselves are "adepts" at concealment; to this I will return later. Thirdly, the secondary pathologic processes are liable to be so extensive and disproportionate to the comparatively insignificant diverticula as to hide the true nature of the case from any but patient and skilled observers. This must be the general experience of all who have studied a series of specimens *in situ*.

The second of these points—the "self-concealment"—turns upon the anatomy of the diverticula. Firstly, they are small, varying from minuteness up to the size of the last joint of the little finger; more commonly they are one-third to one-fifth of this size. Their apertures are often minute, from one-sixteenth to one-third of an inch in diameter, and these apertures usually occur in two rows, mostly opposite the appendices epiploicae, and often completely concealed by the rugose mucous membrane. On the outside of the gut the diverticula are seldom observed except by the trained eye, because (1) they mainly enter the appendices epiploicae as stated, and (2) the gut in which they occur is very frequently fat-laden, necessitating careful dissection to discover them at all. The occurrence of adhesion to other structures, and of peridiverticular hyperplasia, tends still further to conceal and almost to obliterate their presence. Even so, that isolated observation on them for over a century should have failed to lead to complete recognition is a little remarkable, but none the less a fact. These anatomical points must be fully appreciated by every operating surgeon if he hopes to recognize the condition at the time of the operation.

Secondary Processes.

Once the diverticula are "in being" the whole series of possible consequences depends upon the following three facts: (1) Being formed by pressure from within they tend to enlarge; (2) they tend to harbour faecal or other harmful contents; and (3) as a consequence they tend to undergo various secondary pathologic processes. In their enlargement they become flask-shaped, with a bottle-neck; this bottle-neck may greatly elongate, its lumen remaining very narrow. This elongation is brought about by peridiverticular hyperplasia, which often pushes the "flask" to its circumference, where it "sits" on the surface of the tumour and works special mischief of other kinds, such as adhesion, perforation, and fistulous communication.

¹ *British Journal of Surgery*, vol. iv, No. 17. To this article reference may be made for a detailed study, with analysis of cases.

A small paragraph first appeared in the 1910 edition of Osler's *Medicine*.

The narrow mouths tend to promote the retention of faecal contents, soft, or forming actual concretions. Here analogy with appendicitis will largely help us to prophesy results, except in regard to the remarkable hyperplastic peridiverticulitis. The faecal contents form a bacterial nidus, a reservoir of toxins and a source of mechanical irritation. As a result secondary changes supervene; if not, the condition remains a harmless pathologic curiosity, and gives rise to no symptoms or trouble. Perhaps the large majority of instances are largely or entirely innocuous. The main secondary processes which occur, separately or variously combined, are:

1. Ulceration of the mucosa of the diverticula.
2. Perforation as a consequence.
3. Adhesion to other structures, which, when combined with (2) leads to fistulous communication.
4. Peridiverticular fibrous hyperplasia, leading to tumour formation and, as a sequential result, stenosis of the bowel.

Confining our attention to these main and usual secondary processes, which, as has been stated, may be variously combined, a few moments' consideration will show how protean and puzzling the resulting clinical manifestations may be. In the first place, mucosal ulceration will weaken the wall of the sac. This will facilitate perforation, and a concretion will be specially liable to be driven through at any time of increased pressure or violent effort, causing a local or general peritonitis. In quite a number of cases this has actually happened.

The mucosal ulceration also sets up inflammation on the outer surface of the diverticulum, leading to adhesions. These may produce no important results, but may produce vesical or pelvic syndromes, or an acute intestinal obstruction by band or kink. Adhesions plus perforation lead either to local abscess, with its varied symptoms, signs and sequential risks and possibilities, or to fistulous communication with other viscera, of which that with the bladder is the commonest, most interesting, and surgically the most important instance.

The culminating interest is reached, however, in the production of the fourth type of lesion, the *peridiverticular hyperplasia*. This may exist with mucosal ulceration of the diverticulum, but not infrequently occurs without it, and is a common and characteristic result—the one which first led to a systematic investigation. It is undoubtedly due to a chronic leakage of toxins or bacteria, or both, through the sac walls, producing a hyperplastic fibrous tissue formation somewhat similar to that found in a hyperplastic tuberculosis of the caecum, or more closely resembling a scirrhus cancer. Because of the hyperplasia, which may amount to an inch or more in thickness on section, a tumour is produced; because it is fibrous the tumour contracts and stenoses the bowel, tending towards chronic intestinal obstruction. This thickening and stenosis may be so local as to make an annular stricture, and it will be realized thereby how close may be the mimicry of carcinoma. In this way doubtless many of the cases of so-called "cured" cancer in this region may be explained, as well as the placing on museum shelves of examples of peridiverticulitis labelled cancer. Others besides myself have found them.

Relation to Carcinoma.

There is, however, a very special relation of the condition to true carcinoma. A simple peridiverticular stenosis (or possibly other diverticular lesion) may develop carcinoma secondarily, as in the case of a chronic gastric ulcer. A small number of cases have now been put on record, and since my last records were published in 1917 I have had a further case. The patient was riding and felt a sudden pain in the left iliac fossa, followed by temperature and signs of inflammation. I made a diagnosis of perforative diverticulitis, and Sir Berkeley Moynihan operated and confirmed, finding multiple diverticula, one of which had perforated and set up general peritonitis. There was also some thickening and stenosis, but no naked-eye evidence of malignancy. A year later a second surgical inspection was made and malignant disease was then obvious and inoperable.

It is not too much to say, therefore, that no surgeon ought to decide about or operate on a supposed carcinoma of the sigmoid flexure without an accurate knowledge of what may be termed "diverticular possibilities," nor ought any such tumour removed by operation to lack a systematic

examination for the presence of a diverticulum. It was only by this means that Moynihan detected and recorded the first of such cases in the English literature.

Grouping of Secondary Processes.

We can usefully divide the secondary processes into two groups: (a) *Mechanical* (mainly), and (b) *Inflammatory* (mainly). Both processes may go on in the same case, just as there may be present together varying types of inflammatory reaction.

A. Mechanical:

1. Formation of faecal concretions in the diverticula.
2. Torsion of the diverticulum.
3. Lodgement of foreign bodies within the diverticular sac.
4. Perforation.

B. Inflammatory:

1. Diverticulitis: (i) Gangrenous, (ii) acute, (iii) subacute, (iv) chronic, (v) latent.
2. Passage of organisms without perforation.
3. Peridiverticulitis—chronic proliferative inflammation with tendency to stenosis of the bowel.
4. Perforation of the diverticula, giving rise in particular to: (i) General peritonitis, (ii) local abscess, (iii) fistula, especially into the bladder, (iv) suppuration in a hernial sac.
5. The formation of adhesions, especially to (i) the small intestine, (ii) the bladder, (iii) the female genitalia.
6. Chronic peritonitis, local.
7. Chronic mesenteritis of the sigmoid loop.
8. Metastatic suppuration.
9. The secondary development of carcinoma.

Symptoms.

By the aid of this pathologic series it is not difficult to forecast the main clinical symptoms and also to surmise that they will be liable to be variable, complex and puzzling. This is so in fact, as a study of case records abundantly proves. At the same time the majority of cases conform more or less to the following types:

1. Inflammatory trouble or tumour in the left lower quadrant of the abdomen;
2. General peritonitis;
3. Vesico-colic fistula;
4. Pelvic syndromes;
5. Intestinal obstruction;
6. Mimicry of carcinoma.

The frequency of tumour or abscess formation in association with any or all of these is considerable (about 30 per cent.), and one may say that any case from the age of 30 onwards presenting these symptoms calls for a mental reservation as to the possibility of a diverticular origin, and in some instances the diagnosis can and has been made with certainty and accuracy. As general clinical points, it must be remembered that cases occur mostly at or after middle age (though a few cases in early life have been noted), in males more frequently than females, usually with a history of constipation, and very seldom causing blood in the stools. A few comments are called for on some of the foregoing clinical types of case.

Inflammatory Trouble, more or less Acute, in the Left Lower Quadrant of the Abdomen.—Cases of this type constitute by far the largest group. Erdmann has gone so far as to say that the occurrence of left-sided pain, with mass or not, but with tenderness and rigidity, is practically pathognomonic of diverticulitis. This is the extreme view, favoured by the main supporters of the almost exclusive rôle of diverticula in inflammatory troubles in this quadrant. Fitz in 1912 said that the cases comprised in this "inflammatory" group made a fairly complete picture of what must be recognized as a new disease of the lower abdomen—diverticulitis of the left quadrant, analogens to appendicitis of the right quadrant. Various subtypes of the inflammatory group may be distinguished, and a useful clinical classification is as follows:

1. *Acute and Fulminant* (gangrenous).—Symptoms practically identical with acute right-sided appendicitis.
2. *Recurrent*.—Acute or subacute attacks over a long period.
3. *Cases ending in spontaneous recovery*.
4. *Protracted Cases*.—Those which continue till the clinical picture is changed by one or other of the following developments: (a) Simulation of carcinoma, (b) intestinal obstruction (acute or chronic), (c) bladder perforation, (d) general peritonitis, (e) incidence of pelvic symptoms.

Trauma.—The mode of onset of many of the acute cases is of interest as showing the great part which trauma of various kinds may play. It has a definite diagnostic value when diverticulitis is under suspicion and acts as an exciting cause of, at any rate, the acute manifestations. These have occurred while straining at stool, during the administration of an enema, following a dose of castor oil, jolting in a motor car, following a heavy meal, while lifting a weight, jumping or hunting, while at work, and during an abdominal operation. In this group pain of one kind or another (often recurrent and colicky) and tenderness are very frequent. Tumour formation has been noted in 30 per cent. of the cases, and the tumour is not infrequently and then characteristically variable. Abscess formation is very frequent; consequently fever and leucocytosis are often present. Bladder and pelvic symptoms are not uncommon. Apart from actual fistulous communication with the bladder, which constitutes a separate clinical group, there are frequently symptoms of bladder irritability, probably due to the nearness of inflammatory foci or to actual adhesion. Pelvic symptoms are of some frequency, and sometimes make the clinical picture.

Vesico-colic Fistula and Bladder Symptoms Generally.—In a recent review⁷ Bryan has stated that "diverticulitis" is the most frequent cause of signo-vesical fistula. Moynihan was the first observer in England to emphasize this fact. He wrote in 1907:

The formation of a vesico-intestinal fistula seems to be one of the tendencies of a perforated false diverticulum; a search through the literature has shown that it is far more common than was supposed. In cases where a hard growth in the intestine is accompanied by the passage of flatus and faeces by the urethra, a diagnosis of carcinoma seems irresistible; yet the probability is that "the growth" would be simple, and that the cause of the fistula would be a false diverticulum, which had burrowed its way through all the coats of the bowel, and thence through the wall of the bladder which had become adherent.

Experience has abundantly confirmed the truth of this statement, and its recognition has been followed by some brilliantly successful cases at Leeds cured by operation after long periods of suffering.

Pelvic Syndromes.—Much has been written in recent years about the close pathologic relationship between the sigmoid flexure and the other pelvic viscera. Much of it has been written without any or a very extensive knowledge of the rôle of the diverticulum. It is therefore not surprising to find diverticulitis increasingly important in the practice of gynaecological surgeons. Pelvic symptoms of one kind or another existed in 7 per cent. of my collected cases, and a number of examples have been placed on record in which the symptoms were entirely pelvic, bowel symptoms being absent. There is no doubt that Shoemaker⁸ strikes the right note in saying that in any suspected case of pelvic or utero-ovarian disease a routine and thorough examination of the recto-sigmoidal bowel and its functions is just as important as a vaginal and uterine examination.

Diagnosis.

This can only be made after a careful consideration of all the facts of the case. Inflammatory trouble in the left lower quadrant in a person of middle or advanced age carries with it a strong *prima facie* possibility of a diverticulitis being the cause, but beyond this exact diagnosis is often difficult, and all special aids to diagnosis may have to be requisitioned. These include: (1) The sigmoidoscope, which has been disappointing in the main in this condition, though perhaps some members may have had more fortunate experience; (2) the cystoscope, which has been of particular value in a small number of cases; and (3) examination by x-rays. This last procedure holds out most promise, and has been greatly developed during the last few years. As may be expected, the technique is not of the easiest, and there are many fallacies in the appearances noted, but there is no doubt of the general diagnostic value.

The outstanding condition calling for differential diagnosis is carcinoma. It may be, and often is, impossible, not only before operation, but at operation. The following summary of the chief points differentiating diverticulitis from carcinoma may be of use.

Summary as to Diagnosis from Carcinoma.

1. The absence of the "shadows of malignancy" from the general picture.
2. Tendency to obesity, and maintenance of good nutrition generally.
3. Long history of attacks of abdominal pain in the left lower quadrant.
4. History of tumour formation with subsequent disappearance.
5. Absence of blood (visible to naked eye) in stools over a prolonged period.
6. Presence of a vesical fistula, in which malignancy can be excluded by cystoscopy.
7. Negative sigmoidoscopy as regards malignant disease.
8. X-ray demonstration of diverticula.
9. Pyrexial attacks.
10. Examination of blood, the presence of neutrophilic leucocytosis, and the absence of the specific nuclear changes characteristic of cancer.

In carcinoma of the sigmoid loss of flesh is early, pain and tenderness are late, and are often preceded by tumour.

Certain other conditions which have to be considered in arriving at a differential diagnosis are: (a) Sigmoiditis, (b) hyperplastic tuberculosis, (c) actinomycosis, (d) syphilis, (e) pelvic conditions generally.

Treatment.

This is comprised in a single word—surgery—unless operative interference is specially contraindicated. As a physician I shall not venture to discuss particular surgical procedure, but confine myself to a few general points.

In view of the potentiality for mischief of diverticula, all diverticulum-bearing gut should be removed. At operation search should be made, whenever possible, for further diverticula. Recurrence after operation has occurred, presumably from neglect of this point. There seems to be a special liability to post-operative peritonitis, possibly due to the chronic infection of the inflamed tissues in some cases.

Care should be taken in handling the gut, as at least one instance has occurred of rupture of a diverticulum by surgical traumatism. The good results already obtained in certain bladder fistulae should stimulate surgeons to deal with such cases. In at least one very successful case the possibility of successful intervention had been negated by several surgeons of eminence.

Lastly, no case of supposed carcinoma of the lower bowel must in future be regarded as inoperable, either before or at laparotomy, unless diverticulitis has been remembered fully considered and systematically investigated.

DISCUSSION.

Difficulties in Diagnosis.

Sir JOHN BLAND-SUTTON said that thirty years ago colic sacculi were mainly regarded as pathological curiosities and our knowledge of their potentialities for evil was a direct result of surgical enterprise. His interest in them was aroused when trying to find an explanation of the phenomenon known as "spontaneous disappearance of abdominal tumours." This matter was discussed in the Royal Medical and Chirurgical Society in 1894 by Mr. Greig Smith, and increasing experience in abdominal surgery enabled Sir John Bland-Sutton to learn the part played by colic sacculi in producing localized swellings in the belly, which sometimes disappeared by expectant treatment, and the phrase "spontaneous disappearance of abdominal tumours" also disappeared from surgical phraseology when surgeons learnt that acute and chronic diverticulitis, or sacculitis (names as ugly and cacophonous as appendicitis), mimicked many important lesions, especially acute and chronic appendicitis, cholecystitis, tumours of the stomach, subdiaphragmatic abscess, perigastric abscess, splenic abscess, tubal infections, ovarian abscess, cancer of the uterus, and infected uterine fibroids. The extraordinary feature of sacculitis (or pericolicitis) was its mimicry of cancer of the colon. In 1901 he excised the sigmoid flexure of a spinster, aged 60, under the impression that it was cancerous. After the operation critical examination of the tumour proved that the supposed cancerous mass was a pericolic mass due to infection of a sacculus caused by a piece of straw. The patient recovered. This, with a case of epiploic abscess, was described before the Medico-Chirurgical Society of Nottingham in 1904, and full details were published in the *Lancet*, 1903, ii, 1148. Since that date Sir John Bland-Sutton had seen and

⁷ *Ann. Surg.*, 1916, lxiii, 353.

⁸ *Ibid.*, 1914, lxx, 322.

operated on many similar cases, and it was clear that in the past patients had submitted to colotomy and colostomy under the belief that they were suffering from colic cancer; subsequently the lump disappeared and the patients survived the operation many years, and at death there had been no evidence of tumour. This admitted of no doubt. Also cases were not uncommon in which a swelling was detected in connexion with the large gut; a diagnosis of cancer was made, and the patient was advised to submit to an operation, but he obstinately refused, and in due course the swelling disappeared in spite of the gloomiest prognostications of physicians and surgeons of great experience and repute, and the patient lived to mock at his advisers. The disappearance of the mass was due to pus or the exudate finding a channel of escape. During the last ten years acute diverticulitis, especially in the lower abdomen, had been recognized with the same certainty as acute and chronic appendicitis. The disquieting feature of these new things in abdominal surgery was the fact that as we grew older colic sacculi tended to increase in number, and as many as 200 had been counted on a colon. Thus diverticulitis was a newly discovered "bane of elders." As prevention was better than cure, it would be the duty of the family medical attendant to encourage men and women after middle life to have efficient sets of teeth, and warn them against gobbling indigestible food or bolting hot and unpalatable morsels.

Radiography.

Dr. E. I. SPRIGGS referred to some of the earlier papers on the subject of diverticulitis, amongst others to Dr. Maxwell Telling and Dr. Gruner's monograph, and to the paper published by Dudley Roberts on 22 radiograms of diverticulitis. He then gave the results of a series of a thousand cases radiographed at Duff House. In only six of these had there been *x*-ray evidence of diverticulitis. It had to be borne in mind, however, that radiography would fail to show the presence of diverticula if they did not stand out in profile, but were behind or in front of the main bismuth mass. Again, the bismuth might easily fail to enter the diverticulum if it were filled with faecal material. In his opinion bismuth meals were preferable to bismuth enemata for the demonstration of diverticula. After showing radiograms of the six cases of diverticulitis, including an excellent example of diverticulum of the duodenum, Dr. Spriggs expressed the opinion that the disease was due to weakness of the bowel wall at the regions of greatest internal pressure—namely, towards the termination of the small and the large intestines. The cases he had illustrated were of special interest because they were early cases in which no symptoms had yet appeared.

Surgical Treatment.

Mr. McADAM ECCLES expressed the opinion that diverticulitis was commoner than was ordinarily supposed. It affected most commonly the large bowel, and was usually multiple. It was by no means rare to find the diverticula running out into masses of fat, or into actual appendices epiploicae. The acute variety of diverticulitis, when occurring in the pelvic colon, might result in suppuration and a condition erroneously termed left-sided appendicitis. He had on several occasions opened abscesses in the left iliac fossa which he had little doubt were due to perforation of diverticula. The chronic form was of great interest in that it simulated carcinoma. The lesion occurred more frequently in men, and after middle life, giving rise to constipation and flatulence. A tumour formed, and then, with some emaciation, nearly every sign and symptom of malignant disease, with the important exception of haemorrhage, was present. The speaker concluded by showing an excellent pathological specimen removed from an old gentleman of 74 in 1913. Resection of a portion of the pelvic colon was performed for what was believed to be a malignant stricture, but turned out to be diverticulitis. The patient was now 80 years old and in good health. A drawing of a calculus lying in a diverticulum was also exhibited.

Mr. GREY TURNER, after mentioning some of the early papers on diverticulitis, described three cases he had encountered in his own experience. The first of these was a lady of 30, whose condition simulated that of appendicitis

accompanied by extensive thickening of the caecum. The second was a male admitted for retention of urine. Catheterization had been attempted and had failed. As signs of peritonitis were present the abdomen had been opened and a large mass in the descending colon suggesting carcinoma had been found. A gall stone was lying in Douglas's pouch and fistula had formed between the gall bladder and the duodenum. The case, which proved fatal, on later examination proved to be one of perforation of a diverticulum. The third case was also that of a man who had died from perforation. It had been remarkable in that only two diverticula were present. In the speaker's opinion the condition of diverticulitis was essentially congenital in origin. If the histories of these cases were carefully taken it would be found that as a rule symptoms had been present for some considerable period, often for several years. It was true that sigmoidoscopy had been disappointing, but, on the other hand, a negative finding as regards the presence of malignant disease was suggestive. If instead of a single large bismuth meal several meals were given at short intervals radiography might be still more serviceable. It was all very well to say that surgery was the only remedy, but when the knowledge of the existence of diverticulitis became generally known the surgeons would be overwhelmed. It would be impossible to perform wholesale resections, and it would be necessary to come to an agreement as to what surgical measures were necessary. He had treated one case of diverticulitis by inversion and suture, and so far the result had been satisfactory.

Mr. ROWLAND described eight cases of diverticulitis of the colon and one of diverticulitis of the duodenum upon which he had operated. The complications that had brought them to the theatre were in three instances for peritonitis, and in five for intestinal obstruction. One case simulating carcinoma was unsuitable for resection, and short-circuiting had been performed. For early cases the speaker recommended resection with end-to-end anastomosis. For late cases, and cases complicated by vesico-colic fistula, a preliminary colostomy was advisable. In a few instances some form of short-circuiting operation was indicated.

Misleading Term.

Professor RUTHERFORD MORISON being unable to be present, Mr. HAMILTON DRUMMOND read his paper. In it Professor Morison strongly objected to the term "diverticulitis." It was a misnomer, and was liable to cause confusion between the condition under discussion and the congenital sac termed "Meckel's diverticulum." Normal sacculations must be distinguished from acquired. The acquired sacculations were multiple, had no special blood supply, were found in elderly people, and were common to all hollow viscera. The only similarity between congenital and acquired sacculations lay in the liability to similar complications—gangrene, perforation, etc. The sooner the term "diverticulitis" was replaced by that of "sacculitis" the better it would be.

Morbid Anatomy.

Mr. HAMILTON DRUMMOND then gave the results of his own observations during the course of 500 *post-mortem* examinations of patients who had not died as the result of intestinal lesions. In this series 22 instances of pathological sacculations of the large bowel were found. In four of these a similar condition of the small intestine was present, and in one a diverticulum of the bladder. Careful dissections and microscopical examinations were made, and the results had suggested that the condition was due to a general weakness—perhaps congenital—of the unstriated muscle throughout the body. The presence of venous congestion had been suggested as a cause, but the fact that sacculations were not found in cases dying of morbus cordis did not bear this out. The common site of origin of these sacculations was between the mesocolic and lateral longitudinal bands at the spot where the blood vessels pierced the muscular coat of the bowel. This, like the inguinal canal, was a weak spot. A most excellent series of preparations illustrating the pathological anatomy of the condition was thrown on the screen. It showed the tendency of the sacculations to work backwards towards the mesentery, and the accompanying atrophy of all the coats except the peritoneum.

Appendix Epiploica.

MR. GARNETT WRIGHT reported a case on which he had operated in 1911. The patient was a male who had suffered for years from gonorrhoea, and had finally developed signs of cystitis and difficulty in micturition. He had been treated by catheterization until his condition had become so bad that further advice had been sought. Faeces were passed by the urethra, and a diagnosis of recto-vesical fistula was made. At operation a single appendix epiploica was found adherent to the posterior surface of the bladder. This was excised and the openings closed. The condition recurred, and at a subsequent operation, in addition to excising the fistulous tract, the sigmoid was anchored down to the iliac fossa. No further trouble had occurred.

WAR METHODS IN CIVIL PRACTICE.

AT a meeting of the Clinical Section of the Royal Society of Medicine, held on January 9th, the President, Sir ANTHONY BOWLBY, gave an address on the application of war methods to civil practice.

Shock.

He said that the most striking danger to the man wounded in war was shock, a condition which was met with in a far higher percentage of men wounded in war than in those correspondingly wounded in the occupations of peace. This was due to the fact that the man injured in war was suffering from want of sleep, want of water and of food; he was exhausted by physical strain and mental excitement; he was often thoroughly chilled after his injury through lying out in the cold, wet, or even freezing weather. His shock was therefore out of proportion to the severity of his wounds. The most important of all the remedies for shock was warmth, and nothing could take its place. Much of the wound shock could be obviated by sufficient care, first in the early application of suitable splints, which should be employed in all severe injuries and not reserved for fracture cases alone; and secondly, by the supply of well hung and well warmed ambulance cars. By these methods the condition of the wounded man was greatly improved during the war, and it would be by the application in civil life of the knowledge that had been gained that a like improvement would be obtained in peace. He had been so convinced of the importance of care in the transport of injured men that, with the aid of the Army Medical Service and of the British Red Cross Society, he had arranged for the equipment with suitable splints of the motor ambulances which had been supplied to various parts of Great Britain, and arrangements were now being made to see that the ambulance drivers and orderlies were as thoroughly trained in the use of the "Thomas outfit" for fractured extremities as were our orderlies at the front in France. In every county arrangements should be made to teach how badly wounded men might be taken even for great distances without further injury being inflicted upon them by the transit.

With regard to the treatment of shock he said that, as the principal phenomena were loss of blood volume and fall of blood pressure, the obvious aim should be to restore these. The simplest method was to administer fluids by the mouth, or, in cases of severe shock when the patient was unable to keep down any fluid, by the rectum. He considered that both blood pressure and blood volume were more likely to be permanently improved by gastric or rectal absorption of fluid than by the intravenous administration of the same quantity. In many cases of severe shock, however, when delay might mean disaster, it was often necessary to perform intravenous infusion as soon as the patient had been warmed and rested. For this normal saline was useless, but Bayliss's solution of 6.0 per cent. gum arabic in normal saline was often of the greatest benefit in raising the blood pressure for long enough to carry the patient over the danger period. In proportion as the shock conditions were due to excessive bleeding immediate infusion of blood was better than gum arabic solution and was undoubtedly indicated; not less than a pint should be given. Sir Anthony Bowlby suggested that in future sterilized gum solutions should be kept ready for use by operating surgeons and by all civil hospitals, and also that test serums for donors of blood should be regularly

stocked, so that no delay might arise in the choice of a donor. If such treatment was necessary at all there would be no time to waste; the experience of war had shown that if blood was transfused too late it was quite useless.

Choice of Anaesthetic.

With regard to the choice of an anaesthetic he thought that for all slight operations on patients in good condition "open ether" was often quite satisfactory. In wintry or wet weather, when many of the wounded were suffering from bronchial catarrh, ether was very liable to cause grave pulmonary complications, and it was not until the "Shipway apparatus" for warming the ether vapour was introduced that it could be safely administered in such cases. He strongly advocated that in future warm ether vapour should be systematically employed as the better routine method where ether was used in civil practice; it was not only less irritating to the lungs, but it was less likely to cause severe vomiting. In cases of shock neither ether nor chloroform was safe, for after the operation there was often, with these anaesthetics, a reactionary fall of blood pressure and death. Ether might be very injurious also by causing nausea and vomiting in men who needed every ounce of fluid nourishment that could be given, for if this sickness continued for some hours it would destroy the last chance of recovery for the shocked men. The intrathecal administration of storaine proved to be very dangerous owing to the sudden fall of blood pressure which it produced to the shocked man, and it was not so good as novocain. The value of nitrous oxide and oxygen in shock had been conclusively proved by Major Geoffrey Marshall in 1916, and his observations showed that extensive operations could be performed without any immediate or subsequent fall of blood pressure. He believed that the combination of gas and oxygen with local anaesthesia was the very best anaesthetic agent for a number of the abdominal operations of civil life and for many others also, for it caused no fall of blood pressure, it eliminated anaesthetic shock, and it abolished post-anaesthetic vomiting and all its attendant troubles. He urged that gas and oxygen should be supplied, together with suitable apparatus for all the army medical services in the future. It was not always a satisfactory anaesthetic, however, for vigorous and muscular people on whom a prolonged operation was to be done; its administration was lengthy, and required both experience and a special apparatus.

Treatment of Fractures.

The fractures in France during the last half of the war were treated by "extension and suspension," so that the circulation and mobility of the injured limb were maintained throughout as far as possible, and wasting of muscles and stiffness of joints had been thereby largely prevented. All hospitals and medical schools should arrange for much more systematic teaching of how to deal with fractured limbs, so that all young surgeons would in future realize that the so-called "setting" of the fracture was the beginning and not the end of surgical treatment. It would be necessary, therefore, for some at least of the fracture cases in general hospitals to be collected in "special fracture wards" equipped with the necessary apparatus for "extension and suspension," and supplied also with a mobile X-ray outfit, for there were many cases where a good result could only be obtained by frequent radiography.

Wound Infections.

Tetanus was prevented by prophylactic injections so successfully that its incidence immediately fell 90 per cent. as soon as the antitoxin could be supplied in sufficient quantities. If success were to be obtained in civil practice, it must be remembered that the injections should be given within a few hours of injury. No similar success had followed the employment of prophylactic injections for "gas gangrene," but time and experience had shown that the proper treatment was the excision of all devitalized tissue, and the careful and thorough mechanical cleansing of the wound. Lister had realized the uselessness of attempting to sterilize a grossly infected wound by the single application of a powerful chemical agent. After thorough cleansing, the wound was closed by "primary" or by "delayed primary" suture. The

results of suture were not materially influenced by the use of any antiseptic agent, and it was found that wounds could heal well and firmly even though they contained considerable numbers of micro-organisms so long as the latter did not include virulent streptococci. It was evident that tissue cells could destroy the less virulent bacteria provided the latter were surrounded by healthy living tissues, and by closure of the wound the advent of fresh infection was effectually prevented. Not only were many lives and limbs saved by wound closure, but compound fractures healed more rapidly and with much less necrosis, joints were saved from acute arthritis, suppuration of wounds became rare, septic infection with its fever and emaciation diminished, and convalescence was infinitely more rapid. He believed that there was a wide field for the application of war methods to the treatment of the injuries of civil life, but he wished to emphasize that in suturing wounds after the interval of a day or two, it was essential for success to recognize that no further wound toilet was permissible. The packing should be removed as gently as possible, and the sutures inserted and tied.

It was found that not more than 15 per cent. of recent wounds were infected by haemolytic streptococci when examined at the operating theatres or the casualty clearing stations at the front, but bacteriologists at the different bases said that within a week of arrival there over 90 per cent. were infected. Shortly before the war ended an Anglo-American Committee was appointed to investigate the whole question of streptococcal infection. Complete sterilization of hands and instruments after each examination was obviously difficult when the wounded were numbered by the thousand, but instruments being more easily sterilized than the hands it was clearly desirable that the wound or dressing should only be touched by instruments. An investigation was made to ascertain whether many of the medical officers, nurses, or orderlies at the bases were acting as carriers, and 8,000 examinations were made in the American army of their throats, with the result that it was reported at the last meeting of the committee that carriers of haemolytic streptococci had been found at different bases to number from 15 to 25 per cent. of all the hospital personnel. Experience of the general hospitals in France showed the danger of wound infection spreading when large numbers of streptococcal infected wounds were accumulated under war conditions, and explained why the closure of wounds by suture was of such great benefit to the wounded soldier. He suggested that these investigations already begun were worth pursuing in hospital wards given over to the treatment of cellulitis and erysipelas. With regard to the treatment of suppurating wounds two things had been learnt: First, that it was more often possible to suture than was thought; and, secondly, that Carrel's method was often a very great improvement on the drainage tube and the daily syringing. Concerning the first, it was found that many wounds could be successfully sutured even if they were suppurating. Speaking of the second, he said that he believed that where surgeons had had an unsatisfactory experience of Carrel's method this had been largely due to imperfect technique. He considered that the method of irrigation was more important than the particular solution. In civil surgery it was as efficacious in the treatment of an empyema or pelvic suppuration. He had seen excellent results from its use in large appendix abscesses and in suppurating joints. In future he had no doubt that the civilian surgeon would work even more with the bacteriologist than he did before the war, for it had been by collaboration and experiment that many of our advances had been maintained without risk to the patients.

Mr. REGINALD VICK said that he had had an opportunity in Salonica of practising primary suture on compound fractures for a period of eighteen months while at a general hospital on the Seres road, to which large numbers of transport accidents were admitted. The invariable practice was to do primary suture on these cases, and the results were so uniformly satisfactory as to convince him that this method of treatment was as ideal as anything human could be and as successful. The essentials for success were present: facilities for immediate treatment, a good theatre, and no reason for moving the patient until the wound and bones were healed. Since his return to

England he had had the opportunity, while working under Mr. Gask in a surgical unit, of treating all compound fractures admitted during their tour of duty. Primary suture had been performed in these cases, and, where complete closure of the wound was impossible, secondary suture had usually been required at a later stage. In cases of compound fracture of the skull with the dura unopened the end results were excellent. It was important that operation should be performed at once, with complete removal of all damaged tissue, and perfect splinting, with subsequent immobility until healing was complete in cases of fractures of long bones. He had usually used ether in the final stages before closing the wound.

Sir CURTBERT WALLACE remarked upon the difficulty in applying the Thomas splint in the case of women on account of their clothing. In fractures in civil life there was much more extensive injury to surrounding tissues than occurred in fractures under war conditions.

Mr. W. GIRLING BALL said that much had been done during the war in the bacteriological examination of wounds. In a series of 100 cases at the front treated by delayed primary suture, 80 per cent. healed by first intention. Since his return he had endeavoured to carry out the same method of treatment. In the home hospitals cases were too often left to the inexperienced for treatment. This was difficult to avoid unless the house-surgeon had been taught by someone who had actually carried out the method. He thought that large wounds such as were so often met with in civil practice were very amenable to treatment by primary suture.

Sir CHARLES SYMONDS said that he had begun his war work in London, where men were arriving from the Aisne in a highly infected condition. In the case of severe fractures he kept the part in complete rest by putting it up in plaster-of-Paris. When the general inflammation had subsided, in from four to seven days, he removed the plaster. The wounds were generally found full of pus, but this seemed to act as an effective dressing. In the summer of 1916 he had employed first continuous, and later intermittent, irrigation. On his return to England he saw the cases from France and noted the excellent results which followed primary suture. If the wounds were dry and free from pus, it was possible to suture at once. He agreed that failure in the Carrel-Dakin method was due to defective technique. Asepsis should be perfect and the wound should never be touched by the hands.

Mr. A. SHEEN said that in India cases had been received from Mesopotamia ten days after wounding. The wounds did not seem to be so infected as those in France, probably on account of the dryness of the climate and the non-cultivation of the soil. Improvements were needed in organization as well as in treatment. In mines, works, and factories, there was little organization for immediate treatment.

Rebivus.

THREE CAMPAIGNS.

SIR ALEXANDER OGSTON'S *Reminiscences of Three Campaigns*¹ appears at the request of friends who knew that he had kept journals of his experiences in the Egyptian, South African, and European wars. After the fall of Khartoum the autobiographer left London on February 25th, 1885, and was present at the battle of Tamaï. He was invalidated home on April 15th with a desire to do something to assist the Army Medical Service, and in 1899, in the course of the address in surgery at the British Medical Association at Portsmouth, delivered "a heavy indictment of the system on which our services were then conducted." Soon afterwards he volunteered to go to South Africa; with Queen Victoria's support he overcame the impediments placed in his way and left England in December, 1899. After various experiences, including typhoid fever at Bloemfontein, he was again invalidated, and reached England on July 27th, 1900. There is an interesting

¹ *Reminiscences of Three Campaigns*. By Sir Alexander Ogston, K.C.V.O., LL.D., Surgeon in Ordinary to the King in Scotland. London: Hodder and Stoughton. 1919. (Demy 8vo, pp. viii + 235; 6 figures. 16s. net.)

account of his delirium, describing the separation of mind and body and his wanderings through "silent fields of Asphodel."

The third section, on Serbia (1915), is shorter and of relatively much less interest than the fourth, which relates the author's experience in Italy; he arrived at the headquarters of the British Red Cross Ambulance in August, 1916, and when surgical work was not pressing made several trips in different directions, so that he traversed nearly the whole of the Italian front. Like all others who visited the mountain lines, he is enthusiastic in praise of the wonders achieved by the Italian engineers, and he speaks well of the way in which the officers of the Italian Medical Corps made efficient ambulance stations and advanced operation centres on unpromising sites and under circumstances of great difficulty. Sometimes they had to rely on their own enterprise and ingenuity; sometimes they were helped by the engineers as in what Sir Alexander says must have been the strangest field hospital in the world, about a mile to the south of Plava.

There the cliffs of friable limestone on the roadside had been drilled by an electric (?) drill, or scooped out, until a cave six or seven feet broad and forty or fifty in length was formed, so as to run parallel to the roadway; it was lined with bunks like those in a steamer's cabins, in tiers about ten feet high along one side; it was lit by acetylene, and in cold weather warmed by hot-water pipes. One chamber served for an operation theatre, and the drill was at work preparing a larger and better one. It was quite dry and comfortable.

The book, however, is much more than a record of observations and opinions on medical matters; the indomitable energy of the Emeritus Professor of Surgery in the University of Aberdeen, whose portrait forms the frontispiece, led him in the interval of his strictly medical duties to contrive to see a good deal of the actual military operations in all the three campaigns. He has provided some good illustrations, a map of South Africa, and a bird's-eye view of the Italian Isonzo front.

THE PERIPHERAL NERVES.

THE last piece of work done by the late Professor MELVILLE PATERSON, of Liverpool, was to prepare a book entitled *The Anatomy of the Peripheral Nerves*.² His object was to provide a brief account of these nerves for the use of students and surgeons, particularly those engaged in military orthopaedic work. He included an account of the cranial nerves, and of the sympathetic, because of its intimate relation with the peripheral nervous system. The book is divided into four chapters, dealing respectively with the anatomy of the peripheral nerves, the distribution of the spinal nerves, the sympathetic system, and the cranial nerves. It contains a number of illustrations, most of which are very good, though some contain so much detail as to be rather bewildering. The schemes giving the positions of origin of the branches of the limb nerves have been compiled from dissections made by Mr. D. H. Richards; others are borrowed from Cunningham's *Textbook of Anatomy*. Professor Paterson gave a warning with regard to the precise point of origin of any branch of a limb nerve, pointing out that it may be incorporated with the parent trunk for a different distance in different cases. The book will not, of course, enable surgeons to dispense with the larger volumes on anatomy and neurology, but as a summary of anatomical facts it will often be of great use for rapid reference.

TYPHOID FEVER.

THE amount of work dealing with various aspects of typhoid and paratyphoid infections which has been published during the past twenty years is so great that it is difficult for the non-specialist medical reader to keep abreast of the stream. There is an effective demand for a summarizing treatise dealing with the subject as a whole, and Professor GAY of California was well advised to attempt to meet the demand in a volume entitled *Typhoid Fever*.³ In it he has brought together within the compass of less than 300 pages a great deal of information the value of

which is enhanced by an extensive bibliography. Professor Gay's expert knowledge of laboratory methods enables him to explain clearly the very difficult problems arising in connexion with the study of immunity. His observations respecting the difference between the durable immunity due to passage through a natural attack of the disease and the more transitory consequences of vaccination are of interest. The suggestion made is that the former is a cellular and the latter a humoral immunity, and that the possible existence of cellular antibodies in the tissues of those who have passed through a natural attack needs consideration.

It is, however, to be remarked that the exact measure of the protection conferred by an attack of typhoid fever is still to be determined. That second attacks are uncommon does not prove nor even create a strong presumption in favour of immunity. What is needed is a comparison of the incidence of typhoid upon persons of the same age, some of whom had, and others had not, been previously attacked, allowance being made for the differential death rate, since the proportion of persons aged 20 attacked by typhoid fever who will survive to age 21 will probably be smaller than the proportion of those of the same age not attacked. The statistical problem is very complex, and there are the further practical difficulties of securing a materially accurate record. We mention the point since Professor Gay's work is less adequate with respect to statistical and epidemiological questions than in other respects.

To summarize so much and still to retain a pleasing literary form is a task for a giant, and it would not be true to say that Professor Gay's book is altogether easy reading. But its practical value is great, and the author has put many medical men under an obligation to him.

NOTES ON BOOKS.

THE new number of *Medical Science: Abstracts and Reviews*⁴ gives a good deal of space to reviews of recent publications on tuberculosis and syphilis. Under the former head reference is made to scepticism as to the specific properties of tuberculin, a scepticism almost as old as tuberculin itself. The investigations made during the last few years by Schmidt and Kraus at the German medical clinic at Prague appear to show that injection of milk evokes responses closely resembling those produced by tuberculin. The injections are made every three or four days for three weeks; the milk is sterilized by boiling in a water-bath for ten minutes; if it causes excessive pain when injected hypodermically it is injected into the muscles. Reference is made in the same article to Abbott's recommendation to treat broken down tuberculous glands by aspiration, the cavity being then filled with einnamon 1 part, benzoin 3 parts, and corn starch 10 parts, insufflated through a tube if possible, but, if not, mixed with a little water and injected. Among the surgical papers is one on prestectomy, giving a history of the subject, with notes on methods at present in use.

Condensed milk, apparently first invented by Newton, and in a modified form first used for infant feeding by Liebig in 1867, has been more and more employed for the latter purpose during the last two or three decades. A careful study of its manufacture, composition, and value in the feeding of infants and invalids has recently been published by Dr. LASSABLIÈRE.⁵ The book is short, but gives a satisfactory account of the subject so far as it goes. The author is under no misapprehension as to the limitations of infant feeding by condensed milk; as Professor Richet says in his preface to the work, for infants all diets except breast-feeding are detestable; all foods but mother's milk are sufficiently villainous drugs.

The second edition of Colonel KEEFER'S *Elementary Military Hygiene and Sanitation*⁶ contains an account of the subject useful to soldiers and sailors alike. It is short, clearly written, and well provided with illustrations. It may be recommended to all in search of a manual of field hygiene.

¹ Annual subscription, 21s.; a single number, 2s.

³ *A Textbook of Elementary Military Hygiene and Sanitation*, By Frank R. Keefer, A.M., M.D., Colonel Medical Corps, United States Army. Second edition, reset. Philadelphia and London: W. B. Saunders Co. Post 8vo, pp. 340; 55 figures. 7s. 6d. net.)

⁴ *Anatomy of the Peripheral Nerves*. By Professor A. Melville Paterson, M.D., F.R.C.S., London. H. Frowde, and Hoader and Stoughton, 1919. (Demy 8vo, pp. xi + 165; 64 figures. 12s. 6d. net.)

⁵ *Typhoid Fever*. By Frederick P. Gay. New York: The Macmillan Co., 1918. (Med. 8vo, pp. xi + 280. 12s. 6d. net.)

While it is not the province of a medical journal to accept or deny the conclusions reached by Mr. HUGH ELLIOT in his philosophical essay (or series of essays) entitled *Modern Science and Materialism*,⁷ we may be allowed to compliment him upon his rare lucidity of exposition, upon the range of his knowledge in diverse fields of science, and upon the steadiness of his grasp as he takes up one after another aspect of the universe and examines it by the clear cold light of reason. If the first 203 pages should seem rather bloodless and destructive, the reader will perhaps find some slight comfort in the last two paragraphs of the concluding chapter headed "Idealism." "Let us see to it then above all other things," says the author here, "that our philosophy of life is true. Passion is the master: Faith and Reason will for ever regulate the conduct of mankind." After all that has gone before these words may come as a surprise. Yet, despite the note on which he ends, some who have followed unwillingly the author's remorseless argument for a wholly materialistic concept of the world within and of the world without may feel disposed to deny that "there is grandeur in this view of life." The last quotation, we should add, is not from the book under review, but from the final sentence of the *Origin of Species*. But we would not be misunderstood: this work contains a challenge that will be relished by strong minds.

To review Dr. S. GANGI's massive compilation on heat-stroke⁸ in mid-winter may be held to argue a certain lack of sensitiveness, or even propriety, in the reviewer so far as times and seasons are concerned. This, however, is not really the case; the book, though published as long ago as 1915, has only recently come to hand, and so demands instant attention. The subject is one with regard to which scientific clinical observation and scientific histopathological investigation are still urgently called for. Captain Gangi's pages show that isolated observations of interest and theoretical speculations of less interest than ingenuity-abound in the literature of heatstroke. But it is not yet possible to set out any clear picture of the mechanism whereby heatstroke arises, or of the histology of its often recorded morbid anatomy, or of the avenues along which its treatment on truly scientific lines should be approached. The book is full of quotations from other authors, many of them British, and should be of interest to medical men in hot countries. It contains an ample bibliography.

TESTS OF CURE IN VENEREAL DISEASE.

THE Ministry of Health has issued a memorandum containing suggestions as to the tests which should be applied before patients who have been under treatment for syphilis or gonorrhoea are regarded as cured and "discharged after completion of treatment and observation." Attached to the memorandum is a form (V.R. 6) for the annual return rendered by all the venereal treatment centres. The documents are accompanied by two covering letters—one addressed to medical officers in charge of venereal disease treatment centres, and the other to county councils, county borough councils, and the authorities of approved treatment centres.

The Memorandum (V. 21) contains matter of special interest, and we welcome the fact that the Ministry of Health is drawing attention to the importance of subjecting those who have suffered from venereal disease to certain definite tests before discharging them as cured. Venereal disease is being spread at the present time by thousands of individuals who believe themselves to be free from infection merely because they are free from symptoms. In many instances, it is true, these men and women have not taken the trouble to obtain medical sanction before returning to their ordinary mode of life. This, however, is by no means always the case. A great many of these contaminators of society, when reproached for their want of consideration to others, will indignantly reply that they had been examined by their doctor and told that they were free from disease. Anything, therefore, which assists in drawing the attention of the profession to this state of affairs and to the importance of employing stringent bacteriological and chemical tests before discharging such patients as cured is thrice welcome.

Gonorrhoea.

It is unfortunate that, although the gravity of syphilis is generally realized, infection with gonorrhoea is still regarded by perhaps the majority of mankind as a trivial complaint. Yet at the present moment it is gonorrhoea and its sequelae rather than syphilis that constitute the greater danger to the national health. No exact figures are available, but it would be no exaggeration to say that 40 per cent. of the patients attending the gynaecological out-patient departments of our hospitals are suffering from gonorrhoea or from the legacies it leaves. Moreover, it is with gonorrhoea rather than with syphilis that the greater difficulty is found in establishing trustworthy tests of cure. Latent gonorrhoea is no easy matter to detect, and it is only by the conscientious employment of the most exact bacteriological tests that anything approaching accuracy can be obtained. The Wassermann reaction is a more delicate test in syphilis than any available for the detection of latent gonorrhoea, for up to the present the complement fixation test in the latter has proved only of limited value.

The Memorandum circulated by the Ministry of Health has been based on suggestions made to it by various medical officers in charge of venereal disease treatment centres as well as by the Medical Committee of the National Council for Combating Venereal Disease. The examination advised is both bacteriological and clinical. Included in the latter is a careful search by means of the urethroscope for signs of disease in the urethral walls. Whilst under examination the patient resumes his ordinary mode of life, sexual abstinence alone being exacted. On three separate occasions, at intervals of a week, the patient comes up for the test. Films are prepared from any moisture obtainable from the urethra, from secretions expressed from the prostate and seminal vesicles, and from the centrifugized urine. On at least one occasion the examination of films is supplemented by the taking of cultures, and when possible a complement fixation test is performed on the serum. In order to provoke a urethral discharge the patient is encouraged to resume his usual habits as regards alcoholic stimulants, pickles, curries, spices, and so forth. For the same purpose full-sized bougies are passed, instillations of silver nitrate made, or a provocative injection of gonococcal vaccine given. If the results of all these tests are negative, the patient is provisionally discharged as cured, but is warned to return should he subsequently notice anything of a suspicious nature.

The difficulty of being certain that a cure has been effected is even greater in the case of the female than in that of the male. The tests are in this case most profitably made immediately before or after the menstrual period. Provoactive treatment is carried out by the application of silver nitrate solution (15 per cent.) to the cervical canal, or by the use of injections of vaccine. Films and cultures are prepared from the cervical canal and the urethra. The additional use of culture methods is in the case of the female essential, owing to the difficulties of finding the gonococcus in films. Whenever possible the complement fixation test should likewise be employed.

Syphilis.

When dealing with patients who have suffered from syphilis the time factor is of great importance. When more than four years have elapsed since the original infection the risk of conveying the disease to another individual is minimal. The routine recommended in the Memorandum is that until this period has elapsed the patient should report for examination at intervals of one month during the first year and of three months during the second. The examination includes the application of the Wassermann reaction, and the routine inspection of all surfaces of the skin and mucous membrane. At the end of the first and second years of this course of probation a small provocative dose of an arseno-benzol compound is administered, the Wassermann test being performed a week later. If four years have elapsed since infection the patient is regarded for all practical purposes as non-infectious. He is advised, however, in his own interest, to continue under observation until it becomes reasonably probable that the disease has been eradicated.

Copies of the memorandum can be obtained on application to the Venereal Diseases Department, Ministry of Health, Whitehall, S.W.1.

British Medical Journal.

SATURDAY, JANUARY 17TH, 1920.

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND.

AN Association of Surgeons of Great Britain and Ireland was formally constituted on January 8th at a meeting at the Royal College of Surgeons of England, over which Sir Rickman Godlee presided. The suggestion to establish such a society originated with Sir Berkeley Moynihan, who, after some preliminary conversations, addressed a letter to Sir Rickman Godlee, then President of the Royal College of Surgeons, on March 30th, 1914. A meeting of surgeons was held at the Royal College of Surgeons of England on the 26th of the following May, and the suggestion to form a society of the kind was generally approved. It was felt that there had never been the debates on surgery and the freedom of debate which was needed. Not to put too fine a point upon the matter, "freedom of debate" means absence not of criticism but of reporters; it is easy, when the meeting is tiled, to criticize boldly and directly; the tone of the speaker, the attitude of the audience, and the atmosphere of comradeship draw the sting which the same words in the solemnity of print might convey. Opportunity for such outspoken debates has hitherto been scanty, nor has there been any ready means of communication between surgeons on hospital staffs: they have lived a life of too great isolation, comparing themselves too little with other men also actively engaged in surgical practice, and knowing neither the character nor the methods of their fellows.

The establishment of the Association of Surgeons will, it is confidently hoped, raise the standard of the practice of surgery. Its annual meetings in various cities will bring together the active surgeons of England, Wales, Scotland, and Ireland. There they will study the work of the surgeons of that medical school; and the effect of having to operate before a large audience, which if sympathetic to difficulties will be critical of methods, must be to impel the operators to take care that their work shall be good enough to satisfy their critics—in fact, first rate. Some years before the war a little chirological club, founded by Sir Berkeley Moynihan, paid visits two or three times a year to various centres. The effect on hosts and guests alike was admirable. In the words of one of its members, "When you see an expert doing his own work exceedingly well, you find it impossible to be satisfied with doing your own work indifferently." The success of this informal experiment naturally encouraged those who had in mind an association of active hospital surgeons, in London as well as the provinces, to persevere, and with the return of conditions of peace the opportunity came.

At the meeting in May, 1914, a committee was appointed to draw up rules for the proposed association and to communicate with members of the surgical staff of teaching hospitals; the intention then was to summon a meeting of those who responded, but the outbreak of war caused the project to be put on the shelf. The interval, however, was not altogether wasted, for the draft rules were at various times revised, and were brought before the meeting last week in a form which enabled them to be adopted as the constitution of the new association.

Its objects are defined to be "the advancement of the science and art of surgery, and the promotion of intercourse and friendship among the surgeons of the United Kingdom." The two principles underlying the rules are, first, that the fellows of the new association should be actively engaged in practice and limited in number, and, secondly, that discussions at the meeting should be free. It was decided to limit the number of fellows to 250, and that they should all be engaged in purely surgical practice, in the teaching of surgery, or in surgical research. On ceasing to be a member of the staff of his hospital the fellow would become a senior fellow, enjoying the privileges but not exercising the rights of active fellows; that is, he would not vote nor be eligible to hold office, and would not be required to pay any subscription. In addition it was determined to elect a certain number of honorary fellows from among the eminent surgeons outside Great Britain and Ireland, the number not to exceed twenty-five. It was decided that the president should hold office for one year and be ineligible for re-election; and that the secretary and treasurer should hold office for one year, but be eligible for re-election. The business of the association will be conducted by a council consisting of twelve members in addition to the officers already mentioned. Each division of the United Kingdom must be represented on the council, and not more than four members of the Council may be resident in any one town.

Sir John Bland-Sutton was elected the first president and Mr. Herbert Pendlebury secretary. A general meeting of the association will be held once a year, in May, in towns in any part of the United Kingdom where there is a university or medical school. It was arranged that the first meeting, and subsequently at least every third meeting, should be held in London. To carry out the second principle, it has been enacted that scientific communications shall be spoken, not read, that no communication shall last for more than fifteen minutes, that no reporters shall be present, and that no report of the meetings shall be sent to the journals or newspapers. A fellow will be at liberty to publish his communication when and where he pleases. *The British Journal of Surgery*, hitherto managed by a committee of surgeons, will be taken over by the association, and receipt of this journal will be included among the privileges of each active member, who will subscribe three guineas a year. There is also an entrance fee of three guineas. A rule, interesting as showing the spirit in which the association has been founded, is that an active fellow absent from three consecutive general meetings thereby ceases to be a member, though the council may on receiving a satisfactory explanation reinstate him. The rules provide for the appointment of a local secretary to be responsible for the local arrangements needful for the ensuing general meeting; he is to be elected not later than six months before the date of meeting by the members of the association resident in the town where the meeting is to be held.

The new association appears to be constituted on lines closely resembling those of the Association of Physicians and Surgeons of Great Britain and Ireland, which was established twelve years ago largely through the influence of Sir William Osler. It publishes a *Quarterly Journal of Medicine*, does not permit its proceedings to be reported, but publishes brief minutes in its journal. Its meetings have been exceedingly interesting and useful, and the privilege of attending them is highly prized. We can wish the Association of Surgeons nothing better than to attain an equal success.

PENETRATING WOUNDS OF THE CHEST.

AMONG the subjects discussed at the Clinical Meeting of the British Medical Association last April that of penetrating wounds of the chest aroused great interest, because it showed that in what is almost a new surgical field advances had been made during the war which may well prove to be of great value in civilian practice. A statistical report issued recently by the Medical Research Committee,¹ in which some of the surgical results obtained in France are collated and summarized, is therefore of more than passing value, for, in addition to the statistics there tabulated and now made available for general reference, indications for surgical interference are clearly enunciated and the limitations of active treatment are defined.

Though the credit for first advocating systematic surgical treatment of chest wounds by operation must be ascribed to the French surgeons, and notably Duval and his immediate colleagues, the methods advocated were probably more generally accepted and received wider application in the British armies, largely owing to the pioneer work of Gask, Gray, and Lockwood. There was, perhaps, at first a tendency for zeal to outrun discretion, as is apt to happen when a new method employed by an expert with due consideration of all the factors involved is hailed by the many as an essential practice in all cases. The first six months of 1917 saw this swing of the pendulum—from expectant treatment, which had been almost the universal rule, to an enthusiasm for interference not always according to knowledge. This fault was quickly corrected as experience grew; the Memorandum drawn up at a meeting of Consulting Physicians and Surgeons, and issued by the Director-General in July, 1917, laid down clearly the types of case in which operation was indicated as a routine measure. As this memorandum, which outlined the principles governing the surgery of the chest wound, remained in force for the remainder of the war, its main recommendations will be read with interest. They were as follows: "(1) An open pneumothorax should be temporarily closed by suture at the earliest opportunity, either at the field ambulance or at the casualty clearing station. If for any reason suturing is impossible, the wound should be packed and strapped, so as to render it airtight. (2) Extensive parietal wounds, including the above, should be treated as any other large wound. The operation should include the removal of comminuted rib fragments. (3) Where a foreign body is retained, and careful x-ray localization shows it to be accessible and of large size (not a small fragment or bullet), it may be removed, and the parietes closed after evacuation of the haemothorax. (4) Aspiration should be done in the case of any large haemothorax associated with persistent respiratory distress. This is best done after the lapse of about forty-eight hours. (5) Gross infections of the pleural cavity should be treated by rib resection and drainage. Where the infection is mild it is justifiable to resect, thoroughly cleanse the cavity, and close the pleura and parietes, as secondary drainage can easily be established later if necessary. (6) Set operations, for removal of foreign bodies, etc., should not be performed until the initial collapse has passed off. (7) Whenever the thorax is opened for operation the opportunity should be taken to close any wound of the diaphragm. This is especially important on the left side in order to prevent subse-

quent hernia. (8) Where open operations have been performed this case should be retained for ten days after the operation. (9) Reliable x-ray plant, and also immediate access to a bacteriological laboratory, are essential to successful chest surgery."

The first section of the report now issued deals with statistics of 600 cases furnished by Major W. L. Mann, C.A.M.C., and is of great value because he personally treated each case and followed it up from the records of the base and home hospitals. The results he obtained were admitted to be strikingly good and may be accepted as indicating a standard of what sound judgement and skilled surgery in combination can effect. The second section deals with a large series of cases which occurred in the autumn fighting of 1917, on the Passchendaele Ridge. The investigation was undertaken to determine the total mortality from chest wounds and to ascertain statistically the result of operation as contrasted with expectant treatment. Colonel Soltau collected the records of 3,521 cases in the Army area, and as most of the cases were transferred to the Boulogne and Étaples bases, Colonel Elliott was able to trace their after-history there. At the time when this investigation was undertaken the principles of chest surgery were firmly established, and, owing to the circumstance that casualty clearing stations were stationary, could be employed to the full. In consequence, however, of the bad weather and of the great depth of the crater-zone across which casualties had to be conveyed the severity of the wounds was considerably aggravated.

It is inevitable that the mortality of chest wounds should be high, for the structural damage likely to be sustained is severe and the liability to infection of the pleural cavity great. In field ambulances the death rate was 7 per cent. and was entirely due to gross damage. In the casualty clearing stations it was 17.18 per cent. in this series, which, after deduction of the 7 per cent. who died in the field ambulance, would give 15.9 deaths in the remaining 93 cases. Of these about one-third were caused by sepsis, the remainder were due to structural injuries or shock. At the base the death rate was 6 per cent. of admissions, which would give 4.6 deaths on the 77 survivors from the original 100. This death rate was entirely due to sepsis. Hence the total mortality at this period was 27.5 per cent. (at the field ambulance 7 per cent., at the casualty clearing stations 15.9 per cent., and at the base 4.6 per cent.).

In the total of 3,521 cases about 38 per cent. were operated on, and this figure may be taken as representing fairly accurately the proportionate number of cases actually requiring operation in war. The tables show in detail the scope of the operation performed, the mortality, and the end result until transit to England. The third section deals with a series of tables compiled at the bases by Colonel Pasteur and Colonel Elliott during the autumn of 1918, when the condition of warfare had altered from close to open fighting, and the fourth section contains tables comparing the results in 1916, 1917, and 1918.

The practice of operating on chest wounds was introduced with the two-fold object of reducing sepsis and of saving life where gross damage was so considerable as to render recovery impossible or unlikely if no assistance were given. It was quickly seen that to operate merely because a foreign body was present was not necessarily justifiable, since so many cases recovered completely with fragments retained. How far were the two objects attained? To argue entirely from figures is fallacious, but to ignore their lessons is foolish. Statistically, sepsis does not appear to have been materially reduced, and it is probable that, on

¹ Medical Research Committee, Statistical Reports, No. 5. Statistical Reports from the British Forces in France on Penetrating Wounds of the Chest. H.M. Stationery Office, through any bookseller, 1s. 6d. net.

the whole, infection of the wounded chest is not obviated by early operation. On the other hand, it is certain that many lives were saved by operating: more particularly in case of open pneumothorax, the "stove-in" chest, and a wound with multiple comminution of ribs. In the early years of the war these cases almost invariably died, whilst in 1917 over 50 per cent. survived when operated on.

The war has taught us certain broad principles of chest surgery. We have learnt that the thorax may be opened with comparative impunity, and without the necessity for special pressure chambers and other devices to prevent collapse of the lung. The technique has been simplified so that few special instruments are required, and the resection of four inches of one rib has been shown to be sufficient to give access to any part of the pleural cavity. It has been shown, too, that in injuries causing an open pneumothorax or extensive rib injury operation is essential. Many lessons as to the treatment of the infected pleura have been learnt, not the least important being that infection with organisms other than streptococci may often be satisfactorily treated by repeated aspiration, or by opening, cleansing, and then closing the cavity and trusting to subsequent aspiration. This should have an important bearing on the treatment of empyemata, where the slow progress to recovery under drainage, and the resulting lack of expansion, are so frequently a source of anxiety and disappointment. Finally, the results of operating for the late results of infection are full of promise for the future. The operative methods introduced by Tuffier to deal with a collapsed lung bound down by adhesions and thickened pleura have in his hands resulted in restoration to function of a completely useless lung, and may be expected to fructify in a rich harvest of brilliant results.

In civil practice a careful application of these lessons will lead to increasing enterprise in dealing surgically with intrathoracic conditions, whilst the military surgeon of the future will find the procedure he must follow firmly established, thanks to the pioneer work of the French and British surgeons in the war. The Statistical Record, evidently compiled with great care by officers with an unrivalled opportunity for collecting figures, and for drawing inferences from them, and also for observation of the actual work performed, will be a valuable guide for the future; and the Medical Research Committee has in it produced a work of lasting utility.

THE NEEDS OF THE VENEREAL CLINIC.

Much has lately been written on the duty of the medical profession to impress upon the public the importance of the prevention of venereal disease. In the dust of controversy the other duty of the medical profession has, perhaps, been a little obscured—the duty to treat efficiently to a conclusion those cases of venereal disease which neither chemical prophylaxis nor education and moral suasion have availed to prevent. The documents on treatment issued by the Ministry of Health appear at an opportune moment and include an excellent memorandum (an analysis of which is published at p. 89) containing suggestions as to the tests that ought to be applied before patients who have been under treatment for syphilis or gonorrhoea are regarded and classified as "discharged after completion of treatment and observation." The primary purpose of the memorandum is indicated in its title, and the difficulties in the way of certainly determining when the individual has ceased to be infective are not minimized.

If this work, so vitally important to national health, is to be efficiently carried out, every facility for doing it thoroughly must be given to medical officers in charge of treatment centres. The ordinary routine treatment of the crowds of patients attending these centres has already taxed their resources severely. The number of men and women applying for treatment is increasing every month, yet many of these clinics are attempting to carry on their work in premises that have long become inadequate, and with a staff that is quite insufficient. The elaborate and difficult technique required for the conduct of the necessary tests will severely strain the pathological resources of the clinics. All who have worked at this subject agree as to the importance of bacteriology in the diagnosis and treatment of venereal disease; in no branch of medicine or surgery is the practitioner more dependent on the results of the bacteriologist's investigations than in dealing with gonorrhoea and syphilis. For this reason we would strongly urge the vital necessity of providing both experienced bacteriologists and properly equipped laboratories in connexion with venereal disease clinics. The technique of venereal bacteriology is difficult in the extreme, and if trustworthy results are to be obtained, highly trained and adequately paid workers will be needed. On the result of what we still docilely call a Wassermann test, or the report of a culture, great issues may hang, and an attempt to carry on work with an improvised laboratory and an improvised pathologist can only end in disaster. Pathological reports, if they are to be of any value at all, must be beyond suspicion.

That it is the intention of the responsible authorities to afford every facility for carrying out the excellent suggestions made in Memorandum V. 21 we have little doubt. Some of the larger special treatment centres have already instituted testing departments, through which patients must pass before they are discharged as cured. Their value to preventive medicine has already been proved. The issue of this memorandum ought speedily to result in the formation of similar departments in other clinics, and we look forward to the day when no one who has suffered from venereal disease will be authorized to return to ordinary ways of life until it has been established that he or she has ceased to be a potential danger to others. Much work will be required, and great changes will have to be effected in the mental attitude towards venereal disease, both of the medical profession and of the public, before this end can be attained. That the end can be attained and that Memorandum V. 21 is a step in this direction we are confident.

POOR LAW INFIRMARIES AND CLINICAL EDUCATION.

AN important decision was taken at a meeting of the Paddington Board of Guardians on January 7th. The Hospital Committee reported that it had considered a letter from the chairman of the Board of Management of St. Mary's Hospital asking the guardians to co-operate by allowing students to help in the wards of the Paddington Infirmary, under the supervision of Dr. A. G. Stewart, the medical superintendent. The letter began by stating the Medical Committee's belief that for any advance in the care and treatment of sick people something more than legislation was necessary; the foundation of such an advance must be laid by raising the standard of undergraduate teaching. The Board of St. Mary's Hospital had therefore decided on a scheme of reorganization for training students, to include the appointment of four members of the staff, who would devote their time to teaching, and not, as hitherto, mainly to private

practice. After outlining the proposal for co-operation, the letter went on to record the Medical Committee's conviction that the attendance of students in the wards of the Paddington Infirmary, so far from being detrimental to the welfare of the patients, would contribute towards increased efficiency in treatment. In considering this proposal the Hospital Committee of the board of guardians sought the opinion of Dr. Stewart, who indicated various ways in which the infirmary would gain under such an arrangement. Thus, the students would assist as clerks or dressers in the wards, facilities would be afforded for having the help of the pathological and other special departments of St. Mary's Hospital, and the advice of the hospital staff would be available. Dr. Stewart went on to point out that the publicity and inspection of work would stimulate all concerned and so benefit the patients, and finally that, in the public interest, the teaching opportunities of the infirmary should not be wasted. The committee accordingly recommended the board of guardians to approve the proposal for St. Mary's students to attend at the infirmary, at times arranged by the medical superintendent, on the understanding (a) that the ordinary work of the infirmary is not interfered with; (b) that the working conditions are under the medical superintendent's control; and (c) that the scheme may be terminated at will by the guardians. This recommendation was unanimously approved by the board. It is very plain to us that the advantages of such a scheme must flow both ways. The gain to the infirmary has been ably sketched by Dr. Stewart. The students for their part will gain by seeing cases that seldom stay long in a general hospital, but yet figure largely in general practice. The pathological and bacteriological department of the hospital must benefit, too, by the widening of its field of investigation. Should the plan prove a success in its working in Paddington, other teaching hospitals and infirmaries will almost certainly follow suit. The Paddington Guardians and the Board of St. Mary's Hospital are to be congratulated. On their own initiative they have done what certain reformers have for long advocated, for it is a commonplace that the Poor Law infirmaries can, with advantage to their patients, afford opportunities for the clinical training of medical students hitherto almost entirely wasted. That the need for making better use of Poor Law institutions is grasped by the Ministry of Health may be judged from the remarks made by Sir Robert Morant during the discussion on the teaching of obstetrics and gynaecology at the Royal Society of Medicine six weeks ago.¹ Much thought, he said, was being given in the Ministry to the serious and urgent problem of the provision of hospitals, but first of all the whole ground must be systematically surveyed. If the Poor Law was to be reformed, the existing institutions and the infectious disease hospitals of the Metropolitan Asylums Board must all be brought into the survey and every part of the problem considered in its relation to the whole.

TEMPORARY COMMISSIONS, I.M.S.

ONE of the representations made by the British Medical Association to the Secretary of State for India, when it was discussing with him the future of the Indian Medical Service, was that immediate steps of a temporary nature should be taken to meet the hard case of officers of the service who have served continuously for many years in India without obtaining the leave to which they are by regulation entitled. We publish at p. 96 a letter from the chairman of the Naval and Military Committee, Colonel R. H. Elliot, I.M.S. (retired), asking young medical men who have not yet embarked in civil practice at home to consider the terms of the offer now made. Applications are invited from British subjects of European descent, not more than 35 years of age, to take temporary commissions in the Indian Medical Service under a contract to

serve for two years. An officer who has served for three or more years in the Home, Colonial, or Indian forces will be given a commission as captain and will receive pay at the rate of 750 rupees a month. An officer who has not had this experience will receive a commission as lieutenant and pay at the rate of 700 rupees a month. Free passages will be provided both ways, and if the officer is married his wife and family will be sent out at Government expense in the autumn of 1920 provided shipping is available. No mention is made of return passage in this case; Colonel Elliot assumes that this is an oversight, but the matter is being taken up with the India Office. We endorse the opinion of the chairman of the Naval and Military Committee that the terms offered are good. We are advised that an officer without wife and family should be able to live on 400 rupees a month in India. This would leave a balance of 300 rupees a month, which at the present high rate of the rupee in this country (2s. 4d.) would be equal to £420 a year. Taking the expenditure in India at the rate of 15 rupees to the £1 the annual pay may be reckoned as equivalent to £740. This is one side of the matter. The other is that during his term of service in India the officer will have the opportunity of obtaining clinical experience in medicine as well as surgery, more extensive and intensive than he could well hope to gain within the same time in this country. To many a man the opportunity of seeing new countries and new people will be attractive, and, while he will know that he is not bound for more than two years, we make no doubt that, should a good man determine to remain in India, he will encounter no difficulty in obtaining a permanent commission. We may note that the Secretary of State for India is also prepared to give permanent commissions to 136 Europeans. The appointments will be made by nomination, and candidates must be under 32 years of age. The terms and conditions were stated in the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of September 13th, 1919, p. 69.

THE ORIGIN OF POLYMORPHONUCLEAR LEUCOCYTES.

It is generally believed that the white blood corpuscles of mammals come from two distinct sources, the lymphocytes and mononuclears from the spleen and lymphatic glands, and the granular leucocytes from the bone marrow. Ehrlich was probably the first to bring into prominence this dualistic theory, but sceptics have not been wanting. Some interesting experiments bearing on the point have recently been published by De Laet¹ from Professor Bordet's laboratory in Brussels. The research was suggested by certain observations by Gay and Claypole, who in 1913 found that if living typhoid bacilli were injected into the circulation of an untreated rabbit there was, first, transitory leucopenia; this was quickly followed by hyperleucocytosis, which in sixteen to twenty-eight hours after inoculation reached a maximum of 34,000 to 56,000 per cubic millimetre; but if the experiments were repeated on rabbits previously immunized against the typhoid bacillus, the leucopenia was of shorter duration and the hyperleucocytosis very quickly reached a maximum of 80,000 to 274,000 per cubic millimetre. Their conclusion was that the immunizing serum played an active part in exciting the production of the leucocytes. De Laet injected into the internal jugular of guinea-pigs 1 c.cm. of an emulsion of typhoid bacilli killed by heat. The animal was killed twenty-four hours afterwards and its spleen was removed aseptically, cut up into fragments not exceeding one or two millimetres in diameter, and placed in sterile Ringer's solution maintained at a temperature of 38° C. These fragments were removed to sterile tubes by means of pipettes and, by sloping the tubes, were made to adhere to the walls. They were then covered with a

¹ BRITISH MEDICAL JOURNAL, December 20th, 1919, p. 814.

¹ Annales de l'Institut Pasteur, November, 1919.

mixture consisting of four parts of fresh guinea-pig serum to one part of a 2 per cent. solution of agar in physiological saline; the mixture was kept at 42° till it was required. The tubes were covered with an indiarubber cap and placed in a sloping position in the incubator. Controls were made in a similar fashion with untreated guinea-pig's spleen. On the third or fourth day of cultivation a characteristic whitish, somewhat opaque, zone was noticed around the fragments of the "typhoid" spleen, as marked in the case of the larger fragments as in the most minute, reaching its maximum breadth in eighty to ninety-six hours. The untreated spleen, on the other hand, showed merely scarcely visible prolongations from the periphery of the most minute fragments. When these zones were examined microscopically by making films from them a strange appearance was seen. In the case of the "typhoid" spleen enormous quantities of neutrophile polymorphonuclear leucocytes were observed so that the preparation resembled a film of pus. Sections showed that some of these leucocytes by virtue of their amoeboid properties had travelled for almost a centimetre from their focus of origin. This phenomenon did not occur in the case of the untreated spleen. Nor was any such effect produced when the tissues of the bone marrow or lymphatic glands of treated animals were cultivated. It would thus seem that the supposed action of the bone marrow in dispatching leucocytes to the spleen can be ruled out, and that the thorough lavage to which the splenic fragments are subjected during preparation deprives them of any considerable number of myeloblasts and myelocytes. Confirmatory experiments with other bacteria would go far to substantiate the conclusions drawn, namely, that the spleen can itself produce granular leucocytes.

FRIEDMANN'S TURTLE VACCINE.

In the December number of *Tubercle*, a new monthly journal devoted to all aspects of tuberculosis, a critical review is given of the switchback career of Friedmann's turtle vaccine. The review deals with the literature of this subject up to the end of August, 1919, and is not, therefore, quite up to date, as barely a week passes without the publication of a new crop of puffs and counter-blasts in the German medical journals. A Gilbertian touch has been added to the controversy by the appointment of Friedmann to a special professorship in tuberculosis, not only without the advice and consent of the faculty of medicine in Berlin, but even against its emphatic protests. Another means of popularizing Friedmann's vaccine has been devised by Professor Dührssen, who has published a *Festschrift* to commemorate Friedmann's achievements. As a professor of gynaecology, he has been reminded by his colleagues that the cobbler who sticks to his last sets an example that scientists should strictly follow; but this hint has not deterred him from supplementing his *Festschrift* by much polemical writing and speaking. His advocacy, addressed rather to the general public than to the medical profession, has served the useful purpose of drawing from Professor Kirchner some curious facts. Friedmann, it is stated, was advised by Kirchner in February, 1913, to submit his remedy to Ehrlich's examination. The latter agreed to test it, stipulating that nine to twelve months' investigation would be required before any verdict could be given. He was accordingly astonished a few days afterwards by a request for an immediate opinion, and, three months later, by a cable from America soliciting a testimonial as to the harmlessness of the remedy in guinea-pigs. Both these requests were refused. By January, 1914, he had ascertained that 10 out of 18 guinea-pigs had died in eight to eighteen days after an injection, with signs of rapid wasting and severe cachexia, for which no explanation could be found after death. In none of the 20 guinea-pigs inoculated with tubercle bacilli did the simultaneous, and sometimes repeated, injection of the

vaccine prevent the development of fatal generalized tuberculosis. But many of the reports published in 1918 and 1919 deal with cases of arrest of previously severe and progressive disease in patients for whom the outlook before the institution of this treatment was exceedingly black. In a recent number of *Zeitschrift für Tuberkulose* Professor Orth, in the course of a lengthy paper on workmen's compensation and tuberculosis, refers incidentally to investigations by himself showing Friedmann's vaccine to confer on guinea-pigs a considerable degree of immunity from tuberculosis.

MEDICAL SICKNESS ASSURANCE.

THE Medical Sickness, Annuity, and Life Assurance Friendly Society, which was founded in 1884, has done much useful work for the profession, has shown a readiness to adapt itself to needs as they arose or were disclosed, and is continuing its excellent work, which might be more beneficial to the profession if a larger number of medical practitioners availed themselves of the advantages it offers. Besides the usual life assurances in the form of endowment assurances, annuities, etc., the special feature of the work of the Society is the sickness insurance scheme framed to meet the particular requirements of medical men. It is in the nature of a permanent contract, extending to 65 years of age, for the insurance of a weekly sum payable in full for the first twenty-six weeks of incapacity, and of half the full amount thereafter so long as the incapacity continues down to the age of 65. It is important to note that the contract is renewable or terminable at the option of the insured and not of the company; the policy, therefore, provides not only for temporary illness, but also against prolonged breakdown. Many cases have occurred within the experience of the Society in which men have been compelled to draw the weekly sum for many years, and even down to the limiting age. The rates charged are materially lower than those required for similar benefits by certain other societies; this is possible because the Society does not pay commission and does not employ agents; the saving may, we believe, be estimated at about 25 per cent. on the premiums paid. There can be no doubt at all of the importance to medical practitioners of making provision against sickness, for there is no profession in which prolonged withdrawal from work has so disastrous an effect. The Society was founded by medical men and has been continuously conducted in the interests of its policy holders, who are all members of the medical profession. Its position is financially sound, and it is remarkable, considering the advantages it is enabled to offer, that it has at the present time no more than 3,500 policy holders. Particulars of the terms and conditions offered can be obtained from Mr. Bertram Sutton, Secretary, Medical Sickness, Annuity, and Life Assurance Friendly Society, at 300, High Holborn, W.C.1.

WE are informed that the announcement made a fortnight ago to the effect that Professor E. H. Starling had definitely accepted an invitation to become Director of the medical element of the University Unit at St. Thomas's Hospital was premature. Such an appointment was contemplated, but depended on the fulfilment of certain conditions, which it has not been found possible to realize.

A SPECIAL general meeting of the Royal Society will be held on Thursday next, January 22nd, at 3.30 p.m., when H.R.H. the Prince of Wales will attend to be admitted to the Society. Afterwards there will be an ordinary meeting, at which papers, chiefly on physics, will be read. A meeting for discussion will be held on February 5th, when a debate on the theory of relativity will be opened by Mr. Jeans and continued by Professor Eddington, the Astronomer Royal, and others.

Scotland.

PROPOSED LISTER MEMORIAL INSTITUTE IN EDINBURGH.

THE project originated shortly before the war, and described in our columns of March 13th, 1914, for the establishment in Edinburgh of a permanent memorial to the late Lord Lister, has been revived. The University of Edinburgh, the Royal College of Physicians, and the Royal College of Surgeons of Edinburgh have come to the conclusion that the most suitable form for such a memorial will be an institute in which the scientific investigation of disease in any of its forms can be undertaken, and in which the principal sciences concerned can be adequately taught. It was in Edinburgh that Lister elaborated and consolidated his system, and it is appropriate that the scientific spirit which animated him and the methods of research he developed should be commemorated and continued in that city. Lister's work in the wards of the Royal Infirmary would have been fruitless—could not indeed have been carried out—had he not first tested his theories in the laboratory. It was in and through research that his system of treatment came to fruition. Research was the keynote of his work, and it is to research and the teaching of the results of research that the proposed memorial is to be dedicated. The need for such a centralized teaching and research institute in Edinburgh, it is said, is pressing. At the present time the burden of such work is borne by the University Department of Pathology and the Laboratory of the Royal College of Physicians. Of these, the former, built and equipped thirty-five years ago, is now inadequate, and the resources of the latter, particularly as regards the accommodation of the workers, are entirely insufficient, even for present needs. There is as yet no permanent memorial to Lister in Edinburgh, and it is felt that the rapid development of pathology, of bacteriology, of clinical pathology, of pathological chemistry, and of other cognate branches of knowledge has widened the field to such an extent as to render it necessary that the building erected to his memory shall be modern in design and equipment, and sufficiently large to house all the departments enumerated. The proposed new institute will be managed by a board on which the University and the two Royal Colleges will be represented.

A committee has been formed to make an appeal for £250,000 to pay for the site, to erect and equip the necessary buildings, and to provide for maintenance, apart from remuneration to research workers. A site, described as extensive and extremely suitable, has been secured close to the Edinburgh Royal Infirmary and the Medical School of the University at a cost of over £50,000. The President of the committee is the Right Hon. A. J. Balfour, M.P., Chancellor of the University, and the Vice-Presidents are the Duke of Atholl, the Earl of Rosebery, Earl Beatty, Lord Gleuconner, Lord Leverhulme, and Sir J. Lorne MacLeod. An appeal has been issued, signed by Sir J. A. Ewing, Principal of the University, Sir R. W. Philip, President of the Royal College of Physicians of Edinburgh, and Dr. George Mackay, President of the Royal College of Surgeons of Edinburgh. The University has given £10,000, the College of Physicians £10,000, and the College of Surgeons £5,000.

MR. C. E. GREEN, PUBLISHER, OF EDINBURGH.

Mr. Charles E. Green, who died after only three or four days' illness on January 6th, was passing through the medical classes in Edinburgh with the career of a medical missionary in full view when the early death of his father threw him into business. Out of the permutation thus effected in his life grew in time the well known firm of law publishers called William Green and Son, with many fine series of works coming from its presses; but the desire to do something in medicine was only diverted. Mr. Green soon added to his various legal publications, including the world known Scots and English Law Reports (45 and 180 vols. respectively), and such periodicals as the *Scots Law Times* and the *Juridical Review*, various medical publications, including the *Encyclopaedia Medica*, *Green's Encyclopaedia and Dictionary of Medicine and Surgery*, the *Veterinary Review*, and a goodly number of separate works, such as Noël Patou's *Physiology*, Barbour and Watson's *Gynaecological Diagnosis and Pathology*,

Walker's *Dermatology*, Fothergill's *Midwifery*, Ballantyne's *Manual of Antenatal Pathology and Hygiene*, and others. But more, Mr. Green himself ventured into the arena of medical literature with a work on the *Cancer Problem*, which excited admiration for the great number of observations it contained lying behind it, and of the variety of technical matters (outside of what may be called conventional medicine) embraced in it. He could write a good tale, too, as his *Lives in a Lowland Parish* proved, and he had fresh powers of description, as his county *History of East Lothian* showed. He never lost his admiration of the life of the medical missionary; for many years he paid the salary of one of the medical men working abroad under the Edinburgh Medical Missionary Society—of which he was one of the directors and a trustee—and his help made it possible for more than one medical student training for the foreign field to pass through the medical curriculum with greater comfort. In his later years he was much attracted by mother and child welfare work; he was an extraordinary director of the Edinburgh Royal Maternity Hospital, and took a great interest in the ante-natal department of that institution. He will be sorely missed in Edinburgh and in the county, where his historically interesting home (Gracemount) was ever open to his many friends and neighbours, and his comparatively early death—he was 53—will be widely mourned; he could yet have accomplished still greater things in publishing, and might have, at any rate, seen several large works brought to completion under his own supervising mind. Mr. Green was elected a Fellow of the Edinburgh Royal Society some years ago; he was a fluent and effective speaker at meetings for patriotic and charitable purposes. Another side of his activities was farming; he farmed his own land. Indeed, he brought enthusiasm and nearly always success into whatever his hand found to do.

HOUSING.

A gloomy picture of the pre-war and present state of housing conditions in Scotland is drawn by Sir George McCrae, D.S.O., in his *Summary of the Report by the Commission on Housing in Scotland*.¹ At the end of 1913, he says, 474 cases of pulmonary tuberculosis were being treated in houses of one apartment in Glasgow, and 1,589 cases in houses of two apartments, to quote a single example of monstrous overcrowding. The *Summary* is short and well written, and should be of value to all who have any direct interest in the subject with which it deals.

England and Wales.

PRESENTATIONS TO LIEUT.-COLONEL D. G. THOMSON.

A PRESENTATION was recently made by the permanent heads of departments of the Norfolk War Hospital to the Commanding Officer, Lieut.-Colonel D. G. Thomson, C.B.E., in recognition of the successful war work carried on by him during four and a half years, when 45,000 sick and wounded soldiers passed through the wards. The presentation consisted of an illuminated address and a barometer, together with a bouquet for Mrs. Thomson. Warm tributes to Colonel Thomson were paid by the Matron, Miss Hamer, R.R.C., and the hospital architect, Mr. George Smith. A presentation of silver plate has also been made to Colonel Thomson by the medical staff on the demobilization of the hospital. The plate, which was presented by Major Charles Noon, F.R.C.S., on behalf of some twenty colleagues, took the form of a handsome silver salver, inscribed: "From the Medical and Surgical Officers of the Norfolk War Hospital, Therpe, Norwich, to Lieut.-Colonel D. G. Thomson, R.A.M.C., C.B.E., M.D., commanding the Norfolk War Hospital, 1915-1919."

PRESENTATION TO DR. A. E. LARKING.

A short time ago Dr. A. E. Larking, who has accepted the appointment of medical school inspector in the Chesham district, Buckinghamshire, was the recipient, on the occasion of his retirement from practice in Buckingham, of a valuable testimonial, consisting of a wallet with £50

¹ *Summary of the Report by the Royal Commission on Housing in Scotland*. Edited by Archibald Stalker. With Foreword by Sir George McCrae, D.S.O. London and Edinburgh: W. and R. Chambers, Ltd. (Cr. 8vo, pp. 78. 1s. net.)

in Treasury notes and an album containing an illuminated address and the names of 700 subscribers. The address expressed the esteem felt for Dr. Larking's great and devoted services to all classes during his residence in Buckingham for thirteen years. The ceremony took place at the Town Hall; Alderman Osborne presided and the Vicar made the presentation. Dr. Larking, in acknowledging the gift, spoke of the regret with which he had decided, on account of his wife's illness and his own uncertain health, to retire from practice in Buckingham. Dr. Larking is honorary secretary of the Buckinghamshire Division of the British Medical Association and of the Buckinghamshire Local Medical and Panel Committee.

Correspondence.

TEMPORARY COMMISSIONS, I.M.S.

SIR,—Will you allow me to help to clear up the question of the suitability of the terms offered by the Secretary of State for India to temporary officers, with a view to relieving those members of the I.M.S. whose leave from India is long overdue?

The matter was gone into very carefully and at length by the Naval and Military Committee, and the terms fixed by that body were communicated to the Secretary of State. They were:

1. That a two years' contract be offered.
2. That the salary offered be Rs. 650 per mensem.
3. That a free passage out and home should be given.
4. That those appointed should be allowed the option of joining the I.M.S. during or on the completion of their contract, if they desired to do so and if they are found suitable.

In reply to this letter the Secretary of State has offered terms which include the first three of the above provisos; and he has gone even further, since he has offered a salary of Rs. 700 per mensem to a lieutenant and Rs. 750 to a captain. He has not made it clear that the fourth proviso is granted, but this is probably an oversight; the matter is being taken up with him.

With regard to the terms for permanent men I have nothing to say in this letter except to remark that opinion in the British Medical Association is hardening, that the terms mentioned in the letter under review represent the minimum possible. That is, however, a question which I need not deal with for the moment. What I do desire is to impress on young medical men the advantages of these terms for temporary commissions which the Secretary of State has offered them at the instance of the Association. The Naval and Military Committee took pains to name conditions which would be both fair and advantageous to the young doctor, and it would be a thousand pities if the unfortunate mistake, probably a mere oversight, of the India Office in communicating that offer to the public press before it made it known to the Association were allowed in any way to prejudice the case. The utter inaccuracy of the estimate of the pay offered, as computed by a daily paper, should not be permitted to blind us to the facts of the case. I agree with everything that the JOURNAL said on those very misleading figures, and, indeed, had already pointed out its mistake in the paper in question, but it has taken no action to put the matter right.

To look at these terms a little closer. The young man who has taken his qualifications, and has done a certain amount of practice but who feels that he wants more experience, will find an unrivalled field in India, be his bent what it may. At a time when in England his responsibilities would be very small, he will get the chance of doing really big work as a surgeon, as a physician, or as a specialist. He will come back from the East a very different and a very much more capable and self-reliant man than he went out. Apart from professional advantages, he will acquire the larger outlook on life which travel and contact with other peoples bring.

The pay offered him is liberal; he can live on it, and if he is single he can save if disposed to do so, or have a really good time if he prefers. His passage is paid both ways. His wife and family are to be sent out in the autumn of 1920 at Government expense, provided that shipping is available. It is not stated that they will be sent back at Government expense, and this point must be cleared up,

but it would be difficult to believe that any other course could be contemplated.

Another question the young man should ask is whether he is to be allowed the advantage of the fourth condition suggested by the Association in its letter referred to above. If he is, then his position is a very fortunate one, for he will be free, after two years of practical experience, to make up his mind whether he really wishes to decide for permanent Indian service or not. By that time, too, the conditions which are to be offered to the Indian Medical Service will be known and established.

I am convinced that the terms the Secretary of State is offering are well worth the consideration of young doctors, and I know that the same opinion is held by the members of the Naval and Military Committee. My plea is that young men should give consideration to a fair and a good offer made to try and surmount the present great difficulties in the grant of leave to I.M.S. officers, who badly need it.—I am, etc.,

R. H. ELLIOT,

Lieut.-Colonel I.M.S. ret.,

Chairman, Naval and Military Committee,
British Medical Association.

London, W., Jan. 13th.

PUBLIC HEALTH VERSUS THE STATE.

SIR,—I have been immensely amused at reading Mr. Baskett's address (January 10th, p. 41). We are all agreed that a plentiful food supply would have the effect of improving health, but the price of bread did not fall consequent on the abolition of the Corn Laws.

From 1820-1829 the price of wheat was ...	59s. 10d.
From 1830-1839 " " " " ...	56s. 9d.
From 1840-1849 " " " " ...	55s. 11d.

The fall from 1830-1839 was 3s. 1d., while from 1840-1849 the fall was 10d. The price remained over 50s. until the eighties, forty years after the repeal of the Corn Laws, when it fell with a bump.

If it was free trade which made the death rate from tuberculosis come down in England, it should have made it come down in Ireland. I will challenge Mr. Baskett to promulgate this on any Sinn Fein platform. I would advise him, however, to insure his life first.

In New York the rapid fall in the death rate after the McKinley tariff of 1890 proves the very opposite of what he sets out to demonstrate. As to Prussia, he is quite wrong when he speaks of the Caprivi treaties being Germany's nearest approach to free trade. During the first eight years of the empire they practically had free trade. The duties on wheat and rye were trebled in 1885, and immediately the death rate from tuberculosis fell (see Mr. Baskett's Chart IV). The merest tiro knows that the prosperity of the German working classes dates from the adoption of the protective policy of List in 1879.

His paper would be all right for the Cobden Club, but is unworthy of being laid before scientific men. I was brought up as a Liberal at the feet of John Bright; but for four years I was a Poor Law medical officer in Birmingham, where I found men starving as a result of unemployment through our system of *laissez faire*. This led me to study the matter at first hand, and the conclusion I came to was that the Chartist leader was right when he said: "'Cheap bread,' they [the Free Traders] cry, but they mean low wages."—I am, etc.,

Derby, Jan. 13th.

SIDNEY BARWISE, M.D., B.Sc. Birm.

SIR.—It must not be overlooked or forgotten that during the latter part of the period surveyed by Dr. Baskett in his address on Public Health *versus* the State, owing to increased facilities and improved methods for arriving at a correct diagnosis which then obtained, and also to a lesser degree to the disease being then a notifiable one, many deaths were certified as being due to tuberculosis which previously were not so certified. These factors played a vastly greater part in the maintenance of a high mortality rate from tuberculosis than any possible increase of poverty due to the passing of the Insurance Act.

Since the moneys expended on the notification of tuberculosis and on the provision of scientific means for correct diagnosis come out of the public funds, perhaps these matters might also be conveniently considered along with the Insurance Act at the inquiry (should such be held) into its effects upon the nutrition of the poor.—I am, etc.,

Colwyn Bay, Jan. 10th

"NEW LAMPS FOR OLD" IN OBSTETRICS.

SIR,—In the correspondence that is now going on with regard to the question of using forceps unnecessarily in midwifery cases may I give my experience? I was a pupil from January 1st, 1867, for five years with an expert in midwifery, and his advice was—Wait on Nature, and do not be in a hurry to use instruments. After my pupilage was over and I had qualified, I remained on as assistant for a further five years, and during the ten years I attended over 2,000 cases, instrumental cases being rarities.

In 1877 I commenced practice for myself in quite a different part—a manufacturing town—and have been actively engaged and still am so engaged in attending midwifery cases. This district is noted for two things: first, a tendency to narrowing of the brim of the pelvis by prominence of sacrum; and, secondly—and this is more frequent—that is, since midwives have been trained there is a great deal of impatience amongst parturient women against waiting for Nature to complete the case, and a great cry out either for twilight sleep or for chloroform and instruments; patients will not wait. The cases mostly now met with are those in which the midwife sends for help. In the fifty-three years I have been attending on midwifery I have helped at over 10,500 cases, and of later years these have been mostly instrumental or operative or craniotomy or version. I have had one case of Cæsaræan section and seen many cases of eclampsia where operative help has been required. There have been very few deaths amongst my patients and very few cases of serious post-partum hæmorrhage. Craniotomy for deformed pelvis has been resorted to in first cases; later pregnancies of these women have been by induction of labour at seven and a half months, with resulting living children.

Summing up from the work I have done, I come to the conclusion that, rightly used and in the right kind of cases, instruments and chloroform are a boon to parturient women, relieving them of the intense pain of the last stage before birth. It is impossible to lay down any definite axiom that it is wrong to use instruments. Given fully dilated cervix and head well down, then our duty is to conserve the strength of the patient, to save all needless suffering, and to give the help that is required carefully. Districts differ in the build of women, and where the chief employment is of a character requiring the women to sit all day at work this may be a reason for either deformity or less of power to bear pain; and, lastly, the trend amongst women of the present generation is to resent the fate that they have to suffer the pains of becoming a mother, and to do all they can to reduce their sufferings to a minimum. This is partly due to the teaching of "twilight sleep" and also to the emancipation of women and raising them to an equality in work with the opposite sex.—I am, etc.,

January 11th.

A GENERAL PRACTITIONER.

SIR,—I am concerned lest the thesis of my paper read before the Obstetric Section of the Royal Society of Medicine last May, and which your leading article of November 22nd epitomized under the heading "'New lamps for old' in obstetrics," should be lost sight of in the orgy of controversy provoked by Dr. J. Fairbairn's letter of November 29th.

I urged that the teaching of midwifery should be invested with the surgical attitude of thought and its practice safeguarded by all these circumstances of environment, assistance, and asepsis which are accepted *sine qua non* in every department of recognized surgery. In short, that the art should be taught, practised, and recognized as a branch of surgery.

Dr. Fairbairn's letter has drawn a red herring across this line of thought. My paper was not concerned with whether midwifery should be more "operative" or less "operative"; it argued that it should be more "surgical," which is quite another and much larger thing. When we have secured for midwifery those requirements which are elementary in all other departments of surgery, it will be time enough to discuss the percentage of cases requiring operation. Until then such controversy obscures the more important issue.—I am, etc.,

London, W., Jan. 16th.

VICTOR BONNEY.

TICKS AND RELAPSING FEVER.

SIR,—I was interested in the paper on "Tick Fever in Palestine," by Dr. Nicholson, which appeared in the BRITISH MEDICAL JOURNAL of December 20th, 1919 (p. 811), but he is in error when he states that I found that the Miana fever of Persia was a form of relapsing fever transmitted by the tick *Argas persicus*. Since his paper appeared I have been trying to discover how his error arose, and have been looking through the literature on the subject, and papers of my own on spirochaetosis, which might possibly contain some reference to the disease in Persia. In all probability Dr. Nicholson was led astray by a note on p. 246 of the sixth edition of Sir Patrick Manson's *Tropical Diseases*, where I find my name is bracketed along with the spirochaete of Miana disease. I may say that my only visit to Persia was paid during the war, when I spent a short time at Ahwaz on the Karun River and in Shuster, but I saw nothing of relapsing fever at that time, and had no opportunity of making inquiries regarding it.

I cannot discover that I have anywhere stated that Miana disease was due to a spirochaete carried by *Argas persicus*, nor do I recollect ever making any such statement. I find I once said that *A. persicus* was stated in Persia to bite men, but beyond this guarded utterance I do not seem to have dealt with the question at all, although it is possible some reference may have escaped my attention. As a matter of fact our knowledge as regards Miana

Rock tombs or caves in Palestine.

disease seems to rest much where it was when Nuttall wrote his paper. "On the rôle of insects, arachnids, and myriapods as carriers in the spread of bacterial and parasitic diseases of man and animals: a critical and historical study," in the *Johns Hopkins Hospital Reports*, October, 1899, vol. viii. So far as I know we have no definite evidence that *A. persicus* can transmit any human spirochaete, and although Dr. Nicholson's observations are interesting they are by no means conclusive, as it is impossible to say whether lice were absolutely excluded as vectors. There seems, however, to be a very general belief that in Palestine *A. persicus* is a transmitter of the infection of relapsing fever. I remember that when on the road north of Jaffa in July, 1918, I was shown certain rock tombs or caves in which it was said men had slept and had there acquired relapsing fever from the bites of ticks which lived in these miniature caverns (Fig.). At the same time this belief does not appear to have been founded on any sound scientific basis.

In Cilicia and northern Syria, Schneider in 1912 described (*Archiv für Schiff- und Tropen-Hygiene*, vol. xvi) a form of relapsing fever which he attributed to ticks (species not determined), but he advances no conclusive proof in favour of his hypothesis, and does not consider the question of lice being the carriers. Until careful experimental work is carried out on the subject it is inadvisable to attribute either the Cilician or the Syrian type of relapsing fever to *A. persicus*, although we may note that, according to Boyd, the disease in Palestine differs in some respects from that found in Egypt, where it is undoubtedly carried by lice.

I find that under the heading "Relapsing Fever" in the

"Memoranda of Medical Diseases in the Tropical and Subtropical War Areas" I wrote as follows:

"There is some evidence to show that in Palestine, apart from lice-borne relapsing fever, there is a form, possibly like that described in Cilicia and Persia, where the infection is conveyed by the fowl tick, *Argas persicus*."

This, however, is not intended to mean that the disease in Cilicia and Persia is carried by *Argas persicus*, but merely that, clinically, the relapsing fevers of these countries may resemble that seen in Palestine. I admit, however, that if read hastily it might possibly convey a wrong impression.—I am, etc.,

ANDREW BALFOUR.

FORGETTING: PSYCHOLOGICAL REPRESSION.

SIR,—All questions relating to the mind are elusive and evasive, and many theories have of late been propounded to account for the cure of functional mental and nervous conditions, many of these views expressed with more haste than deliberation and consideration.

I have been much interested in the able remarks of Dr. Alfred Carver in the BRITISH MEDICAL JOURNAL of January 10th, and I venture to think that he and others have animadverted without reasonable or adequate cause, certainly without justification, upon the advice given by Sir William Hale-White in his paper on August 23rd, to encourage the "neurasthenic"—to use the term in its widest sense—to forget his war experiences by the practice of mental diversion of various kinds.

I am not so impertinent as to attempt to defend Sir William Hale-White; he is fully capable of demonstrating to the younger school of psycho-neurologists that during the great war the path of progress has been paved with many abandoned theories. There has been a strong tendency to offer some plausible explanation—often very grotesque and inconsequent—of sudden recovery in functional mental and nervous states. Patients suffering from these states are all in a most receptive and susceptible mental condition, and some of them immediately accept any suggestion made to them as to the motives for their strange conduct and actions or as to the origin of their symptoms, which may disappear by suggestion as if by magic and which in many instances return equally without reason or notice.

The unconscious mind is believed to be a great twentieth century discovery, and to this is attributed not only the ordinary phenomena of mental life but also the vagaries of the psycho-neurotic, and this source—variously described as the *elan vital* (Bergson), the *horme* (Jung), the libido of Freud, or the craving for life, love, or action—is regarded as the prime mover of all action.

I have never been able to accept this endopsychic censor as the mysterious unseen power that has until recently escaped detection, although with others I have long realized the great influence of the unconscious mind and its teleological trend, for it helps to perpetuate the individual, to enable him to carry out perfunctorily the everyday routine duties by saving him the necessity of endless repetitions. It has to ignore and "forget," but I doubt the reasonableness in treatment of bringing to the surface and rekindling with emotion what has been usefully and purposely ignored, and I doubt if the unconscious mind has to seek for immediate satisfaction in some other activity, or that this is of necessity sexual.

I question whether it is possible to "forget" by an act of volition or to abolish actively any painful memory from consciousness, or, in other words, whether it is possible to repress what is intolerable, except in so far as this can be attained by bringing in new thoughts, ideas, or impressions to occupy the field of attention and thus build up new associative links, and so help to form new habits. Pain and hurt and danger are not ignored and forgotten because they are unpleasant or intolerable. If this were not so, self-preservation would be impossible, therefore I question whether it is practicable to forget by an act of volition directly.

From a not inconsiderable experience of the war neuroses in the London Command, and from a very long experience of the mild and severe forms of psychoses in civilians, I am of opinion that it is not orthodox mental therapeutics to

lay down an axiom—as is done, if I rightly interpret Dr. Carver, and I quote his own words—that the necessary first step in the cure of mental and nervous states is the making conscious of the forgotten, the bringing to the surface of what is repressed, and the transference of memories by what has been weirdly designated as "ab-reaction." If any claim is made to a cure by recalling war experience, then the investigator must himself possess an absolute and true photographic record of the actual battle scenes, otherwise the effect is purely that of suggestion.

In these cases, as in all mental and nervous states, much must depend upon the nature, and the temperament, and the mental "make up" of the individual patient. For some distracted persons it is possible that the "cathartic" effect of getting rid of unpleasant thoughts by "ab-reaction" may be appropriate treatment, and may tend towards recovery, but to others the opposite would undoubtedly occur. Would any psychiatrist suggest that a woman suffering from one of the functional anxiety psychoses, described as acute restless mental depression, would be cured or relieved by reminding her luridly of the bare home, the cruelties of a drunken husband, or the death of her children through neglect? Is it mental therapeutics to remind the disappointed girl who has become a mental and moral wreck of the broken promises of her faithless lover? Is it rational treatment to remind the first offender, who is endeavouring to reconstruct his life in a new environment, of the crime to which he yielded in a moment of temptation? Does the nervous actor regain his lost confidence if he is reminded of his first-night stage fright; or would he be happier and less nervous if the horrors of the occasion were again represented to him by his candid friends? or would the sensitive musician be able to play better through being reminded of the piece he had forgotten and the fiasco that ensued? Similarly in the case of many a soldier hero who may have broken down, is it sound treatment to bring before his conscious mind the horrors he has seen, the terrifying sounds he has heard, and the awful experience he has gone through, and to have all these unpleasant and forgotten memories brought to the surface, and then "to attach them to suitably associated presentations"? If, as in some instances, an immediate and temporary recovery has taken place, this has more probably been caused by the sudden element of surprise, the emotional shock acting by suggestion from the person who exercises over his patient what has been described as a dominating personality; and the same applies to the sudden cure of obsessions, such as the one recorded of an immediate recovery from "claustrophobia," the patient being relieved, it was said at once, by bringing to the memory the bite from a dog in a narrow passage long forgotten, this also being an example of "suggestion."

The psychoses and neuroses are Nature's means of defence, and I venture to believe they are best relieved by helping Nature to obtain a complete rest and some mental diversion, by providing pleasant memories, new ideas and new inspirations which will enable the patient to bury in the unconscious mind the forgotten sources of his failure. If Nature's methods of restoration are jerkily hastened there will be an inevitable risk of a relapse.

No saner advice was given than by Frances Power Cobbe, who compared the unconscious mind to the faithful private secretary who performed his work silently and in his own way and best when not disturbed, and that the same treatment should be meted to it.—I am, etc.,

ROBERT ARMSTRONG-JONES, M.D., F.R.C.P.

London Military Command and temporary
Lieutenant-Colonel R.A.M.C.)

London, W., Jan. 13th.

PREVENTION OF VENEREAL DISEASE.

SIR,—The letter in your issue of January 10th from the President and Honorary Secretary of the Society for the Prevention of Venereal Diseases seems to require comment.

By invitation I attended the conference held by the society on December 16th, 1919, and in the discussion I joined others in making strong protests that in the printed answers sent to inquirers, and in the "Aims and Objects" of the society, copies of which had been sent to me, and were also distributed at the meeting, there was not a single word of advice or warning against incontinence. The only

Obituary.

SIR THOMAS RICHARD FRASER, M.D., F.R.S.,

LL.D. Aberd., Glasg., Edin., Sc.D. Camb., etc.,

Emeritus Professor of *Materia Medica* and *Clinical Medicine* in the University of Edinburgh.

Of the distinguished quinquévrate who presided over clinical medicine (on the university side) in the Edinburgh Royal Infirmary in the early eighties of the past century, Sir Thomas Fraser has been the last to pass away. Sir Douglas MacLagan resigned in 1897, Sir Thomas Grainger Stewart died in 1900, Sir Alexander Simpson resigned in 1905 and died in 1916, Professor Greenfield passed away in 1919, and now the last of the "Big Five" has gone to his rest full of years and honour. All these were professors of one other subject in addition to clinical medicine, a fact which in itself marks the gliding of the years and the changes in university teaching and infirmary practice, for the tendency now is no longer to burden the clinical staff with such things as medical jurisprudence, pathology, gynaecology, and *materia medica*, but to leave it free to develop along its own lines. Probably none but the most persistent *laudatores temporis acti* would wish it otherwise: but assuredly the five professors named rose brilliantly to the heights of success in their double task, and the subjects they taught suffered no abatement in their capable hands.

Thomas Richard Fraser, who died early in the morning of Sunday, January 4th, was born at Calcutta in February, 1841, and so had reached the ripe age of nearly 79 years. He was educated at public schools in Scotland and at the University of Edinburgh, and the keynote of his whole life was struck when at his graduation as M.D. in 1862 he gained a gold medal for his thesis on the characters, actions, and therapeutic uses of the ordeal bean of Calabar (*Physostigma venenosum*, Balfour), published in the *Edinburgh Medical Journal* for 1863-4. Another event at this time had its determining influence on Dr. Fraser's life, and that was his appointment by Sir Robert Christison as his assistant in the *Materia Medica* Department in the University of Edinburgh. Two other determining steps in his career were his appointment as assistant physician to the Royal Infirmary in 1869, a post which he held till 1874, and his launching out as a lecturer on *materia medica* in the extra-mural school in 1870. Meanwhile he had been busy with pharmacological research, and in 1864 had written on "The moth of the asere or ordeal bean of Old Calabar," and in 1867 had published "A preliminary notice of the Akazga ordeal of West Africa and of its active principle." These papers were soon followed by the more important essays on "The antagonism between the actions of physostigma and atropia" (read before the Edinburgh Royal Society), and in 1873 on "The kombé arrow poison" (*Strophanthus hispidus*, D.C.) of Africa in the *Journal of Anatomy and Physiology*. In 1874 Dr. Fraser resigned his infirmary and extramural appointments to become medical officer of health for Mid-Cheshire, and during the following three years he performed the duties of that office, at the same time retaining his connexion with *materia medica* by acting as examiner in that subject in the Universities of London and Edinburgh. In 1877, however, his incursion into public health terminated, and henceforth he gave his whole energies to the subject of his first choice, *materia medica*, and especially pharmacology.

The way for this decision was opened up by the resignation of his revered and highly distinguished teacher and chief, Sir Robert Christison; Dr. Fraser's appointment to the vacant chair (1877), and to the post of physician to the Royal Infirmary (1878), were fortunate choices, both from the point of view of the new Professor and of the institutions he was thus called upon to serve for so many fruitful years. That his fame was already known outside the limits of Scotland was proved by his appointment (1877) by the Lords of the Admiralty as one of the two medical members of the committee to inquire into the outbreak of scurvy in Sir George Nares's Arctic expedition.

During the following forty years (1877-1917) Professor Fraser was teaching *materia medica* in the university and clinical medicine in the Royal Infirmary to thousands of medical students. In the classroom he had to deal with a somewhat dry subject, but it lived in his lectures, and

took on an unexpected interest and even fascination, especially when he was considering tobacco, alcohol, and the arrow poisons and ordeal beans. There was always (and this applies to his clinical work as well, and to his speaking in public) a note of distinction in what he said, and an unerring instinct for *le mot juste* which held his hearers and never failed to win their applause. He was in the very front rank as a clinician, and in the Infirmary had a following which always included many of the best men of the year. In the laboratory he was in his element, and the wide world benefited by the work done there by Professor Fraser and his assistants, Professor Matthew Hay, the late Dr. Tillie, Dr. Sillar, and others.

But the forty years of which we are speaking held many other things for Professor Fraser. Thus he was Dean of the Faculty of Medicine for many years; he was a member of the University Court between 1904 and 1913; from 1905 he represented the University on the General Medical Council. He was President of the Royal College of Physicians of Edinburgh in 1900-02; of the Medico-Chirurgical Society of Edinburgh in 1901-03; of the Section of *Materia Medica* and Pharmacology in the International Medical Congress held in London in 1881; and of the Association of Physicians of Great Britain and Ireland in 1908-09. He acted also as medical adviser to H.M. Prison Commission in Scotland and was consulting physician to the Standard Life Assurance Company. But perhaps the most outstanding event of the forty years in these, so to say, subsidiary activities was Professor Fraser's selection (in 1898) to be Chairman of the Indian Plague Commission which was investigating that fatal scourge in our great Eastern Dependency. This necessitated absence from Edinburgh, but with the aid of Principal Sir William Turner, who made interim arrangements, and of Professor Simpson, who acted as Dean of the Medical Faculty, Professor Fraser was set free to do a piece of real national service and also to add very considerably to our knowledge of the dissemination of plague and of the best means to check its ravages. On returning from India Professor Fraser received (in 1902) the honour of knighthood from his Majesty King Edward.

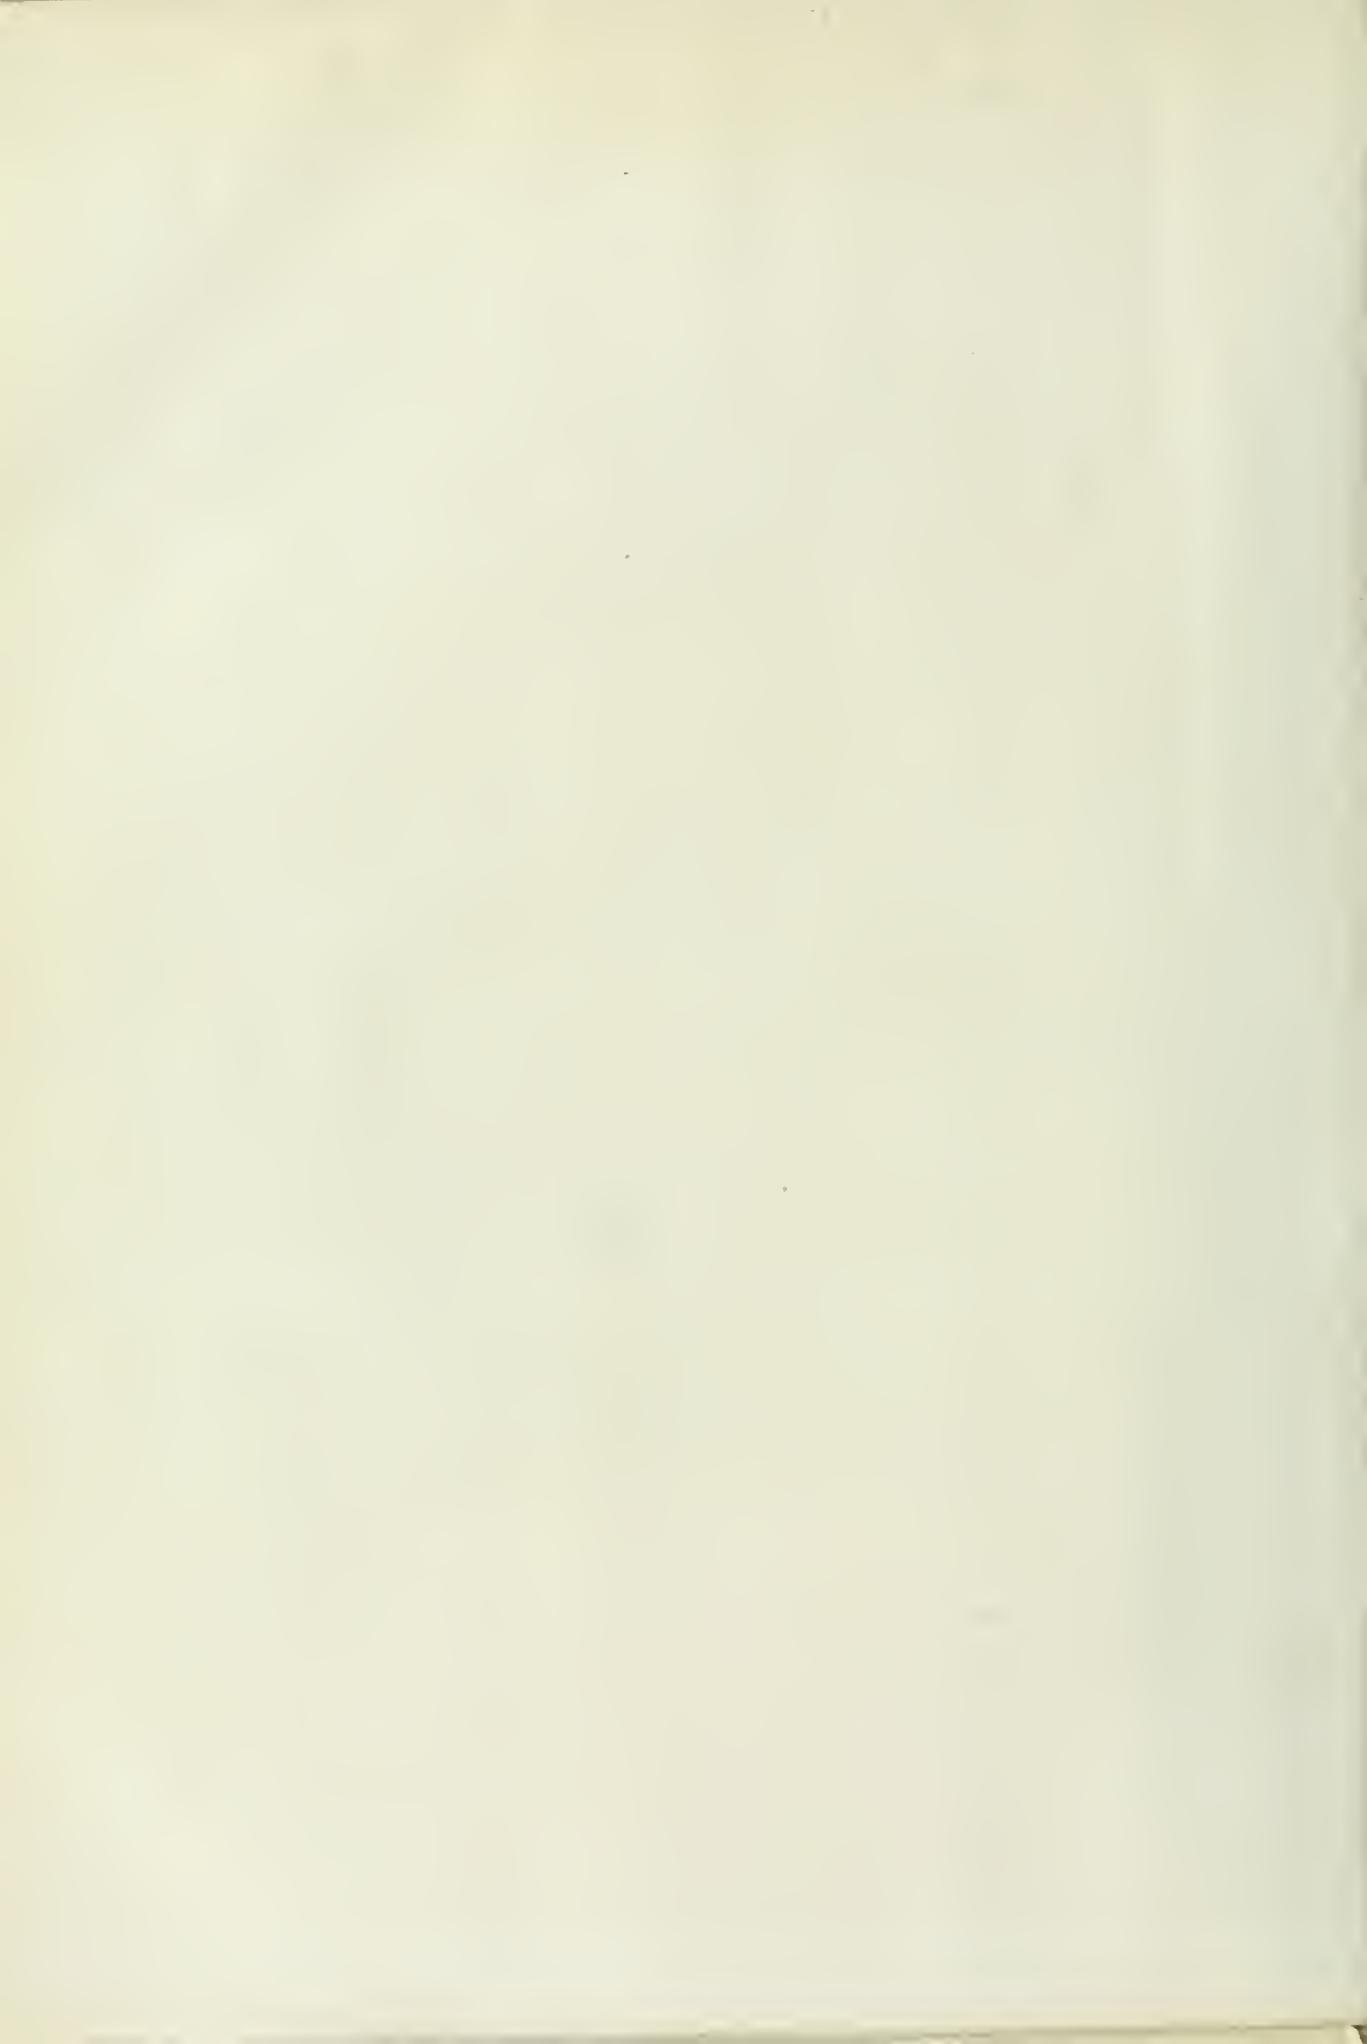

In his later years honours multiplied upon Sir Thomas Fraser. He was already a Fellow of the Royal Societies of London and Edinburgh, and on the death of Sir William Gairdner in 1907 he was appointed Honorary Physician-in-Ordinary to the King in Scotland. The Universities of Aberdeen and Glasgow conferred upon him their honorary degree of Doctor of Laws; he was a laureate of the Institute of France; Cambridge gave him its honorary Sc.D., and Dublin its honorary M.D.; and on his retirement from his chair in 1918 his Alma Mater showed its appreciation by the gift of the honorary LL.D., whilst his many friends presented him with his portrait.

Something has been said of the beginnings of Sir Thomas Fraser's scientific and literary work; but the accession to the duties of his professorship did not check his labours in research, and results continued to flow from his laboratory. An interesting investigation was that which he carried through in conjunction with *Emeritus* Professor Crum Brown on the chemical constitution and physiological action of poisons, and for which the Royal Society of Edinburgh awarded them the Macdougall-Brisbane prize. He was also Keith prizeman (Royal Society of Edinburgh), and Cameron prizeman in therapeutics (University of Edinburgh). More than one communication came from his pen on *strophanthus* (1886, 1891, 1895), and he did much to establish its position in cardiac affections, and it is unnecessary to do more than mention the use of physostigmine in ophthalmology. So, too, his work on serpent's venom, on the limitative to the antidotal power of antitoxins, on immunization against serpent's venom, and on the antivenomous properties of the bile of serpents was of high interest and great practical value. He wrote, with the late Dr. Alexander Bruce, on diabetic neuritis, and, with the late Dr. Joseph Tillie, on the arrow-poison of the Wa Nyika and other tribes of East Equatorial Africa. Outside these, which may be called the distinctive subjects of his work, Sir Thomas Fraser wrote (always instructively) on the salicyl compounds in acute rheumatism; on the nitrites in the dyspnoea of asthma and bronchitis; on bone marrow in pernicious anaemia; on opium, morphine, and codeine in diabetes mellitus; and on potassium bichromate in gastric affections. In all these writings there is to be observed the same note of distinction

SIR THOMAS FRASER, M.D., F.R.S.

Photo A. Swan Watson, Edinburgh.

which characterized his speaking; but, more than this, some of them at least will permanently benefit mankind by reducing disease and suffering.

His recreations were fishing, shooting, golf, and photography, all of which he enjoyed to the full at his country home at Drumbeg, Acharacle, Argyllshire, but recently a bronchial affection seriously hampered him in these pursuits.

Some seven years ago Sir Thomas Fraser met with an accident near the door of his own house in Drumsheugh Gardens, which resulted in fracture of the thigh, and it was feared that this might mean retirement from active work, but his marvellous vitality came to his aid and, reinforcing the assiduous care of his surgeon and physician, placed him once more in harness for all his duties. Of late years, however, the bronchial affection referred to sorely handicapped him, and since he retired from his professorship in 1918 he has laboured under considerable physical disability. About a fortnight before his death he was reported to be seriously ill, but he revived again, only to lose ground once more.

Sir Thomas married in 1874 a daughter of the late Rev. R. Duncan, and Lady Fraser survives her husband. They had seven children; but of these one son was lost in a submarine early in the war, another was killed in France, yet another was wounded there, and a son-in-law was killed. Their fourth son, a doctor in America, went to France and holds an important post with the Army of the Rhine. There were three daughters, one of whom is the wife of Lieut.-Colonel Kenneth Dingwall, D.S.O.

After a service in the Cathedral Church of St. Mary, the funeral took place to the Dean Cemetery on January 8th, and was attended by representatives of the University, the Royal Colleges, the Royal Infirmary, and other public bodies. Sir Alexander Ogston was present representing the King.

Sir JAMES O. AFFLECK, Consulting Physician, Edinburgh Royal Infirmary, writes:

By the death of Sir Thomas Fraser another outstanding figure has been removed from our ranks. He had only recently retired from his position as Professor of *Materia Medica* and of *Clinical Medicine* in Edinburgh University, but during his long tenure of these offices his work had gained for him a foremost place in the world of medicine as an investigator and a physician. His researches, begun from an early period in his career, and continued throughout his whole life, were fruitful in providing the profession with many potent therapeutic agents of proved efficacy with which his name will ever stand associated.

When called to succeed his great master Christison every one felt that the right man had been chosen for the chair. In the affairs of the university and especially its medical faculty he took a leading part, and proved a strong and trusted counsellor.

In the Royal Infirmary, with which his connexion as a physician extended over forty years, he carried on clinical teaching greatly to the advantage of the men who were privileged to act as his students and clerks. His standard was high, and he exacted a like degree from them, inspiring them with the spirit of earnestness and accuracy which characterized his own work. Indeed, the dominant feature in Fraser's whole career was his earnestness in doing the work his hand found to do and in searching for the truth. His personal influence in this direction could not fail to tell upon the lives and the practice of the thousands of pupils who had been under his instruction and guidance.

In the manifold positions he was called to occupy Fraser ever gave the impression of a man of power, while his dignified and kindly bearing won for him the respect even of those who might chance to differ from him. In the later years, although suffering from considerable physical disablement the result of an accident, he showed no lessening of his vigorous mental powers, nor of his interest in all that related to the advance of scientific medicine.

When called a few months ago to receive the degree of LL.D. from his Alma Mater, the enthusiasm which his presence evoked bore emphatic testimony to the academic and the public appreciation of his highly distinguished and honourable career.

Dr. W. C. SILLAR, Lecturer on Experimental Pharmacology in the University of Edinburgh, writes:

With the passing of Sir Thomas Fraser there has disappeared one of the most outstanding personalities of the Edinburgh Medical School and certainly one who has left his impress most deeply on the generations of students who came under his influence. Perhaps the most conspicuous features of his method of teaching were, on the one hand, a power of criticism which exposed unsparingly the weaknesses in the intellectual armour of his pupils, and, on the other, an insistence on accuracy both of observation and of recording which to some may have appeared meticulous, but which was invaluable to those capable of appreciating its value. He was one of the earliest, if not the first, among pharmacologists to aim at the accurate expression of dosage in terms of body weight and to analyse pharmacological action into its component parts, advances which gave to pharmacology a claim to be considered among the exact sciences. Ambiguity and slovenliness of expression were hateful to him. There was no possibility of misunderstanding that which he wished to express clearly, nor were his statements with regard to those facts which he observed himself subsequently found to be erroneous.

His courage and persistence in the face of grave physical difficulties compelled the admiration even of those who feared his undertaking work for which he was no longer physically fit; and those who opposed his opinions could not but be impressed by the ability with which he maintained his point of view, and by the laborious pains with which he collected and marshalled his facts and arguments. His work was characterized by thoroughness and completeness, and many of his observations obtained publicity only in his lectures on *materia medica* and on clinical medicine. His pioneer work on antagonism earned for him a world-wide reputation, and there have been few names associated with one school alone which have added more to the reputation of that school than has the name of Fraser of Edinburgh. As an authority on medical education, from his twofold experience as laboratory investigator and clinician, he always maintained the importance of a philosophical and scientific training preliminary to and accompanying the study of the professional medical subjects, and ascribed the eminence of the best Edinburgh graduates to the insistence upon and emphasis laid on this aspect of education. He was a powerful advocate of the advancement of knowledge by investigation, and constantly deplored the encroachments made on the time available for this which the teaching demanded of him necessitated. His keen glance and polished diction will long be remembered by the successive years of students who listened to his lectures in the theatres of the *Materia Medica* department and of the Royal Infirmary.

THE LATE CHARLES LOUIS TAYLOR.

We have received the following kindly note on our late colleague from the President of the British Medical Association:

The debt of the British Medical Association and of its JOURNAL to Charles Louis Taylor is so great, and yet perhaps so little recognized, that I desire, if I may, to add to the obituary notices of him.

Many years ago, when Mr. Hart was editor of the JOURNAL, I had some conversation on business matters with Mr. Taylor, and a little later we happened to travel together abroad for a short time. During this time unfortunately Taylor fell ill, and I was privileged to render him some little professional assistance, assistance which, after his manner, he appreciated too generously. Thenceforward our friendship became a closer intimacy. We corresponded not infrequently, sometimes on professional matters, more often on literary and general subjects. When I visited at the offices of the Association I generally took occasion also to call upon Taylor. It was one of our little games to test the correctness of my identification of his anonymous articles. These were usually so acute, learned, and witty, that although every now and then one of them would escape my notice, I was very rarely wrong in my positive attributions.

Taylor was a delightful writer, erudite in many ways, general and particular, but especially in historical subjects.

He took pleasure in some by-ways of scientific history on which, and other such matters, he contributed much to the contents, and not a little to the gaiety, of the JOURNAL.

Taylor's wit and keen sense of humour were always entertaining, often brilliant and effective. Many of his paragraphs—fugitive alas!—were in their ironical and humorous vein singularly happy. Moreover, his wit was always barbed with point and precision. No inaccuracy escaped him, and he would smilingly pin the error to the counter, or dismiss it with a whimsical allusion. Sometimes he permitted himself to draw a sharper arrow, when folly and presumption had to smart; but he was too kind-hearted to use the weapon unless the gravity of the occasion required it.

It seemed a pity that so learned and accomplished a man, and so finished and sprightly a writer, should have lived so much in seclusion; but he seemed happiest in his privacy with many books and the few friends who sympathized with his thoughts and studies. I dare say he knew how great and indeed exceptional a power for good his position gave him, both in life and literature, and was content to do it by stealth.

Men of his kind are not turned out in "mass production"; after each one the mould is broken. On Taylor's retirement the Staff of the JOURNAL lost a brilliant colleague; but happily in this world there are diversities of gifts and many kinds of voices, and none of them without significance.

C. A.

WE regret to record the death of Dr. JOHN WAUGH of Toddington, Bedfordshire, on December 30th. He was born in 1850 at Clonakilty, co. Cork, and received his medical education at Trinity College, Dublin, where he graduated M.B., M.Ch. in 1871, proceeding to the B.A. and M.D. in 1882. Dr. Waugh settled at Toddington forty-eight years ago and practised there with conspicuous success. He was highly esteemed by his professional brethren. He was president of the Bedford Medical Society in 1901 and of the Bedfordshire Division of the British Medical Association for three successive years during the war. At the time of his death he was Chairman of the Bedfordshire Medical Committee, a post to which he had been elected in 1912. He had been a J.P. for the Woburn Division of Beds since 1898 and Chairman of Woburn Bench since 1909. He was for many years a member of the Bedfordshire County Council, was a member of the Education and Sanatorium Committees, and chairman of the Maternity and Child Welfare Committee, which, during his term of office, established a service of health visitors throughout the country. He did much to improve the nursing of the sick poor in the agricultural district in which he lived and for the benefit of the maternity and nursing service in the rural areas. Dr. Waugh was a member of the County Insurance Committee and chairman of the Toddington Parish Council. For many years he did most of his visiting on horseback. Some years ago he suffered a severe riding accident from which he never altogether recovered. He was a man of firm conviction, but of much charm of manner, which endeared him to the people among whom he worked so long.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

DIPLOMA OF PSYCHOLOGICAL MEDICINE.

THE Committee of Management of the Cambridge University Diploma of Psychological Medicine announce that examinations for the Diploma will be held, for Part I in October, 1920, and for Part II in December, 1920. A course in preparation for these examinations will be held at the Cambridge Psychological Laboratory from July 19th to August 29th inclusive, and will be conducted as follows:

- Part I: Psychology with Practical Work, J. P. Towson, M.A., M.D.; Anatomy and Physiology of the Nervous System, with Practical Work, E. D. Adrian, M.A., M.D.
Part II: Abnormal Psychology, J. P. E. Prideaux, M.D.; Psychiatry, Lunacy Law and Asylum Administration, M. A. Archdale, M.D., Superintendent of the Cambridge County Asylum.

The fees are for Part I £5 5s., and for Part II £4 4s. Further information may be obtained from the Director of the Psychological Laboratory, Cambridge.

UNIVERSITY OF LIVERPOOL.

THE Diploma in Public Health has been awarded to the following: A. J. W. Cunningham, R. W. Gemmell, D. S. A. O'Keefe.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY Council was held on January 8th, when Sir George H. Makins was in the chair.

The President reported that Mr. John Murray's term of office on the Court of Examiners would expire on February 11th, and that the vacancy would be filled up at the Council meeting on February 12th. Mr. Murray is re-eligible.

The Hunterian Oration will be delivered by Sir Charters J. Symonds in 1921.

The Secretary reported that no essay had been received on the investigation and treatment of injuries of the thorax received in war, the Jacksonian Prize subject for the past year.

Sir Charters J. Symonds was re-elected to represent the College on the council of Queen Victoria's Jubilee Institute for Nurses for a period of three years from March 1st, 1920.

As arising out of the resolutions passed at the meeting of Fellows and Members on November 27th, 1919 (BRITISH MEDICAL JOURNAL, December 6th, p. 760), it was decided to appoint a committee to consider the question of the representation of Members on the Council.

THE NUMBER OF MEDICAL AND DENTAL STUDENTS.

WE are indebted to the Registrar of the General Medical Council for the following particulars with regard to the number of medical and dental students, respectively, registered during 1919 and the seven preceding years. It may be pointed out that as registration of students is not enforced by all the licensing authorities the totals probable fall short of the actual number of students.

Medical Students.

1912	1397	1916	1875
1913	1480	1917	2150
1914	1600	1918	2253
1915	1918	1919	3393

Dental Students.

1912	336	1916	158
1913	361	1917	143
1914	294	1918	161
1915	217	1919	612

Medico-Legal.

PROFESSIONAL SECRECY.

DURING the hearing of an undefended suit for divorce on January 13th, Mr. Justice McCardie made some observations on professional secrecy.

The petitioner was the wife and adultery by the respondent was proved; the cruelty consisted of the communication of syphilis by the respondent to the petitioner. Dr. Salomon Kadinsky, Medical Officer of the Venereal Department, Westminster Hospital, was called to prove that the petitioner was suffering from syphilis. Before being sworn he handed a letter to the Judge from the Chairman of the House Committee, stating that the Westminster Hospital had adopted the national scheme for dealing with venereal disease, and calling attention to the statutory regulations, one of which enjoined secrecy. The regulation referred to is contained in the Public Health (Venereal Diseases) Regulations, 1916, and is as follows:

Article II (2). All information obtained in regard to any person treated under a scheme approved in pursuance of this Article shall be regarded as confidential.

Mr. Justice McCardie made the following observations, as reported by *The Times*: "The doctor [of the venereal centre] was one of those who were desirous of assisting the scheme for treating venereal diseases in every way, and for the purpose he wished loyally to maintain the secrecy which rightly rested upon him. But the witness would appreciate that in a court of justice there were even higher considerations than those which prevailed with regard to the position of medical men. He wished to say that, apart from the obligations which might be imposed on medical men by the order of His Majesty's judges, it was desirable that there should be the most loyal observance of the confidence which was reposed in them by patients. He was glad to say that the history of the medical profession was most honourable, and it was to be hoped that its members would always retain the confidence placed in them."

Dr. Kadinsky was then sworn and gave evidence.

The observations of the judge raise a matter of considerable medical interest, with which are involved legal considerations of some complexity. We propose to refer to the matter more at length in our next issue.

Medical News.

UNDER the auspices of the Fellowship of Medicine and Post-Graduate Medical Association, the British Association of Radiology and Physiotherapy has arranged a series of lectures in radiology and electrology, qualifying for the Cambridge diploma (see BRITISH MEDICAL JOURNAL, January 10th, 1920, p. 55). They will be given at the house of the Royal Society of Medicine, 1, Wimpole Street, London, every Monday and Wednesday, at 5.30 p.m., commencing February 2nd, 1920. The opening lecture will be given by Dr. Turrell of Oxford, who will deal with the history of electrotherapeutics. For those wishing to take the diploma the fee for the course is £15 15s., with the additional enrolment fee of 10s. 6d. to the Fellowship of Medicine and Post-Graduate Medical Association; but members of the Fellowship Post-Graduate Course are invited to attend any of the lectures advertised. A detailed syllabus will be issued shortly and all information can be obtained from Miss M. A. Willis, secretary to the Fellowship of Medicine and Post-Graduate Association, 1, Wimpole Street, London, W.1.

A SUCCESSFUL reunion dinner of the medical men of Cheltenham and district who had served with the R.A.M.C. was held on January 10th at the Lansdown Hotel. A most enjoyable evening was passed, and interesting reminiscences were exchanged, as those present had between them seen service in all parts of the globe. Dr. J. Rupert Collins was chairman, and there were present Drs. Braine-Hartnell, Barret Cardew, Sanderson Clow, D. Clow, Conder, Cox, Lidderdale, Longridge, Macfie, Meyrick-Jones, Moore, O'Leary, Park, Peake, Pearson, Allman Powell, H. Powell, Curtis Webb. The usual toasts were duly honoured, and it was unanimously decided that the dinner should be made an annual one.

A DINNER was held at the Connaught Rooms, London, on January 9th, by the Vermin Repression Society to celebrate the enactment of the Rats and Mice Destruction Bill, introduced last year into the House of Lords by Lord Aberconway on behalf of the society. The chair was taken by Lord Aberconway, and Sir Arthur Griffith-Boscawen, M.P., Parliamentary Secretary to the Ministry of Agriculture, attended and spoke appreciatively on behalf of the Government. The other speakers included Dr. Andrew Balfour and Dr. Louis Sambon, who each made interesting observations on the medical aspects of the campaign against rats and other vermin.

THE annual general meeting of the Harveian Society will be held at the rooms of the Medical Society of London, 11, Chandos Street, on Thursday, January 22nd, at 3.15 p.m.

AT the annual meeting of the Royal Microscopical Society on Wednesday next, at 8 p.m., the president, Dr. J. E. Barnard, will deliver an address on the present status of microscopy.

A MEETING to further the objects of the Peoples' League of Health will be held at Claridge's Hotel, W.1, on January 20th, when Lord Burnham will take the chair at 3 p.m. Among the speakers will be Miss Olga Nethersole, the founder of the League, Sir Alfred Fripp, K.C.V.O., F.R.C.S., and Mr. E. B. Turner, F.R.C.S., Chairman of the Medical Committee of the National Council for Combating Venereal Disease.

SIR ROBERT ARMSTRONG-JONES will begin a course of four lectures on physic at Gresham College, Basinghall Street, E.C.1, on Tuesday next, January 20th, at 6 p.m. The subject of the course is "The animal parasites affecting man, and the diseases caused by them." Admission to the lectures is free.

A COURSE of eight lectures on psychopathology will be delivered by Dr. William Brown, Reader in Psychology in the University of London, at King's College, Strand, W.C.2, on Mondays, at 5.30 p.m., beginning on Monday, January 26th. Although not open to the general public, they will be open to medical students and qualified medical practitioners without fee or ticket.

THE King of Italy has conferred the Cross of Chevalier of the Order of the Crown of Italy on Sir Donald MacAlister, K.C.B., President of the General Medical Council, for services in the war; and permission to wear the decoration in this country has been granted by Royal Warrant to the president.

OWING to the unstable nature of hydrogen peroxide solution, the difficulty of obtaining suitable containers and their cost, the excessive loss by bursting and leakage, the great bulk of the liquid, and the high cost of transport, the

Army Council has issued an instruction limiting the supply to very special cases which cannot be satisfactorily treated by some other antiseptic.

DR. ADDISON will receive on January 23rd a deputation from the British Federation of Medical and Allied Societies, which will place before him its views on certain aspects of the larger questions of the provision of efficient medical services for the community.

DR. JAMES MIDDLETON, who recently retired after practising in Peterhead for thirty years, has been presented by his friends and patients with a silver tea and coffee service, a silver salver suitably inscribed, a revolving bookcase, and a travelling rug.

A COURSE of lectures on syphilis will begin at King's College Hospital on Friday, January 30th, at 9.15 p.m. The lectures will be given in the Medical School, and will be continued on succeeding Fridays to June 18th. They will be illustrated as far as possible by cases, demonstrations of technique, and by the epidiascope. Each branch will be dealt with by a member of the staff with special experience of the subject, and it is hoped that a complete presentment of modern teaching on syphilis, and especially of those aspects which are of interest to practitioners, will be given. Gentlemen taking the course can also attend, by arrangement, for clinical teaching and practical instruction. The fee for the course is £3 3s.; further information can be obtained from the Secretary of the Medical School, Denmark Hill, S.E.5.

THE Faculty of Medicine of the University of Birmingham has instituted this year a course of post-graduate lectures on venereal disease to medical practitioners. Three lectures have already been given by Dr. Douglas Heath on syphilis and soft sore. Mr. Bernard Ward will lecture on gonorrhoea in the male, on January 21st and 28th, and February 4th; Mr. Beckwith Whitehouse will lecture on gonorrhoea in the female, and on syphilis in relation to pregnancy, on February 11th, 18th, and 25th; and Dr. Eric Assinder will lecture on the pathological aspect of venereal disease, on March 3rd. The lectures are given in the anatomical theatre, Edmund Street, at 4.15 p.m. There will also be clinical demonstrations at the General Hospital and Queen's Hospital on dates to be fixed at the end of each section of lectures. Admission to the lectures is free. For the full course of demonstrations a fee of two guineas is charged.

THE Royal Mail Steam Packet Company, in announcing that the *Almonzora* has been put on the service to Brazil and the River Plate, states that the *Asturias*, which worked for three years as a hospital ship, was not sunk as has been generally supposed. She escaped a first torpedo attack but was badly damaged in a second. She is being repaired, and will shortly be working as a mail boat again.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL *unless the contrary be stated.*

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aetiology*, Westrand, London; telephone, 2631, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2634, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin.

QUERIES AND ANSWERS.

LIP READING.

"I" asks where and how instruction in lip reading can be obtained by a deaf person.

Dr. Dundas Grant informs us that all necessary information can be obtained from Mr. W. Nelson, Royal School for the Deaf, Old Trafford, Manchester; Mr. S. Coward, Council School for the Deaf, Crown Street, Liverpool; or Mr. Jno. Brown, Institution for the Deaf, Edgbaston, Birmingham.

INCOME TAX.

"E. M. S. S." entered on an appointment on May 1st, 1919, at £350 a year; there have been no previous earnings. What is his income tax liability?

* * * Income tax liability must be reckoned as for the Government financial year, and "E. M. S. S." is assessable for the year ending April 5th, 1920, on, approximately, twelfthths of £350, say £292, less any appropriate allowances—for example, £120 abatement, life assurance premiums, etc.

"MASS REFLEX."

"W. H. C."—The term "mass reflex" was introduced by Dr. Riddoch to denote a generalized defensive reflex that takes place when the inhibitory action of the proprioceptive system has been removed owing to a lesion of the spinal cord. Thus, if in a case with total interruption of the spinal tracts but with a return of reflex activity in the lower limbs, an appropriate stimulus be applied, say to a foot, both legs are defensively flexed at the hip and knee-joint; the abdominal and pelvic muscles may also contract. The reflex then spreads to the visceral nervous system, the bladder and rectum may be evacuated, and vasomotor changes take place. A similar reflex may be elicited from a very young baby whose spinal inhibitory system is not yet developed.

TREATMENT OF PRURITUS.

"M. B." writes: On November 22nd, 1919, "Subscriber" asked for advice in the treatment of obstinate pruritus. May I suggest that possibly the cause may be an excessive carbohydrate diet and due also in part to an excess of protein in the diet as well? I first made this discovery in my own case after I had long been a sufferer from pruritus and had literally spent half the night, sometimes, in scratching myself. I find that if ever I over-indulge in sweet things invariably within a few hours I get a marked itching of the scalp and whole body, while so long as I abstain from sweets, except in strict moderation, I am entirely free from any suspicion of pruritus.

LETTERS, NOTES, ETC.

COPPER ALANIN IN INOPERABLE CANCER.

DR. JAMES DONELAN, London, W.I., showed at the meeting of the Section of Laryngology of the Royal Society of Medicine on November 1st a case of lingual cancer in which the patient had derived considerable comfort from intravenous injections of copper aminopropionate (copper alanin). Although the advance of the disease would appear to be arrested, microscopic sections taken during the treatment showed that histologically the epithelioma was unaltered; particulars will be given in the *Proceedings*. The credit for suggesting this substance, amongst other forms of treatment, as a palliative for inoperable cancer, is, Dr. Donelan states, due to Dr. Shaw-Mackenzie. Intravenous administration of a 1 per cent. solution in doses of from 1 to 2.5 c.cm. has been attended with benefit, shown in a remarkable improvement in the general condition of the patients after one or two injections. The treatment appears to retard the advance of the disease, but the experience so far obtained does not allow it to be regarded as more than palliative. As long as the injections are continued from once to three times a week the apparent arrest is maintained, but if they are omitted even for a week a fresh advance can always be noted. It would, however, appear from this that the intravenous injection of this copper salt has some influence on the growth of cancer. Messrs. Boots, Station Street, Nottingham, inform us that the price of solid copper alanin is 30s. an ounce, and of the solution, 1 per cent., 6d. an ounce without bottles.

THE UNMUSICAL SWAB.

G. P. B. writes: Here's one for your amusement column. The Clinical Research Association telegraphed the result of a throat swab I had sent for examination, no doubt stating "Organism not found." It was telephoned from the post office "Organism not found." My wife replied, "You mean *organism*." They replied, "*Organist* is on the telegram."

THE TAGLIACOTIAN DOCTRINE.

COLONEL J. SMYTH, I.M.S.(ret.) (Clifton, Bristol), writes: With reference to the note at page 72 of the *BRITISH MEDICAL JOURNAL*, January 10th, on "The Tagliacotian Doctrine," Hindu mythology goes one better, for we read that Ganesha, having lost his head in battle, his followers stitched on an elephant's head quite successfully. It does not appear that he suffered subsequently even from the hoarseness experienced by Rabelais's patient.

WILKSIANA.

DR. S. D. CLIPPINGDALE (London, W.) writes: To the amusing story you relate of that witty physician the late Sir Samuel Wilkes, you may, perhaps, care to add two others:

1. At the banquet given to celebrate his baronetcy Sir Samuel, commencing adversely upon his Christian name, said only three persons bearing the name Samuel had ever obtained eminence. These were the prophet, the writer of the dictionary, and the younger Mr. Weller.

2. Sir Samuel, who was a hater of fads and faddists, once said to a patient, "When your doctor tells you that your

lunch ought to contain so many grains of carbon, so many atoms of hydrogen, and so many molecules of water, all you have to do is to send for a nice mutton chop."

IMPROVING US OFF THE EARTH.

AN account was given in *The Times* of January 7th of another grandiose scheme for improving the Charing Cross area. From the sketch plan it appears that Charing Cross monument is all that the architect, Mr. John Murray, proposes to leave behind. There is a certain Prussian thoroughness about the scheme of demolition, and the vast "monumental buildings that might be erected" are the sort of things the Kaiser would have approved after London had been entered in triumph and rebuilt in the best Berlin style. We are pained, however, to observe that the proposed Imperial Way, joining up Leicester Square and the Strand "through property of minor value at present," deletes No. 429, Strand, from the map. This office narrowly escaped demolition when the German bomb fell in Agar Street in September, 1917; we hope to be spared, too, the frightfulness of the new architecture.

SENILE MELANCHOLIA.

IT is an interesting if somewhat melancholy undertaking to watch the dulling effect on cerebral energy of the circulatory changes incidental to the advance of years, from the time when the rich copious blood supply of youth invests the world with a multi-coloured halo, the "clouds of glory" referred to by Wordsworth, till, as the pulse slows down and the arteries become narrowed, these "fade into the light of common day." The outlook on the world has changed. The sun shines as brightly as ever, the lark sings as loud and as long as of yore, but dulled senses perceive only "as through a glass darkly." Still later the diminished blood supply determines a state of physiological misery which may merge into melancholia, a state which is vividly portrayed by a poem of Sydney Dobell's called "Tommy's Dead." The old man, fast approaching dissolution, takes a despairing view of life and things in general:

The ground is cold to my tread,
The hills are wizen and thin,
The sky is shrivelled and shred.

The rat and the mouse have fled,
And the summer's empty and cold
Over valley and wold.

Appetite and digestion have gone by the board, so he finds

There's something wrong i' the cup, boys,
There's something ill w' the bread.

In fact, wherever he turns,

There's a mildew and a mould,
And the sun's going out overhead.

With such a dismal perception of his environment the aged man's confidence in the future is undermined, and he betrays a feeling of apprehension which is common enough at the sixth and seventh ages of man:

You may give over the plough, boys,
You may take the gear to the stead;
All the sweat of your brow, boys,
Will never get beer and bread.

A feeling that finds ultimate expression in the ejaculation that "Tis time to go to sleep, boys," for "Tommy's dead."

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 36, 37, 38, 39, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 34, 35, and 36.

THE following vacant appointments of certifying factory surgeons are announced: Abergele (Denbigh), Buckie (Banff), Castle Hedingham (Essex), Clogher (Tyronce), Hastings (Sussex), Hoylake (Chester), Leicester, East (Leicester), Leyland (Lancas e.), Nelson (Glamorgan), Northallerton (Yorks, North Riding), Okehampton (Devon), Wakefield (Yorks, West Riding).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE
BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0 6 0
Each additional line	0 0 9
Whole single column	4 0 0
Whole page	12 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *post restant* letters addressed either in initials or numbers.

An Address ON CLINICAL RESEARCH.

DELIVERED AT THE OPENING OF THE ST. ANDREWS
INSTITUTE FOR CLINICAL RESEARCH,

BY

SIR JAMES MACKENZIE, M.D., F.R.S., ETC.,
DIRECTOR OF THE INSTITUTE.

INTRODUCTION.

In proposing to start an Institute for Medical Research we have to answer the inquiry, "Is there need for such an institute?" In all civilized countries there have been institutes established specially devoted to medical research, some of them endowed financially with great liberality, furnished with all the appliances of the most recent scientific discovery, and directed by men of distinction specially trained for the purpose of investigation. There are, moreover, the teaching schools in which research is carried on in innumerable laboratories and hospital wards. What justification can there be for starting an institute in an out of the way place like St. Andrews, seemingly deficient alike in equipment and material for observation?

Certainly our enterprise needs justification, and it is my purpose to-day to give you the reasons for an enterprise of the sort we are about to start, and to show to you how a place like St. Andrews is specially suited for this purpose.

THE SCIENCE OF MEDICINE.

There have been many stumbling-blocks in the path of medical progress. They are mainly due to the lack of understanding of the distinctive character of the science of medicine. The knowledge of disease is so incomplete that we do not yet even know what steps should be taken to advance our knowledge. It has been assumed that the methods which are suitable for various branches of science—as chemistry and physics—should be applied to medical investigation, but the methods of these sciences are not applicable to the investigation of the most important phenomena of disease. The methods which have helped some sections of medicine—as physiology and bacteriology—are not applicable by themselves to the wider fields of clinical medicine.

The present-day conception takes too narrow a view of the field with which medical science has to deal. It assumes that instrumental methods are of necessity the only scientific methods. It has been assumed that because recording and measuring instruments and other methods have greatly advanced such limited fields of medicine as physiology, bacteriology, and chemistry, that therefore clinical medicine should adopt the same methods. In medicine there are phenomena which the scientific instruments of to-day, however delicate, can neither register nor measure, and there are methods necessary for the investigation of disease which no laboratory experience can supply.

As an outcome of this misunderstanding, large fields for investigation which are essential to the progress of medicine have been ignored; methods and principles have been unrecognized or imperfectly applied, while the appropriate investigator has been neither trained nor encouraged to do the work which he alone has the opportunity to perform. Our scheme is not antagonistic to the investigation in other fields of research, nor do we wish to substitute our scheme for others. What we contend is that there are fields essential to the progress of medicine which have been neglected, and it is to some of these fields we intend to devote ourselves, and to use the methods which are suitable for the purpose.

THE AIM OF MEDICAL RESEARCH.

In undertaking any enterprise the first essential is to grasp clearly the objects at which we aim. In medical research the object is mainly the prevention and cure of disease. While that is the chief claim of the medical profession for its existence, much of its endeavour is, however, diverted to the relief of suffering, which is not quite the same thing.

The immediate call for the relief of suffering is so urgent that it absorbs the great bulk of the time and endeavour of

the profession, not only in the attempt to give relief, but also in the search for means to afford relief. Our object indirectly aims at the same result, but by a different method—that is, in the prevention of disease and therefore of suffering.

We must, from the outset, keep clearly in view that the goal of our endeavour is the prevention and cure of disease. This aim is, no doubt, the chief motive in all medical research institutes, but its accomplishment has been hampered because research has hitherto been restricted by the limited experience of the investigator, so that the opportunity has been wanting for that broad outlook which is necessary to see the subject as a whole. The bacteriologist, for instance, has undoubtedly greatly increased our knowledge of the tubercle bacillus, but his work does not help in the discovery of those signs of phthisis which reveal the early stages of the disease when the possibility of recovery is at its best. I am in no sense ignoring or depreciating the great advances that have been made by the different sections of medicine, and our institute is in no sense to be considered either as a rival to these or as a substitute for them. Our work is to be supplementary, and we will employ their methods and discoveries, as well as those that are peculiar to our special needs.

THE BASIS OF OUR SCHEME.

We must grasp the principles we should employ to achieve our object. Common sense as well as worldly experience tell us that if we should try to solve a difficult problem the first step should be to make ourselves familiar with all its aspects. The means for solving a problem or overcoming a difficulty can best be found by knowing what the difficulty is and so coming to understand its nature. Applying this principle to our contemplated endeavour, we find that our problem being the prevention of disease, we require a complete knowledge of disease in all its aspects before we can take steps to prevent its occurrence.

The first principle I wish to lay down is that as *disease is made manifest to us only by the symptoms it produces, it is imperative that the first step should be to understand the nature and significance of symptoms.*

It may be helpful if we consider shortly the stage which the study of symptoms has reached, so that by understanding clearly where our knowledge is defective, we may obtain a direction which will guide us to a subject for profitable investigation. Medicine as a science is slowly emerging from a confused state, and has attained a certain degree of precision with the development of knowledge of structure (anatomy) and with the knowledge of function (physiology). To these have been added more precise knowledge of morbid structure and disordered function (pathology). The knowledge acquired from these branches has been assimilated and put into practice by the physician, who recognizes in the living gross changes due to altered structure and function by what is called "physical signs." The later development of bacteriology has revealed the causes of a great many diseases, and its discoveries have been so striking that for the time being it dominates the field of medical research. Its power for good is greatly restricted, however, by the fact that the attention given to the study of bacteria as they behave in the laboratory has diverted attention from their reaction in the human body—that is, in their production of symptoms.

It is obvious that the stage of disease when it has caused structural damage has been fairly well studied, and in the pathological institutes and hospital wards the damaged tissues have received due attention, while the study of the microbes of disease outside the human body is well provided for.

What of the early stages of disease, the symptoms first provoked by the derangement of function or by the entrance of the microbe into the body? This is the stage where there are no gross physical signs, for the structure of the organs has not been damaged, and consequently no mechanical aid to diagnosis can reveal them. What of the stage that precedes the onset of the disease when the patient is rendered vulnerable by some inherent defect or by the condition of his environment? It is manifest that the surroundings in which research is carried on to-day in laboratories or hospital wards do not provide the opportunities for discovering either the early stage or the predisposing stage of disease.

If, then, we desire to prevent or cure disease, it is

essential that the investigation should be carried on in those places where the early stages can be seen and the conditions that predispose to disease can be detected. That, shortly, is the object of our institute and the justification for our enterprise.

THE EARLY STAGE OF DISEASE.

The question arises, Are there not symptoms provoked before damage is done? We who have had experience in general practice know quite well that the vast majority of patients complain of ill health long before there is any physical sign or signs detectable by mechanical aids. Chief among these symptoms are the feelings of the patients—a consciousness of ill-being produced by some sensations, or by the absence of the indefinable sense of well-being, or by the presence of symptoms perceptible only to the unaided senses of the doctor.

Health may be defined as the harmonious working of all the organs. Ill health occurs when there is some discord in the working of the organs. Disease upsets the harmonious working of the organs and gives rise to the consciousness of ill health. The first symptoms, then, of invasion by disease is invariably a consciousness of some impairment, and the vast majority of patients are conscious of something that tells them all is not well. Now, while this consciousness of ill health or absence of well-being—however it may be described—is often the first sign of invasion by disease, as is admitted on all hands, it is universally supposed to be of such an indeterminate nature as to be of little value in the detection of the disease. Certainly to the superficial observer the patient's description often lends colour to this supposition, but if we seek to analyse the sensations produced by ill health it is remarkable how much information can be gleaned when we are trained to obtain from the patient a description of his sensations. But this is a point I want to impress upon you: it requires a long training to enable you to ask the appropriate questions, and a long experience before you can interpret the answers.

NATURE OF THE PREDISPOSING CONDITIONS.

Medical knowledge has advanced so far as to recognize that a great many diseases which impair the health are secondary diseases—that is, they are grafted on a body which has been weakened by some other diseases of slighter virulence. A great many people suffer from slightly impaired health due to some seemingly trivial cause, from which there is no danger to life, but this impaired health lowers the normal resistant powers of the body so that it is rendered vulnerable to more virulent diseases.

The condition that lowers this resistance may not be disease, but be due to the environment, deficient nourishment, the kind of work, or other circumstances.

It is manifest that, to find out these predisposing conditions, opportunity must be had of seeing the patient while these conditions are in operation, and before the onset of the more virulent disease. The period at which the early symptoms are recognized being nearer the time of onset naturally gives a better opportunity for finding out the predisposing conditions than the study of the later stages, when the time of onset may be forgotten.

The investigator must therefore be one who has the opportunity for seeing the early stages, for seeing the patient when still only affected by the predisposing disease, and for finding out the circumstances of his life.

THE NEGLECT OF SYMPTOMS.

As the basis of our scheme is to obtain a thorough knowledge of disease by the study of the symptoms it produces, it is essential you should clearly realize the necessity for such a study, for it is manifest that if you do not, you will fail to understand the methods necessary for the successful pursuit of our object.

While we are all aware that there are defects in medical knowledge, it is not easy to understand what they are. Yet it is manifest that before we attempt to make good the defect we must realize where the defect lies. When I say we must begin with the study of symptoms, it will be said that this subject has been studied by every physician and surgeon from time immemorial. Indeed, it is stated by some authorities that the study has reached a stage where all the knowledge to be got from symptoms has already been acquired, and if any further knowledge is to be gained it must be by the use of methods not yet invented.

So far from that being the case, it can be said that the knowledge which symptoms can yield is so far from having been acquired that the kind of knowledge which they yield is not recognized, and in consequence the steps necessary to obtain this knowledge cannot be undertaken.

In making this statement I am not reflecting upon the intelligence of the physicians and surgeons in the past, any more than that it would be a reflection on the great surgeons before Lister's day to say that they did not know how to find out the cause of suppuration in wounds. It merely shows that medical knowledge has not advanced so far as to reveal its defects. A clear perception of the defect is the first step to make the defect good.

While I could illustrate this point from the study of almost any symptom, let me give some illustrations from our recent war experiences, where the defect has been demonstrated in a striking manner, but where the demonstration has passed unrecognized.

During the war large numbers of healthy men were rejected for the army because the examining doctors detected a murmur in the heart. Why was that? Because there is a widespread belief that a heart with a murmur is an impaired heart, and although it is also recognized that many murmurs are not of serious moment, yet the absence of a knowledge of which murmurs are serious and which are innocent has not been recognized. In other words, the knowledge of how to assess the value of murmurs is lacking.

Here, then, is a matter essential to the knowledge of symptoms which was found lacking, and this defect of our knowledge gravely affected the interests of the State at a time of crisis; yet the conception of medical knowledge by our military and educational authorities did not permit them to recognize the nature of the defect. To take another example—life insurance examiners, whose duty it is to assess the value of symptoms, have not yet awakened to the fact that the methods they employ are but a species of guesswork, and they have not yet realized that accurate knowledge of this kind is absolutely necessary to the progress of medicine.

Deplorable as was the effects of a lack of knowledge of the significance of a murmur during the war, it was nothing to be compared with the results of a similar defect in regard to other symptoms.

When the stress upon the nation became greater and it was found necessary to introduce conscription, those with impaired health and of older age were called up for military duty. The authorities recognized that many of the recruits would be unfit for full military work, and they set themselves the task of devising some method by which the impaired could be given work equal to their strength. They produced the scheme of placing men in different categories, grading them according to the amount of physical work they were supposed to be fit for. On paper this scheme seemed all right, provided that there was the knowledge necessary to recognize the man's degree of impairment. This, every one will recognize, is an essential requirement to the success of such a scheme, and this is just where it broke down—no one possessed this knowledge. It meant that the ordinary doctor should not only be able to recognize the signs of disease, but able to say how much work a man with a given impairment should be able to perform. This is a kind of knowledge which nowhere exists.

It is not necessary to dwell at length on the complete failure which followed the introduction of this method. While many healthy people were rejected, large numbers of people with impaired health were placed in categories which required of them effort for which they were unfitted, with the result that many broke down, some died, others were crippled and spent most of their time, while in the army, in hospital. So great was the outcry that Parliament had to intervene, and attempts were made to mitigate the evil effects of the system.

The reason I call attention to this is that here, before the eyes of the world, was a revelation of great significance of a defect in our knowledge of symptoms, and yet so backward is the state of medicine that the real cause of the failure is unrecognized.

THE TEST OF EXPERIENCE.

The path of medical progress is strewn with derelict schemes and projects. What reason is there for assuming that our endeavours shall not share this unkindly fate?

While it would be ungracious to dwell upon the unhappy lot of many attempts, for each represents a laudable idea followed by energy wasted and hopes unfulfilled, yet a consideration of their procedures may throw a light which will warn us of the dangers ahead. Without going into details one can see that the failures resulted from the fact, that the nature of the problem had not been clearly realized, so that the steps taken to solve it were inadequate for the purpose. One of the great causes of failure has been that the lines which guided the attempts were based upon theoretical considerations, and were not the outcome of experience. If one turns to those instances where research has been rewarded, as in the discovery of the cause of suppuration and of certain microbial diseases, it will be seen what long and careful study, with testing of methods and training of the observers, preceded the successful issue. The principles on which antiseptic surgery is based seem now so simple that the younger students have no difficulty in comprehending them. When Lister began his researches the state of medical knowledge was so backward that he had to spend strenuous years in acquiring a knowledge that would qualify him for the pursuit of his quest. After that there were many years full of trials and failures to be endured before success at last crowned his efforts.

A hundred years ago no one man nor body of men understood the principles which should guide to the discovery of the cause of suppuration. Before Lister could make headway he had, with much toil, to discover those principles. Once these were discovered progress was comparatively easy.

That which hampered Lister at the outset of his investigations hampers medical research to-day—mainly an absence of a knowledge of the principles that should guide research. We must recognize that the principles which may guide research to a successful issue in certain limited fields of medicine are not applicable to the wider field which is to be the object of our endeavours. Before we enter upon our enterprise we must be satisfied that our methods have been tested. For that purpose I cite a few experiences which, when you have grasped their significance, will be a justification for our proposal.

I have referred to certain experiences during the war which revealed like a flash of lightning certain defects in medical knowledge. One of these was the inability to assess the value of murmurs or their prognostic significance. This defect was forced upon me early in my career as a general practitioner, as I was constantly being called upon to decide whether the presence of murmurs called for treatment, or rendered the patient unfit for work that entailed effort, or made him unsuitable for life insurance. A study of textbooks gave no light on the subject, and I slowly realized that the knowledge did not exist. Here was a matter essential to intelligent practice which required clearing up, and I resolved to try my "prentice hand" at its solution. For a long time I did not know how to proceed, and, looking back now, I perceive that the principles of clinical research were so imperfectly understood that though the lack of knowledge was manifest to everyone who gave the matter consideration—no one understood how to set about acquiring the knowledge. You will see in such an instance what a short distance medicine had travelled on the road to become a science when a matter of such urgent importance was looked upon as insoluble. Thus Sir William Gairdner, one of the most capable physicians, about this time frankly confessed that the basis on which such signs as murmurs and irregularities were assessed for life insurance was a matter of guesswork—the insurance examiners had no clear conception of any principle to guide them. It occurred to me that the only method was to follow the individuals through life to see what became of those who had murmurs. I started to keep records of my patients and watch their behaviour through the varied circumstances of life—the behaviour of the heart when the patient led a strenuous life, during illness, and in women during the pregnant state and all that it involved.

But I was soon held up by the consciousness that I did not know what to watch. I spent some years noting the different modifications of sounds and the regions into which murmurs were propagated. But I found this led nowhere; and, indeed, when you look back upon the history of auscultation, you will realize that it has not

advanced during the last fifty years, simply because it has never been understood how to make use of the method for the advancement of medicine. Time and energy has been wasted in meticulous study of the sounds and their modifications, or in modifying the stethoscope.

Recognizing that my path was blocked, I tried many ways to get a better insight into the problem till it occurred to me to ask the question, What is there to be afraid of in the detection of a murmur? After consideration I found the reply was "Heart failure." What did I know of heart failure and what were its symptoms? Put in this way I had to confess my ignorance, except when heart failure had advanced so far as to produce dropsy and dyspnoea. Again I turned to my textbook, but found that neither physician, pathologist, nor physiologist could explain heart failure nor give the symptoms except in the extreme degrees.

It was evident, then, that I could not hope to assess the value of murmurs until I understood the symptoms of heart failure and how they were brought about. I therefore set about educating myself by watching the onset and progress of heart failure in my patients, and after some years at last acquired a sufficient knowledge to permit me carrying on the inquiry into the significance of murmurs. I achieved a measure of success so that it was possible to lay down certain principles of a simple and easily understood kind, which guide to a sure prognosis in the great majority of cases. There are still some murmurs (as those due to aortic regurgitation) which require further study, as there are factors present in the production of heart failure in aortic regurgitation which I do not yet understand.

Turning to another field of clinical research—the discovery of conditions that lead to ill health. Those who have followed intelligently the more recent developments of cardiology acknowledge that the recognition of the condition now called auricular fibrillation and all the phenomena connected with it has altered the outlook of the profession towards many forms of dangerous heart failure. The manner in which this condition was discovered arose in this way: There had been long recognized, in a confused sort of way, a class of patient with extreme heart failure with an irregular heart. But there was no accurate knowledge as to its significance, nor were its symptoms clearly defined to separate it from other conditions. In my investigations into irregular action of the heart I had recognized this peculiar condition, but for a long time was unable to account for its occurrence and its relation to heart failure. As it was frequently associated with a history of rheumatic fever I followed for years cases with mitral stenosis, taking note of all associated phenomena. One patient whom I had watched for seventeen years suddenly became ill from heart failure, and I found that this coincided with the disappearance of all signs of auricular activity, with the onset of a rapid and irregular action of the heart. The clue being thus given I was able to detect the phenomena peculiar to the condition, and to recognize it as a distinct clinical entity; and by the study of thousands of cases to demonstrate that at least 80 per cent. of all cases with extreme heart failure, as shown by dropsy and orthopnoea, were either due to this abnormal rhythm or had the heart failure greatly aggravated by its occurrence. Moreover, with this knowledge I studied the treatment of these cases, and found certain principles which helped to the discovery of a very satisfactory method, which is now being recognized and generally adopted.

Take a third field of clinical research, that of remedies. In my examination of patients generally, and in those with heart failure in particular, in noting their symptoms I also kept a note of the effect of drugs in modifying the symptoms or in producing new symptoms. In this way I discovered that the action of cardiac drugs could be studied with a fullness and a precision obtainable in no other way. After many years' observation I was able to show that the action of digitalis was not the same on healthy hearts as on diseased hearts, and that of diseased hearts there were many on which it had no effect, while it acted differently in different forms of disease. After much study I was able to lay down principles for the administration of this drug, and to show clearly the cases in which it could safely be given and with benefit, and the cases in which it was of no use. While this subject is far from exhausted, both clinical and experimental

investigation in the action of cardiac remedies are now directed by these observations.

My purpose in citing a few of the results of the application of the principles peculiar to clinical medicine is not to exaggerate their importance, but to demonstrate the principles which achieved such a limited success, so that we may have a guide in our prosecution of medical research. These principles I shall describe to you, and you will see that they are of such a simple and self-evident kind that you will not be surprised that many people consider that they have been recognized and practised from time immemorial. Indeed, you will find them embodied in many eloquent addresses dealing with medical knowledge. But though they are simple and self-evident, no one has thought of putting them into practice with that systematic application which is necessary for the discovery of their real value. For instance, those who have given consideration to my work recognize that the prognosis of heart murmurs has been laid on a sound basis, that the application of these principles was the means of detecting clinically the condition now called auricular fibrillation, with its chief symptoms and its susceptibility to digitalis, long before it was experimentally demonstrated to be due to fibrillation of the auricles. The application of these principles also led to the recognition of the principles of digitalis reaction on the diseased human heart.

When you reflect that these objects had been studied and investigated by great numbers of physicians, as well as physiologists and pharmacologists, who had every conceivable means of assistance, yet their discovery was effected by a general practitioner untrained in methods and lacking in all the accessories supposed to be necessary for research, you naturally wonder how it came about. A little consideration will reveal that it was due to nothing mere nor less than the putting into systematic practice certain principles which are essential and peculiar to clinical medicine.

When I place before you the principles on which our scheme of research is based you will see nothing original in them. Indeed, you will recognize them as those which guided the research of the great physicians and surgeons who have done so much in bringing to light the knowledge of disease as it is recognized to-day. You will find, for instance, that these principles were used by the greatest of all clinical investigators—John Hunter. He made himself familiar with the symptoms of the diseased condition, and then by experiment sought the solution. He not only did not restrict himself to the bedside or the laboratory, but he used both, being trained first as a clinical observer before he attempted research. Moreover, he did not restrict himself to a speciality; though called a surgeon, he was in reality a general practitioner, and his writings to-day are as instructive to the physician as to the surgeon. He was the first, for instance, to describe that peculiar form of breathing which later Cheyne and Stokes described, and which now goes by their name.

The great physician of the past had not that restricted experience which the physician of to-day has perforce to put up with. They were all practically general practitioners, many of them also pathologists and physiologists, so that they had that wide outlook upon medicine which to-day is only to be found in the ranks of the general practitioner. The difference between our work and theirs is that, benefiting by their experience, we can now see clearly the principles by which they made progress, and we can now organize research by the systematic application of these principles. To them we owe the methods for finding out the morbid conditions which caused the physical signs of disease and the knowledge of the later stages of disease. We, strengthened by the knowledge they have given us, turn the other way and look towards the origin of disease by the study of its earliest signs.

THE CHOICE OF THE GENERAL PRACTITIONER AS INVESTIGATOR.

During the past year at the hospital we have been having weekly meetings, and I have demonstrated to you the presence of symptoms usually overlooked or misunderstood, and have shown how little we know of the essential matters connected with symptoms. This was done for the purpose of impressing you with a particular defect in our knowledge, so that you might value the need for an

investigation into disease in a manner not yet systematically pursued.

One of the greatest difficulties I have had in getting physicians and other medical men to understand what I am driving at is, that I have been looking at the subject for thirty years from a point of view they have never seen; for the investigation of disease as it presents itself to the general practitioner has led me to see the symptoms of disease from an aspect different from investigators in other fields. The elementary principles of research in disease have therefore, to me, a meaning different from that which is usually accepted.

Before I recognized this fact I felt somewhat disappointed at the neglect of the work I had done and the misunderstanding of my results. Moreover, I found that the young qualified men, many of whom had been trained in laboratories, could not understand the principles which guided me, and I found in later years, when they recorded their own observations, that they had not grasped the significance of my teaching.

I now recognize that my ideas were the result of over thirty years' observation and study; and while they seemed to me clear and simple, yet those who had not a similar experience could not grasp my point of view. Recognizing this, I saw that I must look for assistance to those who had undergone experiences similar to my own, and it is for this reason I seek the help of the general practitioner in this research.

The reason, therefore, I have asked you to join in the investigation is because you have the opportunity of seeing disease in the human subject in all its phases. As family doctors you have the opportunity of knowing the individuals before they become stricken with disease, of seeing their surroundings and their mode of life. You are consulted at the first appearance of ill health, and you see the patient through the whole course of his illness.

You have from experience had forced upon you the great defect in medical knowledge, and you have gained some experience in the significance of symptoms. You have therefore taken the first step to qualify yourselves as investigators in that you have recognized that there is a problem to be solved. Your vocation as general practitioners has been to solve the problem, and in your attempt to do so you have been faced with the difficulties that lie in the way of solution. Your experience has given you some insight, so that you can appreciate ways and methods which hold out a reasonable expectation for accomplishing the object of medical research. This is a matter of very great importance, because to-day investigators do not see the problem as you see it, and therefore do not take the steps which will lead to a solution.

THE TRAINING OF THE OBSERVER.

I want you to grasp fully what is required of a trained clinical observer, because to-day the essential qualities to a great extent have been lost sight of. This has arisen through an imperfect conception of the requirements for clinical observation. Methods that have been found suitable and necessary for other sciences have been introduced, and have been substituted for these that are essential and peculiar to clinical medicine. Men are now recommended to go into laboratories devoted to one or other of the branches into which medicine is split up, and are trained in methods that are supposed to be more exact and scientific than the clinical methods. This view is the one dominant to-day, so that we find preference given to men trained in this way in all matters concerned with research, and even in the teaching of medicine. This practice is based upon a misunderstanding of what clinical observation requires and what clinical research means, and it leads directly to incompetence of the laboratory trained man as a clinical observer and as a clinical investigator.

A very brief consideration will render this apparent. Take the physiological laboratory, which is assumed to be the most scientific of all our branches. An experiment is performed which produces a reaction which an instrument can record. This record is carefully studied, and certain conclusions—it may be of value—are drawn. From a great many experiments of this kind a large increase of valuable knowledge has been obtained. The success and usefulness of this method is undoubted, but its success has blinded people to its limitations as a method to be applied in clinical medicine. Each of these experiments produced a great many more reactions than the one recorded, but as

these reactions were not capable of being recorded by an instrument, they were ignored. The result is that a laboratory-trained observer cannot recognize any sign except those of a grosser kind, while the subtler and more elusive signs pass unrecognized. It therefore happens that the result of every experiment is only partly recognized. The clinical observer is like the physiologist in this respect, that both are searching for a reaction to a stimulus. In physiology the stimulus is artificial, in clinical medicine it is natural or the result of disease. In both cases a variety of reactions follow the stimulus. The grosser reactions are only noted by the physiologist, and he has no means of detecting the subtler. In clinical medicine the grosser kinds have also to be detected, and the laboratory-trained observer can detect them, but his training has not enabled him to detect the subtler reactions, and hence he fails to attain that skill in observation which is essential to the clinician.

I have already referred to the fact that the bulk of the most instructive phenomena produced by disease are incapable of detection by mechanical aids. Many valuable signs are only perceptible to the trained eye or the trained ear or the trained finger. Still more valuable signs are only revealed by the sensations experienced by the patient. To interpret these requires a training that can only be acquired by many years of patient observation, during which the mind is stored by the experiences of the past, by methods which are peculiar to medicine. These methods can never be acquired by a laboratory-trained observer, and it is because of this that men trained in the laboratory fail as clinical investigators, however distinguished they may be as physiologists, chemists, or bacteriologists.

Before we can make progress towards the solution of any problem there are certain preliminary steps to be taken. The first is the perfecting of the instruments to be used. Before a man shaves he first sharpens his razor. Before we undertake an investigation we must see we have the appropriate implements. One implement essential to the success of our enterprise is a trained observer. It is scarcely realized what a difference there is between a doctor who has systematically trained himself to observe, and another who has perfunctorily examined his patients without attempting to improve his powers of observation. This can be shown in a simple matter like the feeling of the pulse. Many experienced doctors fail to detect irregularities except when very marked. Some physicians will recognize every beat in an irregular pulse; others will fail to detect a large proportion of the beats. Indeed, so common is the inability to count the beats in certain cases that I view many observations with a good deal of suspicion. Certain steps are necessary to train an observer so that he can acquire the ability to detect the peculiarities of the pulse, and to recognize their significance. He must, for instance, have seen a large number of cases, and studied them with great care, so as to correlate the sensations of his fingers with the result of observations made by his other senses. Thus he must correlate the pulse peculiarities with the sounds of the heart, with the movements of the apex and of the jugular veins, and with the character of the sphygmogram. The significance of the pulse can only be recognized by watching the patient for long periods to ascertain what happens to him, and the variations that take place in the pulse and in the other symptoms as the case progresses have to be observed.

The same methods are necessary to train the other senses. A glance at the face will often reveal a great amount of information to the trained observer. Consider the years of study and observation that has been necessary to acquire that knowledge—a kind of knowledge essential to medical investigation, and impossible to acquire by the use of instruments however scientific.

I have referred to the well recognized fact that the symptoms provoked in the early stages of disease are mainly subjective. There are a number of these sensations, and it is evident that, if the early stages of disease are ever to be recognized, the nature and significance of these sensations will have to be understood. There is, unfortunately, a widespread belief that all the information that the patients can yield is easily acquired, and it is generally supposed that the information is often so mislabeled as to be of little value. Moreover, the belief has obtained that abnormal signs revealed by an examination of the patient, especially by the use of an instrument, are

of much greater importance, so that practically all the instruction at the schools is devoted to the study of physical signs. This is a great mistake, and is the chief reason the knowledge of the early stages of disease is so defective.

To bring this aspect of medicine before you, consider for a moment some of the sensations which indicate the onset of disease. Most patients, when they fall into ill health, become conscious of it by the fact that they are easily exhausted—exertion which they used to undertake with ease and comfort now renders them tired. The questions that arise are: "What is exhaustion? and what is the mechanism of its production?" Put in that way you will recognize at once how little we know of this important symptom. An inquiry which I have been making for a number of years has led to a limited knowledge, and I can recognize that this sensation can arise from a number of causes, and where the condition of the patient is carefully investigated it will be found that this sensation of exhaustion can be divided into a number of different kinds.

The same careful training is necessary for the investigation of the most clamant of all symptoms, that of pain. To understand the full significance of pain in any case, we have to know a great many matters which are still hidden from us. The tissues capable of producing pain, the nerves in whose distribution the pain is felt, the manner in which the pain spreads, and the laws governing the spread of pain; the character of the pain itself; the manner of its onset and its variations, and the phenomena with which it is associated, are all matters which it is necessary to understand before we are qualified to undertake an investigation into disease. So with all other sensations.

It is manifest that before a patient's sensations are understood the doctor must have a knowledge of the mechanism of their production and of their significance. As a rule, the patient is merely concerned with detailing the sensation which troubles him most. It rests with the doctor to obtain by means of judicious questions the particulars of the different sensations. But the doctor cannot ask the proper questions unless he has sufficient experience and a knowledge of the nature of the sensations.

You will gather from this that the physician who would undertake the investigation of the early stages of disease must not only be a man of very wide experience, but must have trained himself to observe on lines that have hitherto received little attention. The training, amongst other things, must have included the watching of patients for long periods to see the outcome of the complaint. If you grasp my meaning you will understand how vain it is to expect the early stages to be revealed in hospitals, where the custom is to hand the out-patient department over to the junior physician, who lacks that experience which should make him a competent examiner. I have for many years been calling attention to this error in education and showing how it hampers practice and research.

To qualify a man to be a skilled investigator in bacteriology, in physiology, and in chemistry, many years of special training are necessary. If it be realized that before a man is qualified to undertake on the lines laid down an investigation for the prevention and cure of disease—the real object of medical research—he must have a knowledge of symptoms, it will be seen that a training is required which is bound to take a great many years. It is curious that men see the necessity for this in bacteriological, physiological, and chemical research, and will undergo the training, but so far the necessity has not been recognized for such a training before undertaking research in clinical medicine.

I dwell upon this so that we may recognize that to make ourselves competent observers we must ever be learning. When we are face to face with our patients and are unable to detect the nature of their ill health, we must not say to ourselves that the disease is not capable of recognition, but rather say that the signs of disease are there, but we are incapable of detecting or understanding them. This is a humiliating confession but a salutary one, and its recognition will direct attention to the sources of failure.

PRINCIPLES OF INVESTIGATION.

While the methods hitherto used in the examination of patients will be employed, other methods which are peculiar to clinical medicine, but which have been imperfectly

understood and only partially used, will be systematically employed. These methods will include certain simple principles which I have found useful in conducting observations on disease. These principles are but provisional, but they will be our guide until the knowledge they reveal is exhausted, by which time we will have gained such an insight into research and what is wanted that they will either be added to or supplanted. We must all recognize that in this work we are but learners, and while the steps we are taking to-day may seem very important and our discoveries may bulk largely in our visions, as time goes on their place in the perspective may be very small. First steps are always feeble and uncertain, but they are a necessary prelude to the vigour of full achievement.

As I have said, the principles that I am about to place before you have been in use during the whole history of medicine, only they have been so imperfectly appreciated and applied that their significance has been overlooked.

These principles are, first, the clear differentiation of symptoms; second, the classification of symptoms; third, the employment of the recognition of a new fact as a foothold for further advance (the law of progression); and fourth, the search for other symptoms (the law of associated phenomena).

DIFFERENTIATION.

Having detected a symptom, whether subjective or objective, it is necessary to separate it clearly from all others that it resembles. This proposition is so self-evident that it seems unnecessary to dwell upon it, yet its significance has not been appreciated. The importance of this step was forced upon me many years ago when I began an inquiry into the significance of irregular heart action. I had not gone far in the study of the subject before I recognized that there were different kinds of irregularity, and though others had also, no doubt, recognized this, no one had attempted to differentiate them with any degree of accuracy on a rational basis. This inquiry I undertook, and was able to find a differentiation based upon the mechanism of their production.

But in this inquiry I found that differentiation means more than the mere recognition of the mechanism of production. A differentiation based on the mechanism rarely leads to a recognition of the significance of a symptom. We know, for instance, that physicians have for long differentiated the murmurs of the heart on the basis of the mechanism of their production, but not knowing how to carry the inquiry further they left the matter there, and a misunderstanding of the significance of the murmurs has resulted. We know to-day how widespread is the misinterpretation of the significance of murmurs, and what injury has been and is being done to the individual patients and to the progress of medicine because of this limited differentiation.

Medicine calls imperatively for a further differentiation—one based upon the significance of the sign in its relation to the progress of the disease that produces it. A murmur may be differentiated according to the valve orifice at which it arises, but it is necessary that it should also be differentiated by the effect its cause has upon the functional efficiency of the heart. This you will at once see is of the first importance, not only in the practice of medicine but also in the pursuit of all kinds of research in which the heart is concerned.

Some years after I had begun the investigation of irregular heart action, other investigators took the matter up and helped greatly to determine the mechanism by which they were produced; but I was struck by the fact that they all stopped there, and practically no one but myself undertook the far more difficult task of differentiating them so as to determine their significance. This could only be done by applying certain principles of investigation which are essential to medical research; I will describe them to you later.

It is necessary to insist that we should always keep in mind that not only have we to detect the symptoms of disease, but we must differentiate them clearly on two principles—one on the basis of the mechanism of their production, the other on the bearing they have on the patient's future.

CLASSIFICATION.

The accumulation of symptoms is so bewildering in their numbers and complexity that it seems impossible

to obtain a clear and simple comprehension of their significance. So long as what is called research is but the addition of new symptoms and of new methods for their detection, it can safely be said that little progress will be made in our knowledge of the fundamental principles of research.

A classification based upon nature's laws tends towards simplicity and a fuller understanding. Such a classification I have attempted, and although I am far from stating that it fulfils all the requirements, it is nevertheless of distinct practical use, and as it is based upon natural laws it leads us to clearer understanding of symptoms. In this classification, symptoms can be divided into three groups according to the mechanism of their production, namely:

1. A *Structural group*, shown by a physical sign the result of a structural change in the tissues.
2. A *Functional group*, due to the disturbance of function.
3. A *Reflex group*, arising from a stimulation of the central nervous system.

I pointed out in dealing with differentiation that, in addition to a differentiation due to the mechanism of a symptom, another sort of differentiation is required showing the significance of the symptom. For instance, when we recognize a sign due to a structural alteration, whether it be a change in the size or shape of the organ or a modified sound of the heart due to a deformed valve, it should be recognized that the knowledge obtained from the mere recognition is extremely limited. What it is required to know is what effect has the cause of the sign upon the patient's future? This question, which can be applied to the consideration of every symptom, cannot be answered by the study of the symptom, so we look for other signs, being guided in our search by the natural question, whether the functional efficiency of the organ is affected. Thus we are guided to seek for evidence of the second group of symptoms.

There are a great many diseases in which we fail to detect any structural sign or any functional impairment, yet we can recognize the disease with great accuracy. Most cases of gastric ulcer are recognized by such signs as pain, tenderness of the skin of the epigastrium, and hardness of the upper part of the recti muscles. There may be no structural sign nor sign of functional disturbance. Such symptoms are produced by an irritation of a limited portion of the central nervous system in a reflex manner, the source of irritation being in the ulcer.

While these groups form the basis of a classification, there are combinations of symptoms which give occasion for further grouping and subdivision, which we will discover in the course of our inquiry.

LAW OF PROGRESSION.

For many years no advance has been made in the use of many methods, such as the thermometer or the stethoscope. These and many other instruments are of the greatest use in clinical medicine, but it has been assumed that the limits of their usefulness have been reached. As a matter of fact, the clinical significance of the information which they yield has only been partially understood.

This restricted use has arisen because the laws governing research have not been understood. There has been a desire to improve a method, but it has not been recognized how it could be done. This has usually taken the form of modifying the instrument, as in the different forms of stethoscope that have been evolved. No doubt much benefit has resulted by perfecting the x-ray methods and laboratory methods generally, but the progress has rarely been commensurate to the time and trouble spent, because it has not been guided by an understanding of the principles of clinical investigation.

The discovery of a new fact or a new method must not be the end of the inquiry which has revealed it. Rather must it be looked upon as a means to an end, a stepping-stone to help a further advance. Medicine has failed fully to appreciate this aspect, chiefly because it was not understood how progress should be made. If the path had been clearly indicated, a forward movement would have been made in many instances where our knowledge has stood still, as in the signs discovered by the stethoscope.

The chief causes that have hampered progress are the failure to recognize the necessity for understanding the prognostic significance of symptoms, and the lack of understanding of the principles of investigation.

THE LAW OF ASSOCIATED PHENOMENA.

One principle of supreme importance for the advance of medicine is the law of associated phenomena. This law is based on the fact that ill health is always accompanied by a number of symptoms, and in every case it is incumbent upon us to search for other symptoms besides those which are most prominent. When, for instance, we detect a structural symptom, we must recognize the limited knowledge it reveals and we must extend our observation and seek for signs of functional derangement. If we detect a sign and recognize it as the product of reflex stimulation, we are at once given a suggestion for further inquiry, and we must search for other signs which will lead us to the area of stimulation. The discovery of this area will lead us to the organ at fault, and it may be to the nature of the condition that provokes the reflex, and thus we get nearer the actual disease.

A very little study will soon bring conviction of the necessity for constantly keeping this law in mind. From the simplest complaint, a headache or a cough, to the most obvious physical sign indicating gross changes, the due appreciation of the case will depend on the application of this law.

THE SIGNIFICANCE OF SYMPTOMS (PROGNOSIS).

The law of associated phenomena is necessary to the understanding of another of our main objectives. We intend to find out the effect the cause of a symptom has on the patient's future—that is, we intend to study prognosis, a part of medical science which lies at the foundation of the intelligent practice of medicine. To do this we must keep in contact with the patient, and follow him during the remainder of his life or for the duration of his ill health, and in doing this we must ever be on the look-out for the modification of the symptom and the development of new symptoms—that is, by the detection of all associated phenomena. This, indeed, is a necessary part of our work, and we must formulate a plan by which it can be carried out. We will have from time to time, as experience ripens our judgement, to alter or modify such a plan.

It is by this part of our work that we hope to detect the early stages of disease. At first we may have no true conception of the cause of a symptom we may detect in an individual, but in course of time, as the disease develops, we may be able to recognize it. By referring back to our notes we will see how the symptoms were developed, and thus acquire a knowledge of the early stages. By finding similar symptoms in other patients later we may be able to detect the disease earlier, and so back to the beginning.

THE USE OF LABORATORY METHODS.

The principle on which we will work is that we recognize the symptoms of disease, then endeavour to find out the agents producing the disease. Many of the symptoms will not be recognizable by the unaided senses, so in applying the law of associated phenomena we will use mechanical and other laboratory methods to assist us. We start with a chemical laboratory and an x-ray department, and we will continually resort to these departments for assistance.

So many diseases arise from bacterial invasion that no method of research into the cause of disease would be complete without a skilled bacteriologist, and we have arranged for a bacteriological department. At the outset our endeavour will be to find out the nature of the symptom provoked by the different bacteria. We recognize by the clinical symptoms the occurrence of a great many infectious diseases, where the specific microbe has been discovered, as typhoid fever and pneumonia. The recognition of other diseases is dependent entirely on the clinical symptoms, as measles and scarlet fever. We infer that the symptoms produced by other infections may give rise to specific symptoms, and we will use this idea as a guide in one field of research. It is manifest that bacteriology must be greatly hampered until the symptoms of invasion are related to the infective agent causing the ill health.

THE CLASS OF PATIENTS.

It may seem to you that St. Andrews with its population of about 10,000 people is too small a centre for the purpose of research, and that large towns would afford greater opportunities, not only in numbers but in variety. There are various reasons why a town of small size is better

adapted for our purpose. As a rule the inhabitants are less migratory, and we can more easily keep in contact with them and so have the opportunity of acquiring a knowledge of the significance of symptoms. We can acquaint ourselves more readily with their environment and with the conditions that preceded their ill health.

Thus we have the opportunity for this particular kind of research. It is not our intention to inquire into the rarer forms of disease, but to study those that are most common, and as St. Andrews is far from exempt we will have plenty of material of the sort we want. Indeed, I must warn you against attempting too much. Far more knowledge is to be acquired by the thorough study of a few than by noting the more prominent symptoms of a large number of patients. We hope by this method gradually to lay the basis of a symptomatology that will be available for those who have perforce to see a large number of patients, and who have not the time and opportunity which will be afforded us.

The class of patient we propose to study, while including patients with different kinds of disease at all stages, will chiefly be those at the very earliest stage of their illness. For this purpose the patients that come to you in your ordinary practice complaining of ill health with no definite physical signs will receive our special consideration. Not only will careful note be taken of their complaints, but we will endeavour, as far as possible, to discover the cause and the mechanism by which their symptoms are produced, while special arrangements will be made for finding the outcome of their ill health.

EXPECTATION OF RESULTS.

I must warn you against any immediate expectation of achieving the chief aim in medicine, the prevention and cure of disease. A long and weary road lies to be travelled, and many of us will fall out before that is achieved. As I have said, we have first to train ourselves in the detection of symptoms. Our immediate object, after training ourselves, is to find out the nature of the symptoms of disease, on the lines I have indicated, by discovering their mechanism, and by watching individuals to see what happens. It may be we may detect in this way the onset of some diseases. After that we will have to search for those who show the early signs of a particular disease, and recognizing these signs, seek then for the cause and the factors that favour its onset.

Such a contemplation of our work seems discouraging, for we all like to see the fruits of our endeavours. But it must be borne in mind that all great enterprises are based on work that has been done by individuals whose part is lost in oblivion. Someone has to do the obscure but necessary work of digging a foundation, and if it falls to our part we must be content with the knowledge that we are playing a necessary part in a great enterprise.

POINTS IN THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

BY

THOMAS BEATTIE, M.D., F.R.C.P.,

PROFESSOR OF THERAPEUTICS, UNIVERSITY OF DURHAM COLLEGE OF MEDICINE; SENIOR PHYSICIAN, ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE.

I MAY remind you first of all of a few generalizations concerning pulmonary tuberculosis. Nature is curing tuberculosis of the lungs daily all around you, and the pathological statistics of the world reveal the startling fact that 65 per cent. of the population, especially those of large cities, have definite evidence of having had tuberculous infection of the lung. Some of them, even in advanced stages, become arrested and they die from some entirely fortuitous cause. You must be prepared to find on physical examination tuberculous cicatrices, fibrosed areas, scars, tubercle that has long since been arrested and is no longer active. To put it in another way, more than every second person you meet has to your knowledge tubercle in his lungs which has become arrested, and you therefore may find in some of your patients evidences of arrested tuberculous foci and may be misled into advocating active remedial measures where nothing more was necessary

* Lecture given at the December meeting of the North of England Branch of the British Medical Association.

than general directions concerning choice of occupation, mode of life, etc. It is important, then, to distinguish arrested from active tuberculous lesions.

Family History.

I would emphasize the value or otherwise of family history. When you have discovered signs of pulmonary tuberculosis you are familiar with the constant cry and pleading that there is no history of any such condition in the family. Let me assess the value of that for you. A family history of tuberculosis which has involved several members of a family and in a large proportion of those involved there has been constant retrogression, and, finally, fatal termination—that is a bad family history, indicating that the soil in that family is fertile for the growth of tubercle. In a family history in which there is much tubercle—pulmonary, glandular, articular—but in which the majority of the cases have recovered and are still well after many years—that is a good family history, showing that the soil in that family is not fertile for the growth of tubercle. Where there is no family history of tubercle that history is usually bad. It is certainly exceedingly doubtful at best. It is virgin soil which has never been sown and is more apt to prove fertile than not. Such is the Arab coming from the desert into the city, and succumbing rapidly to tubercle when once infected with it.

Previous History.

There are two points of extreme value. The first is a previous history of pleurisy, concerning which inquiry should always be made. The second is a history of hæmoptysis. It may be that after the occurrence of one or other of these events the patient took sufficient rest or put himself under sufficiently good conditions to bring about a rest of the tuberculous condition at the time. Then at a subsequent date, sometimes remote, conditions of work or of living—or even trauma—may have lowered the general or local resistance and caused a quiescent focus or foci to assume activity.

Subjective Symptoms.

A person who comes complaining of gradual loss of flesh or of constantly increasing languor, lassitude, tiredness, inaptitude for his work, is to be regarded with suspicion. The person who complains of indigestion, dyspepsia, retching, etc., should have his chest examined as a routine practice. Never forget that many a case is passed over and treated with stomachic mixtures for many months before being recognized as one of pulmonary tuberculosis. Other symptoms are anaemia, slight evening pyrexia, feeling dull and tired in the evenings; if the temperature were regularly taken for a week and a slight evening rise demonstrated, these evidences should arouse your grave suspicion.

Objective Signs.

There is no physical sign in the whole range of pulmonary examination that has not been advanced at one time or other as being a sign of pulmonary tuberculosis, and perhaps properly so, because pulmonary tuberculosis is exceedingly variable in its locality and in the pathological changes which it effects in the lung. *Deficient expansion* in itself as a single witness is not of much value and may indicate nothing more than a lateral curvature of the spine, an asymmetrical thorax or an old cicatrix, long since quiescent and arrested. *Impaired resonance on percussion* is of extreme value if taken in conjunction with other signs, but alone is not sufficient to justify so serious a diagnosis. *Cogwheel respiration*; you will find that exactly corresponds to the heart-beats, and is simply interrupted breathing of cardio-respiratory origin. Prolonged expiration merely denotes emphysema and harsh breath sounds may be nothing more than puerile.

The early signs of greatest import are: Slight impairment of percussion resonance in conjunction with enticlement of breath sounds and localized areas of crepitations. The most important of these is the localized areas of crepitations. The crepitations may be so slight as to be properly described as rustling or crumpling crepitas. It is sometimes difficult to determine whether they are pleuritic or alveolar in origin. These crepitations when heard over a localized area are highly suspicious of tuberculous deposit at that site. Their method of elicitation may be remarked upon. You sometimes hear them with

normal respiration, you will hear them more readily with deep forced respiration. You will hear them best by what is termed the post-tussive method.

Post-tussive Crepitations.—Get the patient to take a deep breath, fully exhale, and at the end of expiration to cough one single cough followed by a full inspiration. Crepitations which were previously doubtful may be brought out to their maximum audibility by this method. Quite frequently I have found that the crepitations are not on the side of impaired percussion, but on that side which appears to be the more resonant.

Locality.—Do not be satisfied with having examined the apices. Tubercle may be deposited at any site in the lungs. You must therefore examine not only the apices, especially behind in the supraspinous regions, but also the margins of the lungs and the lines of the interlobar sulci. You must examine the apices of the lower lobes in the interscapular regions and also the bases. You must bear in mind that you may have either scattered foci or localized masses of tubercle at any site in the lungs.

Varieties of Pulmonary Tuberculosis.

There are certain special types of tuberculosis to which I should like to draw your attention. The ordinary tuberculous deposit may occur at any site, as I have indicated. There are also the subpleuritic and the peribronchial varieties and hilus tubercle.

Hilus tubercle starts in the mediastinal lymphatic glands and extends along the peribronchial lymphatics. It gives rise in the early stages to no definite signs other than those of emphysema and bronchitis. If you find that your patient is not responding to treatment in the way that a case of emphysema and bronchitis should, then your suspicions should be aroused, and you must carry the matter further.

Examination of Sputum.

Too much consideration is laid by many upon the examining of sputum. Of course it is an exceedingly valuable piece of evidence if positive, but in the majority of instances the man who cannot diagnose pulmonary tuberculosis until he has found tubercle in the sputum misses a very large number of early cases. If you do find tubercle in the sputum, it means that the tubercle in the lung has been there for a sufficient length of time to have eroded and ulcerated a way out, and to have been capable of discharge through the bronchi—that is to say, the tubercle is now of the open variety, and long before it had ulcerated a way out it was present in the lung. You can have much tubercle present in the lung with no tubercle present in the sputum. A negative sputum report is of no value whatever; a positive sputum report is of great value.

X-ray examination does assist you very materially in diagnosing tubercle of the lung, particularly the hilus variety, which is difficult to recognize by any other method.

Tuberculin Diagnostic Test.

The last point in determining a diagnosis of suspected tubercle is by the tuberculin test. I no longer use the methods of von Pirquet, Morro, or Calmette, for the reason that a local reaction in itself does not distinguish between an old arrested focus and a recent active lesion. I prefer to use Koch's T.A.—1 in 1,000 dilution. Give 1 c.cm. hypodermically, and, if the reaction be positive, you will witness not only a local reaction at the site of inoculation—and a general reaction indicated by some elevation of temperature, which should be taken every two hours—but also, and most important of all, a focal reaction indicated by increased audibility of crepitations at the site suspected.

SOME time ago an Interdepartmental Committee on the Production and Utilization of Alcohol for Power and Traction Purposes recommended the establishment of a small permanent organization under the Department of Scientific and Industrial Research, to continue investigations into the problem. The Fuel Research Board of the Council has now appointed Sir Frederic Nathan to be the Power Alcohol Investigation Officer. After making a survey of the present position, he will submit proposals to the Board for such experiments and research as may appear to be necessary.

THE ROUTINE TREATMENT OF MALARIA IN UGANDA.

BY

J. A. TAYLOR, M.B. EDIN., D.T.M. LIVERPOOL,
MEDICAL OFFICER, UGANDA PROTECTORATE.

AFTER more than ten years' experience of the treatment of many thousands of cases of malaria in Uganda, the results I have obtained with small doses of quinine have led me to conclusions so different from those expressed recently in your columns that I hope they may be worth recording.

Most of the cases of malaria met with in Uganda are simple subtertian without complications, and the routine treatment I adopted for these was as follows:

1. Calomel, in an average dose for an adult of not less than 5 grains, followed in some hours by a saline. This usually meant that the calomel was given last thing at night, and the salts at 6 a.m., or when the patient awoke the next morning; but if there were any signs of the calomel acting during the night the salts were given at once.

2. Quinine, 5 grains of the hydrochloride by mouth one hour after the saline. This was usually about 7 a.m., and between this time and noon three more doses of 5 grains each were given at more or less regular intervals—for example, 8.30 a.m., 10 a.m., and noon. On subsequent days, until the temperature had remained normal for twenty-four hours, 20 grains were given daily in the same manner, the first dose at 6 a.m., or as soon as the patient was awake, and the last dose at noon. After the temperature had been normal for twenty-four hours the quinine was reduced to 15 grains daily—5 grains before the morning, mid-day, and evening meals. This was continued for one week and then reduced to 10 grains daily—5 grains morning and evening. Ten grains daily were continued for a fortnight, and then only 5 grains each evening for two months.

3. Phenacetin in 5-grain doses up to 15 grains daily for headache alone, or aspirin in the same doses if complaint were also made of pains in the limbs and body.

Under this treatment the temperature usually remained normal after the third day, but occasionally, especially if a first attack, after four or five days; no complications occurred in any of my cases from the effects of the quinine or malaria, there were no recurrences of the fever during the three months' treatment, and attacks only occurred later when some definite fresh infection had taken place.

In the most typical cases all the quinine was given before noon while the temperature was little if at all above normal, and there was thus better absorption and little likelihood of vomiting. In the less typical but not uncommon cases in which the temperature had not fallen in the morning, my practice was to give only one or two of the 5-grain doses of quinine at three or four hours' interval in the morning and the remainder of the 20 grains during the afternoon and evening. If the quinine was vomited or the temperature rose above 104° F. before at least 15 grains of the quinine had been taken, an intramuscular injection was usually given. Intramuscular injections, however, were required in less than 1 per cent. of my cases, and usually on not more than one occasion. If the patient made no objection I gave the quinine in solution, but I cannot say I found this more satisfactory than in the compressed form. A very great objection on the part of the patient to taking quinine in solution—and the majority of one's patients have a very great objection—in my experience reacts on the stomach, the absorption is retarded instead of hastened, and vomiting sometimes ensues, whereas tablets would be retained and absorbed.

My remarks apply to subtertian malaria. I have met with no cases of pure quartan. Pure tertian was also uncommon in Uganda before the war, but during the war there was a considerable increase in the number of cases, no doubt brought about chiefly by the troops from India. In tertian I have carried out the same treatment as described for subtertian, but have waited until the temperature has remained normal for two clear days before reducing the dose to 15 grains.

With larger doses of quinine daily I have been unable to obtain results as satisfactory. Nor have I found the method of giving 10 grains of quinine two or three times

a day satisfactory. By the time the evening, and sometimes the mid-day, dose is given, the temperature may have already risen and the quinine may be vomited or only partly absorbed. Also, after an evening dose of 10 grains, the headache and general discomfort are increased, with a restless and sleepless night as a result. Even an intramuscular injection when the temperature is high does not produce the same effect as a smaller dose by mouth when the temperature is low.

I do not think too much emphasis can be laid on the importance of giving the calomel is not less than a 5-grain dose, both in malaria and blackwater fever. The one or two grains sometimes given usually causes severe pain, griping and numerous visits to stool with slow and little result, whereas 5 grains causes little discomfort and acts only once or twice with very good and quick result.

As compared with other purgatives, a dose of calomel (5 grains) at the commencement of an attack of malaria appears to have an almost specific action in preparing the way for the quinine, and to it I attribute to a very large extent the absence of complications and quick response to quinine.

With blackwater fever my experience is that if the 5 grains of calomel can be given immediately an attack begins no serious complications arise, and, with careful general treatment, blackwater fever is removed from the category of the most dangerous diseases. I have had only two deaths among my patients from blackwater fever. In each case I was able to see the patient for the first time only on the third day of the attack; one patient had taken 2 grains of calomel, and had been on and off the stool all night with great pain and discomfort, but with so little result that several soap and water enemata were needed before a saline injection could be made into the rectum. In the second fatal case no purgative at all had been given. Blackwater fever, however, is, in my opinion, a complication of malaria which should rarely if ever occur. It appears to be the result of a final and drastic effort on the part of nature to eliminate the parasites from the body, usually after several untreated or insufficiently treated attacks of malaria. I have seen no case of blackwater fever occur during the treatment of malaria if both calomel and quinine had been given, but I have seen cases, usually slight, after quinine alone. In these, to my mind, the question has not been whether the quinine brought on the attack, but how much more serious the attack would have been if no quinine had been given.

With regard to large doses of quinine it may be of interest to record that during the war several cases of malaria were sent up to Uganda from Mombasa to try the effects of a change of air. Some of these whom I saw at Entebbe informed me that they had been taking 40 to 60 grains of quinine daily for several weeks without the temperature remaining normal for twenty-four hours. With most of these complete stoppage of the quinine brought the temperature to normal within three days. In one case the temperature came to normal and remained normal until the eighth day, when it again went up to 103° F. Subtertian parasites were then found in the blood, and treatment with calomel and quinine as described above was commenced. In three days the temperature was again normal, and there had been no recurrence of the fever when I last heard of the patient three weeks later.

I have had no experience of the treatment of malaria elsewhere than in the Uganda Protectorate. It is possible, although I have not seen this point discussed, that the effect of the altitude of Uganda—more than 3,000 feet above the sea level—upon the blood may help the action of quinine. In Uganda, also, I usually had to deal with only single infections, and earlier treatment was perhaps more often possible. Whatever may be the explanation there would appear to be a great difference between the doses and manner of administration required in other localities as compared with Uganda.

I cannot help thinking that too much quinine, especially too much in a single dose, can be given as well as too little. One grain of calomel given to many Uganda natives will cause intense salivation and other alarming symptoms of mercurial poisoning, while a larger dose given to the same person may have only a purgative action. Some analogous action may occur in the case of quinine. It is possible that too large a dose may, in some as yet undetermined manner, prevent the necessary action.

When giving more than five grains of quinine daily

I have always used the hydrochloride if obtainable, but if only five grains daily, the cheaper salts are just as satisfactory.

As soon as the patient can get about, some combination of arsenic in increasing doses and iron in small doses has proved most useful.

A COMPARISON OF TWO METHODS OF ADMINISTERING ARSENO-BENZOL COMPOUNDS IN SYPHILIS.

BY
H. E. GIBSON, M.D. Oxon.,
LONDON.

A COMPARISON of the two following courses of antisyphilitic treatment may be of interest.

In the first series of cases treatment consisted of one dose of 0.3 gram of kharsivan, followed at weekly intervals by doses of 0.6 gram, until a total of 2.7 grams had been given, but an interval of fourteen days was allowed between the third and fourth doses. This course was thus completed in five or six weeks. For want of a better term it may be termed a "concentrated course" of treatment. If further treatment was necessary owing to the Wassermann reaction being still positive, potassium iodide was given for fourteen days, and then two more injections of 0.6 gram, with one week's interval between them. All the above was given intravenously by the gravity method.

In the second series of cases, which may be termed a "prolonged course" of treatment, three injections of 0.3 gram were given, then two of 0.4 gram, and two of 0.5 gram, all at weekly intervals, except for a fortnight's rest between the third and fourth injections, as in the other series. This course lasted about eight weeks, and the drug was given intravenously as in the "concentrated course." Further treatment, if necessary, consisted as a rule of intramuscular injections of novarsenobillon, at weekly intervals, generally one of 0.3 gram and one of 0.6 gram. Occasionally there were slight variations in the above prolonged course, as, for example, by substituting a dose of 0.5 gram for the second dose of 0.4, or a dose of 0.6 for the last 0.5 gram.

The criterion of cure was a negative Wassermann reaction.

The total amount of arseno-benzol compounds given to any one case was limited to 4 grams, the first course, at the end of which the Wassermann reaction was tested, consisting of a total of 2.6 to 2.8 grams; the second, or "follow up" course, before a second Wassermann test was made, bringing the total to an average of 3.9 grams in the concentrated course, and 3.6 in the prolonged series.

It will be seen from the table that, although the percentage of primary cases which showed a negative Wassermann reaction after the first course is slightly higher in the "concentrated" series, the results are completely changed when we consider the cases showing secondary symptoms.

Cases Treated with a Concentrated Course.

No. of Cases.	Negative with up to 3 grams.	Negative with up to 4 grams.	Positive after 4 grams.	Doubtful after 4 grams.
Total cases... .. 89	47=52.80%	14=15.73%	23=25.84%	5=5.61%
Primary 34	28=82.35%	3=8.82%	2=5.88%	1=2.94%
Secondary 52	17=32.69%	10=19.23%	21=40.32%	4=7.68%
No symptoms ... 1	0	1=100%	—	—
Previous treatment 2	2=100%	—	—	—

Cases Treated with a Prolonged Course.

No. of Cases.	Negative under 3 grams.	Negative under 4 grams.	Positive after 4 grams.
Total cases ... 100	68=68%	28=28%	4=4%
Primary... .. 65	52=80%	12=18.46%	1=1.53%
Secondary ... 35	16=45.71%	16=45.71%	3=8.57%

A 4 cases also received 1 grain of mercury, given intramuscularly, at weekly intervals.

Apart from the question of cure, one great disadvantage of the short concentrated course is that the reactions are much more pronounced than in the prolonged course. These include diarrhoea, vomiting, and sometimes a violent and immediate vaso-dilator effect, in which the patient's face becomes "blown up," and the pulse weak and irregular; this is most alarming when seen for the first time, but apparently it always passes off without active treatment. Opinions differ as to the benefits of adrenalin in this condition.

Although slight reactions, such as diarrhoea, vomiting, and headache, may occur with the prolonged course, they are not so marked as in the other, and I have so far not had a single instance of the vaso-dilator phenomenon.

It has been impossible to follow up these cases to see what percentage of relapses, if any, occurred in the two series.

Conclusions.

Advantage seems to lie with the prolonged course, partly owing to the lesser incidence and violence of reactions, and partly because the total results are better than with the concentrated course; this especially applies to secondary cases.

Should a patient showing only a primary sore have urgent reasons for wanting a short course, the concentrated course may be given, but otherwise it is better to spread the treatment out over a longer period.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TREATMENT OF DELIRIUM TREMENS.

DR. STARKEY has sounded a note of warning, in the BRITISH MEDICAL JOURNAL of January 10th, with regard to Dr. Wyatt-Smith's remarks, under the above heading, in the JOURNAL of December 6th, 1919, which I must support. Prior to the war I made extensive observations on the action of various hypnotic drugs with a view to forming some ideas as to their selection in different types of mental disease. My results were published in the *Journal of Mental Science* (July, 1914), but I feel that it may be of some interest if I record here some of my observations on the drugs mentioned.

Hyoscine.—My opinion is that this drug is a very powerful cardiac depressant and that it ought not to be prescribed in patients who suffer from "heart disease." I laid considerable emphasis on this in my article referred to above and expressed the view that it should not be given to anyone who was not in robust physical condition. In states of extreme maniacal excitement, in strong healthy people, however, when one wishes to obtain the influence of a hypnotic as quickly as possible, it is a most useful drug, and given by hypodermic injection it is very rapid in its action. I have frequently given doses of gr. $\frac{1}{10}$ with benefit; in fact, large doses must be given in these cases and in this way the repetition may be avoided. I have found it especially useful in cases of delirium tremens, as Dr. Wyatt-Smith states, and especially so if combined with atropine and morphine. In milder cases it is of some use in doses of gr. $\frac{1}{10}$ three times a day, but I prefer not to use it for repeated administration, and the warning given by Dr. Starkey is fully justified from the experience I have had of the drug.

Sulphonal.—Most of those who have done service in mental hospitals have considerable experience of the use of this drug, and although Dr. Wyatt-Smith states that he has not yet met anyone who had seen a case of sulphonal poisoning, I must add my name to the list, with Dr. Starkey, of those having had this experience. I have, however, only seen one case in fourteen years' asylum work. It is usually associated with vomiting, diarrhoea, and abdominal pains, and the patient slowly passes into a state of collapse. The warning signal is haemateporphyrinuria, and it seems to me, therefore, of the greatest importance when prescribing this drug to have careful observations made on the passage of urine, and the report of any tendency for it to change to a reddish tinge. It has been my invariable rule to have these instructions written on the box in which sulphonal is dispensed, and this may account for my having seen only one case of poisoning from the drug, but I realize the

risk of its prolonged administration under other circumstances, and think these should not be treated too lightly. I consider sulphonal prescribed with the above precautions to be most useful in cases of old-standing excitement, and especially in cases of senile dementia. It is not a cardiac depressant, but it is very slowly excreted. I prefer it in the powder form in which some makers prepared it in pre-war days, for in the crystalline form it is very insoluble and liable to set up gastro-intestinal irritation, which, in my opinion, may produce attacks of diarrhoea. Its action is slow but cumulative, and it requires to be given several hours before its effect is desired. After testing its action in a hundred cases I found that the average period that elapsed before sleep after the administration of 30 grains was four hours, and that on an average seven and a half hours' sleep followed.

Veronal.—I agree with Dr. Starkey that this is in many ways preferable to sulphonal, and I use it for cases of excitement in the early stages. The drug, however, is very liable to produce a habit; this I throw out as a warning to those who may use it in private practice. It seems to have been procured by drug takers more commonly since the Hove case (BRITISH MEDICAL JOURNAL, 1913, vol. i, p. 566), the newspaper accounts of which may have had some influence in this direction. Veronal is quicker in its action than sulphonal, and I found that on an average 10 grains produced five hours' sleep within forty-five minutes of its administration.

Whilst on the subject of hypnotic drugs I should like to state that I consider their use should be avoided as much as possible. Much can be done to induce sleep in restless patients before drugs are resorted to, and efficient nursing may considerably diminish the strength of the dose required. I venture to suggest that hydrotherapy is not so frequently tried as it should be in cases of acute maniacal excitement, and that the poisonous doses of hypnotics otherwise necessary may frequently be avoided by this line of treatment in the early stages.

RICHARD EAGER, O.B.E., M.D.,
Deputy Medical Superintendent, the Devon
Mental Hospital.

Exminster.

"ACUTE SUFFOCATIVE CATARRH."

THERE seems to be a close resemblance in the description given of the cases of acute suffocative catarrh recently reported to the condition met with in paroxysmal tachycardia. In one form of this the patient stands rooted to the ground, with intense dyspnoea, cyanosed, and expectorating large quantities of frothy, blood-stained fluid. As in the condition described by Dr. Gale, morphine is often extremely efficacious. A good description is given by Dr. Lewis in one edition of his *Clinical Disorders of the Heart Beat*, modified, for some reason which I do not know, in a later edition.

W. DUNCAN LAWRIE, M.D.,
F.R.C.S. Edin.

Longton, Stoke-on-Trent.

HOURLY GLASS STOMACH: GASTRIC AND PYLORIC ULCERS.

THE following case presented some interesting features as an instance of a condition which I believe to be uncommon:

Mrs. E., aged 53, had been troubled with "indigestion" for sixteen years. Pain in the epigastrium after every meal was a marked symptom when I saw her, no matter what food she took, though the degree of pain varied with the consistency of the food—it was less after a fluid diet, such as milk, than after one including potatoes. During the last twelve months she had lived on scarcely anything but milk. She was very badly nourished, and weighed just over 6 st. I advised operation, to which she consented.

Operation.

I found a rather enlarged stomach with the pylorus almost surrounded by dense adhesions and attached to the under surface of the right lobe of the liver. There were signs of recent inflammatory trouble in this area. The pylorus scarcely admitted the tip of the little finger. At the junction of the proximal and middle thirds of the stomach was a large chronic saddle-shaped ulcer extending down both the anterior and posterior surfaces from the lesser curvature, and constricting the lumen to such an extent that here again the tip of the little finger could just be inserted. The edges of the opening were rounded, thickened, hard and smooth; there were no adhesions on the posterior wall of the stomach, and the organ could easily be lifted up. I had no reason to suspect malignancy.

Resection of this part of the stomach with or without the pylorus was not attempted because such a procedure was not to my mind justifiable owing to the poor condition in which the

patient was at the time. I therefore performed double posterior gastro-enterostomy and closed the wound.

Apart from a little vomiting twelve hours after the operation recovery was uneventful, and she was up on the tenth day and left hospital on the fourteenth.

Her condition at present (two months after the operation) is very good and she is eating well. Her weight is now 7 st. 6 lb.

Although hour-glass stomach is not uncommon, this condition combined with ulcerated pylorus is rare. Also in an hour-glass condition a double gastro-enterostomy is perhaps not the best method to adopt, yet I think in this case it was the one and only suitable procedure.

Another interesting point is the relative times of formation of these ulcers; from the condition of things found at operation I should say that the saddle-shaped ulcer was of much longer duration than that at the pylorus.

The possibility of ultimate transition to malignancy did not escape my mind, but, as I have said, resection in any form was not justifiable.

Evesham.

DONALD M. MACLEOD.

Reports of Societies.

DIVERTICULITIS.

THE meeting of the Proctological Subsection of the Royal Society of Medicine on the subject of diverticulitis, which had been adjourned from the previous week,* was held on Wednesday, January 14th. The discussion was resumed by Mr. J. P. LOCKHART-MUMMERY, the President of the Subsection.

Diagnosis.

Mr. LOCKHART-MUMMERY expressed the view that the discussion would be instrumental in proving to the profession that diverticulitis, far from being a pathological curiosity, was a very real disease. As far as he knew, the earliest description of the condition in English literature was that contained in a paper by Sir Humphry Rolleston published in the *Lancet* of 1905. One of the most important points in connexion with diverticulitis was its liability to be mistaken for carcinoma, and carcinoma of an inoperable nature. The result was that such a patient was often left without surgical relief. The points that were of assistance in establishing a diagnosis of diverticulitis were the following: First, recurrent attacks of inflammation, accompanied by a rise of temperature and rigors. Second, a long history without great increase in the size of the abdominal tumour, and without great emaciation. Even when the abdomen was opened the diagnosis often remained doubtful. However, a large mass with marked adhesions suggested diverticulitis. In 4 out of his series of 24 cases perforation into the bladder had occurred, and he suspected that the vast majority of cases of perforation into the bladder which were believed to be due to carcinoma of the bowel were in reality due to diverticulitis. On the other hand, diverticulitis was sometimes associated with malignant disease, and for this reason he recommended that colostomy should be performed early, without waiting for urgent signs of obstruction. Although resection was the ideal proceeding, it could seldom be attained, owing to the density of the surrounding adhesions. In only 4 of his cases had resection been possible. The usual alternatives were some form of short-circuiting operation and colostomy. The results of colostomy were exceedingly good, but care must be taken to get well above the diseased bowel. After colostomy the disease became arrested, and in spite of the objection of patients to this proceeding, their condition was a very satisfactory one. Only in very exceptional cases was it justifiable to perform resection of the bowel without a preliminary colostomy. If, as the result of colostomy, the local condition improved, secondary resection might be undertaken. In his series the average age of patient suffering from diverticulitis was 60.

Etiology.

Mr. W. ERNEST MILES agreed that the discussion had shown that diverticulitis was a very real disease, and one that should engage the attention of every abdominal surgeon. Whether it was a comparatively new form of

* Reported in the BRITISH MEDICAL JOURNAL, January 17th, 1920, pp 82-85.

disease due to modern modes of life, or whether it was one that had existed previously and had not been detected, was a question difficult to answer. Dr. Maxwell Telling had said that there was often a long antecedent history. It might be possible by careful inquiry to associate its onset with certain conditions or habits that might prove to be definite causative factors. He was inclined, with Professor Rutherford Morison, to put the idea of congenital origin out of court. The fact that diverticula often existed in considerable numbers supported this view. Increased intracolonic pressure, causing hernial extrusion of the mucosa through the muscular coats at the weak points of blood-vessel perforation, was a much more likely cause. Flatulent distension had been suggested as a determining factor. He doubted this because of the even distribution of gas pressure. Intracolonic pressure was more likely to be increased through one of the following three causes: First, forcible contraction of the sphincter in order to overcome the desire to evacuate the bowels at an inconvenient moment, as when hurrying to catch the morning train. Second, straining at stool in order to force a formed motion through a narrowed anal orifice. Apart from stricture of the rectum, which of course would have this effect, there existed a common condition of the anal canal which the speaker had described in the *Journal of Surgery, Gynaecology, and Obstetrics*, November, 1919. It consisted of a fibrous deposit in the submucosa of the pecten that materially limited the expansibility of the external sphincter. This condition caused great difficulty in emptying the rectum, a diminished calibre of the faeces, and an increase of intracolonic pressure. The third cause of increased pressure was the habitual use of very large enemata to which the badly constipated often resorted. For these reasons it would be of great interest to obtain accurate information as to the previous habits of those suffering from diverticulitis. If definite causes could be recognized, prophylactic measures might be adopted.

Mr. LIONEL NORBURY, in discussing the etiology of the condition, laid stress on enterospasm as a factor. This was accompanied by hypertrophy of the bowel wall and increase of pressure. The large amount of fat that accumulated round the bowel in these cases was possibly the result of venous congestion produced by the enterospasm. Sigmoidoscopy was sometimes of use in showing a narrowing of the colon, due to spasm, and a thickening of the mucous membrane. This condition when seen suggested diverticulitis.

Dr. A. C. JORDAN showed an interesting series of *x-ray* photographs, several of them illustrating the results of operative treatment in patients suffering from diverticulitis. In speaking of the etiology of the condition, he believed that practically all cases started from a colitis accompanied by enterospasm. The colitis being due to infection, it might be said that diverticulitis was a manifestation of chronic intestinal stasis.

The Subject in General.

Mr. SAMPSON HANDLEY considered that the success of the discussion was in great part due to the clear exposition of the subject given in the opening paper of Dr. Telling. This had provided an excellent skeleton around which subsequent remarks could be hung. A point that assisted in differentiating diverticulitis from carcinoma of the colon was the fact that in the former condition the "tied string" appearance so characteristic of carcinoma was never seen. He entirely agreed with the President's remarks on the subject of colostomy. In very few cases was a primary resection justifiable. He had seen an interesting microscopic section showing infiltration of a diverticulum wall with carcinoma.

Sir CHARLES SYMONDS said that with the new light that had been thrown on the subject by the discussion he could see the explanation of many a previous clinical puzzle. He remembered a case of inoperable carcinoma of the bowel for which he had performed a colostomy. The patient had returned to him years afterwards in excellent health and with his colostomy opening closed. He agreed with previous speakers in believing that perforation into the bladder was seldom due to malignant disease. Would it be possible to diagnose an impending perforation into the bladder before it had actually taken place? He remembered cases in which the chief symptom had been pain when the bladder was distended. Was this suggestive of adhesions between the colon and the bladder?

Mr. LOCKHART-MUMMERY agreed with the previous speaker that it would be a great advantage to forestall so serious a catastrophe as a vesico-colic fistula. Unfortunately the accident usually occurred very suddenly, and without any warning that would allow of an earlier diagnosis being made.

Sir GORDON WATSON called the meeting's attention to a fresh specimen he had brought from St. Mark's Hospital. It consisted of a portion of colon removed after a diagnosis of carcinoma had been arrived at. Now that it was removed it was by no means easy to say whether the condition of the bowel was due to carcinoma or to diverticulitis. The specimen emphasized the difficulty of forming a diagnosis even when the abdomen had been opened.

Opener's Reply.

Dr. MAXWELL TELLING, in closing the discussion, congratulated the Subsection on the excellent way in which the subject had been handled. The result was that there remained little for a speaker to do in the way of dotting i's or crossing t's. He would like to point out, however, that there had been a tendency in the case of some speakers to confuse true diverticulitis with the condition of sacculation of the colon. This confusion would be increased if Professor Rutherford Morison's suggestion as to a change of nomenclature were adopted. The fact that diverticula were often found in the bowel of men past middle life did not necessarily imply that diverticulitis was a common disease. Such diverticula often gave rise to no symptoms, and he would be the last to suggest wholesale resections for such a condition. Operation should be reserved for those cases that were accompanied by definite and troublesome symptoms.

The PRESIDENT then proposed a vote of thanks to Dr. Maxwell Telling and to the other medical men from the provinces who had come to London in order to take part in the discussion. He wished to thank them in addition for the trouble they had taken in providing illustrative specimens. The motion was heartily carried.

LARYNGOLOGICAL CASES AND SPECIMENS.

A MEETING of the Section of Laryngology of the Royal Society of Medicine was held on December 5th, 1919, with Mr. E. B. WAGGETT, the President, in the chair. A number of cases and specimens were shown.

Mr. W. M. MOLLISON showed a rare case of fibroma of the aryepiglottic fold in a male, aged 40, who complained only of earache due to meatitis. Routine examination of the larynx showed a fibroma which was smooth and globular, growing from the above site. The tumour, which was the size of a pigeon's egg, was dissected out and removed by means of suspension laryngoscopy. Microscopically the growth proved to be a hyaline necrotic fibroma. Mr. Mollison showed also a case of lupus of the larynx in a patient aged 18. The larynx showed much heaping up in the interarytenoid space, the right ventricular band was ulcerated, the ulcer extending down to the true vocal cord. The lungs were in a condition of active tuberculosis; the Wassermann reaction was positive. He showed also a case in which melanotic sarcoma of the nose was removed by lateral rhinotomy. The growth arose from the lower portion of the right outer wall and from the inferior turbinal. The patient made a good recovery.

Dr. IRWIN MOORE exhibited a female patient, aged 24, who had suffered for years from enlarged and diseased (septic) tonsils. Enuclation of the tonsils was advised, but the patient refused operation. The tonsils were therefore destroyed by the application of an escharotic (London paste). Dr. Moore also exhibited some instruments for oesophagoscopy and bronchoscopy—namely, an improved adjustable handle for his foreign body forceps; a new pattern cutting shears for cutting up tooth plates; and a forceps for removing growths from the trachea.

Dr. WILLIAM HILL showed a rare case of multiple polyp (oedematous fibromata) of the middle third of the oesophagus, causing stenosis of the gullet. Applications of radium were of no benefit. Portions of the growth were removed by oesophagoscopy and forceps, and shown to resemble the structure of ordinary nasal mucous polyp. Dr. Hill showed also a fish bone which had perforated the inferior constrictor and caused fatal posterior mediastinal abscess. Mr. BELL TAWSE exhibited a case of supernumerary

nostril and cavity in a child aged 16 months. The cavity led up to the root of the nose.

Sir STCLAIR THOMSON exhibited a case of spontaneous cicatrization of a tuberculous larynx in a lady, aged 42, who developed tuberculosis of the lungs seven years previously. Under "silence" treatment alone the larynx had completely healed, though tubercle bacilli still existed in the expectorated sputum from the lungs.

Dr. DUNDAS GRANT showed a case of congenital occlusion of one choana causing nasal obstruction. The obstruction was mainly osseous, and was removed by operation. He exhibited also a specimen of a kinked and obstructed oesophagus, caused by an oesophageal growth.

Dr. G. A. CARTER, with Sir STCLAIR THOMSON and Mr. HOPK, showed a case of laryngo-fissure for intrinsic cancer of the larynx in a female aged 33.

Various other cases and specimens were shown and discussed.

Reviews.

G.H.Q. (MONTREUIL-SUR-MER).

THE two broad bands, red and blue, on the wrapper of *G.H.Q.*,¹ by G.S.O., will recall to many certain moments in France when an obstructed road suddenly cleared itself, for "a G.H.Q. car is so clearly recognizable" by the bands on the wind screen and on the arms of the occupants. Incidentally it may be said that the British army was not peculiar in its addiction to initials, though it may have carried it rather far. To the French their head quarters were known as G.Q.G., and the Germans contracted the name of their own to O.H.L.

G.S.O. tells us no more of himself than that he is a gunner, but we guess that in this book he does not commences author. Like most of the not very senior members of G.H.Q., he had been "crooked," and while under repair on several occasions had formed a very high opinion of the nursing organization. "'Sister' is of many different grades of skill, but of an almost unvarying degree of devotion." He is so gallant as to assert that the design attributed to matrons of assigning all the pretty nurses to sick sisters' wards was frustrated because the supply of pretty sisters was too great to allow of their all being so disposed of. He pays a generous tribute to the medical corps, and shows that he takes a pride in the success of that branch of his service. Moreover, for all his genial bantering style he can see the reason, or one chief reason:—

The fight against mustard gas in 1918 was another fine achievement of the medical services. But this subject of the medicine of the war calls for a volume to itself. Let me only add here that the successful medical results won in this war were largely due to the fact that—contrary to the system of other wars—the doctor had a real influence and power at G.H.Q. In his own department he was supreme. So were solved successfully the vast medical problems which the Great War presented. The greatest armies known to history grappled in a continuous and furious struggle, not for a day or a night or a week, but for months. The wounds caused by hand grenades and high explosive shells were often of terrible extent. The battlefield to a depth of five miles was under constant shell fire, and transport of the wounded for that distance was therefore always under fire, and roads were torn up almost as soon as made. Conditions of infection were extraordinarily favourable. Traffic regulation had to overcome the most serious obstacles, since railways, roads, and tracks had to provide for the constant reinforcements, for the frequent passage to and fro of relieving Divisions, for food and water for men and horses, and also for ammunition unprecedented in quantity.

In describing the multifarious work of G.H.Q. and the necessity to be prepared for either fortune of war, G.S.O. utters a dictum on casualty clearing stations, dealing rather summarily with a matter which excited much difference of opinion at the time and will, no doubt, come in for much discussion in the future. As an example of the way in which, during trench war, units allowed themselves to become immobile, we are told that "many casualty clearing stations had burdened themselves with surgical stores and equipment which should be reserved for stationary hospitals. Thus burdened they were tempted to evacuate too soon." There may be some truth in this, but we do not believe it to be the whole truth.

The author is by no means disposed to make little of

the work and achievements of G.H.Q.; the work meant long hours in offices, and afforded relatively few occasions for getting near the actual fighting. Supply and transport was a huge business, and G.S.O. is enthusiastic in praise of Lieut. General Sir Travers Clarke—he had started the war as Major—appointed Q.M.G. by Lord Haig at the end of 1917. But he knows, and very frankly says, that it was the humour, the good humour and the adaptability, as well as the courage and constancy, of the men of the new armies that made the achievements possible. G.S.O. set out to write not a history of the war nor a contribution to any of the numerous war controversies, but a sketch of life at G.H.Q. as it appeared to a staff officer. But the eyes of G.H.Q. on the hill of Montreuil saw much, and what the eye did not see the ear heard; thus the book gives a vivid general impression of the course of events. As a rule the style is light, and designed to produce an impression rather than a story of events, but the last four chapters, dealing with the spring, summer, and autumn of 1918, are in a more serious tone. They set out the anxieties of the spring of 1918, and relate the painful decisions which had to be taken to meet the possibility of the Germans breaking through to the coast.

ANAESTHETICS.

DR. STUART ROSS, in his *Handbook of Anaesthetics*,² has aimed at giving a "condensed account of modern anaesthetic views and practice." He has succeeded well in his task, particularly with regard to the first portion of it. The four opening chapters are devoted to the physiology of anaesthesia, of shock, and of asphyxia, and to a general account of methods of anaesthetizing. They are clearly written, and, although of necessity in so compressed a work several important matters escape mention, yet all those of greatest practical import are dealt with, and the student is offered an admirable foundation of reason for the principles on which he is to administer anaesthetics. Dr. Ross has drawn upon his experience to give in some detail the treatment of shock among the casualties of war. In describing the origin of mechanical asphyxia he does not mention one of the commonest causes, namely, swelling from congestion of the tongue and fauces. This very often accompanies the inhalation of ether as well as of nitrous oxide. He makes clear the different effects of excessive CO₂ and of oxygen starvation, and draws from them the proper directions for practical treatment of asphyxial states. He points out a truth, often not appreciated, which is that laryngeal stridor may be a reflex effect, and persist even in an anaesthesia so deep that the vital medullary centres are in peril; consequently it is futile to attempt to remove the symptoms by an increased supply of anaesthetic. In the recommendations for the preparation of the patient is included an enema at 6 a.m., when the operation is to be at 10. Many surgeons nowadays believe that to awake a patient early in the morning for the reception of a rectal injection is not calculated to help him to reach the operating table in the best possible frame of mind or body. It is a traditional practice to be generally discouraged. Dr. Ross approves of routine preliminary use of small doses of morphine and atropine, except in young children. For the subjects of severe shock and of sepsis he recommends nitrous oxide and oxygen as the anaesthetic of choice, and gives a good description of recently devised apparatus and how to use it. Otherwise his choice of a routine anaesthetic appears to be open ether assisted by intermittent and most guarded additions of C.E. mixture. He attains anaesthesia with about 2 oz. of ether and 2 drachms of the mixture, afterwards using about an ounce of ether every ten minutes and no mixture. He finds a considerable field for the use of ethyl chloride, which he prefers to give by the "vapour" method, and he approves its use in conjunction with gas in dental cases. The book is one which we warmly recommend to all students.

It is only three years since the first edition of Dr. FLAGG's interesting *Art of Anaesthesia*³ appeared, and no great difference or extension can be expected or is to be

¹ *Handbook of Anaesthetics*. By J. Stuart Ross, M.B., B.Sc., F.R.O.S. Ed. Edinburgh: E. and S. Livingstone, 1919. (Cr. 8vo, pp. xii + 214; 54 figures, 7s. 6d. net.)

² *The Art of Anaesthesia*. By P. J. Flagg, M.D. Second edition, revised. Philadelphia and London: J. B. Lippincott Co., 1913. (Med. 8vo, pp. xviii + 367; 136 figures, 18s. net.)

³ *G.H.Q. (Montreuil-sur-Mer)*. By "G.S.O." London: Philip Allan and Co., 1920. (Med. 8vo, pp. 305; 32 illustrations; 1 map. 20s. net.)

found in this issue. A chapter has been added on the selection of the anaesthetic, and here Dr. Flagg has some very pertinent observations to make regarding the relative importance of agreeableness and efficiency in the anaesthetic chosen. He shows how an anaesthetic, safe in itself, becomes unsafe if it fails to facilitate, or even renders more difficult, the manipulations of the surgeon. These are words that need attention just now when there is a tendency to require of gas and oxygen alone more than they are able to provide. Dr. Flagg looks on ether as the anaesthetic of choice, regardless of sex or age, and has a high appreciation of the anaesthetometer. This instrument, he says, has demonstrated the important fact that when good anaesthesia is established, the percentage of ether needed to maintain anaesthesia is about the same in all cases. The author considers that a "gas-oxygen induction, an ether maintenance, and a gas-oxygen recovery is an ideal anaesthetic for all adult cases." In considering special operations, however, he finds of course many to which this method is inapplicable. The chapter on the point of view of the patient might be read with advantage by every hospital surgeon and anaesthetist. At the same time we confidently believe that the picture drawn of the patient's anticipatory troubles is not commonly true either in America or in Great Britain. The book enjoys a beautifully clear and large print, which adds to its many attractive features.

CAUSE AND TREATMENT OF OBESITY.

THE second edition of Dr. HECKEL'S large book⁴ on the radical cure of fatness and obesity is the work of a physician who has devoted many years to the study and treatment of fat people. The earlier chapters give an account of the etiology, symptoms, pathogenesis, course, diagnosis, and prognosis of the condition. The last quarter of the volume is devoted to its treatment; here the author sets up a high standard, demanding that the patient shall not only be reduced to a proper weight and degree of fatness, but also enabled to maintain that state; in addition, he must be relieved of the various troubles—dyspnoea, indigestion, glycosuria, or what not—that so frequently accompany obesity.

Dr. Heckel considers that obesity is due to over-eating in three-quarters of the cases; in the remainder he incriminates such things as hereditary predisposition, the neurotic constitution, disturbances of the endocrine glands, indigestion, and pulmonary tuberculosis. Obesity may be maintained, especially in females, on as low a diet as one with a heat value no more than 1,200 calories—in place of, say, 3,000. Each case must be studied and the treatment must be individualized; the routine of daily life, the diet, the number of meals allowed, the amount and nature of the exercise taken, the hours of repose and work, must all be looked into and regulated. Success may be looked for in almost all male cases and in 95 per cent. of the female. Dr. Heckel's own contribution to the treatment of undue fatness appears to consist in "methodical morphogenic myotherapy," the extensive employment of exercises designed to bring all the muscles into action, with particular attention to the breathing exercises, or respiratory gymnastics.

The book is still somewhat lengthy, though not so voluminous as the first edition, and contains a great deal of information and many suggestions that should be of great service to those who have to treat obesity. A special word of praise may be given to the publishers for their success in producing so large and well printed a volume nowadays at the price of 15 francs.

ENCYCLOPAEDIA MEDICA.

THE sixth volume of the second edition of the *Encyclopaedia Medica*, under the editorship of Dr. J. W. BALLANTYNE,⁵ contains thirty principal articles, of which five are completely new, and a number of short notes giving condensed information or cross references. The revision of the articles has been undertaken either by the original writers

or by others, and in the main they show obvious evidence of change; this is particularly so in Professor J. Arthur Thomson's article on heredity. On the other hand, the account of that extremely important disease, influenza, by no means exhausts the additions to our knowledge resulting from the pandemic of 1918-19; but in these days of slow printing and delayed publication it is quite possible that articles may have been long out of the author's hands when they appear before the public.

To turn to the new articles, Dr. S. A. K. Wilson gives a clear and masterly review of hysteria, with an able and broad-minded discussion of the various physiological and psychological theories as to the nature of the disease. Dr. W. D. Scott's article on immunity contains an account of anaphylaxis including serum sickness. Dr. W. Armstrong, Medical Director of the Buxton and Bath Dietetic Clinics, who wrote on hydrotherapy in the first edition of this work, now entitles his article on the therapeutic uses and effects of water, hydrology. In his elaborate and well illustrated account of hermaphroditism Dr. Berry Hart advises that children of doubtful sex and *sex-ensemble* should be brought up as boys, as the chances are ten to one that they are atypical male *sex-ensemble* cases, and the risk of sexual mischief and scandal afterwards is thus minimized. The article on housing by Dr. A. M. Williamson, Medical Officer of Health for Edinburgh, deals with the subject under the three heads of the extent, effect, and cure of the housing evil. His observations in Edinburgh show that the death rate increases almost precisely in proportion with the increase in the number of the smaller dwellings.

The editor may be heartily congratulated on this instalment of his arduous undertaking.

NOTES ON BOOKS.

Pocket Notes on Nerves,⁶ by Dr. T. M. MARTIN, is a little book containing a concise summary of neurology, written to benefit medical men who may be confronted with cases of nervous disease and are not neurologists. It is full of facts, but free from the explanations needed to co-ordinate them into a mass of useful knowledge.

Animal Parasites and Human Disease, by ASA C. CHANDLER, is a compilation.⁷ In the preface the author justifies the production of such works and expresses the belief that "no less mental and physical energy, if not perhaps even more, is necessary for efficient mere compilation than for the addition of new facts to scientific knowledge, and the value to civilization, which must be the ultimate criterion by which all scientific work is judged, must be equally as great, if not greater." This is a novel view certainly, but the compiler has forgotten to add that if he has not first-hand knowledge of the subject himself he is almost bound to perpetuate any errors in the originals, and is very likely to add more of his own. This risk is exemplified in the work before us. On page 298 it is stated that Manson first discovered the embryos of *F. banerofli* in human blood, while working on tropical diseases in India; Lewis discovered the embryos and Manson has never worked on tropical diseases in India. On page 133 in the description of Fig. 38 a contractile (*sic*) vacuole is described; one of the chief characteristics of the genus *Entamoeba* is that a contractile vacuole is absent. Again, on page 298 the following statement is made: "Recently in an examination of 949 natives from the Congo-Cameron (*sic*) country of Africa, about 74 per cent. of the men, 79 per cent. of the women and 33 per cent. of the children were found to be filariated." It is not stated with what species of filaria these people were infected, so that the information is valueless. Unfortunately there are other errors scattered through the book, and it cannot therefore be recommended as a source of accurate information to any student of the subject.

⁶ *Pocket Notes on Nerves*. By T. Muirhead Martin, M.D., C.M., Edin. Edinburgh: William Bryce, 1919. (Fcap. 8vo, pp. 58. 2s. net.)

⁷ *Animal Parasites and Human Disease*. By Asa C. Chandler, Instructor in Zoology, Oregon Agricultural College. New York: John Wiley and Sons. London: Chapman and Hall, Limited. 1918. (Med. 8vo, pp. xiii+570; 254 figures. 21s. net.)

THE *Calendar of Durham University College of Medicine for 1919-1920* (Newcastle-upon-Tyne: Andrew Reid and Co., Ltd.) contains all the information required by students of medicine at that university, and gives a brief history of the college, which was founded in the year 1832.

⁴ *Grandes et Petites Obésités: Cure Radicale*. By Dr. Francis Heckel. Second edition. Paris: Masson et Cie. 1920. (Roy. 8vo, pp. ii+536; 60 figures, 12 plates. Fr. 15 net.)

⁵ *Encyclopaedia Medica*. Vol. vi, Heat Fever to Intertigo. Second edition. Under the general editorship of J. W. Ballantyne, M.D., C.M., F.R.C.P.E. Edinburgh and London: W. Green and Son. 1919. (Roy. 8vo, pp. 658; 5 plates (4 coloured), 70 figures. 16s.)

SATURDAY, JANUARY 24TH, 1920.

THE ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

MORE than ever the promotion of medical research is now the subject of discussion from many points of view, and, what is more to the purpose, of active organization. The Medical Research Committee, the success of which during the war did so much, by bringing home to the man in the street the great economic value of expert advice, has stimulated public interest, but the notes and articles in the general press have been concerned mainly with one side of the subject—the laboratory aspect of research, or the application to the art of medicine of the methods essential to the allied sciences. There is another, though more difficult and therefore at first sight less attractive, method of research which has been advocated by Sir James Mackenzie, especially in his remarkable book, *The Future of Medicine*,¹ and now more fully set forth, with conciliatory moderation, in his address on Clinical Research, delivered at the opening of the Institute for Clinical Research founded by him at St. Andrews, and published at page 105 of this issue.

Sir James Mackenzie points out that the methods useful in physiology, chemistry, and bacteriology are not all-sufficient for the investigation of the wider problems of clinical medicine. This proposition may come as rather a new light to men who have been brought up in the tradition that the highest form of research is that modelled on laboratory lines, with instruments of precision to confirm or correct the impressions and the erudite senses of the old-time bedside observer. Sir James Mackenzie originated the modern development of cardiology largely through such painstaking instrumental investigation of the circulation; great weight, therefore, must attach to his opinion that, valuable as are the results obtained by laboratory aid, there are other and extensive fields for investigation untouched thereby and awaiting exploration by methods as yet either unrecognized or improperly applied. He does well to insist on the importance of clinical research; this, though not a new doctrine, urgently needs treatment on fresh lines. The reason why the study of symptoms has not been more successful in the past has been the want of essential guiding principles; thus, the prognosis of heart disease, based on auscultation and the presence of murmurs, remained stationary for years and failed, as did the recent attempt to grade men into classes for war work. On the other hand, Lord Lister spent years in establishing the principles necessary to enable him to evolve the proper treatment of wounds, and a similar apprenticeship was served in the labour that led to the discovery of auricular fibrillation. With a guide so experienced and possessing so firm a grasp of the true scientific method to help them to establish the essential principles, the general practitioners attached to the St. Andrews Institute have the most enviable opportunities for work, the promise of which it seems difficult to estimate too highly.

In order to prevent disease it is essential to understand the nature and significance of its earliest manifestations and also of the conditions, such as deficient

nutrition and injurious occupation, that impair the resistance of the body and render it vulnerable to the first inroads of disease. The earliest symptoms are often merely a consciousness that something is amiss or that the sense of well-being is absent; as such a complaint is vague it does not, unless physical signs are present, excite any great interest, largely because it is so difficult to make any further way in the inquiry. Sir James Mackenzie warns us that it is only after a long training that the art of asking the appropriate questions is attained, and that much experience is necessary to interpret the answers correctly. Opportunity for clinical research into the disposing and early stages of disease is seldom available in hospitals, but it comes within the scope of the general practitioner and is the chief object of the St. Andrews Institute.

The institute, we understand, has started well. Sir James Mackenzie himself is the director, and among his fellow workers are all the general practitioners in the town, with one or two others who had retired from practice. It already has a chemist on its staff, and it is intended to appoint a bacteriologist. The professors in anatomy and physiology in the University of St. Andrews give their help, and so also does the assistant professor of logic; this is, we believe, the first time that the logician has been called in to help in the work of a medical institute. It is perhaps not surprising that this should have happened first in Scotland, and we make no doubt that his presence and advice will be of the highest value. Arrangements have been made with the doctors on the insurance panel under which their patients attend at the institute at regular hours. Each doctor will have a separate room and all the facilities of the institute at his disposal. The experiment in this early stage has fully established the fact that the general practitioner, given the facilities, will become a potent factor in research. But although it is only natural to anticipate results rapidly when an institution is started under such good auspices, it is well to recall the old proverb that Rome was not a one-day's growth, and that great advances take time, much patient investigation, and assistants who have gone through a long training.

CHRONIC DIVERTICULITIS.

THE discussion on diverticulitis at the Royal Society of Medicine, the report of which is concluded in this issue, will have served a useful purpose if it calls more general attention to the diagnosis of a condition which often goes unrecognized. We say "diagnosis" advisedly—first, because in the present state of knowledge there are no very clear ideas as to its prevention, and secondly, because when once developed the only treatment seems to be by operation. That the subject excited much interest among those within reach of the meeting is shown by the large audience, and we make no doubt the report will have many readers. Although the condition to which the rather cumbersome term "diverticulitis" is applied has been recognized for some years by surgeons concerned with operations on the abdomen, it is probably true that to the general body of the profession it is more or less a new disease, but in future years it may become as familiar to students of medicine as appendicitis. Whether the term will be retained, or whether, following the advice of Professor Rutherford Morison, it will be discarded in favour of "sacculitis," remains to be seen. There are several reasons for agreeing with Professor Rutherford Morison in his preference for the latter term. Diverticulitis suggests

¹ Reviewed in this JOURNAL on August 15th, 1919, p. 201.

an inflammatory condition of a congenital sac. The acquired sacculations seen in the large bowel in diverticulitis are entirely different in their pathology from such congenital abnormalities as Meckel's diverticulum, and demand the employment of a term less liable to confusion than that which is at present current. The word "sacculitis" is not really good, but is perhaps equally descriptive of the condition present, and is not more open to objection on the score of euphony.

Acquired diverticula may occur in any part of the intestinal tract from the oesophagus to the anus, but we may follow the example of Dr. Maxwell Telling of Leeds, who introduced the discussion, and limit the applicability of the term "diverticulitis" to diverticula of the lower bowel.* Clinically they are probably of most importance when they occur at the end of the colon or in the sigmoid. The origin of the diverticula is no doubt in some instances—probably a small minority—a slight congenital abnormality or a congenital predisposition to their formation, but the general opinion seems to be that as a rule they are due to increased pressure within the bowel. The fact that they are believed to occur more frequently in the lower part of the sigmoid than elsewhere is held to support the view that they are due to faecal stagnation, since it is greatest at this point. Constipation is a frequent antecedent, but it may be absent, and in some few cases there is looseness of the bowels. It is thought possible that gas is more important than faeces in their production, but impaction of the latter is probably the commonest cause of the inflammation which gives rise to the final clinical symptoms calling for operation. An argument against the congenital origin of the diverticula is that the condition rarely occurs in early life; its prevalence reaches a maximum at ages from 60 to 75. Once a diverticulum has begun it tends to undergo progressive enlargement, becoming a cyst with a narrow neck, so that faecal matter is retained. The sac is very imperfectly drained, a concretion may form, and perforation supervene; but probably more often inflammation ensues in and around the wall of the sac. When several diverticula are produced near together a large mass may form, which will produce mechanical obstruction, and to such cases the term "peridiverticulitis" is sometimes applied, though the distinction does not seem to be of much clinical importance. The clinical picture presented varies very much. There may be a sudden outbreak of general peritonitis, determined probably by perforation, or there may be inflammatory trouble more or less acute within the abdomen, usually within the left lower quadrant. The cases most often mistaken for carcinoma—and most surgeons who recognize the condition admit that they have fallen into this error—are those in which obstruction is the first symptom recognized by the patient. The usual sequence is the occurrence of partial or subacute attacks of obstruction, ending in a condition calling urgently for surgical interference. Sir Berkeley Moynihan, in a paper read to the Clinical Society of London at the end of 1906, observed that while the mimicry of malignant disease in the caecum and ascending colon by a hyperplastic tuberculous process was well known, it was not so generally recognized that inflammatory tumours presenting all the clinical appearances of cancer might occur in any part of the large intestine, and he pointed out that many of them were probably due to the presence of acquired diverticula.

One result of the recent discussion will be to con-

vince the profession that the condition to which the term diverticulitis or chronic diverticulitis is applied is far commoner than has hitherto been generally supposed. As Sir John Bland-Sutton said, many patients have in the past been submitted to colotomy and colostomy, under the belief that they were suffering from cancer of the colon, but subsequently the lump has disappeared, the patient has survived for many years, and at death no evidence of tumour has been found. In a wide-embracing sentence he asserted that the condition, acute or chronic, mimicked such lesions as acute and chronic appendicitis, cholecystitis, tumours of the stomach, subdiaphragmatic abscess, perigastric abscess, splenic abscess, tubal infections, ovarian abscess, cancer of the uterus, and infected uterine fibroids; but he added that the extraordinary feature of sacculitis (or pericolitis) is its mimicry of cancer of the colon. Mr. Hamilton Drummond brought evidence as to the frequency of the condition when he said that he had found it in 22 out of 500 necropsies made at the Royal Victoria Infirmary, Newcastle-on-Tyne. While appendicitis may remain the commonest intestinal lesion that demands surgical intervention during the first half of life, it seems probable—again to quote Sir John Bland-Sutton—that diverticulitis is a newly discovered "bane of elders." It may be expected that once its symptoms become recognized and it ceases to be regarded as a clinical curiosity, the number of cases in which the propriety of surgical interference will have to be considered will be multiplied and the question as to when operative interference is indicated will become extremely important. Resection of the bowel is an operation that cannot be lightly undertaken, especially in the case of elderly patients. Its risks, even with the best of techniques, must always remain greater than the risks of appendicectomy. The arguments for and against surgical interference will need careful weighing before the decision is made. Diverticulitis is of great interest as a clinical entity, but we look forward with still greater interest to future studies of its pathology, diagnosis, and treatment. Much patient work will be required, and a vast amount of clinical data must be collected before its true position amongst the diseases, and its appropriate treatment, both medical and surgical, has been established.

INSURANCE MEDICAL REMUNERATION.

THE recent history of the capitation fee may be said to begin with the last Annual Conference of Local Medical and Panel Committees, arranged by the British Medical Association. On November 27th the representatives declared with one voice that the proposed new Medical Benefit Regulations could only be accepted if the remuneration for service under them was upon a satisfactory basis. With the same unanimity the Conference next resolved to maintain the opinion that 13s. 6d. was the lowest capitation fee that could properly be accepted for an effective service.

These decisions having been taken the question arose as to what should be done if, as seemed not improbable, the Government would not grant 13s. 6d. In our school-days the conundrum used to be put: "What will happen when an irresistible force meets an immovable object?" Nowadays every schoolboy knows the answer: "They will submit it to arbitration." It was certain, therefore, that in the Panel Conference someone would state the case for arbitration. The representative of Hertfordshire moved

* See his very full paper in the *British Journal of Surgery*, 1917, p. 468.

"that in the event of the Government offer being deemed inadequate the Insurance Acts Committee be authorized to ask for an independent arbitration board to fix the capitation fee." Representatives of Hampshire, Durham, Lancashire, and Warwickshire spoke in support of this motion; Southampton and Kent wholly rejected the idea; while one or two cautious voices from London were raised, not against arbitration, but against tying the Committee down to it beforehand. The Chairman was asked whether the figure named by arbitrators would be binding on both parties; he replied quite plainly that it was understood that all persons who went to arbitration meant to accept the award. The outcome of this debate was a large majority in favour of authorizing the executive body of the Conference to ask for arbitration should the Government offer be deemed inadequate. The number of representatives present was 147, representing 153 constituencies in Great Britain. The resolution giving this discretionary power rested upon the belief that the case submitted on behalf of the profession was so strong that it had little to fear from arbitration; and, further, that in the event of a deadlock a proposal for arbitration coming from the doctors would strengthen their case in the eyes of the public at large, and more particularly of the hand-working classes. Some who favoured the idea felt, it is true, a doubt as to the wisdom of applying it should the Government offer a sum very little short of the figure demanded by the Conference; but, as we all now know, this situation did not arise; the Government, on January 14th, through the Minister of Health, offered 11s. Thus the deadlock which had been foreseen as possible came about. The Minister said he could offer no more; the Committee answered that they would advise their constituents to reject that sum. Here, then, was the Committee's opportunity to propose the only alternative to a rupture. After long and anxious discussion Dr. Addison sought and obtained the Government's consent to arbitration, and a provisional settlement on that basis was reached. These terms were published in the SUPPLEMENT last week and are repeated in substance this week.

The position at the moment is sufficiently clear, though what will come of it is quite another matter. There is to be an independent board of arbitrators, to fix the capitation fee; its award will apply as from April 1st, 1920. Meanwhile for the first quarter of this year the rate is 11s. per annum. It must be understood that whatever capitation fee is fixed by the arbitrators it will not touch the special mileage fund of £300,000 for England and Wales, granted in order to compensate for the greater work and outlay of the rural practitioners. The new mileage grant contrasts favourably with the £34,000 allocated for this purpose before the war, and it should do much to stem the medical depletion of remote and sparsely peopled areas, and thus prove a gain to the community as well as to the country doctors themselves. It seems obvious that the proper distribution of this grant will need close thought and the supply of accurate information from the different areas. Over and above the arbitrators' award there will be throughout the country a uniform capitation fee of 2s. a year for those doctors who supply drugs and appliances.

Thus, in brief outline, the matter stands to-day. It remains, perhaps, to add a few words on the temper in which these difficult negotiations have been carried out, and on the criticisms that are sure to be brought against those who are acting on behalf of the insurance practitioners. With regard to the first, we

would only remark that good manners still count in the conduct of affairs, both great and small, and that all history goes to prove that firm statesmanship best gains its ends in an atmosphere of civility. Since the medical profession has always put the public good before its own interests, nothing is lost by behaviour that earns public respect and goodwill, even when the controversy seems to turn solely upon a question of cash. As for the critics, these are of two sorts. The honest critic does service to his generation; it is right that he should always have a hearing, most of all when what he says is disagreeable. There are, besides, those who "dip their pens in faction"; they would be amusing were it not for the mischief they may do at critical times; their weapon is the lie that is half a truth. To them may be applied the dictum of a great Englishman (without laying too much stress on the adjective he uses): "A fly, Sir," said Dr. Samuel Johnson to Sir Joshua Reynolds, "may sting a stately horse and make him wince; but one is but an insect, and the other is a horse still."

THE LATE SIR WILLIAM OSLER.

SIR NORMAN MOORE, president of the Royal College of Physicians, who had intended to deliver an eulogium on Sir William Osler at the meeting of the Section of the History of Medicine of the Royal Society of Medicine on January 14th, was prevented by indisposition. Sir D'Arcy Power, the president of the Section, in moving a vote of condolence with Lady Osler, spoke of the large part Sir William Osler had taken in the foundation of the Section, and the interest he had throughout maintained in its work. He was its first president; he had stimulated the members to original research in the history of medicine and had established the precedent of inviting distinguished authorities on special subjects to give lectures to it. Of Osler's personal qualities it was very difficult to speak without emotion, for he was a personal friend of all members. The vote of condolence was seconded by Dr. Raymond Crawford, a former president, who said that Sir William Osler was a man the like of whom probably this generation would never see again. As a consultant he brought to the bedside a huge fund of knowledge and experience; as an administrator he showed no disposition to insist on getting his own way, because he was unwilling to hurt the feelings of any man with whom he came in contact. The papers he contributed to the section had always a peculiar charm, a biographical flavour, revealing a man able to love not only his fellow men just round about him, but mankind as a whole; his interest in medical history was always in persons rather than in principles. In general literature the variety and scope of his knowledge was great. The catholicity of his affection for the humanities was the counterpart of his affection for mankind. It was as though he extended his charity from men to things. This was the reason why the sum total of his interest was so wide. But there was more than this: the real man who was mourned was a man of great loving-kindness; it was impossible to be in his company without feeling the better for it, and without feeling all good fertilized and fructified by his presence. The lesson from his life was that when the qualities of the heart and of the head were balanced in the scales it was the qualities of the heart which weighed heavier in the sight of one's fellow men. The vote of condolence was passed by the members standing.

THE RESEARCH DEFENCE SOCIETY.

THE Research Defence Society has this month attained its twelfth year. It set out in 1908 to drive antivivisection from its strongholds; to make known the value and the necessity of experiments on animals, the restrictions imposed on them in this country under the

Act of 1876, the nature and the purposes of the experiments which are being made, and the discoveries which have come by help of the experimental method; and to bring about a better understanding between the few who made these experiments and the many who profit by them. Its operations have been attended by a large measure of success, but it is not yet time for it to dissolve. The agitation raised by thoughtless opponents of experimental medicine is scotched, but not killed. The cause of the Society has been aided much by the great demonstration the war afforded of the efficacy of methods arising out of research and experiment, and in particular by the results of antityphoid vaccination. Very much of the success of the Society is due to the devoted work of Mr. Stephen Paget, its honorary secretary, who in his last quarterly report points out that among the fallacies of antivivisection is the assertion that experimental bacteriology and the present methods of protective treatment tend to make doctors forgetful of the value of "ordinary sanitation." No fallacy, he says, could be much more absurd, and the war gave it the lie direct. Among all the many officers of the Army Medical Service and the Indian Medical Service who organized and headed a great sanitary work, there was not one who ever doubted for a moment the importance of bacteriology and the value of the protective treatments. "To all of them bacteriology and sanitation were what a man's two hands are in daily life: he uses now one, now the other, now both at once; and each of them belongs to the other, all the time." In a reference to the death of Sir William Osler it is said that his interest in the welfare of the Society was memorable. He was one of its vice-presidents and was president of the Oxford Branch; his evidence before the Royal Commission ought to be included in any complete edition of his works, as a fine example of his wonderful power of teaching. The report also contains a reference to the death of Mr. C. Louis Taylor, for many years Assistant Editor of the *BRITISH MEDICAL JOURNAL*. The Society, the report states, "loses by his death one of the best and most helpful of all its many friends." The address of the Society is 11, Chandos Street, London, W.1. Captain Walter E. Elliot, M.C., M.B., Ch.B., who sits in the House of Commons as the representative of Lanark, has recently become honorary assistant secretary.

THE BUREAU OF TROPICAL DISEASES.

THE office and library of the Tropical Diseases Bureau have been removed to the new building of the London School of Tropical Medicine, Endsleigh Gardens, Euston Square, N.W.1. The building in its upper stories provides wards for patients and in the lower laboratories for the various departments; by attracting into immediate relation with it a library and an organization for the dissemination of information with regard to tropical diseases, the School is fulfilling one of its purposes, which is to serve as a centre for graduate study and for research. The chairman of the Bureau is the Right Hon. Sir J. West Ridgeway, G.C.B., who is chairman also of the Advisory Committee of the Tropical Diseases Research Fund, through which and in other ways the Colonial Office gives its support to the School. The Bureau publishes a *Tropical Diseases Bulletin* and also a *Tropical Veterinary Bulletin*. The last issue of the former is a sanitation number, and contains a series of notes on the prevention of disease in the tropics. In a section dealing with plague attention is called to some observations made by Dr. William Marshall Philip in the report of the Public Health Department, Colombo, for 1918. It was there stated that the indiscriminate setting of baits for rats was stopped, as it was thought that the poisoning of rats in occupied houses and the consequent liberation of their fleas there was a probable source of danger to the occupants. It was therefore decided to restrict the setting of poisoned

baits to empty houses, and at the same time to fumigate and fill up the rat holes. The Editor of the *Bulletin* points out that this caution is needed. Any persistent interference with the rat population sufficient to make a real impression upon their numbers—for instance, by the combination of poisoning, trapping, and fumigation of their burrows—will induce emigration to the next available food-providing area. A sketch is given of an organized campaign for dealing with rats over a considerable area. It is pointed out, further, that the bug forms an inducement to the cockroach to enter habitations. The rat finds the cockroach a delectable morsel, and it is therefore desirable to get rid of the material on which the cockroach feeds, so that the rat may not find so much inducement to enter the house to feed on the cockroach. Other sections of the report deal with sanitary works and vital statistics. In this last section it is noted that the statistics of the epidemic of influenza in India in 1918 support the opinion that Indians are less resistant than Europeans. Amongst British troops in India the attack rate was 218.2 per mille; the mortality rate 8.96, and for pneumonia 0.65. In Indian troops the attack rate was 135.6 with a mortality of 15.21, and for pneumonia 6.48.

TAR CANCER AND CHROME ULCERATION.

THE new order of the Home Office, published in the *JOURNAL* of December 27th, 1919, p. 852, requiring notification in cases of epithelioma due to tar and its products, and in cases of chrome ulceration, demands a precise knowledge of the clinical manifestations of these conditions. It is well known that workers in tar are liable to several forms of cutaneous eruption, such as "acne," warty growths, ulceration, and finally carcinoma. Notification, however, is only ordered where malignancy has occurred; but it is precisely in deciding for or against this condition that difficulty will be experienced. The criteria leading to a positive conclusion are briefly these: First, healing does not occur even where remedies—including rest—suitable for simple conditions have been employed; secondly, in epithelioma the edges present a characteristic hardness; thirdly, indisputable evidence is afforded by microscopic examination of a small portion of the edge of the growth. It should be noted that lymphatic glandular enlargement is not an invariable accompaniment of skin cancer, and further, that even where such enlargement exists it is not necessarily metastatic, for secondary coccal infection of the primary lesion can occasion inflammatory adenitis. Similar difficulties do not obtain where ulceration from chrome compounds has arisen, as the order clearly states that notification should follow the occurrence of definite ulceration.

TYPHUS FEVER IN POLAND.

THE prevalence of typhus fever in Poland led to the appointment last August, by the League of Red Cross Societies, of an Inter-Allied Commission, consisting of four epidemiologists—American, British, French, and Italian—Dr. G. S. Buchanau, of the Ministry of Health, being the British representative. The commission visited various parts of Poland during that month and presented a comprehensive report to the League, in which the gravity of the position was indicated.¹ The urgency of effective measures was pointed out and the nature of the work and supplies of material immediately needed to prepare for what was to be expected in the winter. It would seem that the expected has happened, for a dispatch to *The Times* dated Warsaw, January 16th, states that the epidemic, which had diminished, again became severe in December. The rapid spread that appears to have taken place is attributed to refugees and deserters from Russia; it is stated that Bolshevik statistics admit 1,340,000 cases of typhus fever during the six months

¹ *BRITISH MEDICAL JOURNAL*, November 1st, 1919, p. 565.

September, 1918, to March, 1919, and it is asserted that during the later months of 1919 the number of cases was half as high again. Typhus fever is endemic in many parts of Russia; it has frequently extended eastward, and even assuming that the accounts of the disorganization produced by Bolshevik methods are exaggerated, the admissions and boasts of Lenin and his followers are enough to prove that all the factors tending to produce typhus are present—insufficient food and fuel, overcrowding, and civil war. *The Times* correspondent, whose dispatch is evidently a reflection of serious alarm in Warsaw, is urgent that help should speedily be given to Poland to get the epidemic under control. He says that the American Commission on the spot and the British detachment of the Society of Friends are doing valuable work, but that they are too few. This is easy to believe, for the control of a severe and widespread epidemic of typhus requires a large organization, with trained personnel, directed on scientific lines by experts of experience. We gather from a statement by Dr. Buchanan that the commission of which he was a member, believed that the claims of Poland, which had applied to the League of Red Cross Societies for help, would receive immediate attention, and that the League would undertake to concentrate Red Cross energies on countries devastated or likely to be devastated by formidable epidemics. Nothing has since been heard of any action by the League to deal with the problem in Poland, which clearly requires immediate attention, not only in the interests of that much-tried country, but of its neighbours. There are experts in this country who during the war gained special experience of the methods by which typhus fever can be combated; but to send a commission without trained assistants and adequate equipment would be useless, even assuming, as it would no doubt be safe to assume, that the Polish Public Health Department will be anxious to give all facilities.

ST. THOMAS'S HOSPITAL.

THE St. Thomas's Hospital old students' dinner was held on January 14th at the Connaught Rooms, with Sir George Makins, G.C.M.G., President of the Royal College of Surgeons and consulting surgeon to the hospital, in the chair. There was a very large attendance; among those seated beside the chairman were Sir Arthur Stanley, treasurer of the hospital; Dr. Addison, M.P., Minister of Health; Sir Robert Hill, Medical Director-General of the Navy; Sir John Goodwin, Director-General A.M.S.; Sir Cutbert Wallace, Dean of the medical school; Sir Charles Ballance, Sir Seymour Sharkey, Sir Archibald D. Reid, and Sir Robert Morant. The toast of "St. Thomas's Hospital and Medical School" was proposed by the chairman, who gave a sketch of the personalities of the four treasurers who have held office during his long connexion with the institution. He said that the greatest need of the moment was proper accommodation for the out-patient department, but the medical school also needed more room. The governors were willing to find space for a residential club upon the new site on the other side of the Lambeth Palace Road. Sir George Makins, in conclusion, referred to the splendid war record of St. Thomas's Hospital. The roll of honour of past and present students, teachers, nurses, clerks, and employees has been compiled by Mr. Robert S. Hopkins. This shows that nearly 1,200 St. Thomas's men served in uniform during the war; of these, 71 gave their lives. The list of honours received is long and distinguished; the Victoria Cross was won by Dr. G. A. Maling, who was present at the dinner. Sir Arthur Stanley, who responded on behalf of the hospital, declared amidst applause that before the voluntary hospitals were killed they would have a good run for their money. Sir Cutbert Wallace, who was in his happiest vein when replying for the school, made reference to the professorial system now being introduced in London; it would, he said, do much to break down insularity. Dr.

Addison, taking up the treasurer's allusion to the voluntary system, said that the Ministry of Health had no disposition to interfere with voluntary hospitals because they were voluntary. The State might help and receive help from the voluntary hospitals without destroying their machinery and character. His Department, he said, was entitled to look to the great hospitals, which had been leaders in medical affairs for generations, to help it to minister to national needs in no narrow spirit. It need not follow that national assistance given to the medical schools must interfere with or check their progress. In return for aid given in this spirit the State looked with confidence to the medical schools for increased assistance in training medical men for specialist services. In conclusion Dr. Addison spoke of the importance of developing post-graduate instruction, and as one who had long taught anatomy, declared himself a believer in proper pay for research and teaching. A most successful evening came to a close with the toast of the Chairman, received with enthusiasm on the proposal of Mr. Samuel Osborn, F.R.C.S., now Master of the Society of Apothecaries, and once a fellow student.

THE BIOLOGY OF THE LYMPHOCYTE.

BERGEL, who has previously published work on the fat-splitting ferments of lymphocytes, has recently remarked on the fact that these cells increase in numbers in the blood of people who are on an almost pure diet of fat, owing, as he thinks, to the necessity for greater fat-splitting activity in the blood.¹ In the blood of patients suffering from under-feeding a similar lymphocytosis occurs, probably because the reserve fat in the body has to be mobilized. Lymphocytic activity is recognized again in relation with the lesions of diseases in which the causal organisms are rich in fat or lipoids, such as tuberculosis, leprosy, and syphilis, and the cellular activity is regarded as a specific form of reaction towards the lipid-containing organisms. Bergel has recently carried out researches on the effects of the introduction of certain oils and lecithins into the peritoneal cavity in rabbits and guinea-pigs. The resulting cellular exudates were withdrawn at varying intervals and examined microscopically. Up to ten or twelve hours after injection the cells in the exudate were mainly polymorph leucocytes. After twenty-four hours small lymphocytes appeared in considerable numbers and very soon some of these became enlarged and exhibited amoeboid and phagocytic activity and took up minute fat droplets. After thirty-six to forty-eight hours the polymorphonuclears much diminished in number, while the lymphocytes remained numerous. In many of them the protoplasm was considerably increased in amount and the nucleus became excentric and developed indentations or assumed a horseshoe shape. These enlarged cells presented great similarity to the large mononuclears (hyalines) of the normal blood. They showed more and more phagocytic power and their protoplasm became filled with fat globules, so that the nuclei were pressed to the side and flattened out. Often large fat globules were observed in the exudate surrounded by rings of the smaller mononuclear forms; they attacked the fat by thrusting out protoplasmic processes towards it, and absorbing minute fat granules into their bodies. After six or seven days the fat had mostly disappeared from the peritoneal cavity, and the majority of the cells in the exudate were again of the type of small lymphocytes. Bergel has convinced himself, by histological examination of the omental tissues of experimental animals, that the small lymphocytes pass out through the vessel walls by their own active movements and later show amoeboid movement in the peritoneal cavity. He concludes that small lymphocytes are attracted chemotactically by fats and lipoids, and that they exhibit

¹ *Berl. klin. Woch.*, September 29th, 1919, p. 915.

phagocytic activity towards such substances. The observation possesses special significance when it is remembered that all the fats absorbed from the intestine are passed through the lymphatic glands in the mesentery before they reach the thoracic duct and the blood. He believes also that he has proved the existence of a close relation between the small lymphocyte and the large mononuclear or hyaline cells of the blood, as cells may be formed from the former which are indistinguishable from the latter. It may be doubted, however, from his descriptions and illustrations whether the large phagocytic forms which take up fat in the peritoneal cavity are really enlarged small lymphocytes, as he maintains, and not originally large mononuclears. The latter cells are already well known to occur in numbers in inflammatory exudates after the first day or so, and they exhibit phagocytic and amoeboid activities.

MILK FOR CHILDREN AND MOTHERS.

THE Ministry of Health and the Food Controller have issued orders modifying the milk orders of 1918 with reference to the supply of milk for expectant and nursing mothers, and for children under five years of age. The new order relates to milk only, and not to food. The power of the central authority to require local authorities to make arrangements for the supply of milk has been omitted, but local authorities are empowered to supply milk free or at less than cost price not merely in necessitous cases but also where such a supply is necessary because of the retail price of milk in any area. The quantity of milk to be supplied is prescribed by the new order to be one pint and a half daily for children under 18 months, one pint for children between that age and 5 years, and for nursing and expectant mothers "the quantity prescribed by the person certifying." The effect of the order is to empower local authorities to supply milk to expectant and nursing mothers and young children without previously obtaining the consent of the Ministry of Health (as is required by the Maternity and Child Welfare Act, 1918, in respect of distribution carried out under that Act) free or under cost price where some person authorized by the local authority certifies this to be necessary by reason of the retail price of milk in its district. It will be understood that the maternity and child welfare grant distributed by the Ministry of Health is limited to the cost of any food, including milk, distributed to necessitous cases who are certified by the medical officer of the centre or by the medical officer of health to be in need of the food or milk. The expression "milk" in the order is to include any preparation of milk which may be prescribed by the medical officer of health or by the medical officer of a maternity or child welfare centre working in co-operation with the local authority. It will include, therefore, tinned and dried milk; the use of one or the other may often be necessary, though never, we believe, desirable.

THE PRICE OF QUININE.

A WHITE PAPER—Profiteering Act, 1919 (Cmd. 499)—presented to both Houses of Parliament tells a curious story. It purports to give the findings of the Board of Trade on consideration of a report by a committee appointed to investigate the position of prices and supply of quinine sulphate. The document begins by stating that 90 per cent. of the world's supply of cinchona bark of the quality requisite for the production of quinine is obtained from plantations in Java, where the Dutch owners number some 229 and the British 6. The former furnish ten-elevenths of the total Java production. At present only 10 per cent. of the bark requisite for the production is supplied by the Government plantations in British India; it is not sufficient to supply the needs of India itself. The Indian Government is taking steps to extend its cinchona plantations, but it will be five to seven years before bark from that source will be available. At the beginning of the present century there

was a period of alleged over-production, and quinine sulphate was sold on the British market at 7d. an ounce; shortly before the war the price was 1s. an ounce. These prices, it would appear, were not remunerative. In order to secure the industry and standardize prices, combinations first of manufacturers and then of planters were formed, and both finally entrusted their interests to an organization known as the Kina Bureau at Amsterdam. It consisted of three representatives of the planters, three of the quinine manufacturers, and an outside chairman. At one time German interests were paramount, but during the war control passed into the hands of the Dutch, and consent to the appointment of a British representative has not been obtained. In December, 1916, an arrangement was made by Messrs. Howards and Sons, then virtually the only British manufacturers, to place the whole of their output at the disposal of the War Office. A few months later the War Office took possession of all stocks of quinine sulphate in this country, and eventually requisitioned two million ounces. In June, 1918, Messrs. Howards, with the assistance of the War Office, made an agreement with the six British-owned plantations in Java under which they obtained practically the whole of their output for a period of ten years. The agreement provided that prices received by the British planters in Java from Messrs. Howards should not be less than the price they would have received had they renewed an agreement with the Dutch. It follows that if the Kina Bureau alters the price of quinine sulphate the price of the bark to the British planters will be automatically affected. In September, 1918, an agreement, made on the advice of an inter-allied committee with the Dutch manufacturers, secured a sufficiency of cinchona bark and quinine for the allied nations. The price in Java was 1s. 8d. an ounce, and the total cost in this country 1s. 10d. In anticipation of the end of this agreement, a British Quinine Corporation, consisting of fourteen leading firms, was formed for the co-operative purchase of quinine from the Dutch combine. The Corporation made a contract with the Dutch and Java manufacturers providing that no member of the British Corporation should sell quinine sulphate, bisulphate or hydrochloride at a price less than that fixed by the Kina Bureau. While the War Office had control the price of quinine in this country was 2s. 11d. an ounce for large quantities, rising gradually for smaller quantities until it reached 3s. 9d. for a single ounce. On August 26th the War Office Contracts Department sold 840,000 ounces of quinine to the British Quinine Corporation at 2s. 11d. an ounce. The managing director of the corporation had expressed the opinion that as soon as control was removed the price would drop to about 2s. 3d. for sulphate; but as a matter of fact it was raised as from September 2nd last to 3s. 5d. an ounce for large quantities, an immediate increase equivalent to at least 6d. The Kina Bureau had already requested the British Government to accept immediate payment for the whole of the quinine; the amount to be paid amounted to £125,000, although it was impossible that speedy delivery could take place. The effect of the increase in price to 3s. 5d. an ounce from 2s. 11d. an ounce—the price at which the purchase from the War Office Contracts Department had been effected—was to increase the value of the quinine purchased by the corporation by £21,000. The Board of Trade expresses no opinion on the matter, and we will follow its example.

THE management of the Harrogate Baths has appointed an analytical chemist to keep the numerous mineral waters under constant scientific supervision. A pathologist and bacteriologist has also been appointed to the staff.

COLONEL A. L. A. WEBB, C.B., C.M.G., Director-General of the Medical Department of the Ministry of Pensions, and Surgeon Vice-Admiral Sir W. H. Norman, K.C.B., late Medical Director-General, R.N., have been appointed Knights of Grace in the Order of St. John of Jerusalem.

EIGHTY-EIGHTH ANNUAL MEETING
OF THE
British Medical Association,
CAMBRIDGE, 1920.

THE eighty-eighth Annual Meeting of the British Medical Association will be held at Cambridge next summer, under the presidency of Sir Clifford Allbutt, K.C.B., F.R.S., Regius Professor of Physic in the University. The Annual Representative Meeting will begin on Friday, June 25th, and the statutory Annual General Meeting will take place on Tuesday, June 29th. The sectional meetings for scientific and clinical work will be held on June 30th, July 1st, and July 2nd. Saturday, July 3rd, the last day of the Meeting, will be given up to excursions to places of interest.

We print below the second of a series of historical and descriptive notes on Cambridge, which it is hoped will prove of interest to members of the Association. The first article, sketching the origin of the University and town and describing the situation and climate of Cambridge, appeared in our issue of January 3rd, 1920, p. 17. Subsequent articles will deal, *inter alia*, with the history of the medical school and of scientific progress at Cambridge (including an account of the medical school of to-day), and with the antiquities and architectural beauties of Cambridge and district.

DEVELOPMENT
OF THE UNI-
VERSITY.

The primary object of the University was to train men as priests and schoolmasters. Accordingly we find that the chief subjects of study were grammar, logic, theology, and music. The term "grammar" (corrupted sometimes to glamour, gramarye, or glomery) included the art of speaking and writing correctly, of literary composition, of poetry, and of rhetoric, both in English and in Latin. Civil law, especially Roman, appears in the curriculum, but medicine was not officially taught until recent times. Music was an important subject in the training of priests and choristers. It is remarkable that architecture, sculpture, and painting, including the illumination of manuscripts, were not taught, though they were hardly less important to the priesthood than music. These arts were the special function of guilds of handicraft, whose work is much in evidence in the University buildings, and was

much more so before the iconoclasts of the Reformation wantonly destroyed the works of art in the churches and college chapels.

In the earliest times the students and scholars lodged in private houses; but already in the thirteenth century the hostels came into existence. In these the men could live with considerable luxury, doubtless in proportion to the quality and the fees of the particular hostel. "Each hostel was presided over by a Principal elected by the students from their own number."¹

As mentioned in our previous article, the first college was founded in 1281, with the name *Peter House*, for fourteen scholars and a master. The college was intended for the housing of deserving men whose means were insufficient to pay the expenses of a hostel, and only the bare necessities of life were provided, without any luxury whatever. The word "scholar" would now be interpreted as *fellow*, or a man who had passed his first degree and was continuing his studies for the priesthood or other profession.

The second college, Michael House, was founded in 1323, but merged in Trinity College more than two centuries later. The next few colleges were named "Halls" instead of "Houses." The name "College"² became general at a later period, but Trinity Hall has retained its first name to distinguish it from Trinity College of later foundation. From the fourteenth to the sixteenth century many colleges were founded, until at the end of the sixteenth their number amounted to sixteen. Then after a long interval the last college, Downing, was founded in 1800.

Late in the nineteenth century the hostel system was reintroduced with modern modifications. In 1876 a large hostel with the name Cavendish College was built outside the town at the south end, but was too far from the centre of

university life to be successful. A private hostel was opened by the Rev. W. Ayerst in 1884, closed in 1896, and afterwards reopened as a hostel for Roman Catholics. Selwyn College, a large public hostel, was founded in the suburb of Newnham in 1882, and is now a flourishing institution.

The early colleges had no fireplaces, and only a minimum of glass, for the windows were mostly shuttered openings, and other provisions for comfort were similarly deficient. But as time went on, pious benefactors provided their colleges with the means of greater comfort, so that

¹ Atkinson and Clark.

² Latin *collegium*, society of colleagues or companions: from Latin *collega*, a colleague. Skeat's Dictionary.

wealthier students were willing to live in them and to contribute to their maintenance. Inventories show that such well-to-do students substituted glazed window-frames for shutters, made structural alterations in their rooms, and had them painted and adorned with hangings. In the sixteenth century, during the changes accompanying the Reformation, undergraduates were received into the colleges and the hostel system was superseded, several hostels being merged in the colleges. Meanwhile provision was being made for candidates for other professions than those of the priesthood and pedagogy. In 1350 Trinity Hall was founded for scholars of Canon and Civil Law; and when Dr. John Caius refounded Gonville Hall as Gonville and Caius College, he founded three new fellowships, two of which were to be held by medical men.

The Regius Professorships of Civil Law and of Physic were founded in 1540. Among the professorships of later foundation which relate to medicine it must suffice here to mention the following: Chemistry 1702, Anatomy 1707, Botany 1724. But the functions of the professors, so far as medicine was concerned, were almost entirely confined to examining. The medical school, as an institution for study and research, was of much later origin, and its history will be described in a future article.

For further information on the development of the University, readers are recommended to the following works, to which the present writer is much indebted: Atkinson and Clark, *Cambridge Described and Illustrated*, published by Bowes and Bowes, Cambridge; A. F. Leach, *The Schools of Medieval England*, published by Methuen and Co.

England and Wales.

INSTITUTIONS FOR MENTAL DEFICIENTS.

We referred a few weeks ago (December 27th, 1919, p. 853) to that part of the fifth annual report of the Board of Control for 1918 which dealt with the insane. The second part of the report deals with mental deficiency, and contains suggestions for the amendment of the law in order to simplify the methods by which defectives already in work-houses may be detained under the Act, and to provide for "supervision" being included in the methods that may be suggested by the Education Authority in the case of defectives leaving a special school.

It is pointed out that one of the most potent influences that has delayed full application of the provisions of the Act has been financial restriction. The annual Exchequer grant towards the expenses incurred by local authorities is limited to £150,000, and, owing to the war, this grant has up to the present been available only for "urgent" cases; these limitations have now been withdrawn, and the Government has gone further by agreeing to propose the abolition of the limit of £150,000 fixed by the Act. On the strength of this the Board issued a strongly worded circular to local authorities early in 1919 pointing out the grave importance from the point of view of national economy and welfare of dealing speedily with the mass of mental defect which hindered and hampered the progress of the community. Local authorities were urged to recognize the importance of carrying out their duties of ascertainment and registration and to appoint suitably qualified officers to deal systematically and continuously with the investigation.

It appears that fifty-six institutions had been certified before the end of 1918; of these, eleven, with 840 beds, had been established by local authorities, and forty-five, with 5,953 beds, by various philanthropic associations

or religious societies. The Board recognizes that the accommodation so available is varied and useful, but finds that, when regarded as provision to meet the Mental Deficiency Act, falls far short of requirement. It is generally insufficient to meet demands, and is particularly inadequate for dealing properly with low grade cases, where the need is urgent and cannot be left to chance. The Board is in favour of the establishment of a few large institutions containing facilities for dealing with all classes of defect, rather than many small ones more or less specialized in character; it intends to issue suggestions, in the form of plans, to show the general lines upon which the buildings should be provided on economical lines. It will be useful to have these plans, and we can warmly endorse the statement that a more costly provision at a time when there is urgent need for national economy would be contrary to the public interest.

Among the new certificates issued it is interesting to note one granted to a small part of the London Lock Hospital. The report contains the following comment:

Imperfect supervision over weak-minded women has some effect upon the persistence of venereal disease, and the power of control is essential to effective treatment. The mentally defective woman, ill qualified to protect herself from sexual risks, is a frequent sufferer from and conveyer of venereal disease. Such a woman can hardly be expected to appreciate the necessity for treatment or submit herself voluntarily to it; action, therefore, is called for on the ground of common humanity, and in the public interest, when a woman suffering from this disease is liable to be dealt with under the Act.

In institutions for mental defectives, as in those for the insane, the restrictions placed on food supplies during the war resulted in a high sickness rate and a proportionately high mortality rate. Tuberculosis was the most common of all diseases, patients appearing to be more liable to attack and less able to resist than under ordinary conditions. The report on this section of the Board's work is, as in the past, valuable and instructive.

MANCHESTER ROYAL INFIRMARY.

The second course of post-graduate demonstrations on diseases of the ear will be held at the Manchester Royal Infirmary (out-patients' department, Nelson Street entrance) on Fridays at 4.30 p.m., commencing January 30th. The courses were founded by Sir James E. Jones of Rochdale, who has done much for the education of the deaf. Three courses are arranged in each year—in the Michaelmas, Lent, and Summer terms; each consists of ten practical demonstrations, and the number attending is limited to twelve at a time, so that each may have an opportunity of examining the patient himself. One lecture in each course will be descriptive of the aural method in teaching deaf children to speak, and will indicate the importance of commencing this education at an early age. The first course was delivered by Sir William Milligan last year, and the next course will be conducted by Mr. Lindley Sewell, assistant surgical officer, Aural Department, Manchester Royal Infirmary. Further information can be obtained on application to the general superintendent and secretary of the infirmary.

WEST LONDON POST-GRADUATE COLLEGE.

The West London Post-Graduate College has arranged a special set of lectures during the present session. Among those who have consented to take part are Sir Clifford Allbutt, Sir George Savage, Sir Arbutnot Lane, Sir A. Pearce Gould, Professor W. M. Bayliss, F.R.S., Dr. Robert Hutchison, Mr. Hey Groves, and Dr. Risien Russell. Future lectures will be given at 5 p.m., at the Post-Graduate College, West London Hospital, Hammersmith, W.6. The lectures are open, without fee, to medical practitioners. Further particulars as to dates can be obtained on application to the Dean.

THE "BRIDGE OF SIGHS," ST. JOHN'S COLLEGE.

Scotland.

DIAMOND JUBILEE OF A SCOTTISH PRACTITIONER.

A FEW weeks ago the diamond jubilee of Dr. George Banks of Wick, who became L.R.C.S. Edin. in 1858 and L.R.C.P. in 1860, was celebrated by a dinner given to him in Wick

by the Caithness Medical Society. The chair was occupied by Dr. Thomas Wright of Wick, and the toast to the guest was proposed by Dr. MacLennan of Thurso, who described the warm regard in which Dr. Banks was held by his colleagues and spoke of the great services he had rendered to Wick as medical officer of the burgh and port and during his many years' practice in the town. Dr. Banks was at one time surgeon-colonel of the Caithness Volunteer Artillery and holds the Volunteer Decoration. Dr. Banks, in his reply, told of his going to Wick as an assistant to the late Dr. Sinclair, whose practice

extended over a wide area, from Canisbay almost to Lybster, and recalled how when a dispensary was opened at Canisbay the event was celebrated by a hare hunt, in which the Earl of Caithness took part. In acknowledging the toast of his health, given by Dr. Banks, Dr. Wright paid a high tribute to their guest as a physician, a consultant, and a friend.

GENERAL NURSING COUNCIL FOR SCOTLAND.

The Scottish Board of Health is taking steps towards the constitution of the General Nursing Council for Scotland established by the Nursing Registration (Scotland) Act, 1919. On the first constitution of the Council thirteen of the fifteen persons composing the Council are to be appointed by the Scottish Board of Health. Four are to be appointed after consultation with persons and bodies having special knowledge and experience of training schools for nurses, of the work of matrons of hospitals, of general and special nursing services and of general and special medical practice, and nine of the persons to be appointed by the Board of Health must be, or must have been at some time, nurses actually engaged in rendering services in direct connexion with the nursing of the sick. The Board is anxious that the new Council should be of a thoroughly representative character and would welcome suggestions for membership of the Council, but all recommendations should be accompanied by a statement of the special qualifications and experience of the persons suggested for membership.

THE EDINBURGH MEDICAL JOURNAL.

The *Edinburgh Medical Journal* appears this month (January) with the name of Oliver and Boyd as publishers on its wrapper (now pale brown instead of green). This is not the first time that firm's name has appeared on its title page; for thirty-six years the monthly parts of this old but ever youthful periodical issued from Tweeddale Court, 14, High Street, with Oliver and Boyd's imprint upon it, under the successive editorship of Henry Duncan Littlejohn, Daniel Rutherford Haldane, George William Balfour, and Joseph Bell. In 1897 Young J. Pentland began to publish it, and later it was printed for the proprietors by W. Green and Sons, Ltd. Now, without changing its able editors (Alexander Miles and J. S. Fowler), the journal has returned to its old home in Tweeddale Court.

In the prospectus which accompanies the January part it is said that the *Edinburgh Medical Journal* enters upon the one hundred and sixteenth year of its existence. This is not quite correct if one has regard to its present name; for it was the *Edinburgh Medical and Surgical Journal* which was founded by Constable in 1805, and appeared (at first quarterly) for fifty years when it united in 1855 with the *Monthly Journal of Medical Science*, and for the first time took the title of the *Edinburgh Medical Journal*. Some fifty years later another union took place—namely, that in 1907, with the

Scottish Medical and Surgical Journal (founded in 1897); on this occasion the *Edinburgh Medical Journal* retained its name unaltered. The January part is interesting, containing, as it does, Professor Meakins's inaugural address on "The Influence of Edinburgh on McGill University and American Medicine," Dr. W. B. Drummond's article on "A Binet Scale for the Blind," and Captain Leggate's "Observations on Beri beri among the Chinese in France." There are also "Clinical Records" of individual cases, and two valuable "Critical Reviews" on surgical tuberculosis and x rays and radium in gynaecology. The annual subscription is 30s.

Correspondence.

PUBLIC HEALTH VERSUS THE STATE.

SIR,—It is a curious thing that just at the time when there is something of a revolt against the interference of the State in the sphere of curative medicine, extension of State activities is all the craze in the sphere of preventive medicine. It is especially astonishing in view of the fact that many still cling to the idea that prevention and cure go together. Schemes for treating the sick should not be looked upon as measures for the prevention of disease. When it is realized that the two are distinct, then the futility, from the point of view of preventing disease, of much that is now being done for combating tuberculosis will become apparent. Tuberculosis is one of the commonest of preventable diseases, and its connexion with social ills is comparatively clear. Therefore it is a good type to study as an example, and Dr. Bertram G. M. Baskett has done good work in presenting your readers with his striking and able article on "Public Health versus the State" (*BRITISH MEDICAL JOURNAL*, January 10th).

His views involve several important implications which should cause doctors to think hard. Even if they do not carry conviction to all, they should arrest attention and lead to a careful survey of the present situation as to preventive medicine and its association with State interference. Personally, I believe his conclusions are correct. At a time like the present, when, through the indirect effects of the war, the municipal and State funds are heavily encumbered, when problems of the burden and true incidence of taxation are of vital importance to the welfare of the people, it is particularly opportune to discuss the effects of these things upon the prevalence of disease. This is especially so, as it appears to me, because we may well be at a parting of the ways. On the one hand, there are those who want to see more regimentation from above, more bureaucracy, more paying out from Government funds, and more public borrowing in some shape or form—for example, nationalization of the railways by buying out present owners at a high figure. On the other hand, there are those who aspire in the near future to a diminution of State interference and an ampler personal freedom, to a gradual cessation of all forms of public borrowing, and to the discovery of a sinless tax which cannot be passed on to the poorer workers and cannot burden production. As doctors it behoves us to study these questions. The more we do so I feel sure the clearer it will become that Dr. Baskett is right when he contends that "when a Government sets itself by direct means, involving expense, to improve the conditions of the poor the usual result is to encourage tuberculosis."—I am, etc..

Mundesley, Jan. 14th.

S. VERE PEARSON.

"NEW LAMPS FOR OLD" IN OBSTETRICS.

SIR,—My letter on your leading article was concerned with attempting to widen the prospect opened by the conception of the new lamp in obstetrics rather than with Mr. Bonney's paper, and I regret with him and Dr. Blair the way the whole hunt has followed the red herring of the use or abuse of forceps, especially as it is over the old ground in the old way. Perhaps I was too emphatic on that matter, or perhaps your correspondents felt the cap fitted or their consciences pricked. In opposition to Mr. Bonney, however, I maintain that the question as to whether there should be more or less interference in midwifery cannot be divorced from the other circumstances of

the surgical methods which should surround midwifery practice, because it is an inseparable part of them. The true surgical attitude of mind seeks to eliminate all unessential manoeuvres by which sepsis may be introduced, as well as to secure asepsis in carrying out those which are essential. The less often the infallibility of our efforts is put to the test the better. To minimize handling and to keep the fingers so far as possible out of the wound is, even in these days of rubber gloves, an integral part of surgical technique, and, applied to midwifery, involves the reduction to the absolutely necessary of all internal manipulations, whether vaginal examinations or operative procedures, especially in view of the impossibility of sterilizing the vulva.

Even if "safeguarded by all those circumstances of environment, assistance, and asepsis which are accepted *sine qua non* in every department of recognized surgery," a diminution in the frequency of internal manipulations when spread over the annual birth rate of the kingdom—about a million—must bring with it a corresponding and appreciable drop in childbed morbidity.

The red herring that Mr. Bonney complains of was my reference to a letter in a previous correspondence (September 27th, 1919) which I quoted as an example of what I hoped the new lamp would dispel. That letter had advocated assistance by forceps or other means, and the removal of the placenta by hand if expression fails, to save "absurd waste of time, as there is when a practitioner waits on Nature." The manual removal of the placenta from the uterus, even when all the resources of a hospital are available, is known to give a high morbidity rate, and the mere suggestion that it should be done without grave reason would explain and excuse my emphasis of the need for limiting interference in labour.

Another red herring which, however, had little following, was an attempt to indicate the approach through physiology. In the one detail which has absorbed this discussion such line of approach would begin before any question of instrumental assistance arises—that is, with the causes of uterine inefficiency in labour and how they may be averted. Other disorders of function—as, for instance, the frequent failure of lactation—would be similarly approached. Dr. Thomson Shirlaw touched on this aspect, and his ironical advice to "swot up Caesarean section" well expressed the want of courage of those who have no opinion of Nature's effort in pressing that opinion to its logical conclusion.

We must all have our own ideas as to how the new spirit in medicine and its application to obstetrics should be interpreted, and an expression of such ideas on broad lines cannot but be helpful and stimulating to others, and I regret the narrow line this discussion has taken.—I am, etc.

London, W., Jan. 18th.

JOHN S. FAIRBAIRN.

SIR.—Let us inter the red herring and deal only with Mr. Bonney's contention. If he means that the elaborate ritual practised in most hospitals before and during surgical operations should be adopted in every case of midwifery, then I can only say that in view of the housing conditions of the people in this country his proposal is as Utopian as it is unnecessary. Parturition differs from a surgical operation from the fact that in the former Nature provides her own antiseptic in the vaginal secretion, and woe betide the practitioner who washes it away or otherwise destroys it. Students should be taught that there is no danger of sepsis provided they keep their hands, arms, and instruments free from infection. Some men will touch with their bare fingers every infectious or contagious case they come across, and often neglect to wash, or at any rate to wash properly. Of course they get septic cases if they practise midwifery. Students should also be taught plain common sense in obstetrics, and should not be allowed to practise midwifery outside hospital until they are proficient in turning and in using the forceps. But I forget—there is the old red herring bobbing up again.—I am, etc.

North Shields, Jan. 17th.

F. C. MEARS.

PREVENTION OF VENEREAL DISEASE.

SIR.—My attention has been called to a letter in your issue of December 27th, 1919, signed by Mr. E. B. Turner and Dr. Otto May, in which it is stated:

Very few statistics are as yet available, but we defy the Society for the Prevention of Venereal Disease to bring forward

a single set of figures showing, to the satisfaction of an actuary, that methods based on their system have ever resulted in any striking diminution of disease. Should the recent debate on this subject lead, as is hoped, to a publication of the actual figures for the Portsmouth area (in which, according to Lord Sandhurst, the incidence of venereal disease is two and a half times greater than for the whole United Kingdom), the profession will be able to judge how little foundation exists for the misplaced optimism of Sir Archdall Reid, whose "experiences" in that town constitute one of the chief assets of the Society for the Prevention of Venereal Disease.

Well, let us get at the facts. For some years past soldiers suffering from venereal disease have been subjected to no penalties. It had been found that punishments led to concealment. When a case occurs the medical officer of the unit must, under stringent orders, immediately send it to the venereal diseases hospital of his area. There the man's unit is recorded and he is questioned (and his answers recorded) as to the source of infection (professional or "amateur"), as to date and place of infection, and as to whether he disinfected after exposure, and, if so, how long after. It will be seen that the M.O.'s returns may be exactly checked from independent official sources. Before the war the 1st Yorkshires were ordered from a hill station where there was no disease to Delhi, a hotbed of infection. The C.O. in alarm consulted his medical officer, who instructed his men to disinfect immediately after exposure with a solution of potassium permanganate. In four years that battalion had six cases of venereal disease instead of hundreds—1.5 per 1,000 per annum. At Mhow venereal disease was reduced by similar means to "negligible proportions." At Portsmouth the M.O. in charge of Clarence Barracks, with an average of about 2,000 troops in charge, had, in twenty-eight months, seven cases *originating* among his men—a rate of 1.5. The method of carefully teaching men to swab immediately after exposure spread throughout the "Portsmouth area" (the greater part of Hampshire and Dorsetshire) with approximately similar results. At the local venereal diseases hospital it was found that while many men, fearing blame, declared at first that they had disinfected themselves immediately, every one on closer questioning admitted he had not done so. At the Naval Gunnery School at Whale Island Surgeon Commander Boydon supplied 496 men who applied, with bottles of permanganate lotion, and instructions to swab immediately after exposure. Only one man was infected, and he delayed disinfection for six hours. The Royal Marine Artillery (nearly 4,000 men), to whom quick disinfection was carefully taught, had only five cases in nine months—approximately 1.5 per 1,000 per annum, which appears to be about the normal for well instructed troops. Many more instances may be quoted, but I give only those which may be easily verified from independent official sources.

I do not know what Mr. Turner's and Dr. May's actuary would make of the above figures, but, unless he possessed the peculiar talents of the gentleman who supplied the Interdepartmental Committee and Lord Sandhurst with their statistics, I do not think he would make much. There is hardly scope for him, since the facts are so simple, and I think he is only mentioned by way of hinting doubts which Mr. Turner and Dr. May would like to diffuse but cannot substantiate, though the materials for investigation are at hand. Will these two gentlemen please explain how my "experiences" can "constitute one of the chief assets of the Society for the Prevention of Venereal Disease"? I have just given not only my records but also those of many medical officers, whose very names are in most cases unknown to me, though I am acquainted with their returns.

In 1916 the army was "rotten" (I use an expression which was often heard) with venereal disease. The hospitals were overflowing and camps were formed, man power was seriously affected, the Colonial Governments (I am told) were threatening to withdraw their forces, in every Dominion the chief cry of those who opposed help to the Mother Country was that clean lads should not be sent to that cesspool—England. The English public heard little of all this, for allusion to it was suppressed for fear of the effect on recruiting; but the soldiers received innumerable lectures exhorting them to chastity and exposing the horrors of disease. Finally, "venereal ablation rooms" were established in which permanganate solution in pails and calomel cream in pots were stored, and to which men who had incurred danger were supposed

to resort for self-disinfection. It is understood that some sort of a bargain was made with "influential" people who opposed "any system of prophylaxis which might be said to afford opportunities for unrestrained vice." Immense good resulted, but in 1917 the authorities, convinced of the superiority of quick disinfection, arranged to introduce it. Delay occurred, and inquiry revealed that the officer who had been placed in charge of the scheme was waiting for the delivery of millions of bottles and tubes which had been ordered. Vehement protests were immediately made; the bottles and tubes unnecessarily introduced the objectionable "packet" system; the disinfectants already in the hands of the medical officers were sufficient, as had often been proved, and nothing but stringent orders to the officers to give careful instruction was required. The protests were unheeded. After prolonged delay the bottles and tubes were sent to the troops *with instructions that the men were to be taught, not to carry them, but to use their contents after return to quarters.* Conceive the imbecility of transferring, at vast expense, chemicals from one set of receptacles to another only to use them in the old inefficient way. More protests were made; the authorities were implored to insist on the one essential thing—the careful instruction of the men. Again the protests fell on deaf ears. To-day, if demobilized officers and men be questioned, it will be found that, in 99 cases out of 100, they know nothing, or next to nothing, about disinfection. Those who were trying to stay the plague were reluctantly forced to the conclusion that whoever was in charge of the arrangements was incompetent, or that he did not desire the success of disinfection.

In 1919 the Interdepartmental Committee assembled. It considered evidence from an army which had been instructed, as far as it had been instructed at all, *not to use "packets" as packets.* Very sapiently on that evidence it decided that packets, used as packets, were useless. If the figures for 1914-15 had been contrasted with those of 1916 and those of subsequent years the difference between the effects of no disinfection as compared with those of some (even if inefficient) disinfection could have been ascertained. Accordingly the statistics for 1914-15 were withheld. In the future much will be heard concerning the evidence produced before this Committee. For the present it will be sufficient to consider Lord Sandhurst's figures which are quoted by Mr. Turner and Dr. May and which were supplied by the same hand and are of the same character and quality as those supplied to the Interdepartmental Committee.

Lord Willoughby de Broke, desiring to ascertain the effects of quick disinfection, asked for information concerning the "Portsmouth area," where it had been widely practised. Of course, he referred only to troops resident in the area and in charge of the Assistant Director of Medical Services at Portsmouth. His question was plain enough, and was thoroughly understood, if not by Lord Sandhurst, yet by the person who supplied his figures. In 1919 there came into the area from elsewhere in the United Kingdom drafts who, relatively few in number brought about twice as much disease as that contracted by the resident soldiers—that is, disease which developed in a few days after, and was admittedly contracted before arrival. Into it, also, came tremendously infected units from abroad. In it were also large numbers of colonial, American, and R.A.F. troops with which the A.D.M.S. had nothing to do and who were suffering severely. Lord Sandhurst ingeniously combining all this infection, announced that the disease in the Portsmouth area was two and a half times greater than that for the rest of the kingdom. The average army rate is about 40 per 1,000 per annum. Therefore the rate for the Portsmouth area should have been about 100. But consider the weakness and incompetency of the army administration which permitted—without protest and without attempt at remedy—this shocking state of affairs. Suppose the disease had been typhoid. Lord Sandhurst has been taxed with the manipulation of the figures I have indicated, and has not denied the soft impeachment. But Mr. Turner and Dr. May quote him, and talk of an actuary. After all, I think the actuary is really necessary.

But consider the case if Lord Sandhurst's figures were true. They would then be even more deadly. Portsmouth is the only large town in the area. The venereal rate, therefore, should be about 150 per 1,000 per annum. Yet a little careful instruction given to some six or seven

thousand men has reduced this huge figure to next to nothing among them.

I hope I have given Mr. Turner and Dr. May sufficiently precise information. I wonder, if they cannot indicate any substantial inaccuracy, whether they will consider the question of joining the S.P.V.D. I speak only for myself, but I should think they would be as welcome as lost sheep.—I am, etc.,

Southsea, Jan. 19th.

G. ARCHBALL REID.

SIR,—In his letter on this subject in your issue of January 3rd, Dr. Herbert Butcher makes one or two interesting observations. Discussing prophylaxis he says: "I fail to see that as medical men we have any concern with the moral aspect of the matter. That had much better be left to others." I am tempted (and fall) to place that statement alongside one that I quote from *The Times* of January 9th, 1919. At a conference on venereal disease in the army the chairman, Lord Sydenham (president of the N.C.C.V.D.), is reported as saying that "the National Council did not regard the moral aspect as part of their propaganda—they left that to the clergymen." If Lord Sydenham be reported aright I rather think the National Council have changed their point of view, but it would appear that in some respects we are not very much further on in this question at the beginning of 1920 than we were at the beginning of 1919. The medical profession is still in a state of doubt and dissension over its standpoint on the moral side. Further, has the question of venereal disease attained any such position, beyond the columns of the medical press, as would justify the belief that the great mass of the people are any less apathetic towards the whole business than they were a year ago? I doubt it.

At present, Sir, the National Council and the Society for the Prevention of Venereal Disease are splitting hairs over the question of whether prophylaxis should take the form of a packet distribution or disinfection under supervision. Is there any insuperable obstacle to the adoption of both? As regards our attitude towards the morality of prophylaxis, I maintain that we *must* make it our concern. If we cannot plead its moral justification we are running the risk of alienating the sympathies and forfeiting the aid of large numbers of thinking men and women. For if a prophylactic scheme of any nature is established, it cannot be brought to the notice of those who stand in need of it without attracting the attention of a large community unprepared to receive into their midst so open an acknowledgement of the widespread existence of sexual vice.

I believe that the preventive value of prophylaxis is proved, and granted in one form or another by both the National Council and the Society for the Prevention of Venereal Disease. Now what is its moral position? Its opponents say it offers an inducement to sin and immunity to the sinner, its advocates that it has in view the saving of the innocent. No one can dispute the justice of the latter object. With regard to the moral objections, any inducement to sin can surely be counteracted and more than counteracted by a coexistent and far-reaching propaganda—moral, social, and educational—depending for its success on the extent to which the active aid of men and women *outside* the medical profession and the Church can be enlisted. But, Sir, counteracting influences are not necessarily a reply to moral objections. Good. "If a man have an hundred sheep, and one of them be gone astray, doth he not leave the ninety and nine, and goeth into the mountains, and seeketh that which is gone astray?" Do we then do wrong if we make our objective those who have gone astray? And what of conferring upon the sinner (for this argument is and will be used) an immunity from the consequences of his sin? Surely that is the one thing that we can safely leave to the judgement of Another.

I repeat, if the campaign against venereal disease is to achieve victory with honour, if we are to secure the services of a large body of helpers, we must justify our prophylaxis. To quote Dr. Butcher again, "We shall have done our duty if we impart to the public the truth that science has imparted to us." But we must beware lest the public interpret the practice of that truth as inimical to the truth that was imparted to mankind 1,900 years ago.—I am, etc.,

JAMES M. STALKER, M.B., Ch.B. St. And.

Dundee, Jan. 5th

SIR,—I am, I hope, as moral as most people, and I do not consider I am assisting immorality if I take the line that I am entrusted with the cure of the body and not of the soul. And prevention is better than cure; if I can prevent, I should do so. The fact that I were doing my best to prevent would not hinder professed priests and others from carrying on their side of the campaign.

If a man suffering from syphilis confided in a priest it would be the duty of the latter to dwell on the ethical side, and when he had finished turn the patient over to a doctor. But if the man came to me in the first place, I should not consider it any part of my duties to lecture him on his morals, nor to be guilty of the impertinence of directing him to make his peace with the Church.

It is undoubtedly the duty of the medical profession and of its individual members to point out the dangers, evils, suffering to the innocent, and the gruesome side of venereal disease. Sometimes we succeed so well that the convert practises self-abuse rather than risk infection. The late Dr. Charles Mercier would have classified this last as a crime against humanity. It is all very well to say that education is going to eliminate immorality, but what is to be said of State education, which has taken the parents' responsibilities out of their hands and thrust them on to the shoulders of the teachers?

What can be said for the education of to-day which teaches hygiene and decency by precept and then allows the scholars to go home to sleep two or three, of opposite sexes, in the same room—even in the same bed? How long is it going to take to rectify this? How long will it be before the proletariat are decently housed? When will it cease to be a crime for a working man to help keep alive an imperial race by bringing up a family of half-a-dozen? Anyone who cares to see it knows that the worse the living conditions the lower the morality of the occupants—and we meet this with "watch committees" and the like. The iniquity is that many of the couples started married life decent and self-respecting until their economic conditions crushed the decency out of them and robbed their children of the chance to grow up decently.

If they want relaxation they go outside the hovels where they live, and this leads to drunkenness, promiscuous sexual intercourse, and other evils. It is useless to expect to reclaim this class of the community by propaganda, and it is absurd to contend that it is immoral to combat venereal disease amongst them by preventive measures. Education can do nothing for them until it has relieved them physically, then, perhaps, its teaching will not stultify itself.

As to the immorality amongst the more fortunately situated classes, it is unwise to shut one's eyes to the fact that Nature intended the sexes to be attracted to one another. The desire is a normal one, fortunately held in check by convention and still more by interest in one's work and hobbies. But here, too, syphilis is rife, from all accounts, and innocent people are becoming infected every day. Is the tale of infection to rise higher and higher whilst religious and educational work is trying to catch it up? This line of attack might possibly assume endemic proportions—certainly not the epidemic proportions of the incidence of the infection. Rather, one fears, will it be sporadic; and the convert probably already suffering from the disease.

For my own part I am grateful to the eminent members of the profession who have been courageous enough to advocate preventive measures, knowing the kind of criticism they would have levelled at them. The least I could do was to apply for membership of the society.

"Sic vos, non vobis . . ." from the "fagging" of school days to the present time.—I am, etc.,

J. CHARLESLEY MACKWOOD, M.C.,
M.R.C.S., L.R.C.P.

Newick, Jan 12th.

MODE OF QUININE ADMINISTRATION.

SIR,—I am much obliged to Colonel W. H. Willcox for his letter in the JOURNAL for January 3rd in reply to my inquiry in the previous number, and I now understand that his estimate of the comparative values of rectal, oral, intramuscular, and intravenous administration of quinine—namely, that these values vary roughly in the proportions of 1, 2, 20, and 40 respectively—was a clinical estimate. I attach no small importance to such estimates when backed by so large an experience as Colonel Willcox had

during the war. But there are many special difficulties in the case of quinine in malaria, all of which must be remembered in every case. Thus when any change of treatment is made we are apt to forget that the benefits of the previous treatment may not declare themselves for some days.

According to the best Italian work from the time of Torti, doses of quinine given shortly before an impending paroxysm, or even given and repeated during that paroxysm, may not modify it in the slightest, but will annul the next paroxysm. Suppose that a bad case of malignant tertian has a paroxysm beginning at noon on a Monday, then the fever is likely to continue from that hour till noon on the Wednesday following or even later, and this in spite of any quinine which may be given on the Monday, Tuesday, and Wednesday; but the next paroxysm, which should commence at noon on Wednesday, will be aborted. Suppose that the clinician sees his patient again on the Tuesday evening; he will find him severely ill, in the so-called crisis of his aestivo-autumnal fever; and, if he forgets these facts, he will think that all the oral quinine which he has given hitherto has failed, and he may then proceed to his intramuscular or intravenous injection. Sure enough next day the fever will probably fall or disappear; but this result will be due, not to that injection, but to the quinine which was given on the Monday morning; the patient may have taken as much as 200 grains on the three days, but the dose given before the Monday exacerbation was probably the one which did the work and broke the fever from Wednesday onwards. It is precisely in cases of this nature that intravenous injections are so apt to be employed, after the previous oral doses have apparently failed; and it is precisely in such cases that we are so apt to attribute the recovery to the injections.

Quinine does not affect the impending paroxysm because, according especially to Antolisei, Golgi, Marchiafava and Bigami, it cannot destroy the segmenting forms, to the breaking up of which, with consequent liberation of toxins, the febrile exacerbation is due. Thus the latter writers say:

Quinine acts upon the malaria parasites in that phase of their life in which they are nourished and developed. When the nutritive activities cease by an arrest of the transformation of haemoglobin into black pigment and the reproductive phase begins, then quinine is ineffectual in its action.

My own observations have always supported these opinions. It follows that the therapeutic value of a dose of quinine may depend more upon the time at which it is administered in relation to the growth cycle of the parasites than upon the mode of administration.

At the same time we cannot say definitely that the mode of administration has no effect on the result. I am inclined to think that it does not have much effect. For instance, very little difference could be proved between the results of oral and intramuscular administration in the numerous War Office researches on the subject—see especially the late Mr. R. W. Harold Row's careful paper in the *Observations on Malaria by Medical Officers of the Army and Others*, just published; and Captain G. B. Bartlett even thought that the oral method is the better. On the other hand, Lieut.-Colonel S. P. James found that intravenous injections had a quicker result in ten carefully taken cases, though the relapses remained as frequent as with other methods (*Journ. R.A.M.C.*, September, 1917). The other literature is large, but conflicting, one-sided, or indecisive.

Hypodermic injections had fallen into some disrepute before the war, owing to occasional local mischief, to tetanus, and, particularly, to the statements of many able chemists, that quinine is actually less readily absorbed from such injections than when given by the mouth. Therefore I for one rightly objected to them, except where oral administration was not possible (though I never said, as some seem to think I said, that injections are entirely useless). More recent chemical work seems, however, to show that there is not much difference in the excretion of quinine, whether it is given by one route or another.

Much interesting chemical work, bearing on treatment, has recently been done by Ramsden, Lipkin, and Whitley (*Ann. Trop. Med. and Parasitology*, vol. xi, p. 434, vol. xii, p. 233, and vol. xiii, p. 149). They conclude that there is a great destruction of quinine in the tissues, especially when large doses are given, and that the concentration of

it in the blood is not much greater with large doses than with small ones—which might explain why moderate doses seem to be clinically as efficient as massive doses. They say also that 90 per cent. of quinine injected intravenously disappears from the blood within one minute. Quinine is destroyed especially by the liver—which would appear to justify D. Sandro when he claimed in 1909 that this is the reason why intramuscular injections are more potent than oral doses of the same magnitude (if this be true). The concentration of quinine is always much higher in the urine than in the blood, except in blackwater fever, in which it would seem to be eliminated in the form of Nierenstein's haemoquinic acid—a very haemolytic substance, the occasional formation of which may explain the symptoms in many cases of that type of malaria.

We have to consider not only the therapeutic value of any mode of administration, but also its administrative advantages or drawbacks. It is much easier to give quinine by the mouth than by other routes. Colonel L. S. Dudgeon has recently shown that, whatever anti-septic precautions may be taken, intramuscular injections cause much local necrosis (BRITISH MEDICAL JOURNAL, January 3rd, p. 25, and *Journ. Hyg.*, 1919, xviii, p. 317), and we hear "stories" of accidents which are not reported in print. On the other hand, I am seeing patients every day who have had many injections, both intravenous and intramuscular, but who have received no permanent injury from them—and also, I fear, no permanent cure. Against oral administration there are the dangers of vomiting, non-absorption, and, not least, of avoidance of the dose; while there is this comfort about the other routes, that the dose cannot be avoided.

The real question is, not whether the injections are as good as oral doses or a little better, but whether they are so much better as to justify the extra pain and risk involved, small as these may possibly be. I have seen no decisive experimental proof of the superiority of the injections; but pending such proof I think we are bound to accept the views of many clinicians who prefer them for dangerous paroxysms, especially such as the attacks referred to by Colonel Willcox and Major Mavor, which usually occur in intensely malarial areas, and also occasionally in England. But for the ordinary attacks, of which we have been seeing thousands during the last three years, good oral treatment has been shown to be sufficient in the numerous malaria hospitals and centres. I see that Colonel Willcox agrees.

The War Office Researches on Malaria did a great deal of work. It is a pity they had to be stopped last year. I have tried in vain to have them continued by other bodies. Even now the British Empire does not know how to manage its scientific affairs.—I am, etc.,

London, N.W., Jan. 17th.

RONALD ROSS.

SIR,—Malarial therapeutists talk glibly of administering from 1 to 3 grams of quinine, more or less, daily, for weeks together, and one gathers that the drawbacks to a course of this treatment are few. But they do not often mention one very serious drawback, namely, the tendency of these large doses to cause deafness, which often proves permanent. They will, of course, ascribe it to idiosyncrasy, but, idiosyncrasy or not, it is a very serious consequence.

I have had considerable experience of the quinine treatment of malaria, and I can recall several instances in which permanent and pronounced deterioration of hearing remained.—I am, etc.,

Algiers, Jan. 4th.

ALFRED S. GUBB, M.D.

FORGETTING: PSYCHOLOGICAL REPRESSION.

SIR,—To one who has for nearly two years employed the old Breuer-Freud method of abreaction, almost as a sheet anchor, it comes rather as a shock to have its utility questioned.

As in the Freudian method of analysis, one has, in the early stages of treatment, avoided suggestion as much as possible and allowed the patient to "work out his own salvation" by the revival of the original emotion in his own way. When the battle dreams and more severe anxiety symptoms have been relieved, as they undoubtedly are, and moreover in a remarkably short time, then methods of re-education and persuasion are employed.

Dr. Carver's article must, I feel sure, express the feelings of many who, like myself, work to relieve the anxiety state of the pensioner and others.—I am, etc.,

London, W., Jan. 18th.

ROBERT M. RIGGALL, M.R.C.S.,
L.R.C.P. Lond. and Edin.

SIR,—In his letter on "Forgetting," etc., in last week's BRITISH MEDICAL JOURNAL, Sir Robert Armstrong Jones writes:

The psychoses and neuroses are Nature's means of defence, and I venture to believe they are best relieved by helping Nature to obtain a complete rest and some mental diversion.

I made a similar statement in 1916, and it was on account of my holding this view that I founded the Country Host scheme.

It is sad, it is passing sad, that only at this late (almost too late) period the neurological experts and authorities are beginning to recognize the truth of the fact I ventured to point out to them in 1917—namely, that psycho-therapeutic treatment such as that given at Maghull, and later at Seale Hayne, removes symptoms indeed, but that it does not cure the patients permanently. For proof of this I quote the 30,000 cases of war neuroses seen yearly by the Special Medical Board in London alone.

As I have insisted over and over again, the only permanent cure for most cases of war neuroses is the natural one of rest and good feeding with suitable occupation, preferably in the country. Most unfortunately, the brilliant results in the way of removal of symptoms dazzled the authorities, and, like Esau, they sold their birthright for a mess of pottage; they overlooked the fact that men so treated were no more "cured" than a man suffering from enteric fever would be cured if his temperature were reduced to normal by placing him in a cold bath. Such treatment may be necessary and helpful, but it is only symptomatic, and is not radical or permanent in its result.

Once more let me insist that all purely neurasthenic cases should be sent to the country under the Country Host scheme now being managed by the Red Cross. All hysterical cases should have their symptoms removed by psychotherapy and should then be sent for three months to the country under the above scheme.—I am, etc.,

London, S.W., Jan. 19th.

THOMAS LUMSDEN.

SIR,—The discussion revived by Dr. Alfred Carver's communication is concerned with issues of such general interest that any member of the profession must hope it will not degenerate into the acrimonious mud-slinging which seems to be the usual fate of an argument wherein the word psycho-analysis is mentioned.

I suggest that the problem is somewhat as follows: One is suddenly tendered a bill for five pounds, and it is inconvenient to pay. One may not have the money, or may dispute the claim; anyhow, one does not pay. Then perhaps the creditor dies, and his executor has no record of the transaction; the debtor is not pressed for payment. Next, one of two things happens to a large majority of debtors: either the whole transaction is forgotten, or it is remembered as a case in which the sleeping dog may be allowed to lie. But by a minority, although the name of the creditor and the nature of his claim have been forgotten, it is remembered that some claim exists. Such persons may make themselves miserable by attempting to discharge debts of £1,000 (to which the principal has grown by very high compound interest) in the most unlikely quarters. How can we still these tender consciences?

1. We may persuade the debtor either (a) that he never owed anybody anything; or (b) that he has already paid his debt; or (c) that money is the root of all evil, and it is better to think of something else.

2. We may try to find out who the original debtor was and what the nature of his claim.

If we proceed by (1), the debtor may discover that his adviser is not telling the truth. He may have been positively assured that the debt was paid to Smith; he may afterwards meet Smith, who is ignorant of the transaction.

If, on the other hand, we adopt (2), we may never find who the original debtor was, or, worse still, we may learn

that he died of starvation owing to want of the five pounds, and left no heir.

Substitute in my apologue "reaction" for "debt" and "painful stimulus"—or any other polysyllabic equivalent you please—for "creditor," and one is close enough for practical purposes to the topic under discussion.

How are we to decide whether (1) or (2) is the better line to follow? We shall obviously not derive anything but amusement from the spectacle of angry psychiatrists bandying such charges as lover of pornography or victim of a "complex" from side to side (the manner of all previous discussions). We shall derive very little, even of amusement, from dogmatic statements that this or that method "cures" patients, or from the spiritual autobiographies of eminent men (thus far the method of the present controversy).

What is meant by the term "cured"? Of those treated how many were "cured"? Were they *in pari materia*? Was the treatment uniform? Have any two of the rivals treated samples of a common population by their respective methods? If so, what are the results? Like Sir Robert Armstrong-Jones, I have asked six questions; unlike him, I have not framed them so that a Latin translation would require the use of the word *num* in each.—I am, etc.,

Loughton, Jan. 18th.

MAJOR GREENWOOD.

THE ORIGIN OF TUMOURS.

SIR,—In the annotation entitled "The Origin of Tumours," in last week's JOURNAL, it is stated that the hypothesis recently developed by Ribbert is not invalidated by the occurrence of *x*-ray cancer, because this type of growth arises as a single focus. This is far from being the case, for in a very high percentage of *x*-ray cancers there are two or more separate and distinct primary growths, two or three or even more fingers, the hand, and perhaps the chin, having all been affected in one individual.

The more one thinks of these cases the more difficult becomes the acceptance of Cohnheim's theory, or any modification of it, such as that now advanced by Ribbert; for in *x*-ray cancer we have a condition—that is, carcinoma of the finger—practically unknown under any other circumstances. Are we to suppose that Cohnheim's cell-rests are deposited only in the hands of those who happen to adopt *x* rays as their avocation? Or, to take another remarkable example, can we imagine that the Kashmiri is the only kind of individual in whom cell-rests occur in the skin of the thighs and lower abdomen—for these are the positions in which multiple kangri cancers are met with very commonly in Kashmir—and is cancer ever seen in these sites in other races?

In my view no hypothesis of the etiology of cancer can satisfy the facts unless it affords some sort of plausible explanation of the origin, not only of such cases as cancer of the breast, about the precancerous stages of which we know nothing at all, but of such conditions as *x*-ray cancer, kangri cancer, soot and fuel cancer, or aniline, arsenic, and chrome cancer, all of which are specialized forms of growth occurring in peculiar situations, and never arising except as the end result of the action of a definite physical, chemical, or thermic agent.

To say that a hypothesis "contains at least as much probability as any other hypothesis that has been made regarding the etiology of tumours" is a damning criticism.—I am, etc.,

London, W., Jan. 14th.

CECIL ROWNTREE.

CHRONIC PANCREATITIS.

SIR,—Consequent on my article on this subject in your issue of November 15th, 1919, I have received a number of communications, several of which controvert my stated opinion that "on the surgeon rests in many of the cases the ultimate diagnosis by means of excision of a portion of the gland for microscopic examination" (by which I mean the removal of a small wedge), and suggest that the pathologist might be in many cases the person to undertake the task.

May I point out that the pancreas stands somewhat pre-eminent amongst the tissues in rapidity and intensity of *post-mortem* changes? Directly death has stopped the circulation in the gland active self-digestion begins, and in a gland examined twenty-four to forty-eight hours after

death autolysis has produced results so pronounced as to obliterate in portions of the gland histological distinctness of outline, and in others to simulate necrotic pancreatitis.

The value of the various methods of examination of faeces, urine and blood, at present under trial, must be decided in many cases by the microscopic examination of fresh sections taken by the surgeon from the living gland.—I am, etc.,

Glasgow, Jan. 16th.

JAS. H. NICOLL.

TICKS AND RELAPSING FEVER.

SIR,—Let me, in reply to Dr. Balfour's letter (January 17th, p. 97), where he says, "So far as I know we have no definite evidence that *Argas persicus* can transmit any human spirochæma," state that in the summer of 1918 I definitely proved that it can. I was then with a small column in North Persia. All the troops were under canvas, with the exception of a section of engineers, who were billeted in a deserted house, where they slept mostly on frame beds.

During the first week of their habitation there they complained of being bitten by bugs. I asked them to secure a specimen, which they did. This tallied exactly with the description of the *Argas persicus* in Mause's *Tropical Diseases*. The interesting point is that every man in that billet developed relapsing fever. The spirochætes were found in their blood and also in the tick itself. None of the other troops developed the disease, though many of them suffered from lice infection. On making inquiries amongst the Persian natives, I found that nearly every house in the town was infested with ticks and that they were considered to be carriers of some sort of fever.

The severity of the infection seemed to vary directly with the number of bites, which were sometimes very severe and healed with difficulty.—I am, etc.,

J. LEEPER DUNLOP, M.B.,

Late temporary Captain R.A.M.C.

Ross, Jan. 18th.

THE WORK OF A PENSIONS REFEREE.

SIR,—It is evident that there is a widely spread fear in the profession that a State medical service will have many objectionable features. My experience, as medical referee to the Ministry of Pensions, lends no support to that view. I have found, from both the Ministers under whom I have worked to the latest joined member of the Local Pensions Committee, a genuine anxiety to do the best possible to restore disabled men to health and working capacity. The medical referee is left with an absolutely free hand to recommend whatever he considers necessary to that end. I am sure my experience can be echoed by all the other medical referees when I say that I have been treated with the utmost kindness and consideration. Letters are answered promptly, and not in the perfunctory official manner usual in some Government departments. The work is worrying at times, as one has to hold the balance true between the State and the pensioners. Mistakes will occur, no doubt, but if the work is done to the best of one's ability, the sympathy and support of all the officials from the Minister downwards is assured. The terms are, in my opinion, generous, and I am pleased to state that genuine malingering is rare. One or two cases in which I suspected it, on further investigation proved to be suffering from very real maladies; and I have found the conditions of work under the Ministry a pleasure.—I am, etc.,

Falkirk, Jan. 12th.

GEORGE C. STEWART.

THE IRISH MOTOR DEADLOCK.

SIR,—It was hoped that through the good offices of Mr. H. G. Burgess of the Ministry of Transport a solution would be found of the deadlock which has arisen out of the Motor Permits Order, but it would seem that the *impasse* is to continue regardless of the consequences.

There is, perhaps, no section of the community which has adopted the motor as a means of locomotion to a greater extent than the medical profession, and one fails to see how the medical needs of the public can be attended to in the circumstances now existing.

Briefly the position is this:

1. The attendance of doctors is essential for the public good.
2. Motors are essential for the efficient discharge of the doctors' duties.
3. Doctors are prevented from using their cars.
4. Hitherto in all warfare the Red Cross has been respected, and belligerents who do not respect it alienate public sympathy.

Many of my professional brethren who have urged me to state their peculiar position through the press have suggested that doctors' cars should bear a red cross and carry a front red light at night for purposes of ready identification, in order to prevent a repetition of the unfortunate occurrence which took place in *co. Clare* a few days ago. It may be urged that this concession, if granted, might be abused, but surely there is none more jealous of respecting the privileges of the Red Cross than the doctors themselves, and anyone found breaking its conventions would deserve severe punishment.

It will be absolutely impossible for us to "carry on" without our cars, and we hope for the sake of the sick and suffering that we be allowed to use them.—I am, etc.,

MAURICE R. J. HAYES,
Honorary Secretary, Dublin Division,
Leinster Branch, British Medical
Association.

Dublin, Jan. 11th.

HYPERNEPHROMA OF THE OVARY.

SIR,—As my diagnosis of the specimens described by me (BRITISH MEDICAL JOURNAL, October 18th, 1919) as ovarian hypernephromata was doubted by Dr. Leith Murray, I sent him the sections, and he was of the opinion that they were lutein bodies. In the circumstances I sent the available material of these two specimens, and another tumour which in my view came under the same category, to Professor Turnbull, who very kindly examined them and sent me the appended report.

I now agree that my original diagnosis was wrong, and that these tumours are lutein formations.

I shall be glad if you can insert this disclaimer, not only to prevent the specimens being recorded unchallenged as hypernephromata, but also because Professor Turnbull's report is so instructive that I think it should be published.—I am, etc.,

London, W.C.1, Jan. 2nd.

A. KNYVETT GORDON.

Report on Sections and Blocks of Ovaries.

The following specimens were received from Dr. A. Knyvett Gordon on December 16th: (1) Sections labelled 217, 1209, and 909; (2) one paraffin block of specimen 217, and two paraffin blocks of specimen 1209. The sections forwarded had been stained: 217 with haematoxylin and Biebrich scarlet, and with acid rubin and Mallory's stain; 1209 and 909 with haematoxylin and Biebrich scarlet. Sections were cut from the blocks of 217 and 1209, and were stained in Ehrlich's haematoxylin with eosine, in Weigert's iron haematoxylin with van Gieson's mixture, in Weigert's fuchsin with neutral red, and by the Weigert-Gram method with neutral red. There is no suggestion of malignant growth in the bodies within the three ovaries. If the bodies are connected with the suprarenal glands, they are either ectopic, suprarenal, cortical bodies, or benign growths thereof. In order to determine, therefore, the nature of the bodies, I first tabulated the points of histological difference, to be seen in paraffin sections, between (a) ectopic, suprarenal, cortical bodies, from the kidneys, liver, coeliac ganglion, and hilum of testis; (b) adenomata of the suprarenal cortex; and (c) lutein bodies.

1. *The Cells.*—In ectopic, suprarenal, cortical bodies, and in cortical adenomata, the cells are acidophil, rendered somewhat granular by minute vesicles, or frankly spongy. They show little variation in shape, being round or, more commonly, rounded polygonal, the surfaces where adjacent cells meet being flattened; measured with an eyepiece micrometer they are very seldom so large as the cells of lutein bodies, and their nuclei are relatively larger. The cells of lutein bodies are much less commonly vesicular or spongy; the great majority have a peculiarly homogeneous appearance. They are usually less acidophil than the cells of cortical bodies, tending to be stained purple or blue in haematoxylin and eosine sections. They vary greatly in shape; they are frequently elongated, the long axis being directed radially to the centre of the lutein body. The average cell is distinctly larger than the average suprarenal cortical cell.

2. *Arrangement of Cells.*—In ectopic, cortical bodies the cells are arranged exactly as in the cortex of the normal suprarenal body. Unless the section is tangential, zonae glomerulosa, fasciculata and reticularis are visible. The zona reticularis is pigmented in subjects of an age at which the corresponding zone is pigmented in the suprarenal body. In cortical adenomata the exact arrangement of these different zones is not seen. In the adenomata, however, as in the ectopic bodies, the cells are very obviously arranged in acini; although the acini are separated only by delicate capillaries and equally delicate strands of connective tissue, the acinar arrangement is conspicuous. The parenchyma of lutein bodies is traversed by a net of capillaries, this net being obvious when the capillaries are engorged. But a definite acinar arrangement, such as is seen in the suprarenal, is not visible. This point of differentiation I have found to be constant, and I consider it therefore of great importance.

3. *General Structure.*—The lutein body has a central core. This is stellate, sending centrifugal, gradually tapering, trabeculae into the surrounding parenchymatous zone. The core at first consists of fibrin and blood corpuscles. Spindle fibroblasts and capillaries pass into it, and it is ultimately organized and vascularized. The organization occurs most rapidly in the outer zone and in the centrifugal radiationa therefrom. In early stages isolated lutein cells or isolated groups of lutein cells are seen occasionally in the periphery of the core in addition to spindle fibroblasts. Trabeculae, carrying large vessels, pass from the ovarian stroma towards the core. The majority of these pass inwards opposite the intervals between the centrifugal trabeculae. These centripetal trabeculae taper in the opposite direction—that is, towards the core. In consequence of these alternating centrifugal and centripetal trabeculae the zone of lutein cells is thrown into waves or crenations. In some lutein bodies groups of cells of smaller size, cells resembling more closely the cells of the theca interna of the Graafian follicle, are seen in isolated groups within the ovarian stroma which immediately surrounds the lutein body. More frequently such cells lie in or about the centripetal trabeculae. In the centres of accessory cortical bodies and cortical adenomata are veins with a relatively broad fibrous wall. Occasionally, also, accessory cortical bodies are divided by one or more fibrous trabeculae. I have never, however, seen in either accessory bodies or adenomata any structure resembling the stellate core of a lutein body, or any suggestion of the crenation described above as characteristic of lutein bodies.

The above differences in general structure are obviously points of great importance in the differentiation.

Determination by these criteria of the nature of the ovarian bodies in question:—

Specimen 217.—The body has a stellate core composed of a delicate, vascularized fibrous tissue. Fibrin is absent. The core sends centrifugal rays into the surrounding parenchymatous zone. Centripetal trabeculae alternate with these, giving the parenchymatous zone the crenated structure characteristic of a lutein body. In the centripetal trabeculae, rarely in the periphery of the parenchymatous zone, are the smaller cells seen frequently in lutein bodies. A definite acinar arrangement of the cells in the parenchymatous zone is not seen. The cells are large, vary considerably in shape, and the majority have the homogeneous cytoplasm of lutein cells. The cytoplasm is less cyanophil than usual.

The body has all the important differential characters of a lutein body.

Specimen 1209.—The body has a stellate core. This is occupied by fibrin (Weigert-Gram stain). The fibrin is invaded by a few fibroblasts. The fibroblasts are most abundant in the periphery of the core, and in places form a definite fibrous zone thereto. Centripetal and centrifugal trabeculae alternate. The small cells are present in the centripetal trabeculae. Definite alveolar arrangement is absent. Homogeneity of the cellular cytoplasm is more conspicuous in this body, and the cells are obviously cyanophil.

This body might be taken for demonstration purposes as the type of a lutein body during early organization of the fibrous core.

Specimen 909.—The interpretation of this section is more difficult, because much of the body is not included. There is a large central core, composed apparently of fibrin; in the absence of the block I was unable to prove this. The outer zone of this fibrin is infiltrated by spindle fibroblasts and also in a few places by occasional cells similar to those in the parenchymatous zone. Centrifugal rays pass from the central core. The parenchymatous zone forms an incomplete ring. Towards one surface of the ovary it narrows, and ultimately disappears. Where the section includes the outer limit of this zone, centripetal trabeculae are seen. Here the typical crenated structure of a lutein-cell zone is recognizable. The cells are not arranged in definite acini. They are, in general, of the homogeneous type, and are slightly basophil. A peculiarity is the extreme dilatation of many capillaries in the zone; the parenchymatous cells appear to be compressed thereby.

This specimen has all the more important characters of a lutein body. It is a flask-shaped lutein body, the lutein zone being absent at the point of dehiscence of the Graafian follicle.

Conclusion.

All three specimens, therefore, show the three main differential characteristics of lutein bodies: (1) The stellate core of fibrin or granulation tissue, (2) the absence of clearly defined acini, and (3) the alternation of centrifugal and centripetal trabeculae. Excepting the apparent lack of basophilia of the cells in specimen 1,209, they also show all the other less absolute characteristics which I have tabulated above after comparing lutein bodies with cortical suprarenal bodies and with adenomata of suprarenal cortex.

(Signed) HUBERT M. TURNBULL, D.M.,
Professor; Director of the Pathological
Institute of the London Hospital.

THE Straits Settlements gold medal, founded by graduates of Scottish Universities practising in the Malay States, has been awarded by the Senate of the University of Glasgow to Dr. R. T. Leiper, for the last fifteen years helminthologist to the London School of Tropical Medicine. His researches into bilharziosis led to his appointment by the War Office, in concert with the Medical Research Committee, to be consulting parasitologist to the Egyptian Expeditionary Force. In Egypt he, with his assistants, worked out the life-history of the peculiar trematodes which cause bilharziosis. It was shown that there were two species concerned—*Schistosoma haematobium* and *Schistosoma mansoni*, and it was established that both passed an intermediate stage in a freshwater snail, but that the snail was not the same; the one species *S. haematobium* entering a *Bullinus*, and the other, *S. mansoni* a *Planorbis*.

THE MILITARY MEDICAL SERVICES IN 1919.

For the last five years an article has been published annually in the BRITISH MEDICAL JOURNAL in January or February dealing with the military medical services, with reference especially to the number of casualties which had occurred and of honours which had been granted during the previous year. This series was continued, and it was hoped completed, in the Roll of Honour published as an appendix to the *Proceedings*¹ of the special clinical and scientific meeting of the British Medical Association held last April. The armistice was declared over a year ago, on November 11th, 1918; peace with Germany was signed on June 28th, 1919, but was not formally ratified until January 10th, 1920. The Roll of Honour gave statistics up to June 28th, 1919, and contained the names of 681 medical officers killed and of 515 who had died during the course of the war up to that date. Out of this number 2 were killed and 63 died during the first half of 1919.

But though peace now prevails, more or less, in Western Europe, military operations still drag their slow length along in other parts of the world. To take Britain alone, during the latter half of 1919 a campaign, which a few years ago would have been considered a war on a fairly large scale, has been conducted on the North-West Frontier of India, and is not yet over. Desultory fighting has also taken place on the frontiers of Mesopotamia, both north and south, and in the Sudan. And only two or three months have elapsed since a British force of some size was withdrawn from Northern Russia. We still seem to have troops on the shores of the Baltic, on the Black Sea, in Persia, and possibly elsewhere. During the latter half of the year three medical officers have been killed in action on the North-West Frontier of India, while a good many others have been accidentally killed or died of disease. But deaths from such causes there must always be in an army of any size, whether at peace or at war.

DEATHS.

The following four names, which should have been included in the Roll of Honour, were accidentally omitted, the last three having been published in Indian Army Lists which have reached England since June 28th.

Sewell, W. T., Captain Royal Inniskilling Fusiliers, killed at Thiepval, July 1st, 1916.

Gopal Swami, Lieutenant I.M.S.(T.C.), died at Madras, April 26th, 1919.

Greenwood, A., Major I.M.D., died June 10th, 1919.

Mathre, S. W., Captain I.M.S.(T.C.), died April 10th, 1919.

The three medical officers killed on the Indian frontier during the latter half of 1919 were:

Andrews, H. J., M.B.E., Captain I.M.S.(T.C.).

Bhargava, M. P., Captain I.M.S.(T.C.).

Middleton, A. H., Captain R.A.M.C.(S.R.).

The following medical officers have died during the latter half of 1919. Those marked with an asterisk (*) had recently retired or been demobilized.

R.N.—Surgeon Commander S. H. Vickery, Staff Surgeon J. Verdon, Surgeon-Lieutenants R. M. R. Thursfield (killed when H.M.S. *Gloucester* blew up in the river Dwina, in North Russia); R. Martin (drowned).

R.A.M.C.—Major-General J. G. MacNeece,* Lieut.-Colonels M. M. Rattray, F. M. Parry, Major H. G. L. Chevers,* Brevet Major N. W. Stevens, Captains J. W. Burton, W. S. R. Steven.

R.A.M.C.(S.R.).—Captains R. O'Kelly, G. A. Mitchell.

R.A.M.C.(T.F.).—Majors E. W. H. Vincent-Ryan,* W. Peart-Thomas,* A. H. Hogarth, Captain C. P. Sells, M.C.

R.A.M.C.(T.C.).—Lieut.-Colonel W. W. Angus, Major A. Neve,* Captains J. F. Stevens,* D.S.O., J. Macleod (accident), C. N. Cobbett, S. W. MacLellan,* M.C., S. Wright,* J. P. Spilsbury, G. H. Baird, W. H. Gray, C. H. Backus.

Australians.—Captain H. South.

Canadians.—Lieut.-Colonel R. Wilson.

I.M.S.—Lieut.-Colonels T. Jackson, C. R. Stevens, Majors

H. Crossle, R. J. Bradley, Captains J. F. Richardson (T.C.), N. Ghosh (T.C.), Lieutenant N. N. Saha (T.C.).

Combatant.—Major G. W. K. Crosland, D.S.O., West Riding Regiment.

HONOURS.

The total number of honours conferred upon members of the medical services, from August 4th, 1914, to June 28th, 1919, was 5,227, of which no less than 1,596 were gazetted in the first half of 1919. The attached table shows those given between June 29th and December 31st, 1919, amounting to 485. About 450 come under the three heads of British Empire (218), miscellaneous (50), and foreign (181). The list includes no K.C.B.'s and only two K.C.M.G.'s and three K.B.E.'s.

It has been stated that the honours gazetted in December would be the last given for war services. The Premier, however, has since announced that another list would be published of honours conferred for special services while prisoners of war. And presumably there will be some for the recent campaigns on the Indian frontier.

The total number of honours conferred upon naval medical officers has been larger than in any previous year of the war; but out of the total of 96, the O.B.E. accounts for 81. The Territorial Force has also done well in actual numbers, but 42 out of the total of 103 are the Territorial Decoration, an honour which is conferred almost automatically for length of service.

Honours, June 29th to December 31st, 1919.

RECRUITING FOR THE R.A.M.C. AND I.M.S.

Both the R.A.M.C. and the I.M.S. are now asking for applicants for commissions. It was announced in September last that 204 new commissions will be given in the I.M.S., 136 to Europeans and 68 to Indians. So far the number of applicants does not seem to have been large, though a few temporary officers of the R.A.M.C. have accepted commissions in the I.M.S. The terms of service offered are improved from the money point of view, as the pay now offered to officers on joining the service is more than double that which the senior men now serving drew when they first joined. Probably the difficulty of obtaining good European candidates for service in India in the present unsettled state of affairs in that country is more political than pecuniary. There should be no difficulty in finding the Indian candidates required. It is to be hoped that only men with satisfactory war service, of whom there must be a large number, will be appointed, and that special consideration will be given to those who joined in 1914-15, in the first year of the war. The R.A.M.C. doubtless will find it easier to get men for permanent service than the I.M.S. It is for many reasons to be regretted that compulsory service, or "conscription," to the extent of requiring a year's service in the army from all men qualifying and physically fit, was not kept up for some time longer, until all men now serving who had left their practices to join the army, and all who joined in 1914-15, whether previously in practice or not, had been relieved and demobilized.

Medico-Legal.

MEDICAL PROFESSIONAL PRIVILEGE.

THE remarks made by Mr. Justice McCardie on this subject on January 13th in the course of the case of *Garner v. Garner*, to which we made brief reference last week, have received considerable notice in the public press, and the vexed question as to the extent to which a medical man can be compelled in a court of law to disclose information obtained by him in his professional capacity is raised once again in a slightly altered form.

As a rule of English law, it is established beyond all question that confidential communications which have passed at any time between a party to an action and his legal adviser in the latter's professional capacity for the purpose of obtaining legal advice for the protection of the client's interests, together with any information which the legal adviser may have procured for the same purpose, are absolutely privileged. This right or privilege is the "property" of the client in the sense that unless the client waives his privilege, his legal adviser is not competent to give evidence in any court of law with regard to any matter which is covered by the privilege.

But the privilege is confined to the relationship of client and legal adviser, and although attempts have been made from time to time to extend it to the almost precisely similar relationship of patient and medical attendant, these attempts have met with little or no success.

In the case of the *King v. Elizabeth Gibbons*, in which the prisoner was charged with the murder of her bastard child, the evidence of a surgeon to whom she had made a confession in the course of a professional visit was admitted, and it seems clear that, subject to the discretion which every judge has to protect confidential communications in cases where he deems that protection is justified in the circumstances, no privilege, such as obtains in the relationship of legal adviser and client, can be claimed as a matter of right by a medical man or by his patient.

It may, however, be of interest to show the views which the Courts have taken of this medical "privilege" at various times.

In a case which was decided in 1828 Chief Justice Best said:

I think this confidence [which obtains] in the case of attorneys is a great anomaly in the law. The privilege does not apply to clergymen, since the decision the other day in the case of *Gilliam*. I, for one, will never compel a clergyman to disclose communications made to him by a prisoner; but if he chooses to disclose them I shall receive them in evidence. There is also no privilege of this description in the case of a medical man.

An attempt was made in *Slade v. Tucker*, which was decided in 1880, to claim privilege in respect of communications made to a Pursuivant of the Heralds' College, who had been employed in the conduct and support of a protest against a pedigree sought to be enrolled in the Heralds' College, and Jessel, then Master of the Rolls, said:

I never yet heard of the doctrine of communications between principal and agent being protected. The rule is that protection is confined to communications between a client and his legal adviser, that is, between solicitor and client or barrister and client, and the doctrine goes no further, except as to the employment of the intermediate agents between the client and the solicitor and the client and the barrister.

Mr. Justice Hawkins in 1896 took rather a wider view, according to a report in *The Times* of March 28th of that year, of the case *Kitson v. Playfair*, and, in summing up the evidence to the jury in that case, said:

I can quite understand a case, especially in a civil case, where a doctor is quite justified in refusing to divulge questions of professional secrecy. The judge might in some cases refuse to commit a medical man for contempt in refusing to reveal confidences. Every case must be governed by its particular circumstances, and the ruling of the judge will be the test.

In 1914 Mr. Justice Avory put it in a somewhat similar way in observations which he made at the Birmingham Assizes in charging the grand jury with a case of murder arising out of an illegal operation. The prisoner in that case had been indicted on a coroner's inquisition, the magistrates having dismissed the charge against her. It was clear from the medical evidence that the deceased had died from the effects of an abortion, but although three medical men had attended her since the operation, to one at least of whom she had given the name of the person who had performed the illegal operation, no information had been given to the police or to the authorities,

and the woman had died without any deposition having been taken from her. Mr. Justice Avory said:

Under circumstances like those in the present case, I cannot doubt that it is the duty of the medical man to communicate with the police or with the authorities in order that one or another of those steps may be taken for the purpose of assisting in the administration of justice. No one would wish to see disturbed the confidential relation which must exist between the medical man and his patient in order that the medical man may properly discharge his duty towards his patient; but there are cases, of which it appears to me this is one, where the desire to preserve that confidence must be subordinated to the duty which is cast upon every good citizen to assist in the investigation of a serious crime such as is imputed to this woman.

In *Garner v. Garner*, which was the case before the Divorce Court on January 13th, the petitioner was praying for the dissolution of her marriage, and relied upon the fact that syphilis had been communicated to her by her husband. She therefore desired to call as a witness the doctor who had attended her for this complaint in a London hospital at which treatment of venereal cases was given under the Public Health (Venereal Diseases) Regulations in accordance with the scheme formulated under those Regulations. The doctor went into the witness-box and then took the point, which he supported by a letter from the House Committee, that his knowledge of the case had been obtained in the course of the treatment of a venereal disease under the Regulations, and was therefore confidential and not to be disclosed in a court of law. It should perhaps be recalled that these Regulations expressly provide that "all information obtained in regard to a person treated under the scheme approved by the Board in pursuance of the Regulations shall be regarded as confidential."

The doctor was, however, being called as a witness by the woman upon whom he had attended; no question of "privilege," therefore, properly arose, and Mr. Justice McCardie decided that the evidence must be given. But the judge appears to have gone a good deal further than the occasion required, and to have made certain general observations from which it may be inferred that even had the doctor been called as a witness by the other side, the judge's decision would have been the same. These observations, according to the report in *The Times*, were to the following effect:

"The doctor [of the venereal centre] was one of those who were desirous of assisting the scheme for treating venereal diseases in every way, and for the purpose he wished loyally to maintain the secrecy which rightly rested upon him. But the witness would appreciate that in a court of justice there were even higher considerations than those which prevailed with regard to the position of medical men. He wished to say that, apart from the obligations which might be imposed on medical men by the order of His Majesty's judges, it was desirable that there should be the most loyal observance of the confidence which was reposed in them by patients. He was glad to say that the history of the medical profession was most honourable, and it was to be hoped that its members would always retain the confidence placed in them."

Put in another way, therefore, the provision in the Regulations of 1916, as to information being regarded as confidential does not, in the opinion of Mr. Justice McCardie, affect the question of a medical privilege. In order to test this opinion from the legal standpoint it is necessary to examine the Regulations a little closely, and not only the Regulations, but also the general scope of the Acts under which they were made.

The Regulations were made under the Public Health Acts of 1875 and 1896 and the Public Health (Prevention and Treatment of Disease) Act, 1913. Under Section 139 of the Public Health Act of 1875 the Local Government Board may make, alter, and revoke such regulations as the Board may think fit, with a view to the treatment of persons affected with cholera or any other infectious disease, and may declare by what authority such regulations are to be enforced or executed; and power is, further, given to the Board by Section 134 of the same Act, whenever any part of England appears to be threatened with any formidable epidemic, endemic, or infectious disease, to make regulations for the provision of medical aid, and for guarding against the spread of the disease. The Act of 1913 gives the Local Government Board power to make county councils authorities responsible for the execution of any regulations made by the Board under Section 130 of the Act of 1875.

With the powers conferred by these Acts the Board, in 1916, made the Venereal Diseases Regulations, which provided that every council was to arrange for the provision of assistance to medical practitioners attending patients

suspected to be suffering from a venereal disease, and that every council should prepare a scheme to be approved by the Board for the treatment of persons suffering from these diseases and for the provision of salvarsan at the council's expense, and the regulations contemplated that this was to be done through the media of hospitals and other institutions. Now, the Board had reason to know that the great difficulty which confronted any attempt to deal with this problem was the fear of disclosure on the part of those suffering from these diseases, and this being of such prime importance it rightly insisted that, as an essential part of any scheme, all information should be regarded as confidential, and the reason is even better appreciated when one reflects upon the number and varied classes of persons in a hospital or other public institution who must necessarily obtain a certain amount of knowledge with regard to patients attending for treatment.

From this, however, it is a far cry to a claim of privilege. The word privilege is not used in the Regulations as one would have expected had that been their intention; and, moreover, the Acts under which the regulations were made do not give any power to create a privilege in the proper sense of the word. Secrecy is a factor peculiarly important with regard to the treatment of venereal diseases, but was not contemplated by any of the Public Health Acts under which the regulations were made.

It seems, therefore, clear that Mr. Justice McCardie was right in his view of the Regulations, and that no legal protection is created by them.

A great deal has recently appeared in the press as to the desirability of medical men being compellable to disclose information obtained by them in a professional capacity, and more particularly in regard to cases of venereal disease; it must be generally recognized that the arguments in favour of such contention are strong.

According to French law, in effect, no witness is obliged in a civil case to give evidence against his will, and by Art. 378 of the Penal Code a doctor who does so in a case of any sort is guilty of an offence. The article may be translated as follows:

Physicians, surgeons, and other officers of the health services, as also pharmacists, midwives, and all other persons who, owing to their status or profession, are depositaries of secrets confided to them, who, save in the case where the law requires them to make notification (à se porter denoncateurs), shall reveal such secrets shall be punished by imprisonment for one to six months and a fine of 100 francs to 500 francs.

It is provided further that such persons may not divulge these confidential communications even though their patients are prepared to waive the privilege.

This view has not commended itself to English jurists, who hold that inevitably from time to time cases must occur in which the judge will consider it essential in the interests of justice that the evidence of a medical attendant should be available, even against his patient. Any hard and fast privilege, on the lines of the French code, is not likely to be approved by Parliament.

At the same time it must be recognized that the preservation of confidence is a prime essential of the relationship of patient and medical adviser, and that this should be respected in the public interest in all ordinary cases. No doubt it might be difficult to lay down any rule of privilege on these lines, but it should easily be possible to improve upon the present position, which is apt to result in definite conflict between the legal and professional duties.

For this, however, legislation is necessary.

The Services.

MEDICAL APPEAL BOARDS FOR OFFICERS.

The Ministry of Pensions announces that medical appeal boards for officers, each consisting of a Deputy Commissioner of Medical Services (as chairman), an appropriate specialist, and a medical assessor, are being established at the regional head quarters of the Ministry of Pensions, or at other convenient places within the respective regions. The medical appeal board will hear all appeals based on dissatisfaction with the assessment of the degree of disablement. It will also deal with claims based on deterioration of health since the last board and made within one month of the date of the last board, such claims being deemed to be based on dissatisfaction with the assessment made by the last board. (Claims in the latter category, where made after the expiry of a month, will be dealt with by special machinery which has been set up for the purpose.)

The medical appeal board will have before it all the relevant medical documents, including proceedings of the previous board and any medical information which the appellant may

furnish, and will be in a position to give an authoritative opinion. The appeal board will have power to raise or lower or confirm an assessment, and the decision will be binding for the currency of the previous award, provided that it will not preclude the review of the assessment during that period, if the officer claims that his condition has become substantially worse since the decision.

Officers desiring to appeal or claim a reassessment must communicate direct with the Secretary, Officers' Branch, Ministry of Pensions, Chester Gate Huts, Regent's Park, N.W.1.

HONOURS.

C.B.E.

MAJOR (temporary Colonel) John Thomas Clarke, C.A.M.C., has been appointed a Commander of the Order of the British Empire (Military Division) in recognition of valuable services rendered in connexion with military operations in Siberia.

Military Cross.

The Military Cross has been awarded to Temporary Assistant Surgeon James Michael Connor, I.M.D., for marked gallantry and devotion to duty at Barley Hill Piquet on July 18th, 1919.

He went out from Fort Mande, and, after being wounded himself, attended the wounded under fire until they were evacuated. He was again wounded while leaving, but continued at duty at Fort Mande until July 20th.

FOREIGN DECORATIONS.

The following are among the decorations and medals awarded by the Allied Powers to British Forces for distinguished services rendered during the course of the campaign.

By the President of the United States of America.

Distinguished Service Medal.—Honorary Major-General Sir Anthony A. Bowlby, K.C.B., K.C.M.G., K.C.V.O.; temporary Major-General Sir Robert Jones, K.B.E., C.B., T.D., A.M.S.; Major-General Sir H. Neville Thompson, K.C.M.G., C.B., D.S.O.; Honorary Major-General Sir Cuthbert S. Wallace, K.C.M.G., C.B.

By the President of the French Republic.

Légion d'Honneur.—Officier: Colonel John Charles Baron Statham, C.M.G., C.B.E., late R.A.M.C. *Chevalier:* Lieutenant-Colonel R. de Lothbiniere Harwood, C.A.M.C.

Croix de Guerre.—Captain (acting Major) James Chambers Sproule, R.A.M.C.

Ordre du Mérite Agricole.—Chevalier: Captains James Clayton, John Duncan Davidson, and John Golding, D.S.O., R.A.M.C. (T.F.).

By the King of Serbia.

Order of St. Sava.—5th Class: Captain John Steedman, R.A.M.C. (T.F.); temporary Captains (acting Majors) William Henry Peacock, Norman Bruce Stewart, and William Halliday Welsh, R.A.M.C.; Lieutenant (temporary Captain) Arnold Guy Harsant, R.A.M.C. (S.R.).

Gold Medal for Zealous Service.—Captain Phillip Henry Mitchiner, R.A.M.C. (T.F.).

By the King of Siam.

Order of the White Elephant.—3rd Class: Lieutenant-Colonel and Brevet Colonel Sir Edward Scott Worthington, K.C.V.O., C.B., C.M.G., R.A.M.C.; Lieutenant-Colonel R. de Lothbiniere Harwood, C.A.M.C.; Major (acting Lieutenant-Colonel) Richard Chapman Wilson, R.A.M.C.; Captain and Brevet Major Robert Craig Dun, R.A.M.C. (T.F.). 4th Class: Captain Joseph Henry A. Paquette, C.A.M.C.

Order of the Crown of Siam.—2nd Class: Lieutenant-Colonel Harold Percy Waller Barrow, C.M.G., O.B.E., D.S.O., R.A.M.C.

By the Sultan of Egypt.

Order of the Nile.—3rd Class: Lieutenant-Colonels Cauldwell Hamilton Anderson, M.C., 2nd Light Horse Field Ambulance, A.A.M.C.; (temporary Colonel) Thomas Henderson Forrest, D.S.O., R.A.M.C. (T.F.), Percy Samuel Lelean, C.B., R.A.M.C.; Major and Brevet Lieutenant-Colonel (acting Lieutenant-Colonel) Herbert Vale Bagshawe, C.B.E., D.S.O., R.A.M.C.; Majors (acting Lieutenant-Colonels) Alexander Glover Conliffe, I.M.S., George Wykeham Heron, D.S.O., O.B.E., R.A.M.C.; Major Alfred William Moore, O.B.E., R.A.M.C. (T.F.); Captain (acting Lieutenant-Colonel) Hugh Stanley Beadles, R.A.M.C. (T.F.). 4th Class: Major Leonard A. Avery, D.S.O., R.A.M.C. (T.F.); Captain Arthur Lewin Sheppard, I.M.S.

By the Shah of Persia.

Order of the Lion and Sun.—3rd Class: Captain Charles James Stocker, M.C., I.M.S.

By the President of the Portuguese Republic.

Military Order of Avis.—Commander: Temporary Lieutenant-Colonel George Henry Usnar, O.B.E., S.A.M.C. *Chevalier:* Captain Frederic Battinson Smith, M.C., R.A.M.C. (T.F.).

By the King of the Hellenes.

Order of the Redeemer.—Chevalier: Captain William Lombard Murphy, R.A.M.C. (T.F.).

Greek Medal for Military Merit.—3rd Class: Lieutenant-Colonel Arthur Durham Waring, R.A.M.C.; temporary Major John Healey Spencer, R.A.M.C.; Captain Harold Edgar Smith, R.A.M.C. (T.F.); temporary Captains (acting Majors) Phillip

Maynard Heath and Robert Scott, R.A.M.C. 4th Class; Captain J. Ratcliffe, R.A.M.C.(S.R.); temporary Captains Ronald E. Gordon Gray, and Charles Sanson Thomson, R.A.M.C.

By the King of the Hedjaz.

Order of El Nahda.—3rd Class: Captain and Brevet Major (acting Major) William Edward Marshall, M.C., R.A.M.C.

TERRITORIAL DECORATION.

The Territorial Decoration has been conferred upon the following officers of the R.A.M.C.(T.F.):

Lieut.-Colonels: John Allison (attached Northumbrian Yeomanry), F. E. Fremantle, O.B.E., M.P. (General List), F. W. Gibbon, V.D. (attached Tyne Electrical Engineers), Archibald G. Hay (3rd Scottish General Hospital).

Major (acting Lieut.-Colonel) James Scott (attached 5th Battalion, Royal Scots).

Majors: William A. Burns (2nd Lowland Field Ambulance), James H. Dixon (5th London Field Ambulance), William Haig, D.S.O. (attached 6th Battalion, Royal Highlanders), Alexander E. Kidd, O.B.E. (3rd Highland Field Ambulance), James Middleton (attached 5th Battalion, Gordon Highlanders), Paul McK. Terry (attached Wessex Division, Ammunition Column, R.F.A.), William D. Watson (1st East Anglian Field Ambulance), James Wood, D.S.O. (1st West Lancs Field Ambulance).

Captain and Brevet Major Keith W. Monsarrat (1st Western General Hospital).

Captain (acting Major) Arthur L. Whitehead (2nd Northern General Hospital).

Captains: Godfrey J. R. Lowe (4th Northern General Hospital), F. W. K. Tough (3rd West Lancs Field Ambulance).

The surname of Lieut.-Colonel Cyril H. Howkins, C.B.E., D.S.O., is as now described, and not as stated in the *London Gazette* of November 4th, 1919.

Obituary.

GEORGE WILLIAM KILNER CROSLAND, D.S.O.,

M.R.C.S., L.R.C.P.

Late Chairman of the Huddersfield Division, British Medical Association.

THE medical profession in Huddersfield and surrounding district has sustained a serious loss by the death of Major Crosland, which took place on the last day of 1919, after a distressing and painful illness. He underwent a serious operation in the spring of last year which necessitated his absence from work for about four months. In the autumn his health had improved so much that he had good ground for believing that he was cured of his ailment. Soon afterwards, however, there were signs of a recurrence, and he began slowly but surely to lose ground. He struggled bravely on in spite of much pain and weakness and did his operative work—hospital and private practice—until within a month of his death.

Major Crosland belonged to a well-known Huddersfield family, and his grandfather, Mr. T. P. Crosland, was Member of Parliament for the borough. He received his medical training at the Leeds School of Medicine, and after qualifying, in 1892, was appointed house-surgeon of Huddersfield Infirmary, and held that post for two years. He then started practice in his native town. In 1905 he was appointed honorary surgeon to the Infirmary, and at the time of his decease was senior surgeon. He served during the South African war as surgeon. Ten years ago he contracted blood poisoning, whilst operating, resulting in a serious illness which laid him aside from work for many months. At the outbreak of the war in 1914 he was a combatant officer in the Fifth Battalion Duke of Wellington's Regiment, and went with it to France, and was exceedingly popular with his fellow officers and men. In recognition of his services he was granted the D.S.O. On returning from the war and resuming his private practice in Huddersfield he had charge of one of the auxiliary war hospitals.

Major Crosland was only 50 years of age, and great regret is felt by his professional brethren and the whole community at his untimely death. He was an able and skilful surgeon, a wonderfully quick and neat operator, and very resourceful in any emergency. He had high ideals of professional honour and acted up to them. He was late in coming to his own, but his skill as a diagnostician and his dexterity as an operator were becoming more and more appreciated by his fellow practitioners, and had he not been stricken down by sickness he had the promise of a busy and useful career. He spent his life in the service of others and delighted in his work for its own sake, rather than for any monetary reward it might bring him. For

several years he was secretary of the Huddersfield Medical Society, and only last year retired from the post of chairman of the Huddersfield Division of the Yorkshire Branch of the British Medical Association. He was an occasional contributor to the *BRITISH MEDICAL JOURNAL*.

Major Crosland was buried with military honours amidst many signs of deep respect. The funeral was attended by a large number of the medical men of Huddersfield and the surrounding district.

THE death took place from encephalitis lethargica, on December 26th, 1919, at Great Shelford, Cambridgeshire, of Dr. JAMES THOMAS CHAMBERLAIN. He was born in Leicestershire in 1856, and received his medical education at Edinburgh University and the Royal College of Surgeons of Edinburgh, winning a medal in midwifery and diseases of women and children. He obtained the Scottish triple qualification in 1886. Dr. Chamberlain practised for ten years in Nottinghamshire, and shortly after his retirement went to live at Great Shelford, where he made himself very popular, taking a warm interest in all local affairs. He was one of the trustees of the Shelford charities. The first part of the funeral service was held in Great Shelford Free Church on December 30th; the interment ceremony took place in the parish churchyard. The wreaths included one from former patients in Nottinghamshire. Dr. Chamberlain leaves a widow.

CAPTAIN H. J. ANDREWS, M.B.E., I.M.S., was reported as killed in action in a casualty list published on November 24th, 1919, aged 48. He went to India as a young man, and was one of the first officers of the Salvation Army in that country. Subsequently he studied in the United States, and took a medical degree at Chicago. During his service with the Salvation Army he designed and superintended the erection of three hospitals—*at Nagerwil, at Anand in Guzerat, and the Thomas Emery Hospital at Moradabad.* He took a temporary commission as lieutenant in the I.M.S. in June, 1917, was promoted to captain after a year's service, and received the M.B.E. in June, 1918.

Medical News.

THE first of the course of three Lettsomian Lectures on tumours complicating pregnancy, labour, and the puerperium, before the Medical Society of London, will be delivered by Dr. Herbert Spencer on February 2nd, at 9 p.m. It will deal with fibroid tumours. The annual oration will be given by Sir D'Arcy Power on May 10th; the subject is "The Rev. John Ward and Medicine."

DR. MILHAIS CULPIN will begin a course of fifteen lectures on neuroses and psycho-neuroses in the London Hospital Medical School at 5.15 p.m. on Tuesday, January 27th. Members of the profession are invited to attend the course.

THE Assurance Medical Society has resolved, by a large majority, not to become incorporated with the Royal Society of Medicine.

DR. EDWIN SMITH, lecturer on forensic medicine and toxicology at St. Thomas's Hospital, has been appointed deputy coroner for Westminster and the South-West London district.

AN ante-natal clinic will in future be held weekly on Thursdays at the Great Northern Central Hospital, Holloway Road, N.7.

AT the meeting of the Hunterian Society to be held at the School of Oriental Languages, Finsbury Circus, on Wednesday, January 28th, at 9 p.m., Dr. A. E. Gow will read a paper on treatment by protein therapy.

DR. LOUIS W. SAMBON will read a paper on tropical and subtropical diseases at a meeting of the Royal Colonial Institute to be held at the Central Hall, Westminster, on Tuesday, January 27th; the chair will be taken by Sir Patrick Manson, G.C.M.G., M.D., F.R.S., at 3.30 p.m.

THE Royal Sanitary Institute announces courses for sanitary officers, meat inspectors, and women health visitors, and child welfare workers. The courses are didactic and practical. Full particulars can be obtained on application to the director and secretary of the Institute, 90, Buckingham Palace Road, London, S.W.1.

THE first exhibition of x-ray prints in this country to be open for any considerable period is on view at the house of the Royal Photographic Society, 35, Russell Square, until February 7th. The prints have been gathered together by a committee of the Röntgen Society, and include nearly two hundred examples by some twenty or thirty of the principal radiographers in this country as well as a few in France. One at least of the prints is of historic interest; it is the first radiograph made in public in London, and was the result of an exposure on the human hand for twenty minutes in the course of a demonstration by Mr. Campbell Swinton at the Camera Club at the beginning of 1896. In addition to the very representative illustrations of medical and naturalist interest, a large number of records of the application of x-rays to the examination of metals are included; and altogether the non-medical uses of x-rays would surprise any visitor who is not familiar with the most recent developments in radiography.

THE first number of *Discovery*, published by Mr. John Murray for the trustees, has appeared. It is a popular journal designed to give its readers an interest both in the sciences and in the humanities. The editor, Mr. A. S. Russell, M.C., D.Sc., believes that there has been considerable opposition between representatives of science and the humane studies, and that the two studies ought to be regarded as complementary. The first conception of the journal was due to the late Professor Julius Macleod, a Belgian botanist who was a guest of the University of Manchester during the war. A joint committee was formed between the Council of Humanistic Studies and the Conjoint Board of Scientific Studies, and it was arranged to establish such a journal and to commit its management to representatives of various bodies, including the National Union of Teachers, the Head Masters' Conference, the British Psychological Society, the Royal Society of Economics, and various associations concerned with classics, history, geography, and modern languages. The first number ranges over a variety of subjects—archaeology, psychology, education, politics, and acoustics as applied to sound-ranging in war. We wish the new monthly success, and hope that the support it receives may shortly warrant its enlargement, for it has a very wide field to cover. The price is 6d.; the annual subscription, post free, 7s. 6d.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitology*, Westrand, London; telephone, 2631, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2634, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin.

QUERIES AND ANSWERS.

INCOME TAX.

"ANXIOUS INQUIRER" has an income of about £100 net from property; what will be his income tax liability if he transfers his practice to his son?

, As from the date of transfer his total income would be reduced by a proportional part of the income tax assessment—for example, if from February 5th, 1920, then by two-twelfths, and so on. If the transfer be effected by April 5th, 1920, and our correspondent has no other income, he would not be liable to income tax on his property for 1920-21, as his total income for that year would be less than £130.

ADOLESCENT OBESITY.

B. G. R. asks for suggestions in the treatment of a girl in her teens who continues to put on fat in spite of strict dieting, exercises, and thyroid treatment. After three years of failure the effect is most depressing (mentally) on the patient.

ALOPECIA.

M. C. wishes to hear if any further treatment would be of use in a girl who at the age of 17 began to lose her hair. She is now 19, in good health, having had a long course of x-ray, ionic, and electrical treatment with no improvement.

LETTERS, NOTES, ETC.

"MINERS' NYSTAGMUS."

DR. CHARLES F. HARFORD (London, E.C.) writes: In a paper which I contributed to your issue of March 4th, 1916, as the result of observation of a series of cases met with in the army I ventured to call attention to the misleading character of the title of the disease, which concentrates attention upon one out of many symptoms in this complaint as if this were the disease itself. One of the results of this has been to relegate the disease purely to the department of ophthalmology, when in reality it is an affection of the nervous system in general. Thus the medical textbooks as a rule ignore the subject altogether, and even modern textbooks on ophthalmology leave much to be desired in their treatment of this affection. The American *Encyclopedia of Ophthalmology*, vol. x, contains an exhaustive account of the literature of the disease, whilst Dr. Lister Llewellyn's monograph, *Miners' Nystagmus: its Causes and Prevention*, is the classical work to which one would naturally turn. Much needs to be done to deal with the prevention and treatment of miners' nystagmus, and a determined effort should be made to improve the conditions of those who are liable to or already suffering from this serious malady.

CERVICAL VAGUS AND SYMPATHETIC.

IN a note on Sir E. Sharpey Schafer's experiments on the cervical vagus and sympathetic published in the *Epitome*, January 17th, p. 12 (paragraph 74) there was a slip of the pen. The penultimate sentence should have read "No functional regeneration of the vagus in the neck was found either in dog or cat." In common with other investigators he found histological and functional regeneration of the sympathetic.

THE SPAN OF LIFE.

LIEUT.-COLONEL FREDERICK F. MACCABE, M.B. (Kildare), writes: Since I wrote *Human Life* and read your review of it I have read the *Bible*. I cannot resent your preference for the words of the Psalmist on the length of life to any words of mine, but I think the following quotations will interest your readers, as they go far to show that, perhaps, after all, I may have been right, even from a scriptural point of view, when I fixed upon 120 years as the intended span of life.

In Genesis, chapter vi, verse 3, I find the following: "And God said, My spirit shall not remain in man for ever, because he is flesh and his days shall be a hundred and twenty years." And again, in Deuteronomy, chapter xxxiv, verse 7: "Moses was a hundred and twenty years old when he died: his eye was not dim neither were his teeth moved." Then in Ecclesiastics, chapter xxvi, verse 1, I find the following interesting quotation bearing on the subject: "Happy is the husband of a good wife, for the number of his years is double." Of course, this leaves me in doubt as to whether such a man's expectation of life is 140 or 240 years.

A DISCLAIMER.

DR. A. C. MAGIAN (Manchester) desires it to be understood that the recent use of his name in an advertisement of a fountain pen is distasteful to him, and that he has taken steps to inform the advertiser of his disapproval.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 43, 44, 45, 46, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 40, 41, and 42.

THE following appointments of certifying factory surgeons are vacant: Duncannon (Wexford), Newmans (Lanark), Rochdale (Lancaster).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under 0 6 0
Each additional line 0 0 9
Whole single column 4 0 0
Whole page 12 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

PSYCHOPATHOLOGY AND DISSOCIATION.*

BY

WILLIAM BROWN, M.A., M.D. OXON., D.Sc. LOND.,

READER IN PSYCHOLOGY, UNIVERSITY OF LONDON (KING'S COLLEGE), LATE MEDICAL OFFICER IN CHARGE OF CRAIGLOCKHART WAR HOSPITAL FOR NEURASTHENIC OFFICERS.

I HAVE chosen this subject because it seems to me an especially interesting part of psychology, and to those who are beginning the subject it opens out prospects of advance in the science which are extremely attractive and stimulating.

Psychopathology is the science of the abnormal or pathological working of the mind. Psychology considers the laws of working of the normal mind, the mind that is in adequate adaptation to its environment, physical and mental. Psychopathology considers the laws of working of the mind that is out of harmony with its environment because of some degenerative process.

The difficulty is to find one guiding idea to carry us along in this very complicated subject. The hint comes from normal psychology. Not many years ago our own English psychologists developed a system of association psychology, explaining the mind in terms of association of ideas—that is, regarding the mind as something gradually built up on the basis of what is given through impressions from without and of what is inherited within. So in psychopathology we might begin our discussion by considering facts of dissociation—indeed, that is the word to conjure with in our subject—dissociation, splitting up of the mind, the antithesis of association. We shall take as examples of pathological states the so-called borderline cases—hysteria, neurasthenia, psychasthenia, and compulsion neurosis. If we go beyond these we come to what are called the psychoses, which are recognized forms of insanity. Much the same kind of explanation will cover all types of mental disease, but the attempt to produce a satisfactory science of mental dissociation was begun within the domain of borderline cases, otherwise known as the psychoneuroses. These diseases may also be called functional nervous diseases. In them there is no demonstrable lesion of the nervous system. The nervous system is apparently intact, but is functioning wrongly or inadequately.

This lecture will be devoted to the problem of hysteria.

Hysteria.

In hysteria we have very obviously a case of dissociation; certain parts of the mind, certain sensations, certain powers of movement, certain memories, are lost to the main consciousness, but still exist somewhere or other, in some form or other, and can be restored under appropriate conditions. The anaesthetics that hysterical patients suffer from are a good instance of the kind of dissociation that occurs. A hysterical patient may suffer from anaesthesia of the hand, or of the hand and lower arm, or of the hand and arm up to the shoulder, ending in a straight line round the shoulder, or, again, from hemianaesthesia extending down the right or left side of the body and ending accurately in the middle line. Many other forms of anaesthesia are possible. All these types correspond in their extent to ordinary, uneducated concepts of the divisions of the body; for example, the hand, in ordinary unscientific thought, is considered as one entity, the whole arm is considered as an entity, ending in a straight line round the shoulder. This holds good even for purposes of tactile association, but from anatomy we know that the nerves supply irregular areas, consisting, for example, of a strip down the forearm, extending towards the fingers of the hand, so that, if there were an organic disturbance of a cutaneous nerve, we would find an irregular area of anaesthesia—the more irregular the smaller the number of nerves affected—we would not find an area of anaesthesia corresponding to the hand, or the arm. Pierre Janet emphasized these distinctions between what are called functional anaesthetics and organic anaesthetics, and pointed out that the anaesthesia illustrates the state of mind of the hysteric, who has lost the power of holding together in one unity all the sensations

from the different parts of his body. A patient may receive a blow on the arm, causing a mental shock, as a result of which his whole arm may become anaesthetic, and the anaesthetic area may end in a straight line round the shoulder-joint. That area does not correspond to the distribution of any set of nerve fibres, but it does correspond with the patient's own conception of his cutaneous sensibility. Moreover, it can be proved indirectly that the sensations in this part of the body still exist. Sometimes we can do this by a trick, as Janet pointed out: We can ask the patient to say "yes" when he feels a pin-prick, "no" when he does not. We get him to close his eyes, and then silently explore different parts of his body. Whenever he is pricked on the normal part of the skin he will say "yes." When he is pricked on the so-called anaesthetic area of the skin he will often say "no," whereas if the area were really anaesthetic he would not know that it had been touched at all. Yet he is probably quite genuine in his belief that he has not felt the pin-prick—though of course we must be certain that he is not malingering. It is very important in considering hysteria to be familiar with the various types of malingering. Cases like this, of anaesthesia combined with functional paralysis of the arm, occurred frequently during the late war.

I have dwelt on hysterical anaesthesia, not because it is very important, but because it well illustrates this theory of functional dissociation. There is dissociated from the entire mind one psycho-physical power, in this particular case cutaneous sensitivity—the power of reacting to stimuli presented to some part of the body. Again, the patient may have loss of motor power: he may be suffering from loss of power in the legs—cannot stand or walk; yet if we investigate his nervous system we may find that it is perfectly normal. Nevertheless, there is loss of sensory power, or loss of motor power, and also, very frequently, a greater or less degree of amnesia, or loss of memory. To sum up the state of mind of the hysterical individual, we may say that it is a state of mental dissociation—dissociation of certain psycho-physical functions from the main personality. Yet these dissociated functions remain, and under appropriate conditions can be recovered—for example, under hypnosis. Hysterical patients are easily hypnotized; in fact, Charcot and Janet hold that any person who is easily hypnotizable is *ipso facto* hysterical, and that, if an ordinary person be hypnotized, he is made hysterical by dissociating his mind—a form of dissociation has been started. With this view I agree.

It is worth while considering this matter a little further. To hypnotize a person we get him to fix a bright object with his eyes, to relax his muscles, and to give his mind up to sleep—to turn his mind away from everything active. We continue to talk to him all the time, telling him to think of sleep, and saying that his eyelids will begin to get heavy, that he will lose feeling in his limbs, and that he will gradually become more and more drowsy. After he has fixed the bright object for a short time and his expectation of sleep has been encouraged in this way and his thoughts fixed on sleep, which (though we have as yet no satisfactory theory of sleep) may be provisionally said to be a quieting down of the mental powers, he will appear to lose consciousness. But there is one power of the mind that is not quieted down, and that is the power of hearing the physician's voice. The physician is talking almost the whole time, and whenever he speaks the patient, until he gets very deeply hypnotized, can respond. Thus we produce dissociation of the power of hearing a particular kind of sound from the rest of the mind. The rest of the mind is lulled to sleep; it is a case of partial sleep. But more than that, there is an emotional element at work. A patient cannot be hypnotized by a gramophone, unless he has been hypnotized before and has an extreme tendency to yield to this kind of suggestion. The patient has to feel an interest in the physician, either of fear or of confidence. These are the two forms of mental reaction. Different people hypnotize in different ways; some have a tendency to hypnotize through fear, others through arousing confidence—one might even say affection—in the patient. There is always an emotional element involved. We shall have later to consider a theory that makes a great deal of this emotional element. In the case of a normal person such an emotional appeal must be very strong; in the case of a hysterical person it need not be so strong, because the patient already shows

* A lecture delivered to Psychology students at King's College, Strand, December 15th, 1919.

a tendency towards dissociation; the hypnotic effects appear more readily. Charcot considered the hypnotic state a form of artificially induced hysteria. Janet agreed with him, and so do I, though many people think that, because almost everyone can be hypnotized to some degree, this theory must be wrong. But there is a tendency to mental dissociation in all of us, based on emotional conflicts. No one is a complete mental unity.

Finally, as an example of a hysterical patient, let me take the condition of almost any bad case of shell shock on the Western front, or any of the other fronts, during the past five years—any of the cases as they reached the casualty clearing station. The patient's condition was always that of dissociation. All such cases agree in showing loss of memory of greater or less extent. They may have forgotten everything that has happened since the shell burst, and they will exhibit other losses of function, greater or less, according to circumstances. They may show loss of voice, of powers of walking, of powers of hearing, of the power of voluntary control. I would emphasize their loss of memory. It will be found that such a patient is very easily hypnotized; if it be suggested to him that he will remember the circumstances of his injury with hallucinatory vividness, he will act again the whole circumstances, and in that process his various dissociated functions will return. If he has been dumb, he will now speak, without the necessity of suggesting this. If he has been paralysed, movement will occur in his limbs. I do not say that he will at once be able to take up his bed and walk, but his limbs will move about, showing that there is power in them, and that the power is linked up with the lost memory. What has been done here? We have re-associated him by bringing up these lost memories. With the memories we have brought up the lost functions. But we have done more than that, we have given him an outlet for an emotion which was originally experienced by him with too great intensity—with so great an intensity that he could not do full justice to it, and his mind split in the attempt. The way in which these patients live again through their experiences shows what terrible sensations they must have had. They roll about, gripping at the sides of the stretcher, or rolling on the floor, tearing at their hair with their hands, contorting themselves in every possible way, foaming at the mouth, becoming purple in the face, their eyes starting out of their head, all their muscles tense. While under shell fire the conscious personality was trying to suppress the emotion of fear, partly from a sense of duty—the duty of a soldier—partly in self-defence—anything to get away from it. There occurs a mental conflict—an attempt to get rid of the painful emotion. The attempt succeeds at the expense of the mental machinery; clouding of consciousness supervenes, the patient goes into a state of stupor, where he is not completely unconscious, but where he is dazed. He gradually recovers from this, but has no memory of it later. We see here the mechanism at work explaining the dissociation. The dissociation is obviously a fact, but it is not an ultimate fact. There is a cause for it, and that cause is mental conflict, an attempt at repression, an attempt which has succeeded to a certain extent, but only at the cost of the production of a pathological symptom or set of symptoms. In curing the patient we bring up the repressed experience once more, we encourage him to work off the emotion involved in it. Just as a person who grieves for someone he has lost finds relief in tears, so we let these patients work off their fear. Thus we are concerned not only with the linking up of the dissociation, but also with the working off of fear, of a certain amount of emotional energy that has been bottled up in the patient.

This illustrates the advance that Sigmund Freud made on Janet in explaining hysteria. Janet explains hysteria simply in terms of dissociation. He says that the patient suffers from weakness of mental synthesis. He compares the hysteric to an old lady who has gone shopping and has made too many purchases. She comes back with her arms laden with parcels. Some of these fall to the ground; she stoops to pick them up, and others fall. So, he says, is it with the hysteric after a shock. He loses the power of holding all his psycho-physical functions simultaneously in his mind so that some of them are lost, and he suffers from an anaesthesia and paraplegia. If you cure him of this by suggestion, later on he will, perhaps, as the result of some slight shock, show some other

functional symptom—he may lose his voice or his hearing. Some other hysterical symptom will take the place of the original one unless he is cured of his general mental state. But Janet did not undertake to explain why the dissociation took place. Freud found, after an investigation of some hysterical cases under hypnosis, that there was very frequently loss of memory, that such memories were always of an emotional character, and that the symptoms disappeared if the memories were brought to the surface of the mind with their original vividness. Breuer and Freud published their first article on the mechanism of hysteria in illustration of this process—this effect of repression of painful emotional experience: loss of memory and dissociation, and the recovery of these by means of hypnosis and the dissipation of the symptoms themselves through encouraging the patient to live through the emotion again. This living again through the emotion and working it off was called "abreaction." At this early stage of his theory, then, Freud regarded dissociation as due to a preliminary mental conflict and a repression of one of the conflicting mental tendencies. Later on he developed this view further. He found that in the case of the dreams of normal persons there was also evidence of mental repression, and of the production of mental symptoms as a result of the repression. His view of the dreams of normal persons was, and is, that they correspond exactly with the symptoms of the hysteric, that they are "disguised fulfilments of repressed wishes," to use his own words. I do not want to go into his theory of dreams in detail, it would take us too far afield; I wish only to recall this part of his theory.* Later on he found, after analysing a number of his own cases, that the emotional tendencies which were repressed were all of a sexual nature, and so he enunciated his dictum that no neurosis is possible in a normal sexual life, and that, if a patient is suffering from neurosis, there must have been some disturbance in his sexual life.

That is the extreme form of the Freudian theory, which I do not accept, though the Freudian school make it an essential part of their doctrine. Freud thinks that we can find evidence of sexuality in the early years of childhood—namely, feelings of attraction of the boy towards his mother and of the girl towards her father, combined with hatred and jealousy felt towards the parent of the same sex—and that these feelings are shortly afterwards repressed. A mental conflict takes place in the child's mind, and sexual repression occurs, partly through the further normal development of the child's mind—other interests arise and crowd out these feelings—partly through the fact of development of feelings of sympathy and of morality, and these repressed tendencies only produce a competing factor if shocks occur later in the child's life.

I have already referred to the production of hysterical symptoms as being due to an emotional shock. That seems to be the general rule—an emotional shock will produce hysteria in persons whose inherited make-up is suited for it. The hysteric is born, not made, but the hysterical symptom is originated through some emotional shock. Freud considered that these emotional shocks were repressed and dissociated from the mind, and continued to act as a foreign body in consequence, but that these repressed memories could be brought to the surface either by hypnosis or by his method of psycho-analysis. In his earlier work he thought that he could prove in every case the actual occurrence of a shock in early childhood of a sexual nature. Later on, however, he discovered that some of the memories brought up by these methods were false memories—that the patient had imagined them—but this did not alter his theory very much. He said that the fact that the patient had the power of imagining such events showed that there was maldevelopment of the sexual life at that time, so that he then explained the neurosis in terms of the process of development of the psycho-sexual life of the child—a theory into which I cannot go now. To be a thoroughgoing Freudian now one must be able to accept this theory, and for many of us it is because we cannot subscribe to it that we should not call ourselves Freudians.

C. G. Jung of Zurich was Freud's most brilliant pupil, and at first an enthusiastic supporter of his views. Later, however, Jung's researches led him to believe that these

* See my articles on "Freud's Theory of Dreams," *Lancet*, April 19th and April 26th, 1913.

earlier emotional memories of the child were not an essential factor in the production of neurosis, but that the principal factor was the present condition of the patient. When a patient falls ill of a psycho-neurosis it is because he is not adequately adapted to his present social and physical environment. Life is too great a task for him; he cannot hold his own; he has not sufficient courage to face facts, with the result that, if he is of a hysterical temperament, his mind turns back to childhood's memories and to more childish modes of conscious activity. What Jung calls "regression" takes place. The mental energy of the individual, which Jung has called the "libido" (corresponding very closely to Bergson's "*élan vital*"), is reflected back, and revives earlier memories of childhood, not only memories of actual occurrences in childhood, but also early fancies. These fancies may be of a sexual nature or they may not. The libido in that way becomes linked up with earlier memories, and is no longer of use to the individual in his present mental situation—thus he becomes still less competent to deal with his environment.

But Jung would use the same method as Freud uses in treating the patient—the method of psycho-analysis, because, he says, we want to get back these earlier memories for the sake of the libido that is linked up with them. Psycho-analysis is simply the method of free association. If the patient is suffering from some hysterical symptom you get him to let his mind pass into a passive state—to recline on a couch, say, with his eyes closed—and passively follow up the sequence of ideas as they occur to him one after another, without any prompting. He begins, say, to think of the time when the symptom first developed, and then just watches his mind drift as it will—gets into a state of meditation—and tells the doctor from moment to moment what he is thinking about without reservation or criticism. His thinking seems to be undirected, to be just determined by free association. The result is that more and more ideas and memories from the past come to his mind, and perhaps eventually memories that are of great significance for his symptom. This occurs because the method is not really a method of free association at all. The series of ideas is, it is true, not determined by conscious mental process; it is determined by unconscious mental process. By letting the conscious selective activity fall into abeyance trends of unconscious mental activity come nearer to the surface of the mind and guide the ideas, and these belong to the same world as those mental tendencies which are at the basis of the hysterical symptom.

The difference between Freud and Jung, then, is, that Freud says that earlier memories and earlier imaginations are directly responsible for the hysterical symptom; Jung says that failure of adaptation at the present moment causes a regression or reflection of mental energy back to the past, and that this revives earlier imaginations and memories and so produces the hysterical symptom. Both agree in adopting the method of psycho-analysis, which proceeds to recall these earlier memories and fancies.

These, briefly, seem to be the fundamental ideas of Freud and Jung on hysteria, as contrasted with the ideas of Janet. They go a step further to the cause of the dissociation—that is, mental conflict and repression. Link up this dissociation and remove this repression and the patient is cured.

Freud, who originally used hypnosis, gave it up, partly because he found that he could only hypnotize about one-third of his patients, whereas psycho-analysis, though it took much longer, could be applied to every case, and produced eventually much the same results. His second objection to hypnosis was that certain resistances are overcome by the recall of particular memories, but in this process the resistance in other directions is increased, so that the mind is limited rather than expanded. He also suggested the germs of the theory that Ferenczi worked out in detail afterwards—namely, that in hypnosis there is really a transference of emotional feeling, of the early sexual feelings of childhood, to the person of the physician. Ferenczi points to the fact that there are two main methods of hypnotizing: the method of command, corresponding to the paternal method with the child, and the method of coaxing and soothing, which corresponds to the attitude the mother adopts towards the child. He then argues that in both types of hypnosis there is a revival in the patient's mind of its early modes of response. When a patient is hypnotized he responds to the physician just

as he responded to his father or his mother in early years—that is, by a reaction that is of a sexual nature—hence the patient's early sexual feelings are fixed on the physician. What has, thus really been done is to replace one set of symptoms by another. Hysterical symptoms, like loss of the power of walking or loss of voice, may thus be got rid of, but in the place of these the psycho-sexual dependence of the patient upon oneself has been produced, and this also is bad. What evidence has Ferenczi for this view? He says that it is taken from actual experience of patients whom he originally treated by hypnosis, but later on psycho-analysed. He found evidence of such transference of feeling in them.

These, then, are, Freud's three objections to the method of hypnosis: (1) Failure of the method in certain cases. (2) Its tendency to produce other symptoms in place of those of which the patient is cured. (3) Fear of the transference of sexual feeling to the person of the physician.*

With regard to the last objection we might urge that Ferenczi's theory is a *petitio principii*; the patient may respond to the physician as he did to his father or his mother in childhood, not necessarily, however, because of sexual feelings, but perhaps simply because at that time he was more suggestible than in later life. A young child has only a few facts in his mind, and if any suggestion is made to him he tends to believe it unquestioningly. He comes into the world with a tendency to what is called "primitive credulity"—a very important attribute. Most of what he learns in early life is learnt through suggestion, not by means of logical reasoning. We like to encourage a child to reason, but if we made it think out everything for itself we should only confuse it and hamper its development, instead of forwarding it. And if that is true of the intellectual side of the child's life, it is much more important on the moral side. We can explain the child's response simply in terms of greater suggestibility. We get our patient into a state in which he is willing to accept the suggestions that are made to him in the same way as he accepted them in his early childhood.

This method is much quicker than that of psycho-analysis, and can produce equally satisfactory results in simple cases. I will give two illustrations.

One is that of a signaller in the Flying Corps who was blown up by an aeroplane bomb whilst taking refuge in a disused trench in France. He became unconscious, and on coming to he found that the trench seemed to be turned round at right angles to the position in which he had expected it to be. When he arrived at the barracks the same thing had occurred—everything seemed to be twisted at right angles to its ordinary position. This feeling of disorientation, as we may call it, persisted for many months. When he came home to England it still showed itself in the following ways: When walking along a street which bent roughly in the form of a semicircle, thus Γ , he would have the irresistible feeling that he had been walking like this γ . If he were riding on the top of a bus, and the bus turned at a right angle, he would have the feeling that he was continuing to go in a straight line, although he knew that the bus had turned a corner. He would think that the whole room he was in, everything, had twisted round to a right angle. I hypnotized this patient and put him through his experiences again, with the result that the occasions on which he got this feeling of disorientation became roughly about half as frequent as before, but the disorientation continued to occur from time to time. He was better, but by no means cured. A few days later he came to tell me that his mother had informed him that at the age of six, as the result of a fall, he had shown much the same symptom; while crossing the Tower Bridge one day he had told her that the bridge was turned "the other way round." I hypnotized him, and put him through this experience again. He lived it through with much vividness. He is sitting on a wooden horse (white with red stripes) in the dining-room. His aunt comes into the room and wishes to wash him; he declines, and edges away from her; the horse tips up on the edge of the hearthrug, and he falls on to the fender. He knows no more until he wakes up and finds himself in bed, with his aunt bathing his face. He continues to recall his

*But all Freudians regard such "transference" as an essential stage in the process of cure, and expect to produce it, in every case, in the course of psycho-analysis. They subsequently "resolve" the transference by further analysis.

experiences, and remembers crossing the Tower Bridge and finding it turned at right angles. After recalling this incident the patient was much better, but a few days later he went to the theatre to see *Going Up* (it is true that there is an aeroplane in *Going Up*), and he suddenly found that the theatre was the wrong way round. He went home, and in the middle of the night he woke up with the feeling of disorientation, got out of bed, and went towards what he thought was the window, and put his hand through the looking-glass. Thus he was by no means cured. I pointed out that there must be some memory in the first six years of his life which was the cause of the trouble. He tried to recall it, but did not make much progress. I then put him through his fourth birthday under hypnosis, and he remembered a frightening dream in which he had thought that there was an animal under the table. He had crawled downstairs and waked up half-way down. The next morning he had thought that the pier was the wrong way round, and had told his mother so. I interpreted his dream for him while he was in the hypnotic trance. He had seen the Giant Ape in a glass case at the Natural History Museum, South Kensington. This had frightened him, and it was this creature which he had thought was under the table in his dream. I took the precaution to get another doctor (Captain P. A. Galpin, R.A.M.C.) to come and see me hypnotize this patient the next time. I then suggested to him that he would go through his first experience of disorientation. When I put my hand on his forehead he shouted out, "Hot coffee!" It appeared that, when a child of nearly three, he had gone into the kitchen one morning, and had pulled the coffee-pot, which was on the table, towards him by pulling at the tablecloth. The coffee upset and poured down his right arm. He felt it as a pain in his left side, over his heart. He knew no more until he woke up in bed, when he saw his father come into the room, and he felt the bed to be the wrong way round. That was his first experience of disorientation—the first he could remember. It occurred to me, as a possible explanation of the dissociation, that the scalding of his arm produced a fainting fit, in which he fell to the left and everything twisted round to the right—he fell through a right angle. That was the beginning of his disorientation.

To make quite sure of this I hypnotized him again to bring up an earlier memory still. I suggested to him that he should remember his second birthday. He suddenly began to shout out: "He has bit me—Gordon has bit me!" Before I woke him up, I asked him all about it, but he could not tell me very much whilst in the hypnotic state—he had gone back to a period when he was too young to be able to describe his experiences. I told him that he would continue to remember all that he had just gone through, and I then woke him up. He told me that Gordon was not a dog, but a little cousin of his. They had been in bed together, standing up in bed, and it appears that he had pinched Gordon in the face, and that Gordon had retaliated by biting him in the left arm. He could remember that at that time he was living near a Fire Station—could remember all the details of the incident, and could remember definitely that he had had no feeling of disorientation. The revival of this incident brought no memory of any earlier disorientation. The next day after this treatment he felt more disorientated than ever, for he had been going through these experiences very vividly. I let him stay in bed, and after two days he recovered completely, and very soon applied for his discharge. I let him go, but asked him to write to me if the feeling of disorientation ever recurred. I have never heard of him since.

This case seems to me to show that such memories date from very early life, and more than that, it shows that the memories need not always be of a sexual nature, because at the age of 2 even Freud would admit that there can be very little sex, and it is very difficult to see where the sexual experience could come in in such a case.

The other case is a much simpler one, but it is what I would call a crucial case of the value of abreaction, or the working off of emotion under hypnosis. It is the case of a gunner who was admitted to the hospital where I was working, after he had spent two years in military hospitals of different kinds. He was suffering from a tremor of the right hand, dating from the time when he had been blown up at Ypres. He did not remember anything more until he reached hospital, and the memory of this interval

had never been recalled to him by any of the doctors he had previously seen. I sent him to sleep—that took just about three seconds—and then suggested to him that he should live again through the experience of Ypres. He did so, and began to shout out all sorts of things which showed what had happened at the time. Bosch shells were falling nearer and nearer to the gun-pit. He was apparently serving the gun, and someone else was handing him ammunition, and this person had evidently lost his head, for my patient shouted out: "What the — do you mean by pulling the — pin out of that — fuse?" Then I noticed that he was moving the handle with his right hand; his hand began to shake violently, and soon he was shaking all over, but especially in his right hand. Then he suddenly became absolutely still. I suggested to him that he would continue to remember all that he had just gone through and then woke him up. He looked at his hand, which was absolutely still, with amazement, and expressed his gratitude, but his mind still appeared somewhat confused, so I told him to go and sleep it off. An hour later he came back and told me that he had not been to sleep, but that he had been thinking it all over. He knew everything that had happened, and told me that he had not been suffering from shell shock but from gun shock. His gun had been blown up, and the emotion which this experience had excited in him had been bottled up for two years, with the result that he had suffered from this tremor in his hand. The next morning he was able to shave himself with an ordinary razor, for the first time since his illness.

Now, was this working off of the emotion the cause of the recovery? The alternative explanation is that the recovery is due to suggestion. When this man came to me, however, he certainly did not expect me to cure him. I saw him the first day that he came to the ward and treated him at once, and he was not likely to have more confidence in me than in anyone else who had treated him. As regards the hypnosis, he went off straight away without realizing that he was being hypnotized—it was not that that impressed him. As far as one can make out, there was no expectation worked up—it was simply the working off of the emotion that cured him. That is why I call this a crucial case. In many other cases it may be argued that the cure is the result of suggestion—for example, in the case of the disorientated man—but this case of the gunner was not of that sort. I do not for a moment wish to deny the working of suggestion in curing such cases, but I wish to emphasize the curative effect of the working off of emotion as a fundamental factor. It is a more causative treatment than suggestion. Suggestion removes the symptom; abreaction removes the cause of the symptom.

The explanation of psychasthenia, compulsion neurosis, and some of the psychoses in terms of the same concept of mental conflict and dissociation must be postponed.

In conclusion, I should like to express my indebtedness to Major R. Worth, O.B.E., R.A.M.C., of Springfield War Hospital, for his courtesy in allowing me to report the above two cases, and for his unflinching help and encouragement while I was working in that hospital.

THE IMPORTANCE OF THE HOUSE-FLY AS A CARRIER OF *E. HISTOLYTICA*.

BY

P. A. BUXTON, M.R.C.S., L.R.C.P.,

FELLOW OF TRINITY COLLEGE, CAMBRIDGE; CENTRAL LABORATORY,
AMARA, MESOPOTAMIA.

THE investigation here described was undertaken to determine as far as possible the extent to which the house-fly is a carrier of the organisms causing diarrhoea, dysentery, etc. No one would now attempt to deny that the fly can carry a very large number of different species of pathogenic organisms; the present paper tries to afford some actual statistical evidence of the extent to which it actually does carry them. So far as I know, we have very little real knowledge of the relative importance of water carriage, flies, carrier corks, etc., either in this country or in any other. The investigation has been carried through in one small area in Amara, on the lower Tigris, between February 1st and November 3rd, 1918

The sanitation here is, of course, very much better than it is further up the line.

The Gross Figures.—These are as follows:

Total number of flies dissected ...	1027
Number containing "apparent faeces" ...	645 63%
Number containing human intestinal parasites ...	42=4.09%
Number containing <i>E. histolytica</i> cysts ...	3=0.3%

The intestinal parasites, as will be seen later, are eggs of worms and cysts of protozoa. The "apparent faeces" which is recorded in 63 per cent. of the flies dissected requires explanation. A fly was recorded as containing "apparent faeces" if its gut contained brownish material enough to be seen by the naked eye, and if on being made into a film the brown material agreed in its appearance with human faeces. Generally it was swarming with bacteria; often one observed portions of partially digested muscle fibres (proving that the faeces, at any rate, was not that of horse or sheep); or one found the characteristic thick-walled cells which appear in the stools of Indians after a meal of dhal (pulse); or groups of yeast stained blue with iodine which are common in human stools in this country. I have frequently found these yeasts in conjunction with such distinctively human parasites as hook-worm eggs. Moreover, the fact that I never found a cyst or egg of any parasite of dog or ox or horse suggests very strongly that the faeces found in the fly was human in origin; and if over 4 per cent. of the flies contain eggs or cysts of definitely human parasites there is nothing unreasonable in believing that 63 per cent. of the flies contain human faeces. One must, however, admit that there is no one criterion which enables us to state that a given substance is human faeces; even the demonstration of the presence of *Bacillus coli* in each of these flies would have been useless, as that organism inhabits the intestinal tract of many vertebrates.

Difference between Male and Female Flies.

It soon became clear that flies from different situations would contain faeces and human entozoa to very different extents, and also that the males were very much cleaner than the females. As the relative abundance of the two sexes varied much in the day's catch, I determined to exclude males altogether from the dissections in order to obtain a uniform basis for my statistics. The relative cleanness of the sexes is shown below:

Males:	
Number dissected ...	206
Number containing "apparent faeces" ...	67 = 33%
Females:	
Number dissected ...	165
Number containing "apparent faeces" ...	107 = 65%

These figures appear to indicate that the female is twice as much a carrier of faeces as the male. As a matter of fact the disparity between the sexes is greater even than this, because the average male recorded as containing faeces often contained but a fraction of the amount one would find in the average female. The above figures are strictly comparable, as in them I have only included males and females taken at the same time and place.

Females from Various Situations.

The females alone will now be considered; the total figures are as follows:

Total number of females dissected ...	796
Number containing "apparent faeces" ...	568 = 71%

The great majority of these females fall within five groups:

Group I, those taken in or on British fly-proofed latrines 100 yards or more from any incinerator. Group II, those taken on or in latrines immediately adjacent to an incinerator. Group III, those taken in one particular British cookhouse and mess 80 to 100 yards from an Indian latrine and incinerator. Group IV, those taken in Indian latrines with incinerators alongside. Group V, those taken in Arab compounds of the lower class.

The system of sanitation provides approximately fly-proof latrine seats with lids for British troops, the walls and roofs rendering the inside partially dark. For Indian troops latrines with any form of lid are impossible to arrange owing to caste; the Indian latrines consist of separate urine and faeces tins on the ground, between two foot rests, with screens of matting and mud and a light roof. The latrine, whether British or Indian, in the

great majority of cases is close to the incinerator, which is a brick cone with a grid about 3 ft. from the ground; a door about 2 ft. square is provided for loading dejecta, etc., upon the grid, and two or three small holes on different aspects for admitting the wind; the top of the cone is truncated, leaving a smoke vent about 2 ft. across. These incinerators burn fairly well even if there is no breeze. Trench latrines and the burying of any form of refuse except that from slaughterhouses have long ago been abolished.

The system of sanitation in Arab compounds, so far as it can be said to exist, is as follows: There is a great deal of promiscuous defaecation, particularly by children, and before dawn by low-class adults, in courtyards and roads and, above all, on the flat housetops. The Mesopotamian sun is only sufficient to render this practice harmless during four or five summer months; in fact, by September isolated deposits of faeces are not only fed upon by swarms of flies, but actually afford breeding places for *Sarcophaga*, etc., and by October for *Musca* itself. Apart from this promiscuous defaecation, all the low-class compounds from which the flies in Group V were collected possess a shallow, partially open cess-pit in the corner of the yard. Dejecta are dropped into an open, sloping trough, and slowly pass down into the pit itself. It is also customary to make basin-shaped holes in the earth in front of the door of each hut, and in these to place household rubbish, partly decomposed vegetables, faeces, etc. It will, I think, be realized that the presence of a number of these compounds close to a military area tends to nullify the efforts of those in sanitary charge of the area. The better class houses in towns are kept much more clean, and have completely closed cess-pit latrines, which cause very little annoyance.

The figures for flies from these five types of locality are as follows:

Group Number and Locality.	Total Number Females Dissected.	Number containing "Apparent Faeces."	Percentage containing "Apparent Faeces."
I. British latrines, no incinerators	99	39	39
II. British latrines and incinerators	80	57	71
III. British mess and cook-house	198	119	61
IV. Indian latrines and incinerators	155	118	76
V. Arab compounds	201	161	80

The difference in dirtiness between flies in Groups I and II is due to the fact that burning in the type of incinerator I have described is so slow that numbers of flies may frequently be seen inside the incinerator feeding on such material as is not directly in the smoke. I think my figures show that these incinerators are an important leak in the system of sanitation; it appears that the fly-proofed latrine for British troops is moderately efficient, but as it is frequently placed next one of these incinerators, in which the flies feed freely, the fly-proofing of the latrine seat becomes a mockery. One concludes, then, that the provision of a door to close the hole through which the incinerator is loaded is an urgent necessity. Of course the burning of faeces on an open grid incinerator is still more strongly to be condemned. There is no reason why sheet-iron doors should not be fitted to these cone incinerators in areas at the base and on the lines of communication—in fact, such doors are often fitted, but only used as draught regulators.

As regards the flies from British cookhouses and messes (Group III), the great majority of these flies were taken in one mess and cookhouse about eighty yards from an incinerator and latrine, and up wind of it when the prevailing north-west wind was blowing. It is rather disquieting to notice that 61 per cent. of the flies from this group contain faeces. As a matter of fact, 5 of these 198 flies contained cysts of human intestinal protozoa, one of them the cyst of *Entamoeba histolytica*.

The Entozoa.

Human intestinal parasites, referred to shortly as entozoa, were found in 42 different flies. This is 4.09 per cent. of the whole number.

The entozoa comprised representatives of ten species—two cestodes, four nematodes, three protozoa, and the organism known as *Blastocystis*. All the species are well-known parasites

of man, and the great majority of them are not known as parasites of other animals. Of the 42 flies in which one or more of these organisms was recognized 39 belonged to Groups I to V; in these groups the flies shown to contain entozoa were distributed as follows:

Group:	I.	II.	III.	IV.	V.	Total.
Total flies examined ...	59	80	198	155	201	733
<i>Hymenolepis nana</i> ...	0	0	0	0	1	1
<i>Taenia saginata</i> ...	0	1	0	0	0	1

Total flies containing entozoa	2	13	5	8	10	39

Note.—The totals at the foot of the table do not equal the sum of the figures above them, because some flies contain more than one sort of entozoon.

The detection of cysts of *Entamoeba histolytica* only three times in over a thousand flies might at first be taken as evidence that the fly under the conditions studied is of minor importance as a carrier of amoebic dysentery. On the other hand, it must be remembered that it is impossible to remove the whole amount of faeces contained in a fly; if a given fly contains but one or two cysts, it is quite possible that these may escape detection. One must further remember that it is by no means easy to see the cysts at all in some films, owing to the presence of the globules described below; also, even in the absence of these globules, a single cyst must often remain undetected behind a mass of debris. It may safely be said, then, that 0.3 per cent. by no means represents the number of flies carrying cysts of *E. histolytica*. We should certainly be nearer the mark if we surmised that the actual percentage was 0.5; possibly it may be higher. Now this represents a very large number when it is remembered that the fly is found throughout the year in Mesopotamia, and that in spite of the excellence of the sanitation of most units in the area, the fly is abundant in messes and cookhouses every spring and autumn. Probably up the line the percentage of flies carrying cysts is higher, as the conservancy is necessarily less perfect.

The identification of the eggs of *Ankylostomum duodenale*, *Necator americanus*, and *Strongyloides stercoralis* rests, of course, on measurements. The egg of *S. stercoralis* was 93.6 μ in length and relatively more elongate than that of the other species.

Technique.

The flies were dissected in the ordinary way, as described by Patton and Cragg.¹

The legs and wings are removed, the trunk is placed on a slide in saline solution, and the head cut off with a needle sharpened like a scalpel. The trunk is then steadied with a blunt needle, while with the sharp needle small incisions are made dorsally and ventrally in the abdominal wall. The tip of the abdomen is then pulled away from the rest of the body and the gut and crop gradually unravelled on the slide. After fragments of fat body, Malpighian tubes, etc., have been pushed aside, those lengths of gut which seem to contain faeces are isolated by cuts from the scalpel needle. The faecal contents are expressed from this as far as possible at one spot on the slide; the crop is also opened at the same place. The contents are flooded with Gram's iodine solution and covered and examined.

During a certain stage of the digestive processes of the fly globules are poured out by the gut epithelium into the gut contents. These globules have an oily appearance and do not closely resemble a cyst, but being round and approximately the size of cysts they make examination of the film extremely slow; in examining an ordinary film

from a stool the trained eye very quickly picks out any round body for further study; in examining a film from a fly this may be rendered quite impossible owing to the presence of many round bodies in every field. Pathologists differ as to the advisability of treating ordinary stool films with iodine; there can be no doubt that in examining films from the fly iodine is almost a necessity, as it enables one very rapidly to distinguish between cysts and globules. In carrying out this work I have never recorded any body as an amoebic cyst unless it had been treated with iodine, to render the cyst wall and nuclei clearly visible. A number of doubtful cysts were seen early in the investigation; they have not been included in the figures. I have not found either fluorescin or eosin of any value in enabling me instantaneously to detect a cyst among a number of globules. Practically all the amoebic cysts have been examined also by Captain G. Lapage, R.A.M.C., and passed by him. His very wide experience of these bodies has been of the greatest use to me; whenever he has been doubtful about any object which I have submitted to him I have excluded it from the statistics. The investigation was begun in conjunction with Lieutenant J. H. Woodger of the Norfolk Regiment and continued for a short time by both of us. I have presumed on his kindness and included a number of his dissections in the statistics, transfer to an isolated force preventing all communication between us. I am very grateful to them both.

The flies examined have all of them been house flies—that is, they would all have been referred to as *Musca domestica* a few years ago. A great number appear to be referable to the species or races now known as *Musca determinata* and *M. angustifrons*; but the whole question of species in the house-fly group is now under revision, and it is probable that new species will be found when the flies of Mesopotamia have been examined along the lines of Awati's² work in India. From the public health point of view the exact systematic position of the insect appears to be immaterial. The habits of all these races appear to be the same as regards breeding in faeces and feeding upon it and upon human foods.

Vomit Spots.

Early in the investigation about fifty were examined with negative results; time failed to examine a large number.

The occasional presence of eggs of worms and cysts of protozoa in the vomit and faecal deposits of flies has, of course, been demonstrated, especially by Wenyon and O'Connor.³ A transfer to another country has prevented me from carrying through a similar investigation on the carriage of pathogenic bacteria by the fly in this area.

Conclusions.

(a) As has already been shown by Wenyon and O'Connor,³ one may expect to find the egg of any human intestinal worm, or the cyst of any protozoan in the fly if only one looks long enough.

(b) It appears that in a well sanitated area in Lower Mesopotamia over 60 per cent. of the flies carry human faeces, over 4 per cent. of them actual human entozoa, and probably at least 0.5 per cent. the cyst of *Entamoeba histolytica*.

(c) One is justified therefore in regarding the fly in this country as not only a potential, but an actual and major factor in the carriage of the bowel disorders which are here so regrettably numerous.

THE triennial meeting of the International Society of Surgery will be held at Paris instead of Brussels this year from Monday, July 19th, to Friday, July 23rd. The subjects set for discussion are: (1) The surgery of the heart and great vessels; (2) the treatment of tumours by radium and X rays; (3) the analysis of the blood and its biological reactions in surgical affections; (4) fractures of the femur; (5) the prophylaxis and treatment of tetanus. The subscription is 50 francs. Members of the medical profession who wish to be nominated for election are requested to communicate with Sir D'Arcy Power, K.B.E., 10A, Chandos Street, Cavendish Square, W.1.

ANALYSIS OF ONE HUNDRED CONSECUTIVE
CASES OF CARDIAC DISEASE.*BY
W. BLACK JONES, M.D., B.S.LOND.,
BUILTH WELLS.

DURING the past few years knowledge of diseases of the heart has been notably advanced, and I will here give an analysis of 100 consecutive cases of cardiac disease occurring in my practice at Llangammarch Wells, and discuss the symptoms, the prognosis, and treatment, in the light of modern research.

When a patient with a disordered heart presents himself it is advisable, before proceeding to the physical examination, to make inquiries as to the symptoms. Frequently they have been neglected, and more stress has been laid on the presence or absence of certain physical signs, and an erroneous impression of the case has been obtained.

At rest the heart uses only a small portion of its energy in keeping the blood circulating, but during exercise a larger amount, called reserve energy, is used; in violent exercise this may amount to three or four times that used at rest. When heart failure begins this reserve energy diminishes, thus lessening the amount of work the patient can do.

Heart failure is indicated by certain symptoms, such as pain in the region of the precordium, shortness of breath, exhaustion, etc. The basis for estimating the strength of the heart, and therefore the amount of reserve energy present, is the amount of physical work the patient can do. The first inquiries are therefore directed to ascertain how far the patient can walk without exhaustion, and whether he can ascend one or two flights of stairs or a moderate hill without feeling short of breath. This is a valuable test, and as the patient recovers he can estimate the increase in the reserve energy by his ability to walk further afield without distress. It is the object of this paper to call attention to these symptoms of primary importance, to indicate their relative frequency and their value in diagnosis, prognosis, and treatment.

Patients with certain physical signs, such as murmurs, have often been misled as to their condition because the physician laid too much stress on the presence of a murmur when no other sign or symptom of cardiac failure was present; and, on the other hand, some practitioners have been puzzled by the condition of a patient, obviously seriously ill with some cardiac disorder, because no murmur could be heard, as if a valvular lesion were the sole cause of heart failure.

In the medical examination for life insurance the examiner is generally asked to state whether the sounds of the heart are normal and whether the organ is enlarged. In many cases these are the only questions directed to the condition of the heart excepting those as to the character of the pulse. It is, however, encouraging to find that one insurance company at least has appreciated the value of modern researches on cardiology, and in addition to the above asks the following questions: "Does the proposed suffer from precordial pain, breathlessness on slight exertion, or any other symptom of impaired cardiac efficiency?"

The following are my methods of examination and the results I noted in 100 consecutive cases:

1. *Age.*

The average age was 54 years.

2. *Occupation.*

It is not enough to learn that the patient is, say, a solicitor or an engineer, without inquiring whether the strain upon him is physical, or mental, or both. When the questions of prognosis and treatment are concerned we have to ask ourselves what proportion of this work he can do in the future, whether he can do half, or must give up all his work. Of 100 cases, 65 were males, and as to occupation 26 were of the working class.

3. *Pain.*

Pain in the chest is a most valuable symptom: it may be regarded as a sign of the degeneration of the muscular

fibres of the heart and of the exhaustion and failure of that organ. It is often slight, but in some cases, especially when the pain is more or less constant, sudden death occurs. Whether slight or acute, it does not necessarily indicate the calcification of the coronary arteries, a lesion which is known to accompany many cases of angina pectoris. The pain is usually felt over the area of the heart. It is of a reflex nature, caused by the irritation of the cardiac nerves, by which impulses are transmitted to the spinal cord, reflected to the sensory nerves, and referred to various parts of the trunk and arms. Pain is a valuable measure of the amount of degeneration of the myocardium and is a guide to prognosis and treatment.

Of the above cases under my care, 73 complained of pain over the heart or neighbouring part of the chest; 9 of them complained of pain in the region of the lower ribs on the left side; in many of the cases the pain was only a dull ache; in all the pain was intermittent. On exertion or excitement the pain often radiates to other parts of the body. Of these 73 cases, 33 experienced an increase in the area of the pain, 30 referred the pain to the left arm, two to both arms, and one to the right arm only.

4. *Causes of the Pain.*

(a) *Exertion.*—Fifty-one patients attributed the pain to exertion. Careful inquiry should be made as to the amount of exertion that causes this pain; it is a valuable indication in treatment, as in many cases the pain can be wholly or partly avoided by reducing the amount of work.

(b) *Excitement.*—Thirty-six persons stated that mental excitement caused the pain. Worries in the daily life that can be avoided must be ascertained.

(c) *Indigestion.*—Thirty-four persons attributed attacks of pain to digestive disturbances. Flatulence due to chronic gastric catarrh is one of the most frequent causes of such cardiac disturbances as pain, palpitation, shortness of breath, etc. The stomach, if distended with flats, may either act reflexly or mechanically on the heart. Probably the latter cause is the more frequent, as it raises the heart up and alters its axis, thus disturbing its anatomical position. The treatment of this condition is of the utmost importance, and in some cases I have devoted my whole attention to the treatment of the gastric rather than of the cardiac symptoms. Frequently immediate relief to distressing cardiac symptoms is afforded by a few simple directions as to diet.

(d) *Pain at Rest.*—Twenty-one patients complained of pain while in bed. This symptom often indicates advanced degeneration of the myocardium, and the prognosis is unfavourable.

5. *Breathlessness.*

In 89 cases patients complained of shortness of breath after slight exertion. This is one of the earliest and also one of the cardinal symptoms of cardiac failure. It is nearly always accompanied by exhaustion.

6. *Exhaustion after Exertion.*

This occurred in 85 cases. In the treatment of the patients these two symptoms—breathlessness and exhaustion—are of great importance, as when they abate they become measures of the progress towards recovery.

7. *Palpitation.*

This was noticed by 36 persons, of whom 13 were males and 23 females. It frequently occurs in neurotic women, and if there are no other symptoms of cardiac failure the prognosis is frequently good.

8. *Faintness and Giddiness.*

Faintness was noted in 6 cases; in only one of these was the prognosis good. Giddiness occurred in 29 persons. It is an important sign often noticed in tall people; the prognosis is generally not favourable.

9. *Pulse.*

(a) *Frequency.*—The rate of the pulse was 76 or under in 71 cases; it was above that rate in 29 cases. In 2 of the latter it was markedly irregular owing to auricular fibrillation.

(b) *Tension.*—In all cases the systolic pressure of the pulse was noted. I have adopted the classification of Oliver, who defined as cases of high tension those in

* Being a paper read before the North Glamorgan and Brecknock Division of the British Medical Association, at Brecon, September 24th, 1919.

which the pressure is above 145 mm. in persons under 40 years of age, and in those above that age in whom the tension is above 160 mm. Out of 100 cases, 36 had high tension; of these, 25 had symptoms of aural pain and 11 were without pain. When the high tension is not accompanied by dilatation or other signs of cardiac failure the prognosis is more favourable than when signs of degeneration are present.

10. Dilatation.

In 61 cases the heart was dilated, and in 22 of these a murmur was present; in one case the murmur certainly had no prognostic significance, as it was the only cardiac symptom present.

11. The Urine.

Albumin was present in the urine in three cases and sugar in one.

12. Prognosis.

In 17 of the 100 cases prognosis as regards life was good, provided the patients did not exceed the limits of the amount of strain put upon the heart. Of these cases, 4 were due to affections of the nervous system, and were all amenable to treatment, and 8 suffered from cardiac pain, but this either disappeared on treatment or was so infrequent as to cause little anxiety. In two cases the cardiac symptoms were of no importance.

Treatment.

The first essential is rest; its degree must be left to the judgement of the physician, (a) whether the patient is to go to bed for some weeks, or (b) whether he is allowed to be up and about, and is to have his exercise graduated according to the amount of work the heart is able to do. All the cases mentioned in this paper are comprised in the latter class. In estimating the capacity of the patient for exercise it is always necessary to inquire how far he can walk without bringing on pain or producing shortness of breath, palpitation, or exhaustion. After a few days' treatment it is often found that the patient is able to walk further without distressing symptoms, and has lost the sensation of lassitude.

The second essential is the careful regulation of the diet, especially if gastric catarrh be present. Frequently immediate relief to distressing cardiac symptoms is afforded by a few simple directions as to diet. The main principles I adopt are as follows:

1. The teeth are to be in good condition.
2. The avoidance of indigestible foods, such as pork, veal, and other hard meats and warmed-up dishes. All underground roots, including potatoes; also sloppy food, such as bread and milk, broth and soup, strong tea, coffee, alcohol.
3. Each meal is to consist of a very few articles, and over-eating is to be avoided. The food is to be well masticated, and eaten dry.
4. Hot water is to be taken after the meal; when flatulence is present, a soda mint tablet may be taken with advantage.
5. A pill containing a grain of calomel is to be taken once or twice a week.

Among the working classes indulgence in strong tea has in many cases caused more damage to the gastric mucous membrane, and thus eventually shortened life, than indulgence in alcohol.

At Llangammarch Wells these patients had spa treatment in addition to rest from their various occupations and anxieties, and change of air and scene; they had the benefit also of balneological treatment, consisting of the internal administration of the mineral water, of baths, and of massage, which I have fully described elsewhere.*

Many of the patients are seen year after year, and the progress made by some of them is noted below.

CASE I.

A man, aged 60, consulted me in July, 1916, having had symptoms of cardiac failure a month previously. He complained of pain over the precordium, which occasionally radiated down the left arm. He also suffered from giddiness, palpitation, and shortness of breath. There was evidence of gastric catarrh, the heart was dilated and the sounds feeble. The pulse was regular, the rate 76 and the tension 150 mm. He had been

addicted to alcohol. I recommended a strict diet, the mineral water, and abdominal massage, and advised him as to the amount of exercise he was to take. He soon began to improve, and lost most of the distressing symptoms and was able to walk much better. The improvement was maintained when he was last seen during the summer of 1919.

CASE II.

A man, aged 32, was first seen in February, 1918. He complained of pain over the heart, which at times was of a stabbing nature, and which radiated down the left arm on exertion or after attacks of indigestion. He had experienced this pain occasionally for two years. He had the usual symptoms of shortness of breath and exhaustion, and was at times in considerable distress. The heart was dilated, and there was marked gastric catarrh. He was a commercial traveller, and had not only been much overworked, but his meals were most irregular.

After several weeks' rest and careful diet all the distressing symptoms abated, and he gradually returned to his duties; at present is able to do a considerable amount of work. He is very careful as to his diet, and often is able to obtain an extra day's rest at the week-end. I am of opinion that the prognosis is good in this case.

CASE III.

A man, aged 55, consulted me in May, 1919. He had worked abroad for many years, and his heart had been weak since 1915. He complained of pain over the precordium and shortness of breath, which were aggravated by exertion. The heart was dilated, the pulse rate was 80, and the tension 140 mm. Occasionally he had Cheyne-Stokes breathing and the stomach was dilated.

After six weeks' treatment the pain left him, the Cheyne-Stokes breathing disappeared, and he could walk several miles without exhaustion. The prognosis in this case is distinctly good.

CASE IV.

A lady, aged 50, had suffered from palpitation and exhaustion for eight years, subsequent to an attack of influenza. She was in poor health, the attacks of palpitation occurred frequently at night, and her sleep was much disturbed. She had slight pain over the heart, was short of breath, and easily fatigued on exertion. There was marked flatulent distension of the stomach, the heart was dilated, and the pulse tension was 140 mm. The diet was strictly regulated and ammonium bromide prescribed. In a few days she began to improve, the palpitation was much less, the digestion better, and she slept well. After a month's treatment she said she was more active and was feeling stronger than for several years. The prognosis in this case is good.

CASE V.

A man, aged 47, consulted me in August, 1917. He had had rheumatic fever ten years previously, and had worked very hard for many years. He complained of a stabbing pain over the heart, but it did not extend down the arm. He often had attacks at night, when he also experienced a smothering feeling. He was breathless and easily exhausted, and the stomach was distended with flatus. The heart was dilated; the tension of the pulse was 160 mm. He was carefully dieted and advised to reduce the amount of his daily work as far as possible, but at the same time my prognosis in his case was bad. I saw him in September, 1918, when he was much improved; the pain was less, and although he still had a smothering sensation at night there was less exhaustion, and he was able to get through his work fairly well. I saw him again in August, 1919, and found the improvement maintained. The pain was not so frequent, and he could walk three or four miles a day.

ON THE DIRECT CULTIVATION OF TUBERCLE BACILLI FROM TISSUES.*

BY

G. HASWELL WILSON, M.B.,

LECTURER IN BACTERIOLOGY, GLASGOW UNIVERSITY; PATHOLOGIST,
ROYAL HOSPITAL FOR SICK CHILDREN, GLASGOW.

THE method of isolating tubercle bacilli from tuberculous tissues described below was devised in the course of an investigation, undertaken on behalf of the Medical Research Committee, into the types of tubercle bacilli found in children. It depends on the use of (a) a special medium for culture, as described below, and (b) the trituration of the tissue with dry quartz sand before the application of antiformin to destroy contaminating organisms.

The efficacy of antiformin as an aid to the detection or cultivation of tubercle bacilli in sputum, etc., is generally recognized, and the benefit derived from its use may be said to depend on two factors. In the first place, the antiformin exercises a disintegrative action on tissues and cells and liquefies mucus, so that the organisms may be concentrated by centrifugalizing, and, secondly, contaminating bacteria are killed off. So far as sputum or

* The Mineral Water of Llangammarch Wells, BRITISH MEDICAL JOURNAL, October 29th, 1913.

* The expenses of this research are being defrayed by the Medical Research Committee, to whom I have pleasure in recording my indebtedness.

other fluid material is concerned, the method as ordinarily employed (1919¹) is satisfactory, since solution is effected in a comparatively short time and the tubercle bacilli are not damaged; but, in the case of tissues, prolonged exposure to the reagent may be necessary before the material becomes sufficiently fluid to allow of its being centrifugalized, and in these circumstances the growth of tubercle bacilli, as well as that of less resistant organisms, may be inhibited. In the methods here described the tissue material is reduced to a very fine state of division by mechanical means, and a very short exposure to the antiformin serves to destroy bacterial contamination.

Process.

The tissue to be investigated is cut up into small pieces with scissors, and is thoroughly rubbed up in a mortar with a small amount of dry sterile quartz sand. The rubbing up is continued till the fibrous tissue is disintegrated as far as possible, and the material forms a slightly moist, crumbling mass. The contents of the mortar are then washed into a wide test tube with 15 to 20 c.cm. of sterile saline solution. The sand is allowed to sediment for a few minutes; as it falls, it carries down with it any coarser particles of tissue which remain. The supernatant fine suspension is then pipetted off, and thoroughly mixed with an equal volume of 15 per cent. antiformin. After five minutes, during which it should be stirred continuously, the mixture is centrifugalized at high speed for a few minutes, and the supernatant fluid is discarded. The sediment is shaken up with sterile saline solution and again centrifugalized. The shaking up of the sediment with sterile saline solution and centrifugalizing are carried out three times in all, so that no trace of antiformin remains. The sediment resulting from the final centrifugalizing is used for making cultures, or, after emulsifying with a convenient amount of sterile saline solution, is injected into a suitable animal. It may be mentioned at this point that in none of a large number of films made from the sediment obtained by this procedure was any evidence found that the bacilli tended to be broken up. It is certain that their vitality cannot be seriously diminished as in some cases growth was obtained although the tubercle bacilli were present in such small numbers that none could be demonstrated in films. Further, in many instances, control cultures on agar were put up at the same time as the egg medium cultures. These invariably remained sterile.

Preparation of Medium.

The medium used is simple to prepare and is a modification of Dorset's medium (1919²), in which the contents of eggs are mixed with a tryptic digest of horse heart instead of with water. Various digests were tried, including horse heart digested for varying periods, Cole and Onslow's casein digest (1916³), and a tryptic digest of gelatine. All the media containing a protein digest were found to yield a more rapid and abundant growth than the original Dorset medium, but the product which so far has given the most satisfactory result is that obtained by digesting horse heart with trypsin for a period of three weeks.

Preparation of Horse Heart Digest.

Take:

Horse heart, freed from fibrous tissue and fat as far as possible, and minced	...	500 grams.
Water	...	1,000 c.cm.

1. Render faintly alkaline to litmus, using 20 per cent. sodium hydrate, and heat slowly to 80° C.
2. Cool to 40° C. and add 1 per cent. liquor trypsin co. (Allen and Hanbury) and 30-40 c.cm. chloroform. Shake well and cork with a loose stopper.
3. Incubate at 37° C. for ten days, shaking daily.
4. Add a further 1 per cent. liquor trypsin co. and leave in incubator for another ten days without shaking.
5. Render slightly acid to litmus with glacial acetic acid and boil for fifteen minutes.
6. Leave overnight in ice chest and decant off clear fluid, or filter through Chardin paper.
7. Adjust reaction to 1.2 per cent. acid to phenolphthalein; autoclave at 118° C. for twenty minutes; cool and filter; sterilize.

It is important to test the reaction of the digest at intervals during the period of incubation, as it tends to become acid, and should this occur, a further addition of alkali must be made till it is again just alkaline to litmus.

The contents of several fresh eggs are well beaten up, and the above digest is added in the proportion of one part to three parts of the beaten eggs and thoroughly mixed. The mixture

is filtered through muslin to remove air bells and filled into tubes which are heated in the sloped position at 70° C. till complete solidification has occurred. The medium is then sterilized high up in the Koch sterilizer (to avoid bubbling) for twenty minutes on each of three succeeding days. Prepared in this way the medium forms a smooth slope, free from air bells, of a pale yellow colour. Glycerin is added to the medium before solidifying, when desired.

An important point to be observed in the preparation of Dorset's medium or of this modification is that the eggs used must be as fresh as possible. Commercial "fresh" eggs are often quite unsuitable, and the more nearly the eggs approximate to "new laid" the better are the results likely to be. Whatever the component of now-laid eggs may be which renders their use in the preparation of media more favourable to the growth of tubercle bacilli, it not only resists the heating incident to sterilization, but is actually rendered more stable by it, since media prepared from fresh eggs retain their growth-producing properties for many weeks at least, whilst these properties are lost in a few days if the eggs are kept before being made into medium.

On this medium growth, both in primary cultures and in subcultures, is rapid, being visible, as a rule, in less than a week, sometimes in four days, and copious in less than three weeks. Bovine types of bacilli are markedly inhibited by the presence of glycerin in the medium, as occurs in Dorset's medium prepared in the ordinary way. The differences between the cultural characteristics of the human and bovine strains are very well brought out, the human type producing a copious, heaped up, dry and wrinkled growth, often with a slight brownish tint; the bovine a growth which is flatter, fairly smooth, and with a distinctly slimy appearance. So far, direct cultures of tuberculous material from twenty-five cases have been made on this medium, and in twenty-four of these growth has been obtained. The remaining case was one of tuberculous meningitis in which only one tubercle bacillus could be found in films from the sediment obtained on centrifugalizing a large amount of cerebro-spinal fluid.

SUMMARY.

1. The disintegration of tuberculous tissue and the destruction of contaminating bacteria by antiformin can be greatly facilitated by a preliminary trituration of the tissue with quartz sand.
2. This procedure appears to exercise no deleterious effect on the bodies of the bacilli or on their vitality.
3. The growth of tubercle bacilli on egg media of the Dorset type is enhanced when the media are prepared with a twenty-one day tryptic digest of horse heart instead of with water.
4. Egg media intended for the growth of tubercle bacilli should be prepared from eggs which are as nearly as possible new-laid.
5. The addition of glycerin to such media inhibits the growth of bovine strains, and the other cultural characteristics of bovine and human strains are well defined.

NOTE.—Further experiments with these and other digests are being carried out with a view to the preparation of fluid media; and also, by the use of more delicate indicators, for the determination of the optimum reaction of the various components.

NASAL DRILL: AN INVESTIGATION OF ITS VALUE IN THE TREATMENT OF ADENOIDS.

BY

GERTRUDE H. HICKLING, M.D., D.P.H., B.Sc.

In the *Lancet* of August 24th, 1918, and in several later issues, some remarkable results were published of the effect on adenoids of systematic nasal drill, as conducted by Mrs. Hancock. At that time, owing to the depletion of staff at the various hospitals, numbers of cases of adenoids waited month after month for operation. Thus the moment seemed opportune to ascertain whether the troublesome symptoms of these children could be alleviated by means other than surgical. I therefore went up to London and Mrs. Hancock kindly demonstrated the method to me.

Subsequently a class conducted on similar lines was held weekly for six months at the out-patient department of the Manchester Children's Hospital. For test purposes various types of cases were sent to the class. An average of twenty children attended, ranging in age from 3½ years to 14 years. The parents were present at the drill, and by their regular attendance showed their interest in the proceedings.

Method.

The children stand in rows with as much space as possible between each individual in a room with widely opened windows. Each child is given a piece of soft paper to serve as a handkerchief. Then at the word of command:

One: All stand erect (chest out, shoulders back, etc.).
Two: Hold paper ready (spread out in the left hand beneath the nostrils).

Three: Grasp the top of the nose (between the eyes, with the right thumb and forefinger, the elbow being raised to shoulder level) leaving the nostrils open.

Four: Blow down the nose (bowing the head forward and down and at the same time depressing the right elbow to the waist line, the top of the nose still being held).

Five: Breathe in.

Exercises three, four, and five are then repeated in a rhythmic manner about ten times, the action somewhat resembling that of a pump. After this each nostril is "pumped" separately in the same way, each side being held closed in turn. The soiled paper, which catches the discharge as it flows unimpeded from the uncompressed nostrils, is now burned and replaced.

The nose and its accessory sinuses having been to some extent cleared by this preliminary pumping, irrigation of the nasal cavity from above down is now obtained by means of a free flow of lymph induced by sneezing, thus: A mild, non-irritating nostril snuff is handed round. Mrs. Hancock's powder was used at first; afterwards a similar preparation made by the hospital dispenser, Mr. Teesdale, containing menthol and a soap basis. Each child takes a pinch of the powder, and lightly flicks the septum just within the nostrils. The powder is not sniffed up. This feeble stimulation is sufficient in the majority of cases to induce a sneeze. Immediately after sneezing "nose pumping" is resumed. Sneezing and pumping may then be repeated until discharge from the nostril ceases or becomes scanty. Lastly, nose breathing exercises are performed, the nostrils being used alternately and together.

The importance of nose breathing and of regular daily nose "toilet" is constantly emphasized, and powder is provided for the drill to be carried out at home.

Results.

General.—Improvement in the physique of the class was soon noticeable; the carriage is better, chests are fuller and shoulders less curved, mouths gape less, and there are fewer cases of sniffing and running noses. Mothers report greater freedom from colds, less restless sleep, and cessation of snoring. Speech is clearer and hearing more acute. One child got through the winter without having his "annual" February attack of bronchitis. No member of the class contracted influenza during either of the two epidemics, although in some cases other persons in the household had the disease. Improvement of appetite and of digestion and a gain in weight coincided in several instances with the disappearance of the nasopharyngeal discharge. One case of relapse after operation is now free from symptoms.

Local.—With the exception of a diminution, amounting in some cases to an actual cessation of the nasopharyngeal discharge, very little local change was observed in the throats—that is, the relief of symptoms is out of all proportion to the visible improvement in the local condition. Certainly in some cases slight shrinkage seemed to have occurred, but in no case could it be said that the growths had disappeared. This result is disappointing, in view of the cases recorded in the *Lancet* referred to above.

Nevertheless the experiment would seem to show that:

1. Cases where operation is inadvisable on general grounds may be relieved of their main symptoms by this method of nose drill.
2. Some cases of chronic nasopharyngeal discharge attributed to the presence of adenoids can be cured without operation.
3. Operation may be avoided, that is, rendered unnecessary in cases of slight adenoids.
4. Daily nasal drill lessens the chance of contracting infections.

Two special fields of usefulness of the drill suggest themselves in addition.

Post-operative.—To keep the nasal passages clear and so avoid recurrence.

Preventive.—The introduction of nose drill into the daily routine of nursery schools and infant schools should do much to bring about a decrease in adenoid case incidence

and do away with the majority of those cases of sniffing, sore-nosed children to be seen by the dozen at any medical inspection of school children.

In conclusion I should like to take this opportunity of thanking the hospital staff for permitting and assisting the experiment, more especially Dr. Lapage, at whose out-patient clinic the class was held, and who, on his return from service overseas, allowed me to continue the class, and Dr. Arnold Jones, aural surgeon to the hospital.

Note by C. P. LAPAGE, M.D., M.R.C.P.

On my return I found that Dr. Hickling, who had been conducting my out-patient department during my absence, had instituted a nasal drill class. I asked her to continue to hold the class in order to finish the experiment. From personal inquiry I can support all that Dr. Hickling has said about the progress and relief of symptoms in those cases who had not markedly enlarged tonsils and adenoids. The results certainly justify the continuation of this class, and I intend to hold a further trial, and if successful, to make the class part of my out-patient practice for a certain selected class of case.

One does not for a moment wish to give the impression that cases of hypertrophied tonsils and adenoids of any size can be cured without operation, because no amount of drill can remove tissues which are hypertrophied; but some cases are inflamed and swollen rather than hypertrophied, and in such there is no doubt that methods making for removal of stagnation and chronic inflammation are a very important factor in treatment. It is quite possible for reduction of inflammation to cause shrinking sufficient to relieve symptoms in mild cases. It is not an unknown experience to find that in cases in which operation has been decided upon but which have had for some reason or other to wait for a little time for that operation, the tonsils and adenoids have shrunk so much in the interval that operation has become unnecessary.

I hold that the majority of cases of tonsils and adenoids are due to infection, which becomes chronic and leads to obstruction, first by inflammation and swelling and then by ultimate hypertrophy of the lymphatic tissues. Under modern conditions children are more exposed to infection than formerly, because they have so many more opportunities for such infection. Gatherings of children indoors, as at school and places of amusement, or in badly ventilated chambers such as trams and railway carriages, are specially fertile sources of infection. Other causes, such as debilitating factors acting on the general health and vitality, also play an important part, probably because they lead to lowered general resistance to infection. Again, irritating atmospheric conditions and any unhygienic state of the mouth have an effect, the former being especially shown by those cases who suffer from chronic catarrh and frequent colds in town atmospheres but do well in country air or at the seaside. Whatever the cause, there is no doubt that there is a very large number of cases of inflamed and enlarged tonsils and adenoids at an out-patient department who have troublesome symptoms and yet are not sufficiently bad to need operation, either because the enlargement is intermittent or because it is slight.

As a summary one can say that in cases with much hypertrophy the local results are, as can only be expected, poor, but in cases with inflammation and little hypertrophy the relief of symptoms such as headache, restless sleeping, and liability to colds, is marked. Nasal drill is therefore of great value for such cases, and it should also be of value as a post-operative measure. It is of value over and above the physical exercises employed, because the improvement in the nasopharyngeal symptoms was far greater than could have been accounted for by the mild physical exercises which were used as an adjunct to the nasal drill. For cases which are hypertrophic and not largely inflammatory, and which are therefore sent for operation, nasal drill may be useful as a post-operative measure. The best methods of conducting nasal drill and the period of time over which such exercises should be continued can only be determined by experiment.

SIR GEORGE FRAMPTON'S monument to Nurse Cavell has been placed in position at the point where Charing Cross Road meets St. Martin's Lane. The crowning figure on its lofty pedestal will look down on Trafalgar Square. Among the monuments of London it will be remarkable for its dignity and the originality of its conception.

MESSRS. CHAS. J. SAWYER, Ltd. (23, New Oxford Street, London), have issued a catalogue of works on medicine, surgery, anatomy, etc., from the sixteenth century to the nineteenth, with a selection of engraved portraits of medical men. The prices of both strike us as moderate.

ECTOPIA VESICAE TREATED BY IMPLANTATION OF THE URETERS IN THE RECTUM.

By C. C. HOLMAN, M.B., F.R.C.S.

ASSISTANT SURGEON, NORTHAMPTON GENERAL HOSPITAL.

ECTOPIA VESICAE is a sufficiently rare deformity to justify publication of the following case :

A boy, aged 8 years, was admitted into the Northampton General Hospital in March, 1918, suffering from ectopia vesicae. He was small for his age and pale, exhibiting all the symptoms characteristic of his unhappy condition.

First Operation.

On March 15th, 1918, after the patient had been anaesthetized, a No. 1 gum elastic catheter was passed into each ureter for about three inches and tied in. A median incision was made through the bladder and a circular incision round each ureteral orifice. The ureters were then, in turn, freed by blunt-pointed scissors, taking care not to trespass on their blood supply. After a finger in the rectum had demonstrated its relations, a pair of fully curved forceps were passed through the anus and pressed against the rectal wall below the peritoneal reflection. A small incision was made, the forceps passed through and the right ureter with its catheter drawn into the rectum as far as it would go. The wound in the rectum was closed by one stitch which took a grip of the wall of the ureter. This procedure was repeated on the left side. The rest of the bladder was trimmed away and the wound left open. At the conclusion of the operation the catheters were withdrawn as they seemed calculated to do more harm than good by their presence in the ureters.

Subsequent Progress.

The patient's general condition remained good, but the temperature ran an irregular course for a fortnight, rising each evening to 101° or 102° F. The bowels acted naturally on March 17th, and by March 19th the boy could keep dry during the day. On April 6th there was thought to be some leakage of urine through the wound.

Second Operation.

On April 17th granulations were cut away, the skin edges undercut and brought together. Both ureters could be felt projecting into the rectum. The wound healed by first intention, and there was no leakage of urine.

Present Condition.

In January, 1920, the boy's general health is good and his gait normal. He has complete control over his urine, which he voids two or three times during the night and at intervals of from three to four hours during the day. The operation scar is sound and dry.

The operative procedure in this case was practically that described by Peters,¹ with the minor difference that the ureters were fixed by a stitch into the rectum and the catheters removed at the conclusion of the operation. There was probably some slight infection of the kidneys in this case, as shown by the irregular pyrexia and by thirst. It might be wise in a similar case to allow an interval of some weeks to elapse between the transplantation of each ureter, as suggested by Mayo.² He utilizes the sigmoid in preference to the rectum, but, in the hands of the average surgeon, such a procedure would involve more risk to the patient. Some writers seem to assume that by transplanting the trigone (Maydl) or the whole bladder (Moynihan) the risk of ascending infection of the kidneys is diminished. I know of no statistics which prove this assumption. The statement that the valvular orifice of the ureter is maintained after transplanting the trigone is open to question, as the transplanted portion of the bladder is necessarily severed from its nerve supply.

MEDICAL, SURGICAL, OBSTETRICAL.

A CASE OF DERMOGRAPHISM.

(From the Neurological Department, 2nd Northern General Hospital, Leeds.)

PTE. W., aged 20, was admitted to this hospital in May, 1919, with a gunshot wound of the right upper arm and ulnar nerve injury.

His attention had first been drawn to the case with which his skin whealed three months previously when, while washing himself, he received a slap on his chest from a fellow patient, which was followed by a raised impression of the hand. Since then he noticed that a tight shirt wristband, a tight collar or bandage would cause a raised wheal on the underlying skin.

The words in the photograph were traced by moderately firm pressure with a blunt piece of wood. The urticarial wheals took about three minutes to develop fully. As they rose they were at first uniformly pink, but finally wore white and bloodless in the centre with a bright pink border. They subsided in from half to three hours,

according to the pressure used to create them, and vanished rather more quickly from the arms than from the back and chest. There was no itching of the skin. The readiness of the patient to sweat on slight exertion furnishes further evidence of vasomotor instability.

The patient exhibited no signs of hysteria, and examination revealed nothing else abnormal either in the nervous system or elsewhere, except that, although a Yorkshireman, he spoke quickly, almost to the point of clipping and slurring his words, and unintelligibility.

His family history furnished no sign of neurotic heredity, his parents, brothers, and sister being quite healthy, and, as far as the patient knew, none presented this phenomenon of factitious urticaria.

The patient himself stated that he had always been healthy, was classified A1 on joining the army, and during

his six and a half months in France suffered from nothing until he was wounded. The only other feature of interest is that about two months previous to his first noticing the condition he was in hospital in London, and whilst lying in the anaesthetic room waiting for some small operation a bottle of ether exploded and caught fire. He assisted the nurse to extinguish the flames, and was rather scared and tremulous afterwards. He was anaesthetized, however, and the surgical procedure carried out. There were no ill effects on recovering from the anaesthetic.

I have to thank Lieut.-Colonel C. E. Ligertwood, D.S.O., the administrator of this hospital, for permission to record the case.

Captain R.A.M.C.(S.R.).

SUBLIMED SULPHUR IN MERCURIALISM.

MERCURIALISM is caused by the accumulative action of mercurial salts, but the exact mechanism is not definitely known, though two theories have been advanced, one by Almkvist and the other by Professor Gaucher.

Almkvist's Explanation.

Protein foods are pressed into the sockets of the teeth or into the recesses of the mouth. Here they are attacked by putrefactive anaerobic organisms, such as the *Spirochaeta dentium* and the fusiform bacillus of Plant-Vincent. These bacilli form sulphuretted hydrogen. The mercury circulating in the capillary loops of the gums is precipitated as black mercurysulphide. The nourishment of the gums and the alveolar process of the jaw is interfered with and degeneration and necrosis of the involved tissue results.

Professor Gaucher's Explanation.

Mercury, on absorption into the system, becomes converted into a chlor-albuminate-peroxide of sodium and mercury. It is an irritating salt, and is not allowed to circulate freely, thereby

DERMOGRAPHISM.

causing stomatitis and other symptoms of irritation. He recommends that sulphurous waters should be drunk, and reports a case in support of his theory. He further states that the irritating mercury salt is converted into a non-irritating mercury sulphide, which circulates freely in the system. The mercury sulphide is easily excreted and is well tolerated.

Professor Gaucher's theory, in view of the fact that sulphur improves the condition, is the more feasible.

As a prophylactic measure all tartar should be removed from the teeth at the commencement of treatment, although this may not always be possible. The teeth should be cleaned after every meal, using a tooth-brush, and a tooth powder containing preferably potassium chlorate. As a mouth-wash, a weak solution of hydrogen peroxide should be used.

As a large percentage of the syphilitic patients who present themselves have bad teeth, and as time cannot be spared to send them for treatment by the dentist, and in view of the fact that the theory of Professor Gaucher appeared to me to be quite feasible, I resolved to try an experiment on this theory. As no natural sulphurous waters were available I put all the patients in this dermatological section who were being treated for syphilis by intramuscular injections of mercury on one teaspoonful of sublimed sulphur nightly (by the mouth). From the very beginning the results were astounding. Not only was mercurialism prevented, but patients actually suffering from the condition, who had frequently to be excused their weekly injections on this account, improved rapidly, and in the course of a short time were on full and regular treatment again.

After using the sulphur in this method I have obtained such confidence in its action that I would now waste no time in sending a patient to the dentist for preliminary treatment for a mouth condition, however bad it might be. I have even stopped prescribing gargles except in the worst cases, and then only as a preliminary measure. Patients are simply advised to "wash their teeth after meals."

This treatment has now been in progress for the past nine months, and in no case has mercurial treatment had to be suspended on account of mercurialism.

"ACUTE SUFFOCATIVE CATARRH."

I HAVE been much interested in the cases of acute suffocative catarrh lately published in the BRITISH MEDICAL JOURNAL.

I have seen two cases presenting similar conditions, but in both the patients were suffering from diabetes; one was not aware of his condition, the other knew he had at one time suffered from diabetes, but thought he had completely recovered:

CASE I.—I was called out late at night some years ago to see a young man who was a complete stranger to me. I knew nothing of his previous history; I learned he had suffered from some stomach complaint, and had, in fact, been up that same day to see a specialist in London. I found him suffering from extreme dyspnoea, and râles were heard all over the chest. I was presented with a vessel full of a pinkish-looking fluid, with a white scum; he had been expectorating this in large quantities. I was quite at a loss to account for the condition, but happened to think of lipsemia in diabetes, as described in Taylor's *Practice of Medicine*. The urine was found to be loaded with sugar. He died within twelve hours.

CASE II.—Some two years later I was called to a patient, also a young man, who was suddenly seized with difficulty in breathing. I found him sitting with a pail between his knees, into which he was expectorating a fluid similar in appearance to that in Case I. From my previous experience I at once told his wife that he was suffering from diabetes; to this she replied, "He has not got diabetes now; he had it at one time, but we thought he was cured." This patient also died within twelve hours. The urine was found to be loaded with sugar.

In Taylor's *Medicine* it is stated, "It has been found in a small number of cases that the capillaries of the lung are blocked by globules and masses of fat, and Drs. Saunders and Hamilton, who first described this, attributed the whole train of nervous symptoms to this 'fat embolism' of the pulmonary capillaries."

Kempston, Bedford.

A BASKET-MAKING shop will be erected and equipped at the Euham Village Centre from a fund of £500 raised in the town of Southampton.

Reports of Societies.

OXYGEN THERAPY.

A discussion on the therapeutic uses of oxygen was held on January 20th, 1920, in the Section of Therapeutics and Pharmacology of the Royal Society of Medicine.

The discussion was opened by Mr. J. BARCROFT, C.B.E., F.R.S., who said that the subject of oxygen therapy was no new one, and it had now reached a stage at which there was considerable diversity of opinion. In such circumstances the best method of treating a subject was to produce facts, and the work of himself and his colleagues had been limited to the treatment of a particular class of case—namely, soldiers and munition workers who had been gassed—and the endeavour of Miss Dutton, Major Hunt, and himself had been to get at the facts, formulate them in such a way that they should be simple, intelligible and capable of repetition, and take care that in their interpretation neither their opinions nor those of the patients should play a part.

Chronic Gassed Cases.

The cases treated were all chronic cases, and the treatment adopted was partly worked out from experiments on animals and partly from reports from France. The method adopted at Cambridge was simple.

A glass room of about 1,000 cubic feet capacity formed a living ward and contained three beds. The ward was gas-tight and fitted with air locks. The composition of the atmosphere within was kept at 40 to 50 per cent. of oxygen and 50 to 60 per cent. of nitrogen. The CO₂ and aqueous vapour were removed by passing the air from the ward through an external circuit containing scrubbers of soda-lime and calcium chloride and potassium permanganate.

The chief object in adopting this method was to attain simplicity and ensure that the only altered condition of the patient's life was the change in the composition of the atmosphere he breathed. No attempt was made to study the question of the best method of administration. Their object was solely to make observations on the results of oxygen treatment. For many purposes for which oxygen was wanted a chamber was clearly out of the question. The routine was to put the patient in the chamber from about 5 p.m. till 10 a.m. for five consecutive days. Between 10 a.m. and 5 p.m. the patients left the chamber for varying periods for exercise, etc. A chronic case of chlorine, phosgene, or chloropicrin poisoning usually complained of one or both of the following symptoms: nocturnal attacks of dyspnoea and physical distress on exertion out of all proportion to the effort put forth. The latter afforded the better means of obtaining an objective indication of the patient's condition. The response to exertion of either the circulatory or the respiratory system might be taken as the guide. Each had its advantages and drawbacks. The pulse was easy to count, its variations in rate were susceptible of simple and accurate statement, but its significance in relation to the strain put upon the heart or the volume of blood propelled round the body was obscure, whilst the mechanism of its regulation was also obscure at the time of their experiments. The respiratory system was in some respects more hopeful: not only the frequency of the respiratory rhythm could be measured, but the total ventilation, the composition of the air expired and of that retained in the lung, and the depth of respiration could be recorded. On the other hand, the respiration was more under the influence of the will than was the pulse.

Results of Treatment.

In the first fourteen cases studied they took the response of the pulse to effort as the criterion; in the last twelve the respiratory response. The procedure with regard to the pulse was as follows:

After a general examination the patient was made to rest for fifteen minutes. His pulse was then counted. He was given an exercise to perform, the severity of which was judged appropriate to his condition. His pulse rate was counted again after the exercise, and the time observed which elapsed between the end of the exercise and the return of the pulse rate to within six beats per minute of its resting value.

In nearly every case the pulse of the gassed man took an unduly long time to return to its normal. These same observations were made immediately after treatment. Every one of the patients received more or less benefit as judged by this test, but the degree of improvement naturally varied.

A typical case was that of S., gassed April, 1915, presumably with chlorine; treated October, 1917. Pulse before treatment took nine to ten minutes to fall to within six beats per minute of resting rate after test exercise. After treatment it returned in the fourth quarter-minute.

With regard to the question as to how long the improvement lasted they were able to give some data. Of five patients examined two and a half months after treatment three were normal as regards the response of their pulse rate to exertion and two were nearly normal. A sign which was frequent but by no means invariably present in cases gassed with chlorine or phosgene was a high red blood corpuscle count. It was largely the occurrence of this sign which suggested the oxygen treatment to them. Occurring as it did in persons exposed to an atmosphere deficient in oxygen, they argued that this sign in patients breathing a normal atmosphere showed that they were nevertheless suffering from want of oxygen and that an increase in the oxygen inspired might reduce the red count to a normal value. Observation fully bore out this expectation, the red counts falling after the oxygen treatment and being two and a half months later still lower than before treatment. The third sign, to which they paid a good deal of attention, was nocturnal dyspnoea. Of six cases in which such attacks were a marked feature one only showed no improvement. In four cases the attacks were completely and permanently abolished. No man had an attack during treatment.

Interpretation of Results.

With regard to the possibility that the results could be attributed to some subjective cause three remarks might be made: (1) It was unlikely that the red count would drop from 7.5 to 5 million as a result of suggestion. Moreover, in gassed rabbits the same phenomenon was observed. (2) As regards the pulse, twelve cases of D.A.H. not attributable to gassing were given oxygen. These taken as a whole showed no clear benefit. (3) As regards nocturnal dyspnoea. In one case oxygen was blown into the chamber in such a way as to make the patient believe that he was getting the treatment, while in reality he was not doing so, as the oxygen was expelled unknown to him as rapidly as it entered. He complained that the treatment did him no good and his nights were not improved. On the fourth night the oxygen treatment really began and he at once improved.

Dyspnoea Ratio.

Dr. G. H. HUNT said that, with regard to the respiratory symptoms in chronic gassed cases, their object at Cambridge was to find some exact method of measuring improvement. They were faced with the difficulty that there was no numerical measure of dyspnoea which satisfied their requirements. Any standard must fulfil three conditions:

First, it must be fairly constant in any one individual, provided his physical condition did not alter appreciably; secondly, it must give approximately the same result for a number of men in the same condition of physical fitness; thirdly, it must distinguish between healthy men and those suffering from any pathological cause of dyspnoea.

Their method was as follows: The subject breathed through a meter while at rest. His total ventilation and respiratory rate were noted. He then did a definite amount of work on a bicycle ergometer, and the observations were repeated during work and for several successive minutes after. A few experiments showed that total ventilation and respiratory rate in all these periods varied considerably in the same man, and were widely different in different healthy men. The above mentioned requirements were therefore not satisfied by these observations. It was well known that in healthy men the respiration after exercise returned to the state occurring during rest much more quickly than in breathless men. They found it impracticable to estimate the time taken after exercise for the respiration to return to the pre-exercise condition.

Instead they compared the total ventilation during the second to fifth minutes after exercise with that during four minutes at rest. Dividing the former by the latter they obtained a figure which they called the "dyspnoea ratio." This ratio fulfilled their requirements satisfactorily. It was reasonably constant for the same individual doing the same work in a given time, it was approximately the same for ten healthy men who were in good training and for six who were in bad training, and it clearly distinguished between healthy men and those suffering from any disease known to cause dyspnoea. A chart was shown giving the dyspnoea ratios for a number of different subjects over a series of exercises of increasing severity. With light work the ratio of trained and untrained healthy men was approximately the same. With harder work the untrained man had the higher ratio. In gassed men the ratio was higher than in healthy men even with light work. These observations also afforded a measure of a man's efficiency as judged by his respiration. Healthy trained men doing 10 000 foot-pounds per minute for 1½ minutes had a dyspnoea ratio of 1.64. The dyspnoea ratio of gassed patients was found to rise to 1.64 when doing from 3,000 to 5,000 foot-pounds per minute for 1½ minutes. Therefore their efficiency was only 30 to 50 per cent. On applying this test to seven gassed patients both before and after oxygen treatment it was found that one did not improve at all, in one the efficiency rose 11 per cent. and in five between 17 and 21 per cent. In three of these cases the efficiency rose to over 70 per cent. as compared with the value 77.5 per cent. found for untrained healthy men. In the other two cases the efficiency was but slightly less.

Anoxaemia.

Dr. J. S. HALDANE, F.R.S., wished to emphasize two points: (1) That very slight anoxaemia had a very serious effect if persisting for a long time. For example, seriously unpleasant symptoms of mountain sickness often followed exposure for some hours to slight lowering of the oxygen pressure of the atmosphere. The same effect followed slight CO poisoning, and the serious symptoms were apt to be delayed and come on after the cause provoking them was no longer operative. (2) That anoxaemia was very common in acute illnesses. In such cases it was desirable to prevent the anoxaemia and to do so at an early stage. If not ameliorated the condition was likely to become serious. The failure to recover in fresh air after CO poisoning referred to above was due to want of oxygen, and not to the effect of some obscure toxin. A reliable method of detecting slight degrees of anoxaemia was to administer oxygen and note any resulting change of colour. If anoxaemia were present the lips would become redder. The occurrence of anoxaemia in acute illnesses was well shown by recent work in America. Stadie had analysed the gases of arterial blood in cases of pneumonia, etc. Nearly all showed a deficiency in the degree of saturation of the blood with oxygen, which might amount to as much as 50 per cent. in some cases. Such cases with only half the normal amount of oxygen in the arterial blood all died. Similar results were obtained in heart disease and bronchitis. Anoxaemia (deficiency of oxygen in the arterial blood) might be due to two causes:

1. Thickening of the alveolar epithelium of the lungs. This was studied years ago by Lorrain Smith in lungs injured by exposure to excessive pressures of oxygen, and was best seen in cases of phosgene poisoning.
2. Unequal ventilation of different parts of the lungs.

He had noticed that, in patients suffering from the chronic effects of gas poisoning, the type of respiration was commonly very shallow. Working with Colonel Meakins and Captain Priestley at Taplow he found that artificially induced shallow breathing in healthy people caused anoxaemia, even though the rate of respiration was increased sufficiently to maintain the CO₂ output at its normal level, and though the total ventilation per minute was increased. The shallow ineffective breathing of the chronic gassed cases similarly caused anoxaemia. They suffered from dyspnoea, not merely from hyperpnoea. The same effect on the breathing and consequent anoxaemia was produced by fatigue and by exposure to lack of oxygen. A striking symptom of anoxaemia was nocturnal attacks of dyspnoea, which were relieved in a remarkable manner by the administration of oxygen.

War Experiences.

Colonel S. L. CUMMINS, C.B., said that it was unfortunate that knowledge tended to be shut up in the heads of ultra specialists. There was no one in the Regular Army when the gas attacks began who had an expert knowledge of the methods of oxygen administration and the indications for its use. By the end of the war, however, the effects of oxygen were much clearer and more widely known, but were not yet completely explained. The impressions he had gathered by the end of the war were: (1) That it was certain that oxygen did much good in acute gas cases, pneumonia and shock; and (2) that many medical men were reluctant to use oxygen as freely as it should be used. As regards the method of administration, it was easy to put a patient in an oxygen chamber, but in some cases, especially where anoxaemia was intense, it was difficult to give oxygen by means of a mask. For instance, Dr. Haldane's apparatus was excellent, but was difficult to apply in some cases. It was clear that further research was required as to methods of administration, and perhaps it might be found that a small modified oxygen chamber enclosing the patient's head might be of value.

Lieut.-Colonel C. G. DOUGLAS, C.M.G., said that in France he saw acute cases of gas poisoning. The good effects of oxygen were seen after the first gas attack, even before the time when it was possible to be sure how much good the oxygen did. Four methods of administration were used in France: (1) A simple tube and funnel; (2) the ordinary nitrous oxide apparatus; (3) the nasal tube; (4) Dr. Haldane's apparatus. With patients suffering from anoxaemia much good was done by giving oxygen, provided that the patient got the oxygen. Unfortunately, by many methods in use the oxygen was expended on the surrounding air, and not on the patient. Colonel Douglas went on to describe the remarkable effect of oxygen in two representative cases, and laid stress on the great improvement in all symptoms brought about by oxygen, more especially in the pulse—for example, a weak, irregular pulse of 140 changed to a stronger, regular pulse of 120 immediately oxygen was breathed, but relapsed when the oxygen was stopped. He also laid stress on the necessity for continuity of administration as long as symptoms of anoxaemia persist, and the need for increasing the amount given until the beneficial effect was observed. It was often noticed that the vital necessity for continuity of administration was not realized, and it was not unknown for bad cases to be given oxygen for five minutes only in each hour. Such a proceeding was useless. Apparently there was a tendency for medical officers to be alarmed at the apparatus. In badly gassed cases it was clear that the earlier the oxygen treatment was begun the quicker the recovery of the patient. Some cases which were apparently moribund were so far improved by two hours' oxygen treatment as to be in a state to be further benefited by venesection.

Dr. RYLE said his observations were clinical and dated from the gas attack of August, 1916. He found the funnel method ineffective and improvised masks were not tolerated. The nasal catheter method devised by Captain Adrian Stokes was a great improvement. It had the advantage that the patient could adopt any position, was easily fed, and could and did readjust the catheter himself if necessary. A difficulty with the Haldane mask was caused by the oedema fluid in phosgene cases. As regards oxygen treatment after gassing the cases might be divided into three groups: (1) Mild—sufficiently treated by fresh air; (2) medium—sufficiently treated by pure oxygen for five minutes in every fifteen; and (3) severe—requiring oxygen continuously. Other conditions in which oxygen was found to do good were the lung oedema of trench nephritis, acute purulent bronchitis, and severe haemorrhage.

Dr. R. H. PETERS corroborated the remarks of Colonel Cummins and Colonel Douglas with regard to the good effects of oxygen in gassed cases. He described one severe case of bronchopneumonia which he had treated with oxygen. The patient was getting progressively worse, the breathing became feeble and the pulse bad. Chayne-Stokes respiration set in. Two litres of oxygen per minute added to the air breathed for ten minutes in each hour initiated an improvement which was continuous.

Oxygen Wards at Stoke.

Dr. SHUFFLEBOTHAM said he must omit much of what he had meant to say, for want of time. He described the oxygen wards at Stoke-on-Trent, installed with the help of the Medical Research Committee. They had treated one hundred patients in fourteen months. The cases were mostly gas poisoning, but included some cases of pneumonia and two of pernicious anaemia. Many of the cases improved and could resume their work after the treatment, though previously quite incapacitated. The cost of the oxygen was a difficulty. At Stoke it was £1 3s. 6d. per day per patient despite the utmost economy. Dr. Harker had suggested the use of the residual gas after removal of nitrogen from the air for technical purposes. Possibly liquid air might be an economical source of supply. The question of oxygen therapy opened up a great field of usefulness and research. Dr. Shufflebotham showed an interesting model of the oxygen wards at Stoke, and drew attention to the necessity for great care in the use of oxygen chambers, owing to the danger of fire.

Dr. SOWRY described the work done with the oxygen chambers at Stoke. He thought the chamber the most efficient way of giving oxygen; there were no complaints from patients so treated. Seventy-seven cases of gassing in soldiers and munition workers were treated. The patients were the victims of various kinds of gas and came under treatment at varying periods after gassing. The routine treatment was a stay of five to six days for twenty hours each day in the chamber; oxygen at first 25 to 40 per cent., later 50 to 60 per cent. Full notes of the cases were taken, x-ray examination of the chest made, and the patients were submitted to exercise tests before and after treatment. These tests were: (1) A short and acute effort, (2) the stair test, and (3) eighteen minutes' vigorous walking on the level. The patients showed the usual symptoms of the effort syndrome, cough and nocturnal dyspnoea. There was cyanosis in 15 to 20 per cent. of the cases, but it was never severe. Emphysema was noted in 40 per cent. Râles, etc., were common, and fibrosis was shown by the x rays. Two cases of active tuberculosis were proved bacteriologically. The patients reported for re-examination two, four, and six weeks after treatment. The majority remained much better than before. Of 70 cases 23 were very much improved, 30 were much improved, 10 were improved and 6 were not improved. There was marked improvement in asthmatic symptoms and in the response of the heart to exercise. In 29 cases blood counts were made. Polycythaemia occurred in some cases, but was not the rule. Indeed, low counts were not uncommon. Whether the count was low or high, it tended to return to normal after oxygen treatment. No other treatment was allowed. Two cases of pernicious anaemia were improved subjectively, but later, after the oxygen treatment was stopped, continued to get progressively worse. In five acute respiratory cases very good results were obtained.

Dr. P. HAMILL described the effects of oxygen on cases of opium poisoning investigated by Dr. Clarke and himself. They had Chayne-Stokes respiration, and the blood pressure rose to nearly normal after the period of respiration, and fell during the apnoeic periods. Oxygen made the respiration more regular, and kept up the level of the blood pressure. Dr. Hamill suggested that sodium peroxide might be a useful source of oxygen on the score of cheapness; the drawback was the heat engendered.

After the meeting Dr. HALDANE demonstrated the apparatus devised by him for the administration of oxygen.

HYDATIDIFORM MOLE.

At a meeting of the Edinburgh Obstetrical Society on January 14th Dr. F. J. BROWNE gave a lantern demonstration on the histology of hydatidiform mole in its relation to prognosis. He claimed that Langhans's cells were found in hydatidiform mole in two stages: (1) The small inactive cell lying between the syncytium and the core of the villus; (2) the large cell in active mitosis, which before invading the decidua lay in closely packed masses forming a mosaic pavement. These large cells indicated malignancy. They must not be confounded with the "vacuolation cell" formed from syncytium by the appearance of vacuoles around the syncytial nuclei. These now cells lost their vacuolation, their protoplasm became more

condensed, and they ultimately formed the syncytial wander cell. When present in relatively large numbers the vacuolation cells indicated a benign mole. Before invasion of decidua these cells were easy to distinguish from each other, but afterwards, owing to the tendency of both to become syncytial-like, and also to the presence of decidual reaction cells, their differentiation became more difficult. The amount of syncytium present had no prognostic significance. For the histological prognosis uterine curettings alone were necessary. The paper was favourably commented on by Drs. BERRY HART, BALLANTYNE, LAMOND LACKIE, JOHNSTONE, and YOUNG. It was pointed out by the speakers that if Dr. Browne's observations were confirmed, valuable information would be at hand in regard to the question as to which cases of hydatidiform mole should be considered malignant and which simple.

INFANT WELFARE CENTRES.

A MEETING of the London Association of the Medical Women's Federation was held on January 20th, at 11, Chandos Street, W., the President, Mrs. FLEMING, M.D., in the chair. A discussion on infant welfare centres was opened by Dr. FLORA SHEPHERD, who described the organization of such work. She said that in order to be successful each centre should be under the administrative control of the medical officer of health, and that the medical officer of the centre should send him monthly reports of the work done. Each centre should be responsible for all the work required so as to avoid overlapping by health visitors sent by different authorities. No centre should be more than twenty to thirty minutes' walk from the homes, and not more than thirty children could be satisfactorily attended to in one session of two and a half hours. In a well organized district there should be an attendance of 60 to 70 per cent. of all the births notified. Antenatal consultations should be entirely separate from infant welfare consultations. Mrs. ROBERTSON, M.B., B.S., in a paper on natural feeding of infants, referred to some of the causes of inability to feed infants, and described how they could be helped by treatment at welfare centres. Among the points mentioned were nasal obstruction in the babies, depressed nipples in the mothers, and bad health due to dental disease. She added that some babies got on well when fed only four times in twenty-four hours, and that it was generally better not to wake them for feeding. Dr. C. A. KING, in a paper on the artificial feeding of babies, said that no rules could be given, as cases had to be judged on their own merits, and methods appeared to vary within fairly wide limits. She advised fresh cow's milk, boiled; in estimating quantities, weight and size are of much more importance than the baby's age. Dried milk should be used as a routine when hygienic or atmospheric conditions were unfavourable. Dr. King found that dried milks were better tolerated than ordinary cow's milk by infants with feeble digestive powers, especially when prepared by the Bévenot-de-Neven as compared with the Hatmaker process. She preferred plain desiccated milk, which could always be modified as required, to those modified in preparation. The antiscorbutic and antirachitic properties of milk were not decreased to any great extent by desiccation, but fresh fruit or vegetable juices should invariably be given with a dried milk diet.

THE University Medical Advisory Committee at Johannesburg has recently presented a report on the organization of the medical school to the senate of the University College; its recommendations are published in full in the *South African Medical Record*. It is advised that the chairs of anatomy, physiology, and pharmacology should be whole-time appointments and that the professors should receive a salary of £1,000 a year each, but that the chairs of medicine, surgery, obstetrics and gynaecology, pathology and bacteriology should be part-time appointments. The suggestion to make the professors of clinical subjects whole-time officers also was considered, but rejected, as it was felt that the teachers of the practical branches must be men in daily contact with the practice of the profession, as the chief aim of the medical school is to train general practitioners and not specialists. The course contemplated extends over six years. The first year would be given to the preliminary sciences, the second and third to anatomy and physiology, and organic chemistry, but in the third year the second term would be given to elementary medicine, surgery, pharmacology, pathology and bacteriology. The fourth and fifth years would be clinical; the sixth year would be given to special subjects. There would be five professional examinations, at the end of the first, second, third, fourth, and sixth years.

Rebicus.

THE SCOTTISH WOMEN'S HOSPITALS.

AMONG the books on the medical aspects of the great war one of the most attractive is undoubtedly *The History of the Scottish Women's Hospitals*,¹ edited by Mrs. SHAW McLAREN, and told almost entirely by the women who did the work. It is most appropriately dedicated to the memory of the late Dr. Elsie Maud Inglis, who originated and organized this great undertaking by Scots medical women. Interest, therefore, naturally centres in the personality of this devoted woman, who, after qualifying in 1892, practised in Edinburgh, where she took an active part in the medical education of women and was for some time honorary secretary to the Scottish Federation of Women's Suffrage Societies. In the appreciative chapter on "Our Chief," Miss Mair writes: "In outward appearance the leader of the Scottish Women's Hospitals was no Amazon, but just a woman of gentle breeding, courteous, sweet-voiced, somewhat short of stature, alert and with the eyes of a seer, blue-grey and clear." After the outbreak of war, as in the case sixty years before of Florence Nightingale, with whom she is compared, all her energies were devoted to one object. After the offer of a unit had been declined by the War Office, she organized three units entirely staffed by women, which went, in December, 1914, to Calais, Royauumont, and to Serbia. Early in 1915 typhus became rampant in Serbia, and in May Dr. Inglis went out; in November she went through the great retreat before the German-Austrian invasion, and what this entailed is graphically expressed by a Serbian writer: "If the skies were all paper and the sea were all ink we could not even then write the sorrows of our country." The story of the retreat is fully told. After being a prisoner in Austria Dr. Inglis returned home, and at the end of August, 1916, took a unit with a personnel of 75 via Archangel to Odessa for service with the Serbian division of the Russian army; she went through the vicissitudes of the retreat from the Dobrudja; in November the unit was on its way home, but the leader was so ill that she passed to the land of shadows soon after landing at Newcastle on November 26th, 1917.

The story of the Scottish Women's Hospitals naturally falls into six parts, some of which have been mentioned above; they are the early days up to the establishment of the Calais unit, the history of the hospital at Royauumont (1914-18), Serbia (1915-16), with the Serb division in Russia and Rumania, continued work for the Serbians in Corsica and elsewhere, and the Girton and Newnham unit's work. The Calais unit, under Dr. Alice Hutchison, who had previously worked in Bulgaria during the first Balkan war, and later, in 1915, was active in Malta and Serbia, was busily occupied for three months with enteric among the Belgians. From December, 1914, to December, 1918, Miss Ivens, M.S., was in charge of the unit at Royauumont, and, with Miss Cicely Hamilton as administrator, rapidly transformed an abbey 700 years old and without light or water into a most efficient modern hospital. The Girton and Newnham unit, under Miss Louise Mellroy and Miss Sandeman, was for six months at Troyes in France and for three years at Salonica, and after the armistice was moved to Belgrade as the nucleus of the Elsie Inglis Memorial Hospital.

This volume gives a well written and well illustrated record which moves the reader to sincere admiration for all concerned.

X-RAY LOCALIZATION OF FOREIGN BODIES.

CAPTAIN HAROLD C. GAGE, of the American Red Cross Service, has published the results of his work in a book with the title *X-Ray Observations for Foreign Bodies and their Localization*.² It is a compact and well written essay, illustrated by numerous diagrams, radiographs, and photographs. These observations are based entirely upon

¹ *A History of the Scottish Women's Hospitals*. Edited by Eva Shaw McLaren. London, New York, and Toronto: Hodder and Stoughton, 1919. (Demy 8vo, pp. 408; 57 illustrations. 7s. 6d. net.)

² *X-Ray Observations for Foreign Bodies and their Localization*. By Captain Harold C. Gage. London: William Heinemann (Medical Books), Ltd., 1919. (Demy 8vo, pp. 87; 55 figures. 6s. net.)

the personal experience of the author and are the result of four years of war work. Having convinced himself that the usual report from the radiographic department—that a foreign body was situated so many centimetres under a certain mark made on the skin—was insufficient for the operating surgeon, he evolved the method of the three intersecting lines joining up three sets of two marks. Colonel Blake, of the U.S.A. Medical Corps, reports that as a result of this method, out of 306 localizations, 302 foreign bodies were successfully removed; in two of the other four cases the operation was abandoned for surgical reasons unconnected with localization.

This monograph is a valuable contribution to the many books and articles on the same subject which have resulted from war experiences. In addition to the standard method described, we come across, all through, various little hints which are helpful in difficult cases. The chapter on the method of localizing foreign bodies in the eye—a description of the work done by Drs. Belot and Fraudet—is of distinct value.

Now that the war is over the demand for this class of work must necessarily diminish, but for many years to come cases will be coming for examination—cases in which foreign bodies have been left undisturbed, but at a later date begin to give trouble. Books of this kind should be distinctly helpful to workers in x-ray departments.

THE PSYCHOLOGY OF EVERY DAY.

THIS volume on *Psychology and the Day's Work*,³ by Mr. EDGAR JAMES SWIFT, Professor of Psychology and Education at Washington University, consists of a series of studies in which psychological principles are utilized to interpret the common matters of everyday life. The essays cover a wide range of subjects, the general trend of which is towards the elucidation of those factors in mental life which increase or diminish efficiency in the business and social world. With this end in view the question of adaptation, the process of thinking and acting, and the development of habits are fully discussed in the opening chapters. A consideration of the psychology of "learning" contains personal researches of the author, and incidentally includes interesting curves representing the scores of an enthusiastic golfer which should afford some ground for hope to the despairing beginner. They indicate steady, though undramatic, progress, with some bad days which will excite the sympathy of the reader. Under the heading of fatigue the author, in an account of much experimental work, furnishes a useful summary of the voluminous literature of the subject. A similar comment applies to the chapters on memory and the psychology of digestion, the latter containing an account of Pavlov's researches. A practical and ingenious investigation into the value of evidence is detailed in the chapter on "testimony and rumor."

A number of useful facts are gathered together in this volume, but there is perhaps a certain diffuseness of treatment which may make it difficult for the reader to acquire from it any fundamental view of mental life. Though the author craves freely upon incidents in daily life to make his points clear, yet there is a certain academic atmosphere about his book which fails to emphasize in certain directions the struggling, dynamic aspect of mental life; insufficient stress is, perhaps, laid on the conflict between instinctive trends and the demands of modern life to give a tone of vitality to the psychology here presented. The chapter on "our varying selves" might possibly have been developed less superficially along these lines. The volume, however, contains much of value and will be found useful, especially to those engaged in educational pursuits.

NOTES ON BOOKS.

THE *Cambridge Note Book for Practical Zoology*⁴ is a most admirable member of its class. It is simple and to the point. The short introduction gives an excellent and concise statement of the importance of personal dissection

³ *Psychology and the Day's Work: A Study in the Application of Psychology to Daily Life*. By Edgar James Swift, Professor of Psychology and Education in Washington University, Saint Louis, London: George Allen and Unwin, Ltd. (Post 8vo, pp. viii+388, 10s. 6d. net.)

⁴ *The Cambridge Note Book for Practical Biology (Zoology)*. Edited by J. Stanley Gardner, M.A., F.R.S., and L. A. Bordaile, M.A. Sixth edition. London: H. Frowde, and Hodder and Stoughton, 1919. (Cr. 4to, pp. viii+76. 5s. net.)

and of making graphic records of the work done. A short account is also given of the more general methods of fixation, staining, and mounting of specimens. The book covers a good representative field, and if it be used as intended it should prove invaluable to the student.

The subject of open-air schools and sunshine schools for tuberculous and debilitated children is discussed in a French pamphlet⁵ published by the Comité National d'Éducation Physique et d'Hygiène Sociale of Paris, with details of some of the work being done in this direction in France. Sunshine schools open at the end of April and close in mid-October, and rules for the amount of exposure to the sun's rays have been formulated. Details of the equipment and conduct of such schools are given, and the pamphlet is copiously illustrated with photographs showing how they are carried on in practice. The little book is an encouraging comment on the open-air system started by the London County Council in 1907, and will interest educationalists as well as medical men.

Professor S. B. SCHRYVER'S *Introduction to the Study of Biological Chemistry*⁶ is a brief and clearly written account of the elementary principles of organic chemistry, as seen from the point of view of a biologist. But for the fact that it interests itself mainly in the organic substances formed by the living body, and eschews mathematics as far as is possible, both admirable features so far as students of medicine and biology are concerned, the book resembles other introductory accounts of the subject. In addition, it contains excellent brief summaries of the present views on important subjects, distinguished by being printed in italics.

Two short but well written books for the industrial chemist are *Catalysis in Industrial Chemistry*,⁷ by Professor HENDERSON, and *The Applications of Electrolysis in Industrial Chemistry*.⁸ Both these highly scientific and technical works deal with subjects of great and increasing interest in the manufacturing world, concerned as they are with the practical applications of science to technology. Both are well furnished with references to the literature of the subjects of which they treat.

A third edition of the handbook of physiology⁹ by ZUNTZ and LOEWY, of Vienna, has been published. The first edition appeared in 1909. It is a big book, without any outstanding merits or demerits, and may occasionally be of use to British teachers for purposes of reference. British students have many works better balanced and written on a sounder philosophical basis.

⁵ *L'Ecole de Plein air et L'Ecole au Soleil*. By MM. P. Armand-Delile, Médecin des Hôpitaux de Paris, et Ph. Wapler, Médecin du Dispensaire Antituberculeux de Versailles. Paris: A. Maloine et Fils, 1919. (Med. 8vo, pp. 30; illustrated. Fr. 4.)

⁶ *An Introduction to the Study of Biological Chemistry*. By S. B. Schryver, D.Sc. London: T. C. and E. C. Jack, Limited, 1918. (Cr. 8vo, pp. 340. 6s. net.)

⁷ *Catalysis in Industrial Chemistry*. By G. G. Henderson, M.A., D.Sc., LL.D., F.R.S. Monographs on Industrial Chemistry. Edited by Sir Edward Thorpe, C.B., LL.D., F.R.S. London: Longmans, Green and Co. 1919. (Demy 8vo, pp. ix+292. 9s. net.)

⁸ *The Applications of Electrolysis in Chemical Industry*. By Arthur J. Hale, B.Sc., F.I.C. Monographs on Industrial Chemistry. Edited by Sir Edward Thorpe, C.B., LL.D., F.R.S. London: Longmans, Green and Co. (Demy 8vo, pp. 148; 58 figures. 7s. 6d. net.)

⁹ *Lehrbuch der Physiologie des Menschen*, 1920. Leipzig: F. C. W. Vogel. (Sup. roy. 8vo, pp. xiv+789; 302 figures. M. 38.)

ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Case Committee sixteen cases were considered and £224 10s. voted to twelve of the applicants. The following is a summary of some of the cases relieved:

Daughter, aged 61, of M.R.C.S. Eng. who died in 1861. Until recently has been a school matron, and received from £30 to £40 a year. Now unable to obtain a post, owing chiefly to age, and to the demobilization of so many women. Voted £10.

Daughter, aged 46, of M.R.C.S. Eng. who died in 1908. Has no income, and is entirely dependent on her mother, who is an annuitant of the fund. Rent, 15s. for one room. Voted £12 in twelve instalments.

Daughter, aged 67, of L.R.C.S. Edin., who died in 1893. Applicant lets rooms, from which she receives about £40. Has occasional help from another charity. Suffers from ill health. Cannot manage owing to the high cost of living. Relieved three times. £31. Voted £18 in twelve instalments.

Daughter, aged 67, of M.D. Edin. who died in 1873. Applicant lives with two sisters, and they take in paying guests. Receives £48 from dividends and £30 from sister-in-law, and £15 by teaching. Requires help towards paying coal bill. Relieved four times, £45. Voted £15.

Widow, aged 39, of M.R.C.S. Eng. who died in 1914. Has no income, and is living with mother, whose income is limited. The Guild is helping to educate her one daughter, aged 11. Suffers from ill health. Relieved five times, £60. Voted £12 in twelve instalments.

L.R.C.P. and S. Edin., aged 62, widower. Receives £20 from another charity, and £50 from his only son. Rent and rates £28 10s. Suffers from ill health. Relieved fifteen times, £130. Voted £12 in twelve instalments.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters J. Symonds, C.B., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild is overwhelmed, in these days of exorbitant prices for clothing and household necessaries, with applications for coats and skirts for ladies and girls holding secretarial posts and suits for working boys. The Guild appeals for second-hand clothes and household articles for the benefit of the widows and children who, in happier times, would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

THE STATE AND VENEREAL DISEASE.

POLICY OF THE MEDICAL WOMEN'S FEDERATION.

WE have received this week a print of some suggestions as to the duty of the State in the control of venereal disease, drawn up by a committee of the Medical Women's Federation, and approved by the members of that body at an extraordinary general meeting held on December 13th, 1919. The committee begin by stating their belief that the problem is highly complex, and that its consideration involves far-reaching social and moral questions which cannot be separated from it.

To grapple successfully with these diseases will involve a radical reform of the social conditions and moral habits of the society in which the disease flourishes.

This, then, in the committee's view, is the chief and most important part of the task with which society is faced; but, while the campaigns against other infectious diseases and against the conditions under which they flourish can be simultaneously pursued, in the case of venereal disease there is the risk that activities along one line may, unless wisely planned, bring to nothing the other half of the campaign. Hence the need for great caution and a study of the problem from all its aspects and in all its implications before deciding upon action.

The principal cause of the dissemination of venereal infection in a modern community is promiscuous sexual intercourse. Any action which neglects this fact, or which may even tend to increase promiscuous intercourse, is bound, we believe, to fail to decrease the spread of the disease, and may even lead to its increase. Much the most important factor in the cure of the disease is early treatment, and any method of dealing with the disease which is likely to lead those infected to conceal their condition and to delay treatment will be a most dangerous expedient, and may easily lead to a serious increase of the disease. These two facts must be borne in mind in considering the desirability of any method of grappling with the disease, and we believe that no method has any chance of success which neglects either or both of these factors.

The memorandum next discusses the six principal means so far suggested for a direct campaign against venereal disease. Regulation, that is to say examination and registration of prostitutes, is wholly rejected. Notification, the committee think, is impossible without a legally accepted criterion of infectivity; and even were accurate notification possible they hold it undesirable because it would do nothing in itself to diminish infection if it were merely numerical and no names were given. On the other hand, notification by name, as a step towards compulsory treatment, would lead to concealment of early cases and delay in treatment during the curable stage. The difficulties in the way of penalizing those who infect others are held to be insurmountable, this view being based on the working of Regulation 40 D under the Defence of the Realm Act; nor would extension of the offence to both sexes in any way diminish the difficulties. Moreover, there is the practical difficulty of obtaining trustworthy evidence upon which a verdict can be based as to whether the plaintiff had been infected by the defendant or vice versa, or in some other way.

With regard to prophylaxis and the so-called "packet system," the committee associate themselves with the findings of the Interdepartmental Committee on Venereal

Diseases in connexion with Demobilization.¹ They hold that the immunity obtained in this way among the civil population would certainly be incomplete. They agree that the issue of prophylactic packets "tends to give rise to a false sense of security, and thus to encourage the taking of risks which would not otherwise be incurred," and that "under any mechanical system which does not give absolute protection, the venereal incidence must be proportionate to the risks taken." They hold that the increase in the number of exposures which they consider would certainly follow the introduction of such a system might well increase absolutely the spread of the disease. While strongly impressed with the dangers of this system the committee do not advocate the retention of the disease in order that the fear of infection may deter from promiscuous indulgence. Their point is that such indulgence would not be safe, while the attitude of the State would encourage a false idea that it was safe and countenanced by the authorities, and so would lead to increased indulgence and quite possibly to increased disease. The provision of "early preventive treatment" at the public expense at day and night clinics is condemned for the same reasons. But they add:

The sale by chemists, to those who wish to purchase them, of calomel ointment or of permanganate of potash solution is a matter with which we have no concern as long as the public is aware that these things are not remedies for venereal disease and that chemists are under a legal obligation not to sell them for the purpose of treatment of these diseases.

Having thus rejected one by one these six lines of attack upon venereal disease the committee proceed to define their own constructive policy. First, there must be a recognition of the causes of casual intercourse in a modern community, and then an organized attempt to get rid of them. Among the causes of promiscuous sexual intercourse they include the public opinion which accepts a different standard of morals for men and women. They urge social reforms which would tend to lessen the difficulties in the way of continence under existing social conditions. Such are:

Facilities for early marriage.

Facilities for divorce, where otherwise people would be doomed to a celibate life for causes such as, for example, incurable insanity and chronic alcoholism; such facilities for divorce to be equal for men and women.

Adequate reform in housing conditions.

Provision by the public authorities of opportunities for both sexes to enjoy rational recreation together and share their social life and public work.

Provision for study and higher education for both sexes and a real share in the organization of the society in which they live.

Disencouragement of the system of segregating either sex for long periods of time, thus removing them from the influences of home and normal social relationships.

Recognition of the important part played by alcohol as an ally of promiscuous intercourse and so of venereal infection.

The training of children in sex and allied subjects and the inculcation of self-control from infancy are considered to be an essential part of the campaign. Such teaching should, at any rate in the earlier stage, be given by the parents, but "it is the ultimate duty of the education and health authorities to see that adequate teaching is provided."

Among other measures the committee advocate raising the age of consent to 18 for both sexes; the systematic registration and inspection of lodgings for young persons (but this, they insist, must not be done by the police); stern punishment of brothel keepers; reform of police court procedure by requiring the presence of a respectable woman unconnected with the case during its hearing; and an adequate force of women police armed with full powers. They admit the urgency of the danger and the need for prompt and effective action, but think that the results of the radical measures of reform they suggest would be quickly apparent and cumulative. "Public opinion can be changed in a generation, nay, in a few years, and the instruction of children may bear fruit practically at once." Beyond this they urge free secret efficient treatment in every area for all patients suffering from venereal disease, and they deprecate any legislation that might in its effect deter patients from seeking advice at the earliest possible moment. The address of the Medical Women's Federation is 9, Clifford Street, New Bond Street, London, W.1.

¹ BRITISH MEDICAL JOURNAL, September 13th, 1919, p. 349.

THE FUTURE OF VOLUNTARY HOSPITALS.

SCHEME FOR RED CROSS ASSISTANCE.

A LARGELY attended conference of the British Hospitals' Association was held at St. Thomas's Hospital, London, on January 23rd, under the presidency of Mr. WADE DEACON, chairman of the Liverpool Royal Infirmary. The purpose of the conference was to consider a draft scheme for Red Cross assistance for the voluntary hospitals of the country. The proposal is to use on behalf of the voluntary hospitals the collecting organization which was evolved during the war by the Joint Committee of the British Red Cross Society and the Order of St. John at the time when it was responsible for 1,600 auxiliary war hospitals. The Joint Committee has practically finished its work, but it proposes to live on as a Joint Council and to act as a channel through which the generosity of the public may flow out to the relief of civilian suffering. It is suggested that in addition to collecting funds, the Red Cross (which term is understood to include the two bodies forming the Joint Council) shall help the hospitals by acting as a central dépôt and office for information in various ways, such as—

1. The preparation of statistical tables similar to those issued by King Edward's Hospital Fund so as to afford hospitals all over the country the means of comparing their own expenditure with those of other hospitals and thus detecting possible loss and waste.

2. The codification and tabulation of information and statistics at a central office in London, where there would be a reference library in which the latest details could be obtained regarding all matters connected with hospitals, such as planning, construction, heating, and lighting.

3. The Joint Council could utilize the storage accommodation it has in London by inviting gifts of hospital stores from which grants could be made to hospitals in need; non-perishable drugs, dressings, etc., could be stored in bulk. In the purchase of stores (especial requirements of surgery and of the dispensing department) the Council would be in a position to buy on most advantageous terms under expert advice, and facilities would be provided for the analysis of articles of hospital consumption and for the supply of details with regard to prices of hospital commodities.

4. The work parties that did valuable services during the war in providing hospital garments, etc., might, it was hoped, be induced to continue their work for hospitals and child welfare centres.

5. The War and Peace Hospitals Library would be continued for the supply of books and magazines.

The scheme was to be regarded only as an outline of the way in which a central voluntary organization might help voluntary hospitals. If it were accepted, details would be settled in consultation with the representatives of the hospitals. The money grants which could be made to hospitals must depend upon the measure of financial support received from the public by the Joint Council; but even if this were not large it was believed that much money might be saved in the manner indicated above. The scheme aimed at helping, in the first place at all events, the provincial hospitals, in view of the fact that the London hospitals have the benefit of the King Edward's Hospital Fund, the League of Mercy, and the Sunday and Saturday Hospital Funds.

Sir ARTHUR STANLEY (Chairman of the Local Committee and Treasurer of St. Thomas's Hospital) said that he wished to make it clear that the Red Cross was not in any way trying to infringe on the duties or rights which ought to be exercised by the State or the local authorities. Whatever the State did, however, there was always scope for the voluntary agency, and his own conception of the Red Cross was that it should stand to the Ministry of Health in time of peace in the same relationship as it stood to the War Office in time of war. It was not for the Red Cross to say what policy should be pursued by the State, but to bring to the help of the State everything that voluntary effort could supply. He believed it to be the determination of those to whom he spoke that the voluntary system should be continued. If only the machinery of collection was provided, and the public was satisfied that the money was being well spent, funds would certainly be forthcoming. Formerly the hospitals only made application to the well-to-do, but the ordinary patrons had been severely hit by the war, while on the other hand the working classes, who he believed to be as ready to give as anybody else if only the matter was presented in the right way, had to a large extent benefited financially. He proceeded to give some figures which he admitted were purely illustrative. If there were 300 voluntary hospitals in the country, each with an average of 150 beds, the maintenance

of each bed requiring £150 a year, the annual cost of the voluntary hospitals would be £6,750,000, and deducting one-third from this sum as covered by endowment, it would be necessary to raise every year between four and five millions. Out of the forty million people in this country, surely one million could be found who would put aside a shilling a week for the hospitals and another two millions who would put aside sixpence. This would yield five millions, and yet only 7 per cent. of the population would have been touched. He could not believe that the raising of this money was an impossible task, but a necessary condition of effective giving was that hospitals should be properly administered, and for this purpose a central bureau for the issue of statistics and other comparative data would be valuable, as it had proved to be in dealing with the auxiliary war hospitals, which at first showed the most extraordinary divergences in expenditure. It had been made possible for Sir Napier Burnett, K.B.E., M.D., who had gathered wide experience in connexion with hospital administration under the Red Cross, to devote his whole time to the furtherance of this scheme, and the promoters hoped much from his direction.

Viscount KNUTSFORD proposed, without making a speech,

That the thanks of the British Hospitals' Association be conveyed to the Joint Council of the British Red Cross Society and the Order of St. John for its offer of assistance, which is cordially and gratefully accepted by the hospitals represented at this meeting.

After the Rev. G. B. CRONSHAW had seconded, a general discussion took place, and the scheme was very cordially received, especially on account of the fact that the body which had come to the help of the hospitals was not an austere officialized organization, but sympathetic and allied. Questions were asked as to how the general collection for the Red Cross would affect special local efforts on behalf of a particular hospital; and one or two representatives of the London hospitals criticized the omission of London from the present scheme, more especially as the new agency was likely to tap the constituency of the Hospital Saturday Fund, which was one of the great collecting organizations on behalf of the London hospitals. A Bradford representative wished for an assurance that the State or municipality would not take the hospitals over, and said that until this point was cleared up donors would withhold their money. The same point was put forward by Mr. C. E. L. LYLE, M.P., who said that as a result of his interrogation of Dr. Addison he believed that the Government had no intention of nationalizing the hospitals, but it was doubtful whether the Government could prevent a municipality from setting up a hospital. Sir HENRY BURDETT said that it was evident that the Government would not nationalize the hospitals, and, in his opinion, it would not allow them to be municipalized either.

Sir ROBERT MORANT said that the Minister himself had been very anxious to come to that meeting in order to repeat the statement he had already made, that there was no foundation whatever for the rumours that the establishment of the Ministry of Health meant the imposition of bureaucratic control over the voluntary hospitals. No such intention was on the horizon at all. On the contrary, the Ministry was eager to encourage all voluntary effort.

Sir NAPIER BURNETT said that the purpose of the scheme was to supplement, not supplant, the efforts of individual hospitals. The utmost care would be taken not to collide with any local efforts. Before the central organization set to work in any district it would communicate with the authorities of the local hospital to discover whether they wished its assistance. He dwelt upon the value of the scheme as a means of co-ordinating hospital administration, not only in regard to treatment of the sick, but to the provision of research facilities and work on the preventive side of medicine.

Sir JOHN LYNN-THOMAS expressed the opinion that the cost of providing an adequate hospital service for the country would be larger than Sir Arthur Stanley had estimated. The Prince of Wales's Hospital for the Limbless at Cardiff had been established for the treatment of soldiers and sailors, but inquiry in Wales showed that the number of civilians who had lost limbs was large even when compared with the injuries of war. To meet their needs no hospital provision had previously been suggested; provision must be made to restore and reconstruct the limbless for work which war experience proved need not

fall short of the normal wage-earning power. This fact afforded an indication of the extent of the whole problem. During the war properly equipped general and special hospitals were found for soldiers and sailors, irrespective of their rank and pay, the only passport for admission being the need for treatment. Under the stimulus of war conditions the Government willingly agreed that the Army Medical Department should find sufficient hospital beds, but so far no Government department had felt it to be its duty to encourage the provision of adequate hospital accommodation for the sick and injured of peace. In future everyone who needed it should be entitled to hospital treatment.

Sir ARTHUR STANLEY, in reply to a Newcastle representative, who urged that it was too much to expect a subscription of a shilling a week from the working classes, said that his figures were purely hypothetical. It might be better, instead of getting a million people to give a shilling a week, to get twelve million to give a penny, and even then only 30 per cent. of the population would have been touched. The danger of a municipal hospital was remote. Some Government department must have the power to prevent a municipality from borrowing the money for the erection of a municipal hospital when it could be shown that the existing hospital might be supported by voluntary means. The new collecting organization wished to work in harmony with King Edward's Fund; indeed, that Fund was at the moment distributing on behalf of the Red Cross a quarter of a million among the London hospitals. But the principal work of the Red Cross was to render first aid, and he thought that the provinces were more in need of first aid than London; the second branch of its work was home nursing, and perhaps London might come in later in that category.

The resolution was carried unanimously.

DISCUSSION AT BIRMINGHAM.

An interesting discussion on hospital policy took place at a meeting of the medical profession of Birmingham and the West Midlands, called together by Dr. Thomas Wilson, president of the Birmingham Branch of the British Medical Association.

Sir BELTRAND DAWSON spoke of the need for more hospitals, a better classification of them, and a better distribution. In the large changes that would be necessary the aim should be to foster the traditions that existed in the voluntary hospitals. Not only, he said, were the present hospitals inadequate in number, but they were not performing the right functions; they were consequently called upon to do too much work and to do the wrong kind of work. Hospitals in future must be more widely distributed so as to be available for all, and there must be grades of hospitals. A distinction should be made between the "primary" hospital, where the patient would be looked after by the doctor of his choice, and the larger hospital to which he should be sent when the care of a staff of specialists was needed. The primary hospital would create an intellectual atmosphere in the medical life of its district, and around it should be assembled the machinery of health, thus linking up the preventive and curative sides. The great mass of routine cases would be received at the primary hospitals; cases needing special skill and equipment in the central hospitals; while at accessory hospitals—for instance, adapted Poor Law infirmaries—cases could be treated which, though not necessarily of great clinical interest, were of enormous importance from the economic point of view. From the educational point of view the work of these different hospitals should be co-ordinated so as to widen the field for the students. He warmly supported the plan of associating the present Poor Law infirmaries with the hospitals, but it would, he thought, be a pity to attempt a permanent arrangement. How, he asked, was the additional accommodation to be provided? All the evidence suggested that any new hospitals must be maintained by public authority. If the whole cost of curative treatment were provided free this would impose a heavy burden on the State. In the primary hospitals there might be standard rates for public and for private wards. He suggested an elastic rate, taking account not only of what a man received, but also of his responsibilities. In the public ward a standard rate would include medical treatment, because the patient would have passed from the care of his doctor to that of the consultant.

In private wards the patients should pay both for their accommodation and for their medical attendance.

Sir GILBERT BARLING, Vice-Chancellor of the University of Birmingham, spoke of the inadequate hospital accommodation in Birmingham, and the parlous financial plight of the hospitals. Frankly, he thought it hopeless to try to provide what was needed for the future by the voluntary system, though he trusted the voluntary principle would be retained side by side with and supplemented by municipal or State aid. He emphasized the need for an exhaustive survey of the hospital accommodation of the country; decentralization should be the keynote of the scheme for the future.

Dr. JOHN ROBERTSON, M.O.H. for the City of Birmingham, remarked that while there was a serious shortage of accommodation in voluntary hospitals, his own authority was swamped with beds for fevers, tuberculosis, and mental diseases. They had three times as many beds as the voluntary hospitals had for the treatment of all other ailments.

Dr. THOMAS WILSON urged the desirability of setting up an authority to correlate the various hospitals of the country with the necessities of the community. All grades of the medical profession should be largely represented on that authority.

Professor J. T. J. MORRISON postulated three factors that would in the main determine the final form of the hospital system in this country: (1) The demand of the people for greater facilities and a far larger volume of hospital service; (2) the refusal of these people to accept charity; (3) the immense political power possessed by that section of the community. He felt hopeful that the vast changes that would be brought about by these factors would turn out to be for the benefit both of the hospitals and of the community.

PROPOSED PUBLIC INQUIRY INTO THE MEDICAL SERVICE OF THE COMMUNITY.

A deputation from the British Federation of Medical and Allied Societies was introduced to the Minister of Health by Sir W. WATSON CHEYNE, M.P., on January 23rd. The object of the deputation was to urge that a public inquiry should be held as to the conditions of service under National Insurance medical benefit, and as to whether these conditions promoted the efficiency of the medical profession, and gave commensurate results to the community.

Dr. ARTHUR LATHAM said that the five years' experience during the war had stirred the public and medical conscience, and had shown what medicine could give to the community. The Regulations made with regard to medical service under the Insurance Act seemed to be designed to catch the erring doctor, but to impair the efficiency of health services. There must be regulations but they should be elastic. None of the lessons of the war had so far been incorporated in the regulations, and, owing to the limitations imposed under the Act, they could not be incorporated. The most effective means to reach a mutual understanding was publicity, and public inquiry was essential if suspicion was to be replaced by willing co-operation. Dr. STANCOMB, in supporting the plea for a public inquiry, spoke of the grave dissatisfaction both among the medical profession and the community.

Dr. ADDISON, in his reply, said that he was grateful for efforts to focus trained medical opinion upon the question how the medical service of the country could be placed in a position most usefully to serve the public. He was anxious to know in what respect the medical profession was tied up or prevented from doing its best, and undertook to find a remedy should this prove to be the case. He asked for help in devising a scheme whereby a strongly individualistic profession could be brought to give their devoted services to the public with goodwill and by common consent. The Government had agreed to inquire into the question of remuneration, and he did not want to oppose a further inquiry. The Medical Consultative Council had been asked to report upon the type of medical service required, and this report, which he hoped to receive within three weeks, would be made public. Further, he had the authority of the Cabinet for saying that it held itself free to institute a wider inquiry if it appeared to be desirable or necessary, either as a result of the findings of the arbitrators with regard to remuneration or of the report of the Consultative Council. If he became convinced that any advantage could be gained by a public inquiry he would not hesitate to recommend it.

A WHOLE-TIME STATE MEDICAL SERVICE.

At a meeting of the Marylebone Division of the Metropolitan Counties Branch of the British Medical Association on January 16th a discussion took place on the desirability of a whole-time State medical service. The discussion was opened by Professor BENJAMIN MOORE, D.Sc., F.R.S., and Sir WILMOT HERRINGHAM, K.C.M.G.

Dr. C. O. HAWTHORNE, who presided, said that circumstances with which all were familiar had compelled reconsideration of the form in which the medical profession could best discharge its responsibility as the protector and promoter of public health. Some changes in this direction had already taken place, and it needed no very penetrating eye to discern other changes on the horizon. One change proposed by certain members of the profession was that a whole-time State medical service should be established. There was a strong feeling both for and against this proposal; but however much the protagonists on the opposing sides might differ with regard to choice of methods, they were at one in their desire to preserve the best of all professional traditions—that of effective service in the public interest.

Professor BENJAMIN MOORE said that the proposal for a whole-time State salaried service was still resented by a large majority of the profession as being too revolutionary, although he believed that certain prejudices were wearing away and some misapprehensions being dispelled. Frankly, if he thought that a national medical service would be bureaucratically administered from Whitehall, and that medical men would be simply paid servants of a bureaucracy, he would have nothing to do with it. But it was quite evident that certain methods of co-ordination must be introduced into medical practice, and if only the profession was alert and careful he did not think that a lay bureaucracy need be the result. He looked forward to an organization something like the old-fashioned guilds which used to exist in London and in the country; under such a system the management of all professional matters would be in the hands of the profession, its rank and file as well as its leaders. Central co-ordination would be necessary, but it must not override local control; and even local control—that is to say, control by mayor and burgesses—must not be suffered to override the feeling of the profession. It might be asked why any such change was needed. The answer was that medical science, so far as concerned the treatment of certain diseases, had made the domiciliary methods of the past altogether inadequate. The staffs of hospitals were far too slender to meet the existing need. In an out-patient department on any day a few doctors would be found endeavouring to cope with a great number of patients, while perhaps at that very hour there were dozens of practitioners in the neighbourhood seeing no patients at all. He dwelt upon the need in slum tenements and in factories for some more effective system of early diagnosis; if the profession was to deal in a scientific way with disease it must go out and seek disease in its early manifestations. The question of a salaried service as against some other basis of remuneration was quite secondary; the important thing was that the service should be well paid. He did not accept the view of some people with regard to the low range of salaries likely to be paid under a State service.

Sir WILMOT HERRINGHAM said that what had been laid before the meeting was surely the slightest sketch of any proposal ever brought to the notice of a body of men. Professor Moore's contention seemed to be that they were not to see patients when they were ill, but were to go to every house in the country to find out who was likely to be ill, and the only way in which this could be done was by having a salaried service, with salaries of at least £1,000 a year! The case for a whole-time State salaried service needed a little more elaboration and refinement. His own feeling was that the difficulties and disagreeableness contingent upon such a service considerably outweighed its advantages. He had often talked over the matter in France, and had occasionally found a mess inclined to favour the idea, but when he asked how they would like to go on living always under their A.D.M.S., they invariably said that they would like no such thing, and said so with a forcefulness which recalled Uncle Toby's saying that our armies swore terribly in Flanders. He did not think he ever heard a man say that he would deliberately choose to go on living in that state of life to which Government conscription had called him. The sense of discipline under which it was necessary to live was not good for a profession which must be continually feeling its way towards changes and improvements. Public service, however much the people at the top might desire to prevent such a result, did militate against

originality and enterprise. He did not believe for a moment that medical men under such a system would be able to obtain the complete control on which Professor Moore insisted. No other body of men in similar circumstances had been allowed to do it when their interests were apart from, and in a sense opposed to, the interests of the public. Bureaucratic control there must always be, let it be tempered as much as they liked. They could no more claim to regulate public affairs than anyone else, except as advisers. Professor Moore seemed to think that payment would be extraordinarily large. How could it be larger than the payment of medical officers in the army and navy? The speaker thought it very important to consider what ought to be done to improve public health. More hospital and maternity accommodation was desirable, also better facilities for consultations, and, if possible, better communication between the doctor who was looking after the case privately and the doctor who treated the case when it came into the hospital. These, however, were not the necessary consequences of a whole-time service.

Dr. R. FIELDING-OULD remarked that from the ranks of general practitioners he did not find any great champions entering the lists for State service; there was a silence on the matter so far as clinical medicine was concerned. Under State service the spiritual and psychical interest between medical man and patient would diminish. One terrible example of State interference with medical practice was the work under the Insurance Acts. He referred to the likelihood of official duties stopping up the springs of freshness and enthusiasm, and declared himself ready to fight the proposal for a State-salaried system tooth and nail.

Sir WATSON-CHEYNE, M.P., said that it was quite impossible to carry out treatment under orders from the Government. He understood, however, that Professor Moore was not proposing that the Government should rule the doctors, but that doctors in the various districts should mass together and rule themselves. The speaker did not believe that the Government or the local authorities would allow that.

Dr. C. A. PARKER said that private practice had not produced all the results that could be desired. He instanced Sir George Newman's statistics with regard to the health of school children and the records of army recruiting; also the huge incidence of tuberculosis and the prevalence of epidemic disease. Some form of public medical service seemed to be the only solution. Half-time work might lead to undesirable differentiation between State and private practice.

Dr. ALEXANDER BLACKHALL-MORISON pointed out that the collaboration of medical men, before legislation was thought of, had effected a great deal for the health of the community. Dr. T. P. BEDDOES held that no whole-time service would be satisfactory, and did not believe that the health of the nation would be increased under such a service. Dr. A. G. AULD thought that special service under the State was necessary in order to find out the beginnings of disease and to rectify the conditions under which disease was produced. Dr. B. F. HARTHORNE said that it would be hard on senior practitioners under a State service system if, having arrived at a time of life when they might justifiably look for more leisure, they were to be assigned certain tasks and called upon for a definite number of hours' service each day.

Professor MOORE, in reply, said that in his original remarks he had been intentionally sketchy, believing that the general contentions of those who favoured State service were by this time understood. Those who had been working on this problem for seven or eight years had seen many of their dreams already realized. State service was coming by a process of evolution, and if it was desired that bureaucratic control should be avoided, it was time that medical men were alive to the matter. He pointed to the amount of research which had been done in the Indian Medical Service as telling against the view that keenness and enthusiasm in health matters disappeared when medical men were brought into Government employment.

Sir WILMOT HERRINGHAM, in his reply, said that he was filled with admiration for the evident enthusiasm which prompted Professor Moore's advocacy, and with amazement at the absolute want of reason with which the case was argued. Dr. Parker had said that because the profession had not been able to stamp out this, that, or the other disease, therefore a whole-time medical service must be set up. Why should disease be more likely to be stamped out under such a service? To say that because a nation still had a large amount of disease the present system of medical practice was a failure and must be superseded was to his mind a typical instance of the absolute want of reason with which the question was discussed.

British Medical Journal.

PREVENTIVE MEDICINE: TEACHING AND RESEARCH.

THE public has heard many sermons on the importance of preventive medicine during the last year or two. But it may be surmised that the results have not corresponded to the intentions of the preachers, since the level of current discussion does not seem appreciably higher than before, and some fallacies which we had hoped were dead prove merely to have slept during the war-time shortage of paper. Perhaps the public is not the only culprit. One may aim too high, and also too low. A discourse on methodology, an appeal to general principles, may be a trifle dull. The immortal name of Sydenham does not make all hearts burn; some men do not rise to their feet and cheer wildly when the importance of harmonic analysis to the sanitarian is expounded. But sometimes even practical discourses on the way to save babies or to stamp out venereal diseases, bring up into consciousness the irrelevant names of Mother Seigel or Dr. Collis Browne, and the lecturer's message is lost.

We forbear from the appropriate Horatian tag, and merely remark that Professor F. W. Andrewes deserves universal thanks for the model address he recently delivered to the Abernethian Society of St. Bartholomew's Hospital.¹ Professor Andrewes took as his text the last London Life Table, the precise meaning of which he explained with a lucidity professional statisticians must admire; he pointed out how life capital is squandered, and gave one of the chief reasons why this happens. "Unfortunately preventive medicine makes no such immediate appeal to us as the treatment of existing disease. What a glow of pleasure we feel when by our skill we have saved a life! How justly gratified is the house-physician who wrestles all night with a case of hyperpyrexia, wrapping him in wet sheets and rubbing him with blocks of ice till his temperature comes down! How well does the house-surgeon merit congratulation when he has dealt promptly and successfully with a dangerous haemorrhage! You can't get that sort of satisfaction by preventing a hundred babies from getting measles and whooping-cough; yet the man who could do this would serve the State far better. And so, for lack of this immediate dramatic appeal, preventive medicine gets pushed rather on one side in medical education. We are given a short course of lectures on public health, and get signed up for them by attending as few as we can, and come away with a few ideas about ventilation and water-closets which seem to bear little relation to medical or surgical practice."

It would be hard to characterize the essential weakness of the position more aptly. It is the plain truth that the average medical student does not regard preventive medicine as his business, and receives extremely little encouragement so to regard it from those set in authority over him. Up to a few years ago (and we are not quite sure that things are very different now) it was possible to obtain the most prized of professional degrees and diplomas without having acquired information even about water-closets, while the medical student who knew as much about

life tables as he can learn in ten minutes from Professor Andrewes's lecture and yet did not propose to take the D.P.H. would have been thought to have missed his vocation.

This is a state of affairs which no oratory can alter. So long as the ordinary medical student is ignorant of the general principles of preventive medicine, cannot use the simplest intellectual tools of the epidemiologist and vital statistician, and knows nothing of medical history, that which should be the intellectual heritage of the whole profession will remain the possession of the few, will be tainted with the intellectual vices of particularism, and will appear to some a forbidding wilderness of technicalities, to others a more or less beneficent witchcraft, and to yet others a source of tedious oratory.

It is easy to say that we ought to have more lectures and whole-time teachers, but that is not a remedy; the student hears too many lectures, and if talking, or rather being talked at, could make young men wise we should reckon our Simons and Farris by the hundred. Apart from the dramatic element noted by Professor Andrewes—if it be not an ingredient of the drama—is the greater reality of clinical instruction. The teaching surgeon is not only handling real patients, but he is doing so before the eyes of his students. He not merely tells them that in such and such circumstances such and such things are done; he does those things, not upon wax models or dissecting-room subjects, but upon living flesh and blood. The medical student has no such contact with the realities of preventive medicine and epidemiology. There is, of course, a reason for this. The unit of the clinician is the individual patient, that of the epidemiologist a group of individuals, a collectivity, and he is therefore forced to adopt what, for want of a better word, we may call the statistical point of view. Hence his *milieu* approximates more closely to the chambers of a barrister or the office of an army staff than to the consulting-room of a physician or the operating theatre of a surgeon. But there is no lack of reality in the chambers of a lawyer or at the head quarters of an army staff. Many have commented on the great value of the legal training a pupil in chambers receives. There he sees real business and how it is handled. Between this education and that to be acquired from books and lectures is as wide a distinction as between the knowledge of the professional detective and that of the disciple of Mr. Sherlock Holmes, or between campaigning and sham fights. An ordinarily intelligent youth who had access to the chambers of an epidemiologist, followed the history of the most trivial outbreak of disease, noted the waxing and waning statistics of morbidity and mortality, the action taken, the opinion of the expert—not when the battle had been lost or won, but while its issue was doubtful—would get nearer to the essence of scientific prevention than any number of eloquent and systematic lectures or of personally conducted tours over municipal sewage works would ever carry him.

But these chambers of the epidemiologist, where are they? In the health departments of great municipalities and in Whitehall; regions into which the ordinary medical student never strays. It is in the nature of things, both as they are and as they must be, that such a separation should exist: if the only remedy were to turn the student loose in Whitehall or give him open access to the offices in the City Hall, we should have to despair of his education in preventive medicine. We certainly think that facilities should exist for young graduates to act as voluntary assistants in the great state and municipal health departments, and that such service should confer the same

¹ *St. Bartholomew's Hospital Journal*, January, 1920

advantages (not merely upon those definitely entering the career of a public health official) as the tenure of hospital house appointments; but this does not meet the needs of the merely average man.

The solution of the difficulty is to be found in further development of the wise and enlightened policy of the Medical Research Committee. It is obvious that the administrative epidemiologist or sanitarian cannot conveniently be located in a medical school or university. There is no reason why the investigator should not be so housed. If in a medical school we have investigation continuously pursued, the investigator being systematically supplied with all the information which is received in the routine course by the administrative departments, we shall reproduce as nearly as is practicable the atmosphere of the barrister's chambers. It is true that one element of reality will be lacking: the investigator will have no responsibility for administration; this, we fear, is inevitable; but if the record of administrative action is faithfully transmitted, if the student can really see from day to day what happens, we do not think the loss overwhelming. It is upon these lines that the teaching of preventive medicine should, we believe, be organized. At present it is sterile and despised because it is unreal, a mere sham fight. We have aimed at a systematic course, and achieved a lifeless formalism. It is not more lectures, not even more "practical" work—in the ordinary sense of the terms—but more humanity, more of the excitement of a battle, that the student needs.

REMOULding THE HOSPITAL SYSTEM.

DURING the last few months our columns have contained many evidences of a great stirring of opinion, medical and lay, with regard to civil hospitals, and we publish this week (p. 156) reports of the proceedings on three occasions on which the subject was more or less directly discussed.

At the meeting summoned by Dr. Thomas Wilson, President of the Birmingham Branch of the British Medical Association, on January 15th, Sir Gilbert Barling added his testimony to the current view that not only is the financial position of voluntary hospitals very difficult, but that the accommodation they supply is insufficient. In an address to the same meeting Sir Bertrand Dawson, while admitting that great changes would undoubtedly be necessary, affirmed that there were few institutions in which this country could more justly take pride than in the voluntary hospitals; they were animated by an enthusiasm for the best work and a sense of brotherhood which could not be found in any State institution in this country or abroad. He asserted that the proportion of the community needing hospital treatment was steadily increasing, and likely further to increase, and supported this opinion by pointing to the growing complexity of methods of diagnosis and treatment involving an increase in the cost of treatment which an increasing proportion of the population could not meet. He also pointed to the distinct but related fact that many illnesses, including many not very severe, were more efficiently and far more conveniently treated in an institution with proper equipment and nursing than in ordinary domestic surroundings. He then outlined a scheme, with which the readers of his Cavendish Lecture and other addresses will be more or less familiar, for an organization of medical service from the periphery to the centre. In rural and small urban areas he would like to see what he called "primary hospitals," where the patient's own doctor could con-

tinue treatment under conditions far more satisfactory than obtain in most private houses, whether those of industrial or middle class families. In this way the preventive and curative sides of medicine would, he hoped, be brought together. From these primary hospitals patients would, when necessary, be referred to the central hospitals with medical schools, and he indicated that these hospitals would require accessory institutions, to which certain classes of cases might be transferred. Such cases would include many of a minor character in a medical or surgical sense, but of great economic importance, and others in which, though the patient's general health may be excellent, prolonged special treatment is required; and here it is of consequence to remember that continuity of treatment is often essential to cure.

In addressing, last October, the inaugural meeting of the Medical Consultative Council, the Minister of Health said that its first reference would be to report on an ideal system of medical and allied services towards the realization of which the Ministry could work. The Chairman of the Council, Sir Bertrand Dawson, in replying to Dr. Addison, said that the activities of the Ministry of Health were bound to extend and to affect all branches of medicine more and more closely, and that if the results were to be satisfactory a good understanding and close co-operation with the medical profession must be maintained throughout. This understanding and co-operation it is the function of the Consultative Council to promote, and success cannot be attained without constant reference to the working of the National Insurance scheme.

The second instance to which we refer is the interview the British Federation of Medical and Allied Societies had with Dr. Addison on January 23rd, to ask him to institute a public inquiry into the conditions of medical benefit and how far those now in force promote efficiency on the part of the medical profession and give commensurate results to the community. Dr. Addison, in his reply, said that he was not in principle opposed to such an inquiry, but he would await the report of the Consultative Council, which he hoped to receive within three weeks, and would then publish, and also the result of the arbitration on the question of remuneration. He added, however, that the Cabinet held itself free to institute a wider inquiry should the result of the findings of the arbitrators (whose names are given in the SUPPLEMENT this week) or the report of the Consultative Council render its institution desirable.

The third incident was the meeting of the British Hospitals Association at St. Thomas's Hospital on January 23rd, when a scheme of the Joint Peace Committee of the British Red Cross Society and the Order of St. John for coming to the assistance of the voluntary hospitals was unfolded. The Council proposes to tabulate hospital statistics so as to afford to each institution the means of comparing its own expenditure with that of other hospitals; it proposes also to help them more directly by accumulating stores, and by purchasing at the lowest price and on expert advice after analysis and examination of the articles sold. Not very much was said about the war experiences of the Joint Committee, but Sir Arthur Stanley in introducing the subject said that Sir Napier Burnett, K.B.E., M.D., who had gained wide experience of the administration of hospitals under the Red Cross, would devote his whole time to the furtherance of the scheme.

The general effect of the scheme and of the meeting at which it was discussed was therefore to institute an organized plan for assisting the finances of the voluntary hospitals both by collecting money and by

helping to make economies. But there is no doubt a not inconsiderable number of persons who are a little disposed to assume that the experiences of the Army Medical Department during the war can be transferred directly to peace. There is undoubtedly a certain analogy, but it must not be pushed too far. Sir John Lynn-Thomas stated the general principle to be deduced from our war experiences when he pointed out that the difference between the conditions then and now was that the country insisted that money should be provided to enable the Army Medical Department to find a sufficient number of hospital beds, to which the only passport was illness or injury. This principle, he contended, ought to be applied to civil conditions, but it is common experience that it is not, for almost every hospital has a long waiting list. We agree, and we feel sure the whole profession agrees, that the cure of existing diseases is as pressing a need as prevention of disease, and that adequate modern hospital accommodation is as necessary as housing, though it does not involve a financial problem so gigantic.

Sir Robert Morant assured the Hospitals Association that there was no foundation for the rumours that the Ministry of Health desired to impose bureaucratic control on the voluntary hospitals, and we would add that over-centralization is also to be avoided. We find some evidence of failure to appreciate the second point in an article published in *The Times* by Mr. Basil E. Mayhew, a chartered accountant, described by our contemporary as an authority on hospital finance. The military medical problem was relatively simple. Mr. Mayhew speaks of the county director as being in daily touch with the "local War Office Command," which acted as a clearing house for all beds in the command, so that the Army Medical Service was able to allocate convoys of wounded to the various hospitals promptly and accurately. The analogy breaks down at once. In civil life there is never a convoy of wounded, except after some extraordinary catastrophe. Again, he speaks with a complacency we do not share of the auxiliary hospitals. The enthusiasm with which they were established and the unremitting labour with which they were conducted were worthy of all praise, but as instruments of an efficient medical service they often, if not usually, left much to be desired. When Mr. Mayhew gets on to his own ground and talks of the need for a uniform system of hospital accounts we believe that he is altogether right, and anything the Joint Peace Committee can do to promote this system and to favour economical purchase and expenditure will be all to the good.

CLINICAL TEACHING "ELEMENTS" AT WORK.

WE are glad to be able to announce that the hospital teaching organization at University College Hospital, the establishment of which was mentioned a few weeks ago, has been in working order since the first day of this year. The Director of the Medical Element is Dr. T. R. Elliott, C.B.E., D.S.O., F.R.S., physician to the hospital. Dr. J. W. McNee, D.S.O., recently assistant to the Regius Professor of Medicine and to the Professor of Pathology at Glasgow, has been appointed first assistant and deputy to the Director. Dr. F. M. R. Walsh has been appointed second assistant to the Director to control neurological teaching and research, and also to take charge of the department of electro-therapeutics and massage at University College Hospital. The Director of the Surgical Element is Mr. C. C. Choyce, C.M.G., C.B.E., F.R.C.S., and he has as his first assistant Mr. E. K. Martin, M.S., F.R.C.S., and as his second assistant Mr. F. J. F.

Barrington, M.S., F.R.C.S. The Directors of the Elements are responsible for the general arrangement of systematic teaching on the principles of medicine and surgery in both hospital and school. The instruction of junior students in physical signs and elementary laboratory methods and the systematic demonstrations and lectures for senior students are to be organized by them, although the teaching in these courses is in certain cases given by other members of the staff. Every student is to take duty during his first year for two months' clerking and two months' dressing with the Medical and Surgical Elements respectively. These terms of clerking and dressing are intended to follow as far as possible the four months' term of duty with other members of the staff. Thus every student will in due course pass through both elements. During his course of two months' duty under the Director of the Medical Element the student will be attached for clinical clerking to some of the special departments, such as the Cardiographic Department under Dr. Thomas Lewis, F.R.S. Arrangements have been made at the Medical School by which the Directors of the Elements and their assistants have been furnished with ample accommodation and facilities for research work in the Graham Laboratories of Pathology, endowed by the late Professor Charles Graham, who was so long a member of the staff of the Chemical Department of University College. Both the directors and their assistants are on the whole-time basis—that is to say, they are debarred from private practice. This, it is considered, is an important part of the new organization, but it is at the same time realized that the students should receive clinical instruction from teachers who are in close touch with private practice, as has been the case in the past. Such instruction will in future be given by the remaining members of the staff not belonging to either element, who will devote their time more especially to clinical teaching, and will have the more leisure and energy for this, inasmuch as they will be relieved from systematic teaching. Three-fourths of the total approved cost of the elements will be paid from the parliamentary grant, the remainder must be found by the medical school. The entries at the medical schools this year are generally large, and University College Hospital Medical School has shared in this. The hospital is somewhat small for a large scheme of this kind; it now provides 320 beds, but the committee of management has recently acquired a site in the immediate vicinity of the hospital on which it is hoped to erect a nurses' home in the near future, so as to liberate the part of the hospital at present occupied by nurses for the purpose of providing additional beds. The hospital itself stands on an island site, and there will therefore be little temptation to add to the number of beds in Gower Street. The wisdom of the policy of increasing the number of hospital beds in the centre of great towns is more than doubtful. The high cost of a site is a serious financial burden, and many patients would be much better off if transferred, as soon as their condition permitted, to a linked hospital less elaborate in construction and on a site less costly and more health-giving, outside the town.

THE ACADEMIE DE MÉDECINE.

THE Académie de Médecine, which meets in Paris but has associates and correspondents throughout France and all civilized countries, is about to celebrate its centenary. It was founded by royal decree on December 20th, 1820, and to-day under the third Republic is in the full vigour of maturity. During its hundred years it has numbered among its officers such great leaders of medicine in France as Laënnec, Pinel, Dupuytren, Magendie, Trousseau, Cruveilhier, Claude Bernard, Pasteur. In this, its centenary year, it has chosen as its President M. Laveran, the discoverer of the malarial parasite, and

the first name on the list of its foreign Associates is Sir Patrick Manson, elected in 1900, and among its foreign correspondents is Sir Ronald Ross, elected in 1904. It is curious to look back to the time before these men began their work on malaria, to recall the slim octavo in which Laveran, then a French army surgeon in Algiers, described and figured the haematozoa—description and figures received with indifference worse than incredulity—the well reasoned hypothesis of Manson, and the brilliant demonstration given by Ross. The Académie de Médecine holds a position unique among the medical societies of the world. To it sooner or later, and usually quite early, comes all the best work done in clinical and experimental medicine in France. But it concerns itself also with the practical application of scientific principles to the prevention of disease, and reports directly to the Minister of the Interior, by whom it is frequently consulted. It combines the functions of the Medical Consultative Council of the Ministry of Health and the Royal Society of Medicine with some of those of the British Medical Association. Its influence with the public, the medical profession, and the Government of France is great, and always wisely exercised.

INTRACAROTID SALVARSAN INJECTIONS.

OWING to the extreme toxicity of arsenic and its compounds to nervous tissue, it has not been feasible to inject salvarsan into the subdural space in the treatment of cerebral lues and the parasymphilitic affections. Hersley's practice of applying mercuric lotions to the cortex directly through a trephine hole will be recalled, as will also the method of Swift and Ellis, who introduced salvarsanized serum into the spinal theca. Later, Levaditi, and Marie and de Martel, put similar serum beneath the dura, whilst Hammond injected it into the lateral ventricles. Knauer, believing that a more efficient method would be to introduce the salvarsan directly into the cerebral blood stream, has devised a way of doing this. Animal experimentation proved that a needle could be pushed through the wall of the great arterial trunks of the neck without a leak occurring when the needle was withdrawn. This he attributes to the thick muscular coat the vessel possesses. Emboldened by these trials, he first applied the method to man by injecting neo-salvarsan into the internal carotid exposed at operation. The obvious disadvantage of having to wait some fourteen days, for the healing of the wound in the neck, before the next injection could be made caused him, with Enderlen's assistance, to try direct subcutaneous puncture of the common carotid. The puncture was made at the level of the thyroid cartilage at the anterior border of the sterno-mastoid. He used a Record syringe, and says that the operator can tell when the point of the needle reaches the vessel by the resistance which its wall offers. On pushing the needle still further bright red blood spurts out; the syringe barrel is then fitted on and the injection slowly made. Knauer has made upwards of sixty carotid injections in this manner on eight different patients without a single mishap or untoward incident. By both methods—that is, by incision and puncture and by direct subcutaneous puncture—he has made 128 injections. One patient has had 22 injections, and no sign of aneurysm has developed. The drug used has been, in the main, neo-salvarsan, though latterly he has made a trial of a new drug which he calls "silber-salvarsannatrium," devised by Kolle of Frankfurt. With this compound he has treated five patients; the dose used was 0.1 gram. His impression is that the new compound is less toxic to nerve tissue than salvarsan. His interesting paper concludes with two tables giving the Wassermann, Nonne, and Pandy reactions before and after treatment. These show that it is easier to get the blood negative than the cerebro-spinal fluid, which often gives a strongly positive Wassermann reaction when the blood is clear.

THE EXPERIMENTAL PRODUCTION OF PULMONARY TUBERCULOSIS.

IN the experimental study of pulmonary tuberculosis it is extremely interesting to have a means whereby the lesions in the animals may be confined to the lungs. Bossan¹ states that this can be effected by a method he has used for over two years. A certain quantity of living tubercle bacilli are emulsified in a cubic centimetre of some oil, preferably olive oil, and injected into the marginal vein of the ear. The oil, which circulates very slowly in the pulmonary capillaries, parts with its bacilli there. There is, in fact, filtration. Of more than 200 rabbits so infected none has shown, at any stage of the disease, the slightest lesion in any of the other viscera. In a large number that died of caseous pneumonia affecting both lungs and presenting enormous cavities the liver and spleen were quite normal. The method is important, for it allows us to follow the evolution of a purely pulmonary tuberculosis unaccompanied, as has hitherto been the rule, by visceral tuberculosis. Knowing thus the exact date of infection, we can follow step by step the modifications of the tissues produced by the bacterial invasion, and by knowing the age of the lesions we can determine the activity of the process, the degree of virulence, and the quantity of germs injected. By varying the quantities of organisms injected, or the strains of tubercle bacilli, it will be possible to study the various modifications of lung infection, the length of incubation, and other problems hitherto impossible of precise solution.

THE ORIGIN OF GASTRIC PAIN.

THE difficulties in the way of determining the exact cause of stomach pain are great. It is not due to excess of hydrochloric acid, nor to a diseased condition of the mucous membrane in gastritis. Even the presence of an ulcer is not invariably accompanied by pain. Müller (*Muench. med. Woch.*, May, 1919) believes that pain coming on some time after the taking of food is caused by unusually strong contractions of the *pars pylorica*. The presence of an ulcer in this portion of the stomach determines painful contractions because motor nerve fibres of the mesenteric plexus are exposed in the base of the ulcer. Pain coming on before food, as in "hunger pain," is explained as due to abnormally strong contractions. In carcinoma pain is experienced when the growth has spread so as to cause partial obstruction, and thus increase the tension of the gastric contents. Besides the pain due to tension and abnormal contractions, there is also the peritoneal pain of an ulcer involving the abdominal parietes. Attention is directed to pain in the back in gastric cases, which Müller holds indicates the presence of a penetrating ulcer on the posterior surface of the stomach in which spinal nerve fibres are laid bare. X-rays are of great assistance in the diagnosis of such an ulcer, and it has been found that when deep pressure is applied during screening, the point of greater sensitiveness corresponds with the site of the ulcer. On the other hand, even when marked gastroptosis is present, the patient suffering from gastric ulcer invariably refers the site of the pain to the epigastrium. A third source of stomach pain is that described by Head and Mackenzie, a viscerosensory reflex, entailing hyperaesthesia of the correlated skin segment, which may be acutely sensitive. A discussion of the path of this reflex is illustrated by two good diagrams indicating that painful sensations from the stomach pass along the splanchnic nerve to sympathetic ganglia, and thence by way of the grey rami communicantes to the spinal nerves. Although Dogiel has discovered cells of a sympathetic character in spinal ganglia, the evidence tends to support the opinion that the arc is only completed within the cord itself. Müller insists that it is essential in the treatment of gastric pain to make a clear diagnosis of the origin of the pain; whether due to

¹ *Muench. med. Woch.*, June, 1919.

¹ *Comptes rendus de la Société de Biologie*, January 10th, 1920.

abnormal contractions, to peritoneal involvement, unusual hyperaesthesia of the skin area corresponding to the diseased organ, or to a combination of these.

CAMBRIDGE NATURAL SCIENCE CLUB.

THE Cambridge Natural Science Club, founded in 1872, celebrated its 1,000th meeting by a dinner in the combination room of St. John's College, Cambridge, on Saturday, January 24th. The President, Mr. J. M. Wordie, was in the chair. There were eighty-three members and guests, and the occasion was taken to bring out a complete list of the members of the club since its inauguration. This shows that of the 330 members 52 are dead, 10 having been killed or died on active service during the war, and that 55, or 16.7 per cent., had received the blue ribbon of science—the F.R.S. Indeed, in returning thanks for the guests, Sir J. J. Thomson, who, although President of the Royal Society and Master of Trinity, had never been a member of the club, thought that the proportion of Fellowships of the Royal Society was probably higher among members of the club than among Fellows of colleges elected on account of their attainments in natural science. He confessed that he had never taken the Natural Sciences Tripos, though he had often examined others for it, and pleaded in defence that, like Professor W. H. Bragg, also a guest, he had made some vicarious amends by submitting a son to the ordeal. It may be noted that Professor W. H. Bragg and his son divided the Nobel Prize in 1915 for work on x rays. "The Club" was proposed by Dr. J. G. Adami, the recently appointed Vice-Chancellor of the University of Liverpool, who insisted on the educational value of the club, which, as a past professor, he seemed to rate higher than that of lectures; that ideas thus struck out in a discussion were often of great value was accepted as true by Professor Marr, who, as one of the senior honorary members, replied to the toast in an amusing speech. On the cover of the menu there was an attractive reproduction of Kneller's portrait of Sir Isaac Newton, painted in 1689, two years after the publication of the *Principia*, and apparently the only authentic portrait done in his prime. The original portrait is in the collection of the Earl of Portsmouth, but the reproduction was a photograph of the Trinity College engraving executed about 1866 by Oldham Barlow.

THE UNITED STATES ARMY MEDICAL MUSEUM.

THE Army Medical Museum at Washington, D.C. was founded in 1862, and at first consisted very largely of material collected from the Civil War; subsequently it received specimens from civil practitioners as well as from army surgeons in the tropics and at home, so that at the outbreak of the European war it contained approximately 48,000 specimens and photographs. A recent report by the curator, Colonel C. F. Craig,¹ states that a museum unit for service with the American Expeditionary Force in Europe was organized in 1918 and placed in charge of Colonel L. B. Wilson, the Assistant Director, Division of Laboratories, A.E.F. The number of museum specimens has more than doubled since the outbreak of war; 18,000 specimens have been received in the pathological department alone, illustrating especially the morbid changes in streptococcus and influenzal pneumonia, gas gangrene, and the effects of poisonous gases. The material, in fact, is so greatly in excess of the actual needs of the museum that arrangements are being made for distribution to medical institutions for educational and research purposes. Some months after the declaration of war a department of moving pictures was established as part of the instruction laboratory, so as to illustrate methods of treating disease and wounds, sanitary procedures, and other activities of the medical department. There are also departments of still photography to

which 10,000 additions were made during the war, of wax modelling, and of entomology, which has been of the greatest service to the Division of Sanitation of the Surgeon-General's office in showing the prevalence of disease-bearing mosquitos in certain districts and their relation to the existing diseases.

INFLUENZA.

Judging from the statistics of influenza in the ninety-six great towns during the thirteen weeks ending January 17th there has been no distinct increase in the number of deaths. The highest in any one week was 81—in the week ending December 13th. In the week ending January 17th the number was 62. An increase in the number of notifications of pneumonia is, however, to be observed. The Ministry of Health has thought it well to issue to the press a paper of advice on prevention and treatment founded on the memorandum issued last month, and noticed in our columns of January 3rd. The Ministry expresses the opinion that in view of the almost simultaneous increase of influenza in great American cities, in Europe (Poland), and in the Far East (Japan), there is a considerable probability of another wave of influenza developing in this country at an early date. As to the factors that may produce the new wave nothing more can be said than that it may be due to direct introduction by infected persons arriving from abroad or to the development into an epidemic of the endemic influenza usually present. The Ministry is making special inquiry in selected districts into such questions as immunity, the effects of overcrowding, and age incidence.

PROFESSOR THOMAS SWALE VINCENT, who has held the chair of physiology and biochemistry in the University of Manitoba since 1904, has been appointed to the University chair of physiology tenable at the Middlesex Hospital Medical School. He was a Birmingham student, and was at one time demonstrator of physiology in that university. Afterwards he was Sharpey scholar and assistant professor of physiology at University College, London. Dr. H. E. Roaf, lecturer on physiology at St. Mary's Hospital Medical School since 1911, has been appointed to the University chair of physiology tenable at the London Hospital Medical College. He is a graduate of the University of Toronto; he held a Johnston Colonial Fellowship in the University of Liverpool, where he became assistant lecturer and senior demonstrator of physiology and histology, and lecturer on chemical physiology.

VITAL STATISTICS FOR ENGLAND AND WALES, 1919.

WE are indebted to the Registrar-General for the following statement showing the birth rates and death rates and the rates of infantile mortality in England and Wales and in certain parts of the country during 1919.

ENGLAND AND WALES.

Birth Rate, Death Rate, and Infant Mortality during the Year 1919 (Provisional Figures).

	Birth Rate per 1,000 Total Population.	Civilian Death Rate per 1,000 Civilian Population (Crude Rate).	Deaths Under One Year per 1,000 Births.
England and Wales*	18.5	?	89
36 great towns, including London (populations exceeding 50,000 at the Census of 1911)	19.1	13.9	95
148 smaller towns (populations from 20,000 to 50,000 at the Census of 1911)	18.4	12.7	90
London	18.6	13.6	85

* The civilian death rate for England and Wales cannot be stated at present, the number of non-civilian deaths in the fourth quarter of 1919 not being available.

¹ *The Military Surgeon*, Washington, D.C. 1919, xlv, 679-687.

PUBLIC HEALTH IN 1918-19.

ON the occasion of the issue of the forty-eighth and last medical report of the Local Government Board¹ we were able to publish, in our issue of January 10th, an article on the early history of the medical department of the Board. Sir George Newman's introduction to the Report, in which he discusses briefly the circumstances that led to the establishment of the Board in 1871, may therefore be read to best advantage in the light of the consecutive story told on p. 56 of our present volume. The medical report now issued is, as Sir George Newman says, the last of a famous series dating from 1856 (when Sir John Simon first reported to the old General Board of Health), and marks the close of an epoch of public health administration. More than half a century ago Simon advocated the formation of a Ministry of Health; last summer, fifteen years after his death, the Ministry of Health was created, taking over *inter alia* the medical activities of the Local Government Board. The Report has been prepared by Dr. G. S. Buchanan, Dr. R. J. Reece, and their colleagues, all of whom have become medical officers of the new Ministry, and the preliminary general survey is signed by Dr. Buchanan.

Influenza: Cerebro-spinal Fever.

As might be expected, great attention has been devoted to the influenza pandemic of 1918-19, which (it may be noted) first manifested itself not in Spain but in Asia and America, and which attained such magnitude as to cause, for example, 100,000 deaths in England in 1918. A separate and fuller report is being prepared by the Ministry of Health, but the present Report shows the complexity of the problems involved and the great difficulties lying in the way of their investigation. Epidemiological inquiries appeared to show in some localities that one attack confers a considerable degree of immunity; in other areas the incidence of the disease was the same in those who had and in those who had not suffered attacks during the previous wave. It is suggested that these conflicting observations are explained by the existence of several strains of the influenza virus, varying in virulence and antigenic potency. Investigations made in London, Wales, and Lancashire showed that industrial workers exposed to sulphur-dioxide fumes enjoyed a relative immunity. Conferences between the Board's inspectors and local authorities were held in eighty-six areas, and it became evident at an early date that attempts to control an epidemic by school closure and regulation of places of public entertainment were useless. "The most hopeful course lay in organizing public assistance and treatment, rather than in prevention." Judgement is withheld concerning the etiological parts played by Pfeiffer's bacillus, the various cocci, and a filter-passing virus.

Much more definite are the conclusions gained from the study of 2,000 cases of cerebro-spinal fever occurring among civilians in 1917-18. Careful investigations showed that the majority of cases could be traced to association with soldiers (or with "contacts" of soldiers) who were carriers. Bacteriological examination of contacts was made in 40 per cent. of the cases. The prevention of the disease, apart from the removal of insanitary conditions of housing and overcrowding, is shown to depend on the detection and treatment of those among the contacts who harbour the meningococcus in their nasopharynxes. With the disbanding of naval and military communities a great diminution of the disease is anticipated among the civil population. A brief account of encephalitis lethargica distinguishes it by pathological and epidemiological criteria from acute poliomyelitis. Interesting case-groups from various regions of the country are adduced to show that although the disease as a rule occurs sporadically, there may be multiple cases under one roof, and one outbreak (still under investigation) is briefly recorded, wherein twelve cases with five deaths occurred among the twenty-one inmates of a home for girls. This evidence strongly supports the view that encephalitis is due to an organism which may be conveyed by subjects presenting no clinical manifestations of its presence. An analogy is traced with acute poliomyelitis, which was at first thought to be a

sporadic disease, and the report emphasizes the possibility that an epidemic of encephalitis may occur.

Malaria: Dysentery: Rabies.

The question of the possible spread of malaria has received very close attention, and notification was made compulsory in March, 1919. Nearly all the cases have occurred in ex-service men, who are so carefully followed up by the army authorities and by those of the Ministries of Pensions and of National Service that no exceptional precautionary measures are thought to be called for. When, however, two or more cases are contracted within any one sanitary area, the local authorities may now be required to provide for systematic inspection, for distribution of mosquito netting, and for collection of blood films and supervision of quinine treatment by a qualified medical practitioner. Indigenous cases have been happily few in number, and, save for certain regions in Kent, wherein the endemic type of malaria formerly prevailed, have occurred in widely separated areas. Similar attention has been given to the prevention of infection of the civil population by returning soldiers in the cases of typhus and trench fever, now known to be louse-borne. The thorough cleansing and bathing of men prior to their return on leave or discharge, together with the systematic issue of clean clothing, has prevented any increase in leishmaniasis of the population, and infection of a civilian by a soldier with a louse-borne disease seems practically never to have occurred.

With regard to dysentery, the attitude is one of watchfulness. No further outbreaks of bacillary dysentery, such as occurred in the autumn of 1918 (with 9 fatal cases out of 39 at Kingston), are reported. The notifications during the first half of 1919 were 700, of which 500 were relapses in demobilized men. The remainder were mostly asylum cases, and it was such cases which afforded the only instances of acute bacillary dysentery. Hospital isolation and other preventive measures may be enforced, according to the Public Health Regulations, 1919, in infected institutions and households.

The report contains a brief account of the rabies cases which appeared first in Plymouth in September, 1918, and subsequently in Wales, Surrey, and Manchester. At first those bitten were taken over to Paris; at a later date (as recorded in these columns) treatment centres were opened locally, and in view of the probable extension which was anticipated, the preparation of the antirabic vaccine was finally begun at the Board's laboratories in Carlisle Place. Up to June 30th, 1919, 109 patients had been bitten, including 23 by untraced dogs; 69 patients received treatment—21 in Paris, the remainder in England. All patients who were treated recovered, and in only one case was treatment refused when the dog which had caused the bite had been proved to be rabid.

Tuberculosis.

The section dealing with tuberculosis can scarcely be said to afford encouraging reading. Deaths from pulmonary tuberculosis have steadily increased during the last six years, and in 1918 amounted to nine thousand more than in 1913. This increase is greater among women; this is attributed to their more extensive employment (of late) in the industrial occupations, with the associated conditions of long working hours, increased mental strain, and overcrowded lodging accommodation. All the organizations dealing with the treatment of tuberculosis—sanitary authorities, sanatoriums, dispensaries, home-visitors and after-care workers alike—were constrained, owing to the war, to work with depleted staffs; at the same time "an all-round shortage of sanatorium accommodation" was caused by the embargo upon building operations, by the conversion of certain sanatoriums into auxiliary hospitals, and by the demand for the immediate admission of ex-service men to sanatoriums, where "their pension and treatment allowances rendered it possible for them to remain longer than had been practicable for civilian cases." The need for accommodation for cases of surgical tuberculosis, especially in adults, was very great "and is still urgent." The Board pressed the local authorities, with some degree of success, to increase the accommodation for sanatorium treatment wherever possible, both by freeing buildings which had been diverted to other purposes, and by addition of pavilions to existing institutions. In view of the greatly increased cost

¹ Forty-eighth Annual Report of the Local Government Board, 1918-19. Supplement containing the Report of the Medical Department for 1918-19. London: H.M. Stationery Office; or to be purchased through any bookseller. Price 1s. 3d. net.

of construction, equipment, and administration, there seems to be little immediate prospect of the building of new sanatoriums upon anything like an extensive scale.

Much stress is laid upon the importance of the provision of training colonies and village settlements—the former to provide sanatorium treatment on a simplified scale, and to serve as a half-way house between sanatorium life and productive occupation. Certain colonies, it is suggested, may be given over partially to cases which are not likely to recover, but who still retain a greater or less capacity for working and earning. Allusion is made to the economic difficulties lying in the way of the prolongation of treatment for patients who are not pensioned or who have dependents. Those acquainted with the inner working of sanatoriums will read without surprise the reference to disciplinary difficulties—"Investigations of complaints took up a considerable part of the time of the (Board's) medical staff during the year."

Maternity and Child Welfare.

Turning to the section dealing with maternity and child welfare, we find the grave statement that in the last quarter of 1918 there was for the first time since the establishment of civil registration an excess of deaths over births of 79,443, causing an actual decrease in the population to that extent, and this in spite of the favourable circumstance that no rise in infant mortality resulted during 1918 as a consequence of war conditions and the influenza epidemic. Much work was done by the Board in many directions in connexion with maternity and child welfare problems. The exertions of the Board in stimulating the local authorities appear to have led to a general improvement in the matter of prompt notification of births. An unfortunate feature of the Act of 1915 was that no necessity is imposed of embodying in the notification a statement of living or stillbirth; it follows that stillbirths can only be estimated by inference and inquiry—that is, by enforcing strictly the Act, and by the organization of very prompt home visits by a health worker.

Antenatal treatment suffered greatly, as might be expected, from the scarcity of medical practitioners during the war; but it is claimed that an immense saving of life and health was secured by the conjoined action of the Food Controller and the Local Government Board in providing during 1918 for the supply of fresh and dried milk and of extra meat and butter for expectant mothers. Similar provision was made of milk for infants, and of sugar for artificially-fed babies attending at infant welfare centres. Gratifying results appear to have ensued from the Act of 1918. We learn that there only remain sixty-eight districts, representing 1.75 per cent. of the population of England and Wales, which have taken no action in the matter of maternity and child welfare. The health visitors have increased during the year from 2,555 to 3,038 and the number of centres from 1,278 to 1,365. Many additional crèches and day nurseries have been provided or are in course of preparation.

A great deal of attention is devoted in the Report to matters bearing directly or indirectly upon the actual accouchements. The provision of midwives both in urban and rural districts was aided by grants from the Board, and the Midwives Act of 1918 has enabled the local authorities, working in conjunction with the county nursing associations, both to provide midwives and to assist in their training. It is curious to note that of the certificated women on the Midwives' Roll one fifth only are in actual practice as midwives; but 845 candidates out of 1,548 successful at the last examination declared their intention to practise as midwives—including 471 proposing to settle in rural districts. The Board has also authorized grants for the "home helps" so necessary in the working-class household at the time of confinements. Emphasis is justly laid upon the necessity for the provision of maternity beds in homes and hospitals for the very large numbers of women, married and single, who cannot find suitable accommodation in their homes or lodgings. This urgent requirement "is one the need for which has been very slowly comprehended both by the local authorities and voluntary associations." In certain conditions the utilization of a ward—named the "district maternity home"—in union infirmaries has been authorized. A substantial development of dental facilities for

expectant and nursing mothers and for children below school age is recorded.

Small-pox.

The venereal disease section gives the courses of treatment in vogue at various centres, together with that suggested by Colonel L. W. Harrison; the small-pox report records one case a week, drawn from as many as fifty areas, up to June, 1919; and in the section dealing with Port Sanitary Administration, we find an interesting account of the energetic and successful measures taken when a refugee ship arrived at very short notice from Russia, having on board 1,700 refugees with sixty cases of small-pox and other infectious disease. Considerations of space forbid more than a passing reference to these sections, but attention may be directed to two somewhat disquieting matters of which the Report treats. Sir George Newman refers specially in his introduction to the circumstance that the percentage of children successfully vaccinated in 1917 was only 43.3, and the percentage exempted was 37.9. Owing to numerous revaccinations consequent upon war conditions, the adult population is better protected against small-pox than was previously the case, but only about half the children under 10 years of age have been vaccinated. The possibility of the rapid spread of an epidemic among the infants of this age (in whom the heaviest mortality is known to occur) has thus to be faced.

Meat Inspection.

The other matter calling for serious reflection is the report on the inspection of home-killed meat. When in the early part of 1918 the regulations of the Ministry of Food came into action, the attention of the Board's inspectors was actively directed to the public and private slaughterhouses; and the provision according to which Grade IV carcasses had to be killed in special "Government authorized slaughterhouses" led to close supervision by the local medical officers of health. Three points emerged very clearly as a result of these and other observations. First, that existing inspection arrangements are ludicrously inadequate—for example, in some districts inspectors' visits took place as infrequently as twice a year, being made chiefly "to see that the by-law requirement of limewashing was carried out." Secondly, that the sanitary conditions in large numbers of private slaughterhouses are unsatisfactory. Thirdly, the great increase in the amount of food condemned in the "Government authorized slaughterhouses" compared with that condemned previous to their establishment, leads to the pertinent inquiry, "What became of this class of meat in normal times?" The Report states that before the institution of control a large and lucrative trade was conducted in numerous areas, whereby diseased animals were bought surreptitiously, slaughtered in unauthorized and un-inspected places, dressed *secundum artem* and sold in the ordinary way for domestic consumption or to sausage and pie factories. When one remembers that the criteria of the unfitness of a carcass lie almost entirely in the viscera, and that inspection of dressed meat is generally quite useless, the importance of these disclosures will be realized. The gist of the Board's recommendations, which deserve careful study, is to be found in the following paragraph (p. 142):

There is only one method of ensuring the freedom of meat from disease, and that is by careful examination of the carcass at the time of slaughter, when all viscera are available for inspection. The only practicable means whereby this can be brought about is by requiring all animals intended for food purposes to be brought to a public abattoir, and by providing skilled inspectors in sufficient numbers to inspect thoroughly both before and after slaughter every animal brought there. This would result in the closure of all private slaughterhouses as such, and, in order to be of practical advantage to public health, the requirements would need to operate in town and country alike. Their application to urban areas alone would not be sufficient, as this would merely accentuate past evils by driving the trade in diseased animals exclusively into rural areas where there is no inspection at all.

THE late Mr. Arthur Hill of Eaton Square bequeathed £1,000 to St. Bartholomew's Hospital and £500 to the Great Northern Central Hospital.

THE thirtieth annual report of the New York State Hospital Commission contains a vast amount of statistical and other information bearing on the management of the State's asylums for the insane, which dealt with nearly 40,000 patients in the year 1917-1918.

England and Wales.

LIVERPOOL MEDICAL INSTITUTION.

At the annual meeting of the Liverpool Medical Institution on January 22nd the following were elected officers and members of council: Dr. John E. Gemmell, President; Drs. R. W. Mackenna and J. Ernest Nevins, Vice-Presidents; Dr. John Owen, secretary of ordinary meetings; Mr. Robert E. Kelly, secretary of pathological meetings; Mr. George C. E. Simpson, librarian; and six members of council—Drs. and Messrs. Robert Craig Dun, Vera Foley, J. Leggate, J. Hepworth Shaw, Richard Stopford-Taylor, and W. Thelwall Thomas. A recommendation of the council to raise the subscription from two guineas to two guineas and a half for a member resident within a radius of eight miles of the Liverpool Medical Institution was referred to the new council for consideration, and a committee was appointed to initiate a systematic effort toward increase of membership.

VENEREAL PROPHYLAXIS.

The London County Council, at its meeting on January 27th, received a report of its Public Health Committee advising that the methods of prophylaxis against venereal diseases commonly spoken of as the "packet" system should not be provided by the Council. The report stated that recent and extended information obtained with regard to the results of preventive treatment did not warrant the Council in differing from the conclusion of the Inter-departmental Committee, which reported to the Ministry of Health last August that the evidence in favour of the packet system was insufficient. The Public Health Committee did not consider that authoritative teaching on the subject of immediate self-disinfection should be provided by local authorities, nor that the means, together with approved instructions, should be readily accessible to the public. The Council's scheme for the diagnosis and treatment of venereal diseases in London fulfilled the Inter-departmental Committee's recommendation, that energy should not be dissipated on measures of doubtful value, but concentrated rather on wise propaganda and the provision of early, prompt, and skilled treatment. The report was adopted.

MEDICAL DINNER AT CARMARTHEN.

A large number of medical men of the South-West Wales Division of the British Medical Association who had served in the war were entertained by some members of the Division at a luncheon held at the Boar's Head Hotel, Carmarthen, on January 16th. Dr. Owen Williams, Burry Port, President of the South Wales and Monmouthshire Branch, presided; he was supported by Dr. Alfred Cox, Medical Secretary of the Association, and a representative gathering of the members of the profession. After the usual loyal toasts were proposed by the Chairman, "Our Guests" was proposed by Dr. D. L. Williams, Ferryside. Dr. Williams referred to the sacrifices made by the men who had joined, and the debt of gratitude owed to them. The toast was responded to by Dr. Roland Thomas in a most interesting, humorous, and racy speech; and by Dr. E. Evans, Llanelly, and Dr. J. Francis. The toast of the British Medical Association was proposed by Dr. R. Hopkin, Llangadock, who referred to the great work of the Association on behalf of the profession and to the great increase in membership which had lately taken place. Dr. Cox, who was received with musical honours, said it gave him very great pleasure to go to Carmarthen to meet the members of the Association. He was especially glad as it was the occasion of recognizing the services rendered by the men of the profession who had helped to win the war, and also to meet his old friend Dr. D. R. Price, whose services were to be recognized that afternoon. Dr. Cox referred to the work of the Association, and said it was the duty of every member of the profession to join the Association; it was very unfair that those men who were not members should benefit by the work of the Association. A presentation of plate was then made by Dr. Brigstocke, Haverfordwest, on behalf of a number of members, to Dr. D. R. Price, Ammanford, who was honorary secretary of the Division for a number of years and has lately resigned on account of ill health.

Dr. Brigstocke referred to the untiring energy and tact displayed by Dr. Price, and hoped he would soon be restored to his former condition of health. Dr. D. J. Williams, Llanelly, supported. Dr. Price returned thanks, and said that the work of the Association had been a very great pleasure to him.

LUNCHEON TO SIR HENRY GAUVAIN.

A complimentary luncheon was given at the Trocadero Restaurant, London, on January 23rd, to Sir Henry J. Gauvain, M.D., M.Ch., Medical Superintendent of the Lord Mayor Treloar Cripples' Hospital and College, in order to mark the knighthood conferred upon him at the New Year. The chair was taken by Sir William Treloar, and among the large number present were Viscount Burnham, Lord Downham (Chairman of the London County Council), the President of the Royal College of Physicians, the President of the London Chamber of Commerce, the Treasurer of St. Thomas's Hospital, Sir Watson Cheyne, Bt., M.P., Sir Francis Champneys, Bt., Sir Cuthbert Wallace, Sir Gordon Watson, Sir Forrest Fulton, K.C., and Sir John MacAlister. The Chairman, in proposing the health of their guest, conveyed the congratulations and good wishes of all present, and of many others who were not there. He spoke of Sir Henry Gauvain's ability, enthusiasm, and devotion to duty; during thirteen years of happy work together for the children at Alton he had learnt the worth of the man they were delighted to honour that day. Brief speeches of appreciation and congratulation were made by Lord Burnham, as one of the trustees, and by Mr. John H. Morgan, C.V.O., on behalf of the honorary medical board, and the toast was received with musical honours. Sir Henry Gauvain modestly expressed his gratitude to Sir William Treloar, to the honorary medical board, and to the staff at Alton and at Hayling Island, where the seaside branch has been established. He had seen the institution grow from one of 20 beds to one of 350, and now looked forward to further expansion. Sir Norman Moore, Bt., P.R.C.P., proposing prosperity to the Alton Cripples' Hospital, spoke of Sir Henry Gauvain's admirable work on surgical tuberculosis, and described him as the direct descendant of Dr. Christopher Bennet, who in the seventeenth century was the true founder of the study of tuberculosis in England. Great, however, as the advance had been since those days, it must be remembered that we were still only at the beginning of knowledge of that disease, and much remained to be done. The toast was replied to by Sir William H. Dunn, Bt., treasurer of the institution, and a vote of thanks to the chairman was proposed by Lord Downham. The menu card was enlivened with a sketch by Mr. G. L. Stampa showing the founder and the medical superintendent amidst a group of happy cheering little patients.

Scotland.

SCOTTISH POOR LAW MEDICAL OFFICERS' ASSOCIATION.

The annual report of the Scottish Poor Law Medical Officers' Association recalls that, in reply to a question in the House of Commons by Mr. Mackinder, M.P., the Secretary for Scotland agreed to consider the advisability of appointing a committee on superannuation for employees of local authorities. A memorial in favour of this course was presented to each Scottish Member of Parliament, a circular was sent to each Poor Law medical officer, the assistance of the British Medical Association was enlisted, and an appeal was made to the Scottish Board of Health asking that two or three members of the Scottish Poor Law Medical Officers' Association should be called to give evidence. At the invitation of the Scottish Board of Health, Dr. William Bryce of Glasgow and Dr. W. L. Muir, Secretary and Treasurer of the Scottish Poor Law Medical Officers' Association, were nominated to serve on the Medical Consultative Council in Scotland. The number of appointments advertised during the year was small and the terms in all cases satisfactory. In one instance a member was advised in regard to the replies he should make to the charges made by a parish council with regard to neglect of duty; the charges were not substantiated. The annual subscription of 5s. should be sent to Dr. W. L. Muir, 1, Seton Terrace, Glasgow, E.

SIR JAMES SIMPSON'S DAUGHTER.

The death of Miss Evelyn Blantyre Simpson severs the last link with Sir James Simpson. She was born in 1856 and was his last surviving child; with her died many memories of that pioneer of general anaesthesia. She, like her brother, was a friend of Robert Louis Stevenson, about whom she wrote two books. With Dr. Berry Hart she wrote the life of her father for the *Dictionary of National Biography*. Her best book was *Dogs of Other Days*. She was a well known personality in Edinburgh, epigrammatic in speech, but a general favourite.

Ireland.

TRIBUTE TO SIR JOHN BYERS.

On the evening of January 20th Sir John Byers was entertained to dinner by his professional colleagues on the visiting staff of the Royal Victoria Hospital, who presented him with a handsome Chippendale silver salver, on the completion of his term of office, after thirty-seven years' service as gynaecological surgeon to the hospital. Professor James Lindsay, chairman of the staff, presided; all the members of the staff except two, unavoidably prevented from attending, were present.

After the toast of the King, the chairman proposed the health of Sir John Byers, and made the presentation on behalf of the medical staff. In doing so he referred in terms of high praise to Sir John's long connexion with the hospital, his skill as a surgeon, his powers as a clinical teacher, and the administrative ability he showed as a member of the board of management. He mentioned also the keen interest Sir John had always taken in the public health of the city, especially with regard to tuberculosis and infant welfare. Sir John was also an authority on the folk-lore, phraseology, and antiquities of the province.

Professor Sinclair, C.B., then spoke in warm terms of Sir John Byers, as his lifelong friend, and referred to his early work in the Queen Street Hospital for Sick Children.

Dr. Walton Browne, D.L., a member of the consulting staff, and Mr. R. J. Johnstone, F.R.C.S., also joined in the expressions of good-will; the latter said he had worked with Sir John for many years as his assistant, and spoke of his great power as a lecturer, and his constant desire to forward the interests of the younger medical men.

Sir John Byers, in returning heartfelt and deepest thanks to his colleagues for their complimentary hospitality and beautiful gift, said that he valued the latter not merely for itself but because engraved thereon were the autographs of his twenty-three colleagues on the visiting staff. Sir John then gave some interesting reminiscences of his thirty-seven years' work, twenty-one of which were spent in the old Royal Hospital in Frederick Street and sixteen in the present Royal Victoria Hospital. He traced the growth of his department from a ward of four beds to the present wing, which was already far too small. He also described the growth of gynaecological work in general, referring especially to Caesarean section and other modern operations.

The toast of the Medical Staff, proposed by Sir John Byers, was acknowledged by Professor Lindsay. That of the Secretary of the Staff was proposed by Mr. Johnstone and responded to by Colonel Fullerton, C.B., C.M.G., F.R.C.S.I.

DOCTORS' THREATENED STRIKE.

The doctors in the Castlecomer Union have threatened to strike on February 1st unless the guardians accede to their demands for increased salaries. At a large meeting of Kilkenny and City medical practitioners a resolution was passed unanimously expressing thorough sympathy with the action of the medical officers of the Castlecomer Union in their determination to cease work and to refuse to attend any patient, private or otherwise, until their reasonable demand is acceded to. The following resolution was also passed:

That the initial salary for all dispensaries in the county Kilkenny be £300 per annum, with £5 annual increments until a maximum of £365 is reached, and to be retrospectively applied.

Correspondence.

PUBLIC HEALTH VERSUS THE STATE.

SIR,—Dr. Barwise's diatribe is indebted rather to his imagination than to his mastery of my argument. He has plainly not read the article he criticizes. Let me state what I *did* submit—namely, that the constant factor in the determination of a nation's tuberculous mortality is the height of real wages, and that the State's function in dealing with the problem should be to raise real wages. Economic *laissez faire*, I stated, in England has twice been shown to raise real wages. Of *laissez faire* free trade is the conspicuous illustration, and protection the emphatic contradiction, just as is State paternalism. I submitted that paternalism, like protection, must necessarily do unseen mischief more than compensating the good done. To that point he does not address himself. He confines himself to the Corn Laws in his first paragraph; I never mentioned them. From the dates he could see that I attached great importance to the succession of Peel's free trade measures before the repeal of the Corn Laws; the paragraph, therefore, is irrelevant.

There are several things to depress or to enhance real wages. He must see that his second paragraph is also irrelevant, unless he maintains that in Ireland, during the rise of the tuberculosis mortality, real wages were rising. If he does so maintain, in a country torn by intestine troubles as Ireland was from 1860 onwards, he is surely alone in that opinion. He knows that when comparative peace was attained and wages rose, the rate fell. He says that the rapid fall after the McKinley tariff in Koch's New York chart "proves" the opposite of my theory. He is bold. A more shrinking modesty (I dare not say a more scientific mind) would have said "suggests." If that fall "proves" the opposite, what does the check after the Dingley tariff "prove"? I am anxious for the truth; I pointed to facts which seemed to negative my hypothesis. Let him be equally sincere. It, of course, "proves" nothing; it lasted for only three years, followed Cleveland's historic administration, and was followed by the low Wilson tariff. But even so, in the Massachusetts chart it shows, after three years, a slight slackening of the fall.

He is right to remind me that the Caprivi treaties were not the nearest approach to free trade which occurred in the early years. I should have written (as elsewhere I had) "return." I apologize, but it can have misled no one; it was plain that I began with the history of the empire after the immediate effects of the war might be supposed to have worn off and after protection began. He is right in saying that the German duties on wheat and rye were trebled in 1885. But he is again irrelevant unless he can show that real wages fell. He may be a little more cautious in his condemnations in the future, if he knows that the Board of Trade shows that in Germany the prices of breadstuffs and meat were conspicuously lower in 1835-89 than the average. As a fact, we know that real wages were rising in Germany as in most other countries.

He is again right in saying that the "merest tiro knows that the" (never offensively great) "prosperity of the German working classes dates from the adoption of the protective policy of List." He is badly wrong when he forgets to add that no one else (unless he has an axo to grind) does; as wrong as when he implies that Germany adopted the system of List. That childish fallacy has been a thousand times exposed.

In a burst of confidence he tells us that he was brought up at the feet of John Bright, and had to desert his camp at the sight of men starving under *laissez faire*. I confess that that seems to me a miserable *post hoc ergo propter hoc*. I find a lack of perspective in Dr. Barwise. Did he never realize the appalling conditions due to State control of trade which John Bright and his school did so much to ameliorate? Does he expect that conditions which depend on the nature of things can be altered forthwith by Parliament? And what is he to do now, into what camp to take refuge, when he finds a tuberculous death-rate unnecessarily and unprecedentedly swollen under the system he advocates, or sees the ulcerous sore of unemployment scabbed over by loans, to pay which generations yet unborn, with their own evils to correct, will have to sweat and bleed?

I would by no means curtail his enjoyments; if it pleases him to father on me the figments of his own fertile brain and then destroy them, it does not hurt me, though I am quite unable to understand the tone of his letter. But this I may say: he would be more usefully employed (especially since men of his way of thinking are new on their defence) in trying, with me, honestly to find out why tuberculosis from a dying has become a flourishing disease, the more the State and the municipality have joined in the struggle. Is there, in a word, any other explanation than the economic?—I am, etc.

Rayleigh, Essex, Jan. 19th.

B. G. M. BASKETT.

TEMPORARY COMMISSIONS, I.M.S.

SIR,—Granted that a bachelor can exist—not live—on 400 rupees a month in India, and even have a good time on 700, may I ask what grounds there are for suggesting that a married man, even without a family, can live under present conditions on 700 rupees a month?

From irreproachable data, more than fifteen years old, I find that a newly-married couple, practising the most degrading economy, expended, on the average, 714 rupees a month during the first three years of married life (and 1,111 rupees a month, ever fifteen years), and this did not include house rent. The cost of living has doubled since then!

I would also like to ask Colonel Elliot how many men does he know who, during their first two years, have had the "chance of doing really big work as a surgeon, or as a physician, or as a specialist"?

As regards permanent commissions, can anyone say what are the prospects of a new recruit, in twenty years' time, either in the way of administrative appointments, well-paid billets, or pension?—I am, etc.,

January 18th.

ENQUIRER.

*** We referred this letter to the Chairman of the Naval and Military Committee of the British Medical Association, who replies as follows:

SIR,—I have to thank you for so kindly affording me an opportunity of answering "Enquirer's" letter in the same issue in which it appears. I would first remind your readers that there are three sets of interests to be considered: (1) Those of the young men whom we desire to see sent out to India on temporary commissions; (2) those of the tired I.M.S. officers whom we wish to see relieved at the earliest possible moment; and (3) those of the India Office.

It may clear away misunderstanding if I first explain the basis of the Secretary of State's present offer. The Naval and Military Committee has asked that the pay of permanent officers shall be increased by 50 per cent. of the total pre-war pay as reckoned by the India Office in its circular dated August, 1919. According to that circular a lieutenant in charge of a regiment drew 450 rupees a month. According to our demands he would in future draw 675 rupees. It did not appear to us that we could fairly ask as much as this for temporary men, whose passages were to be paid both ways, and who would have the option of becoming permanent if they chose. We therefore fixed 650 rupees a month for our figure. In doing so we had in mind that the men who went out would be young men, and that most of them would be unmarried men. If a man marries before his prospects are assured, he gives hostages to fortune, wherever he serves. This must be borne in mind in the present case. The Secretary of State has met us most generously. He has fixed the pay at 700 rupees and 750 rupees; he has granted passages both ways, and in reply to our later inquiry, has hastened to assure us that the return passages apply to the wives and families, as well as to the officers. He has further assured us that the privilege of counting in this temporary service toward permanent service will be enjoyed by those who elect to remain permanently in the I.M.S. No one can deny that he has behaved promptly and generously, and it is for this reason that I include the interests of the India Office amongst those which must be considered if we are to retain a reputation for fair play and honourable dealing.

And now to answer "Enquirer's" questions:

I. It must be admitted that the cost of living differs greatly in different parts of India, and according to conditions under which a young man lives. The

estimates contained in my last letter were derived from information afforded to the British Medical Association by officers who have recently written to us from India and by others, who, being home on leave, have kindly given us verbal evidence. Since reading "Enquirer's" letter I have prosecuted further inquiries, which have only tended to confirm me in the estimates already made. There is one point on which all are agreed—namely, that the Secretary of State's offer is liberal when it is remembered that it is extended to untried young men without tropical experience.

2. I have to thank "Enquirer" for his second question. I certainly did not mean to imply that a young man in his first two years of service would be likely to occupy one of the responsible appointments which are reserved for senior men. What I did mean, and I repeat it, is that any young man who goes out to India who is keen on the scientific side of his work, and who is willing to do a bit—if necessary, a big bit—over and above what he is bound by his contract to do, can always obtain opportunities which would be denied him at home, no matter how great his enthusiasm might be. The reason for this is that the material is so immense and the number of trained workers so very few. As a young man, on my first arrival in the country, such opportunities were afforded me by my senior officers. I took them and profited by them. The same was true of several of my friends; but the complaint made by the senior officers of those days was that so few young men would give up their leisure, their convenience, and their amusements for such a purpose. When, as a senior officer, I held charge of one of the most important hospitals in India, I extended the same facilities to all young men who were keen enough to make use of them. Some of the seniors among my friends did the same; but once again history repeated itself, and our experience was that very few of our juniors were keen enough to avail themselves of our offers. I have heard from young men who have recently returned from India that the same fine tradition of the service is being carried on. I stand by every word I said in my letter. The keen young man in India can always get his opportunities if he is willing to take them. The East is waiting for him if he has learnt the lesson, which the world just now seems to be forging, that success is only to be won by strenuous and continued effort. Fortune has no time and no use for the forty-five-hour-week man.

3. Then "Enquirer" asks what will be the prospects of a new recruit in twenty years' time. Who can answer that question for any service or for any business? In two years' time the young man will know far more about the probable prospects of the service than the best informed of us can guess to-day. The British Medical Association has put forward certain conditions of service—call them demands if you will, I would prefer not to—and we are bound to know very shortly whether these conditions will be fulfilled or not. If they are fulfilled the young man will know where he stands; if they are not, I fear the service will die of inanition. Of one thing I am assured, that the Secretary of State and his medical adviser know the facts of the case and are in sympathy with our aims. They are not all-powerful, and they have never pretended to be so. It is up to us to give them fair play and to help them to cut the present vicious circle by securing opportunities for leave to the many over-tired officers of the service.—I am, etc.,

R. H. ELLIOT,

Lieut.-Col. I.M.S.(ret.),

Chairman Naval and Military Committee,
British Medical Association.

London, W., Jan. 25th.

MODE OF QUININE ADMINISTRATION.

SIR,—The letter of Sir Ronald Ross in your last issue (p. 130) is an exceedingly interesting and valuable contribution to the literature on the treatment of malaria, and the opinions of so eminent an authority are bound to carry great weight.

I entirely accept his views as regards the oral treatment for ordinary attacks of malaria, on the lines carried out at the various malaria hospitals and centres in this country, and agree with him that in such cases, taking into account the relative advantages and disadvantages of the various modes of administration, injections of quinine are not desirable.

It is in the exceptional cases of severe and intractable malaria of the types quoted previously that I have been compelled, as the result of clinical observation, to believe in the superiority of intravenous and intramuscular injections. No one who witnessed the results of treatment of the cases referred to in Northern Persia, and of some of the severe cases of malignant malaria in Mesopotamia, could fail to appreciate the value of these injections, and in not a few of these cases oral administration carried out over a period of ten days or more had failed to produce any beneficial result.

I have not the least doubt that in Mesopotamia and Persia very many lives were saved by the timely use of quinine injections, and this belief was shared by the medical officers who were in charge of the cases. Much more chemical research is necessary before a scientific explanation can be given of the precise mode of action in the different methods of quinine administration, and too much importance should not be attached to estimations of quinine in the circulating blood, for it is well known that the liver and spleen have the property of rapidly absorbing other alkaloids and organic substances—for example, morphine, strychnine, and salvarsan—in like manner.

My conclusions were based entirely on clinical observations.—I am, etc.,

London, W., January 25th.

W. H. WILLCOX.

FORGETTING: PSYCHOLOGICAL REPRESSION.

SIR,—Years ago, when a medical student, I used to find relief from the dogmatic assertions of professors and textbooks in the correspondence pages of the BRITISH MEDICAL JOURNAL. It came to me as a pleasing discovery that neither were infallible, and that statements confidently made in the lecture theatre could be found contradicted, reasserted, and contradicted again in the battle-ground of your columns. Since then I have continued to delight in the evidence which your paper affords, that the art of medicine is not a fixed thing hedged about by impassable limitations, but a living organism, assimilating, rejecting, and always growing. *Magna est veritas*; but readers of your JOURNAL may well echo the question of Pilate—"What is truth?" The obstetrical *mêlée* in one part of your paper is likely now to have its rival in the differences between the old and new schools of psychiatrists.

Your issue of January 10th contains a very able article by Dr. Alfred Carver on "Psychological repression." On January 17th Sir Robert Armstrong-Jones, whose eminence we all admit, contributes a letter in which he very courteously but very firmly repudiates the methods of Dr. Carver. As a member of the new school as represented by Dr. Carver I cannot refrain from ranging myself on his side, little though he needs such poor reinforcement. Sir Robert Armstrong-Jones questions "whether it be possible to forget by an act of volition." It is not; but it is possible to consistently ignore until the thing ignored is so overcast that it is no longer present to the consciousness, and has to be "dug" for before it can again impress the consciousness. This process of burial may be exceedingly rapid—as in the case of the shell-shocked soldier, or may be the result of years of repression—as is more usual in the case of the neurasthenic civilian. Whether or not the incident thus buried acts as a psychic irritant depends entirely upon the associations linked with it. If these are normal no harm is done, and the mind can continue to ignore the past with impunity, however unpleasant or horrible such past may be. Psychic trauma is, however, caused when the associations linked with the repressed incident are morbid and unnatural. As Dr. Carver points out, the discovery of the repression is but a step, and the important thing is to bring the idea into line with a normal outlook. In the case suggested by Sir Robert Armstrong-Jones of the woman depressed by a drunken husband I agree as to the futility of merely recalling her past to her; but supposing it were elicited that for some reason she blamed herself for her husband's drunkenness, the greatest possible good might result from showing her the unreasonableness of her fears if these were based on overconsciousness. This, however, as also the other examples suggested by Sir Robert, are really beside the point, as the experiences he mentions are very unlikely to have been repressed to the point of "forgetting." In practice what one finds is that the depressed woman, the disappointed girl, the broken down

actor, are sent to a nursing home, told not to talk of their worries, seen by the physician for five or ten minutes daily, drugged to sleep if restless, and finally turned out sufficiently drugged and disciplined to carry on an approach to normal life until the next breakdown.

The new school substitutes for the ten-minute visit of the physician and his inquiries—limited to the condition of the pulse, tongue, and bowels—a stay of an hour or more, during which the patient is encouraged to talk freely of her feelings and worries, while the light of common sense thrown on to them often succeeds in giving the sufferer a newer and healthier point of view. Direct suggestion, combined with the feeling that she has found in the physician a sympathetic and helpful friend, usually suffices to bring sleep, or hypnosis can be used for that purpose only. At first the troubles talked of will only be the obvious and more recent ones. Then one morning the doctor finds the patient excited and restless; questioned, she will say that something has come into her mind which she had "forgotten"; she feels she would like to talk about it but cannot—it is too dreadful or too trivial; but whichever she says, it is obvious to the physician that the excitement can only be allayed by a free talk. Then begins a tug-of-war, which might remind the obstetrician of a difficult forceps case. The greatest care must be taken not to suggest to the patient the nature of the revelation, but she is made to understand that her peace of mind depends on speaking out. Time and time again the confession is trembling on her lips and allowed to die away or evaded, and time and time again the physician tries to pin her down to the utterance she is longing to make. No one who has witnessed the mental disturbance caused by such a conflict can reasonably doubt the existence of psychic trauma caused by continued repression. At last out it comes, and the effervescent excitement dies away, leaving the patient exhausted but relieved. Delivery is safely accomplished. But what of the *mus* brought forth by this labour? Usually it is some incident in early childhood, sometimes of a definite sexual nature, harmless in itself, but distorted and magnified by morbid imaginings and disproportionate associations. The way is now clear, but the work is not done. Convalescence may be long and tedious; but the physician has now a firm foundation on which to build, and his building is the more likely to stand firm against the stress of everyday life. Introspection has served its purpose and is now discouraged, while by precept and practice the patient is taught that adaptation to environment the lack of which is the root of all neuroses.—I am, etc.,

Harrogate, Jan. 16th.

R. G. M. LADELL.

SIR,—My only reason for intruding into the controversy in the issues of January 10th and 17th which has arisen between Sir William Hale-White and now Sir Robert Armstrong-Jones on the one hand, and Dr. Alfred Carver on the other, is to plead that the question at issue should not be allowed to rest where it is. The principle involved appears to be a vital one, for it is nothing less than the correct treatment to be pursued in certain cases of mental and nervous disorders. On the one hand we have men eminent in their profession, of great experience and the highest integrity, advising patients to forget their war experiences, and employ mental diversion to help them to forget. On the other hand, we find men also of high professional standing, large experience, and equal integrity, telling us that

The forgetfulness thus advised is nothing other than repression, and psychological analysis invariably reveals the fact that the patient's anxiety condition is directly attributable to it.

Later in his paper Dr Carver states:

I would say that the remarks here made apply with equal force to civilian psychoneurotics.

I suggest, Sir, that it is quite time this question should be settled one way or the other. We older men, who have followed a certain line of treatment for many years, must naturally feel some diffidence about abandoning it without strong reason. All my professional life, upwards of forty years, I employed the methods recommended by Sir William Hale-White in the treatment of certain mental and nervous disorders, and with results by no means unsatisfactory. Nevertheless, if the claims made by Dr. Carver, and many who think with him, for their treatment of bringing

to light unpleasant and repressed experiences are made good, then I for one would feel it obligatory on me to give my patients the benefit of the treatment. I strongly urge full, frank, and fair discussion of this important question, so that some decision may be arrived at.—I am, etc.,

CECIL A. P. OSBURN, F.R.C.S.Ed.

Old Catton, Norwich, Jan. 20th.

SIR,—“It is sad, it is passing sad,” that Dr. Thomas Lumsden continues to “insist over and over again” on his untenable theories of treatment of the war neuroses. There is really very little difference of opinion among those who from actual experience are competent to judge. Mono-symptomatic hysterical manifestations, such as mutism, aphonia, blindness, deafness, paralysis, and contractures can generally be completely and permanently cured at a single sitting by explanation, persuasion, and re-education. Such cases hardly ever relapse. On the other hand, psychasthenia is much more difficult to treat; prolonged psychotherapy of some kind is always necessary, combined with congenial occupation, such as was afforded at the Seale Hayne Hospital by the farm, workshops, and pottery. If arrangements can be made for these patients when they have recovered to go straight from hospital to suitable employment they rarely relapse. Unfortunately, however, the official arrangements are so inadequate that it is rarely possible to arrange for this except as a result of the personal efforts of the patient's medical officer. When he fails the vain search for work and the worry in connexion with pensions and medical boards after discharge from hospital only too often lead to relapse.

This would not be prevented by postponing discharge for three months, as advocated by Dr. Lumsden. His Country Host scheme was very wisely rejected by the War Office after careful consideration by a committee of experts of all the available evidence, as it was the universal experience that such treatment resulted in the perpetuation of the symptoms and made it exceedingly difficult for a man ever to learn to depend upon himself again.

The great majority of the 30,000 pensioners referred to by Dr. Lumsden were never in any special neurological hospital, such as Maghull and Seale Hayne, and the comparatively few relapses from such hospitals were almost invariably cases of psychasthenia, and not of hysteria.

I should like to protest once more against the supposed distinction between a rapid and a slow method of treatment. Presumably Sir Henry Davy bases his criticisms of the “rapid methods” of Seale Hayne on his two or three short official visits with inspecting generals. I can assure him that he was only shown gross hysterical cases under treatment, because it was obviously impossible to demonstrate before an audience the slow methods required for psychasthenia. If a man can be permanently cured of hysterical blindness in an hour, it is difficult to understand what advantage would be gained by prolonging the treatment over a month or a year.

To substitute “natural treatment by rest and good feeding” for the various forms of psychotherapy (which obviously exclude neither rest nor good feeding), as employed at Seale Hayne, Maghull, and all the other special neurological centres for soldiers and pensioners. In the way we are asked to do by Sir Robert Armstrong-Jones and Dr. Lumsden, would be to reject all the advances which have been made in our knowledge of the psycho-neuroses during the last five years.—I am, etc.,

London, Jan. 25th.

ARTHUR F. HURST.

SIR,—I should like to thank Sir Robert Armstrong-Jones for his courteous criticism of my article. I quite agree with him that all questions relating to the mind are elusive, but this must not prevent us from putting forth our most earnest endeavour practically to grapple with them.

In the small space at my disposal I tried to confine my remarks to the subject of repression and readaptation, but Sir Robert shows an inclination considerably to enlarge the issue and assumes that I am committed to several other far-reaching hypotheses. The thesis I put forward is that the recognition by the patient of the cause of his failure is a necessary first step to his re-education, but I do not consider it an axiom that this must be obtained by abreaction; my mention of the fact that the bringing to light of ideas repressed because of their unbearable nature

is accompanied by signs of emotion on the part of the patient was merely incidental and had no reference to the abreaction theory; considerable advances have been made since 1895. Only in comparatively rare instances does a bare knowledge of the repressed material suffice for the cure of the patient. The psychotherapist is far more concerned with combating the patient's “resistance,” which was in the first instance responsible for the repression. If this resistance is not removed by a readjustment of the patient's attitude, relapse—either with the same or new symptoms—is only too liable to follow apparent cure. For this reason “lightning cures” should be regarded with suspicion. Adaptation is generally a difficult and, therefore, rather slow process.

I rather suspect that Sir Robert Armstrong-Jones is trying to lure me on to less safe ground by introducing the subject of the psychoses, which was beyond the scope of my article, and is too large for discussion here. I must, however, insist in this connexion also that merely to draw the patient's attention to events with which he is declining to deal is only a first step; it is not the ultimate aim of treatment, for to brood over and yet fail to tackle an unpleasant reality is almost as disadvantageous a procedure as repression. Maeterlinck has truly said: “Though over certain external events our influence is of the feeblest, yet we are all-powerful over what these events shall become within ourselves.” In other words, the event is not the most important factor; what matters is whether we respond to it by repression and withdrawal, or by facing it courageously and adjusting ourselves to reality. As Havelock Ellis remarks: “It is a necessary task to adapt the universe to man, but it is sometimes also necessary to adapt man to the universe. When this adaptation is incomplete we are in the presence of disease.”

I cannot follow Sir Robert Armstrong-Jones in considering that the lack of adaptation which psychopaths display by repressing what is disagreeable to them should be regarded as Nature's method of restoration. True there is a “psychopathology of everyday life,” but even in small matters man pays a certain proportionate penalty whenever he shirks.

I regard a physician who aids and abets his patient's repression in much the same light as I should regard a dentist who advised a person suffering with toothache to seek diversion, and try to ignore this symptom rather than undergo the discomfort associated with a dental chair. Not by such means will either contribute to the real peace and health—psychic or somatic—of his patient.

Once the necessary adjustment has been effected I do not think any one could reasonably object to the patient being given a holiday under Dr. Lumsden's Country Host scheme.

Finally, with Dr. Major Greenwood, I trust that the discussion of a theme at once so interesting and so dangerous may not degenerate into acrimonious abuse. The question as to what is meant by the term “cure” is equally pertinent to both sides.—I am, etc.,

Birmingham, Jan. 25th.

ALFRED CARVER.

“NEW LAMPS FOR OLD” IN OBSTETRICS.

SIR,—Truly, on reading the letters under this heading, one comes across some extraordinary views. I suppose we have to live with people to know them. One correspondent mentions the difficulty of applying forceps properly. It is their very ease of application, and the satisfaction of getting the case over quickly that, in 99 cases out of 100, induces men to use them. Another states that he can deliver a woman five minutes after the forceps are applied. Perhaps $\frac{1}{2}$ c.cm. of pituitary would have done it in four minutes. I wonder what kind of perineum he has to deal with, for in some primiparae I take with forceps as long as three-quarters of an hour to guide the head over the perineum.

But we return to the old question—Is interference in normal labour desirable?—in other words, Are we justified in converting a perfectly natural process into a surgical operation? I say decidedly, No, and in their inner consciences most men say the same. Medical men have no business to attend normal confinements; they have now too much to do, and have no time to sit waiting, making frequent vaginal examinations, and asking themselves, “How much longer?” Doctors in bygone times acted more as midwives; they would remain at the bedside hour

after hour, holding and squeezing the belly. Now more common sense prevails, and all the spade work is done by a good nurse.

There is nothing seriously the matter with the old lamps which are well and truly made. They require trimming—that is all.—I am, etc.,

Upholland, Wigan, Jan. 26th.

J. THOMSON SHIRLAW.

SCOTTISH COLLIERY SURGEONS AND THE MINERS' UNION.

SIR,—In a recent issue (January 3rd) you stated that as a result of negotiations between the Scottish Colliery Surgeons' Committee and the Miners' Union, an agreement had been reached for a uniform flat rate of 3½d. per week without the supply of medicine and 4½d. where the latter was supplied. Some of us are wondering how this came about. At the early meetings held to discuss the matter all were firmly resolved that the payments would be 6d. and 5d. weekly respectively. Later we signed a document to the effect that in the event of the miners refusing these terms we would revert to private practice, that is, regarding their wives and families. Little more was heard on the subject until the middle of December last when we received notice that at a meeting held in Glasgow the miners' representatives offered 3½d. and 4½d., whereas our men came down to 4d. and 5d. as the lowest acceptable minimum. We were asked to state our preference between the two, and in the event of our adhering to the larger sum to indicate again whether we would revert to private practice in the case of the miners' refusal. Every medical man I have spoken to, who had any colliery work whatever, stuck out for the larger fees. The next we heard was from the columns of an evening newspaper that the surgeons' representatives had once more retreated. Not another word have we heard on the subject. A good few of us fancy that if the miners' officials had shown a bit more backbone we should have found ourselves committed to attend their dependants at, say, ½d. per week—with medicine thrown in to balance matters!—I am, etc.,

January 16th.

SCOTTISH COLLIERY SURGEON.

SIR,—In reply to the foregoing letter which, by your courtesy, I have been permitted to read, I beg to state the facts as far as known to me.

In the spring of last year the Colliery and Public Works Surgeons' Committee formulated a policy on the following lines, namely:

1. That recognition of the committee, as representing all the colliery doctors in Scotland, should be demanded from the Miners' Union.
2. That a uniform flat rate be demanded, applicable to all areas in Scotland, for medical attendance apart from the supplying of drugs.
3. That no area should accept any settlement unless all the areas received the terms agreed to by the committee.
4. That 5d. per week per worker be asked as the rate for medical attendance; and that in areas where medicine is supplied, the additional rate should be not less than 1d.

In furtherance of this policy notices of termination of existing agreements were sent in by the local executives in each area, and practitioners were asked to sign an undertaking to refuse to continue treatment of dependants on a contract basis when asked to do so by the committee. That undertaking was signed almost universally.

After considerable negotiation items 1 and 2 were obtained, but the 5d. rate asked for was refused, and the miners' final offer was 3½d. for medical attendance and 4½d. for attendance and medicine. The Committee neither accepted nor refused this offer, but referred it back to the areas. Each delegate was instructed to obtain a mandate from his constituents, and at the meeting in December every delegate present reported that he had been instructed to try to secure better terms, but not to vote for a strike in the event of these terms not being obtained.

At no time did the Committee say that resignations were to be sent in if the 5d. rate was not obtained; and at every stage the representatives were understood to have consulted their constituents. If any representative failed to do so, the Committee was not made aware of the fact.

A word as to the relationship of the British Medical Association to this Committee. The Scottish Committee of the British Medical Association, in return for a contribution made to the funds of the Colliery Surgeons'

Committee, has three representatives on it, and undertakes to support any action taken by the latter Committee if the policy be approved by the former. When the policy was formulated last year the Scottish Committee circularized every practitioner in the areas concerned, urging their support of the policy and offering the help of the Association in furtherance of it.—I am, etc.,

JAS. R. DREYER,

6, Rutland Square, Edinburgh,
January 20th, 1920.

Scottish Medical Secretary.

THE ORDER OF ST. JOHN.

SIR,—May I be allowed to thank you for the very valuable information in the reply to my query about the conditions under which the various grades in the "Grand Priory of the Order of St. John of Jerusalem in England" are awarded? It has cleared up some knotty points.

May I further trespass by asking if the "Priory of St. Torphichen" in Scotland and the "Priory of St. John in Wales" grant similar awards under conditions which seem to me to be strangely out of keeping with modern ideas, which apparently govern each of the other Orders of Chivalry, old and new?

Some years ago, when I was actively interested in the granting of certificates in "first aid" and "home nursing," those of the St. John enjoyed exclusive privileges, especially in relation to the Police and the Marine Department of the Board of Trade. Can you inform me if these privileges are still in existence, or have they been extended to other bodies which today undertake similar services, such as county councils and Red Cross societies?—I am, etc.,

January 12th.

"ONE INTERESTED."

** There is no Priory of the Order of St. John in Scotland. There is a St. Andrew's Ambulance Association in Scotland, but there is no Order of St. Andrew and no Orders are conferred by the St. Andrew's Ambulance Association. The old buildings of Torphichen Priory still exist, but they have no connexion with St. Andrew's Ambulance Association. The first-aid certificates granted by the St. Andrew's Ambulance Association are interchangeable in England as well as Scotland with those granted by the St. John Ambulance Association, and equally fulfil the requirements of the Home Office and the Marine Department of the Board of Trade. We understand that the first-aid certificates, first and second class, granted after examination by the British Red Cross Society and by certain county councils are accepted by the Board of Trade as certificates of competency as master or mate in the Mercantile Marine, and by the War Office as evidence of competency for voluntary aid detachments. It appears, therefore, that the St. John's certificates have not any exclusive privilege, and that the recognition they confer attaches also to similar certificates granted by several other bodies. We have no information as to the "Priory of St. John in Wales" nor do we know how it is regarded by the authorities at St. John's Gate, Clerkenwell.

Universities and Colleges.

UNIVERSITY OF OXFORD.

At a congregation held on January 22nd the degree of Doctor of Medicine was conferred on:

R. St. A. Heathcote, C. P. Symonds, T. B. Heaton; C. H. Barber (in absentia).

UNIVERSITY OF CAMBRIDGE.

MR. O. R. A. THACKER, M.B., B.Ch., Fellow of Sydney Sussex College, has been appointed additional demonstrator in physiology, and Mr. M. B. R. Swann, M.R.C.S., demonstrator in pathology.

At a congregation held on January 23rd the following medical degrees were conferred:

M.D.—H. V. Deakin, B. W. M. Aston Key.
M.B., B.Ch.—H. W. C. Vines, G. H. Oriel.
B.Ch.—O. G. Morgan, J. Hale, C. S. Dodson, A. C. M. Coxon.

UNIVERSITY OF LONDON.

DR. H. L. EASON, C.B., C.M.G., senior ophthalmic surgeon to Guy's Hospital, has been elected by the Faculty of Medicine as its representative upon the Senate, in succession to Sir Cooper Perry, who has resigned on his appointment as Principal Officer of the University.

CONJOINT BOARD IN SCOTLAND.

THE following candidates, having passed the final examination, were admitted L.R.C.P.E., L.R.C.S.E., L.R.F.P.S.G.:

Lizzie R. Clark, J. Campbell, R. J. C. Meek, A. Strang, W. F. S. Webb, A. F. W. Thompson, E. F. Birkenstock, Janet A. A. Sang, T. Blarney, R. Carl Febber, T. W. Stewart.

The Services.

ARMY PAY OF CIVILIAN MEDICAL PRACTITIONERS. A ROYAL WARRANT (dated January 18th, 1920, and published in Army Order No. 10 of 1920) increases the rate of remuneration of civilian medical practitioners engaged under Article 364 of the Pay Warrant to render medical attendance and examine recruits where army medical practitioners are not available. The substituted rates for medical attendance (including vaccination and cost of medicines) are £7 10s. a year if there are fewer than 10 persons entitled to medical attendance; and when there are 10 persons or more, £15 for every complete 25 or portion of 25, provided that the total emoluments for all services exclusive of the examination of recruits shall not in any instance exceed £1 10s. for any one day. For examination of recruits 2s 6d. is allowed for each recruit for the regular forces, subject to a maximum of £2 a day for services under this head. The new rates come into force as from January 1st, 1920.

HONOURS.

Military Cross.

AMONG the immediate awards conferred by Major-General Sir W. E. Ironside, K.C.B. (under powers vested in him by His Majesty), for conspicuous gallantry and devotion to duty in North Russia, is the Military Cross to Captain James Vallance, R.A.M.C., attached 45th Battalion Royal Fusiliers.

For great gallantry and devotion to duty in dressing and attending wounded under fire. As each objective was gained he followed up immediately, dressing and bringing in all wounded on his way. In one village the Bolsheviks landed a party of sailors, and it was only through his untiring efforts that the wounded were removed to a place of safety.

Mentioned for Services Rendered.

The names of the following officers of the Indian Medical Services have been brought to the notice of the Secretary of State for War for valuable services rendered in India during the war:

Lieut.-Colonels: H. Boulton, (temporary Colonel) H. Burdon, C.I.E. Major (acting Lieut.-Colonel) J. B. D. Hunter (attached South Persia Rifles). Captains: J. B. Hanafin, J. A. A. Kernahan (attached South Persia Rifles), (temporary Lieut.-Colonel) J. V. Macdonald, M.C., R. R. M. Porter, J. A. Sluton, V.C., (temporary Major) M. A. Rahman, Temporary Captain H. S. Hensman. Temporary Lieutenants: L. J. P. Mordaunt, A. Noble (attached 124th Baluchistan Infantry), T. Mahomed Nawaz.

Foreign Decoration.

Surgeon Commander Robert W. B. Hall, R.N., has been appointed by the King of the Hellenes to be an Officer of the Order of the Redeemer for distinguished services rendered during the war.

The Territorial Decoration has been conferred upon Colonel Percy C. Burgess, A.M.S.

Obituary.

CECIL RUPERT CHAWORTH LYSTER, M.R.C.S.,

Lately Medical Officer in Charge of the Electro-therapeutic Department, Middlesex Hospital.

WE have to record with much regret the death on January 26th of Dr. Cecil R. C. Lyster, who was for seventeen years medical officer in charge of the electro-therapeutic department of the Middlesex Hospital. He was born in London in December, 1859, the eldest son of the late A. C. Lyster of Abbey Wood. He received his professional education at Charing Cross Hospital, and obtained the diploma of M.R.C.S.Eng. in 1881. After holding various house appointments at Charing Cross Hospital he was appointed medical superintendent and honorary secretary of the Bolingbroke Hospital, Wandsworth, in 1885, and remained there until 1902, when he joined the staff of the Middlesex Hospital as electro-therapist. Dr. Lyster was one of the first medical men to undertake x-ray investigation, more particularly in relation to the treatment of cancer. He became president of the electro-therapeutic section of the Royal Society of Medicine, and during the war he served as medical officer directing radiology, electro-therapeutics, and massage at Queen Alexandra's Hospital, Millbank. In the early days of experimentation with x-rays, when their harmful properties were little under-

stood, Dr. Lyster sustained severe dermatitis on his hands from exposure to the rays. Despite repeated amputation of the fingers, and much suffering, he remained at work until November last, when, a dying man, he at last gave up his post at the Middlesex Hospital. Speaking at the court of governors, held on November 27th, the Earl of Athlone announced Dr. Lyster's resignation, and made sympathetic reference to his self-sacrificing devotion to duty. The Chairman of the Middlesex Hospital added:

One of the pioneers of scientific research, Dr. Lyster applied himself to the study of x-rays and their use in the treatment of disease, especially cancer, and more recently he has been concerned in an attempt to determine the effects of radium, and to standardize its applications as a remedial agent. He himself, by exposure to the rays in the early days when the knowledge of their power was slight, fell a victim to the disease he sought to conquer; though suffering and compelled frequently to seek the surgeon's aid, he declined to be set aside from his purpose, and continued his good work until now, when work is for him no longer possible. Such a record of service for others, a life spent in the advancement of science, with no regard for personal safety, commands our admiration, wonder, and respect.

The funeral service took place in the Middlesex Hospital chapel on Thursday morning, January 29th.

GEORGE A. HICKS, M.D., F.R.C.S.ED.,

Surgeon Samaritan Hospital for Women, Belfast.

IT is with deep regret that we announce the death of Dr. George Adam Hicks, F.R.C.S.ED., which took place at his residence in Belfast on January 24th. He was in good health until a fortnight before his death, when a small wound on the thumb was infected during attendance on a septic case. A haemolytic streptococcus was isolated which had also been found in the patient. Despite the unremitting attention and skill of several of his colleagues he sank under the infection.

Dr. Hicks was a native of co. Sligo, studied at Queen's College, Belfast, and graduated M.B., B.Ch., B.A.O. in 1897; he obtained the M.D. in 1904 and the F.R.C.S.ED. in 1912. He was for a time demonstrator of physiology in Queen's College. He had engaged in general practice; when, on the retirement of the late Dr. J. St. Clair Boyd from the Samaritan Hospital for Women, Dr. Hicks was elected gynaecological surgeon in his stead. Thereafter he confined his work to gynaecology and obstetrics, and at his death had one of the largest consulting practices in this department in the north of Ireland. As one of the surgeons to the Samaritan Hospital he had three or four students as clinical clerks every month, and his list of students was always filled for several months in advance. His lucid teaching and painstaking care were in keeping with the conscientious discharge of all his professional duties. His contributions to the medical societies were highly appreciated, and proved his ability, skill, and familiarity with all recent research. There is no doubt that constant and ever-increasing arduous work undermined his powers of resistance, and thus yet another name is added to the roll of those who succumb to disease contracted in the discharge of their duty.

Dr. Hicks was held in great affection and esteem by his patients, professional colleagues, and the students who worked under him, and his loss will be severely felt. Deep sympathy is felt for his widow and only child.

WE regret to record the untimely death, on January 24th, of Dr. FRANCIS NORMAN VICTOR DYER, in his 26th year. He was the only son of Mr. and Mrs. Dyer of Harrogate. He was educated at Marlborough, Clare College, Cambridge, and St. Thomas's Hospital, and qualified M.R.C.S. and L.R.C.P. in January, 1918, graduating M.A., M.B., and B.Ch. in October last. When war broke out he served as a dresser in the 1st Eastern Hospital, Cambridge; he was six months a surgeon probationer in H.M.S. *Buttercup*, then resident anaesthetist and casualty officer at St. Thomas's Hospital; afterwards surgeon R.N. in H.M.S. *Birkenhead* until the surrender of the German Fleet, when he transferred to the R.A.F., and was a member of the Invaliding Medical Board at Hampstead. He was demobilized at the end of October last, when he was appointed assistant medical officer at the London Fever Hospital, where he contracted scarlet fever and died at his work.

Medical News.

THE Minister of Health has promoted Dr. Richard J. Reece, C.B., to be a senior medical officer of the Ministry.

SIR BERKELEY MOYNIHAN will give a Hunterian lecture at the Royal College of Surgeons of England on the late surgery of gunshot wounds of the chest on Monday next at 5 p.m. A Hunterian lecture on the surgical aspect of dysentery will be given on Friday, February 6th, at the same hour, by Mr. V. Zachary Cope, M.S., F.R.C.S. The dates of other Hunterian lectures will be announced in subsequent issues.

DR. ROBERT WILLIAM MACKENNA has been appointed honorary dermatologist to the Royal Infirmary, Liverpool, in succession to Dr. H. Leslie Roberts, who retired at the beginning of the year under the age rule.

THE Lord Mayor of London will preside at a meeting at the Mansion House on Thursday, February 5th, at 3.30 p.m., when the views of the Society for the Prevention of Venereal Disease on the importance of immediate self-disinfection, as a means of preventing the spread of venereal diseases, will be stated by Lord Willoughby de Broke, Lord Riddell, Sir William Arbuthnot Lane, Sir James Crichton-Browne, Sir Ray Lankester, Sir Arehdall Reid, Sir Arthur Sloggett, and others.

THE Ministry of Health has issued to the councils of counties and boroughs a memorandum on the duties of local authorities under the Sale of Food and Drugs Acts. The Ministry states that it is aware that in many areas this work was necessarily curtailed to some extent during the war, owing to the shortage of staff and pressure of special work, but it urges local authorities now to take steps to ensure that the powers conferred upon them are fully utilized. The memorandum reminds authorities of the obligation upon them to transmit the analyst's reports at once to the Ministry.

MR. DAVID ANDERSON SHENNAN, a director of the Buenos Aires Great Southern Railway, has by his will bequeathed £5,000 to the London Hospital, the income to be applied to research work in connexion with the septic form of Bright's disease. He has also bequeathed £3,000 each to St. George's Hospital, the Victoria Hospital for Children, Chelsea, and the British Hospital, Buenos Aires.

WE gave some account last week of a White Paper issued by the Board of Trade containing the report of a committee appointed to investigate the position of prices and supply of quinine. A reply to the White Paper has been published by the managing director of the British Quinine Corporation in the *Chemist and Druggist*. It is in the nature of a *tu quoque*. He alleges that on the sale of 840,000 ounces of quinine at 2s. 11d. the Government made a profit of 1s. 3d. an ounce, or about £45,000, whereas the Quinine Corporation, by the rise in price which occurred immediately after the purchase, made only £21,000. It is stated also that during the whole of the war the price of quinine was higher in the United States than in this country, and is to-day 90 cents an ounce in first hands.

DR. CHRISTOPHER ADDISON, M.P., Minister of Health, declared open the new head quarters of the British Dental Association (23, Russell Square) on the afternoon of January 23rd. Mr. Montagu F. Hopson, president of the association, presided over a large company. In the course of his address Dr. Addison expressed the thanks of the Government to the Dental Services Committee and the Dental Tribunal for the work they did for the nation during the war. He spoke of the serious shortage of qualified dentists, and suggested that in view of the heavy expense incurred in training for the dental profession the length of the curriculum might be reduced. He referred also to the need for a co-ordinated service linking up medical men, dentists, nurses, and kindred workers. In helping to bring this about the British Dental Association could do work which would be of value not only to their own profession but to the community. He undertook that in this task the Ministry of Health would do all in its power to assist.

THE current number of the *Edinburgh Review* contains a well informed and sympathetic account by Mr. de Castro of the Rev. Stephen Hales, the first to measure the blood pressure, one of the first to study the physiology of plants, the first to devise a method of ventilating ships, and one of the founders of the Royal Society of Arts. He was buried at Teddington, of which he was perpetual curate, and to which he brought a supply of pure water, but the Princess of Wales of the day erected a monument to him in Westminster Abbey with a portrait bas-relief.

SIR ARCHIBALD GARROD, director of the medical clinic at St. Bartholomew's Hospital, will give the Schorstein Memorial Lecture at the London Hospital Medical College on Friday, February 20th, at 4 p.m. The subject is diagnosis of disease of the pancreas.

THE Milroy Lectures before the Royal College of Physicians of London will be given by Dr. Aldo Castellani, C.M.G., M.R.C.P., on February 26th and March 2nd and 4th. The subject is the higher fungi in relation to human pathology. The Goulstonian Lectures by Dr. J. L. Birley, C.B.E., physician to out-patients, St. Thomas's Hospital, and consulting physician R.A.F., will deal with the principles of medical science as applied to military aviation; the first lecture will be given on March 9th. The Luncheon Lectures by Sir John Rose Bradford, to begin on March 18th, will be devoted to "the clinical experiences of a physician during the campaign in France and Flanders, 1914-1919."

THE Women's Medical Association of New York City has made a generous offer to medical women. It has for award to a woman physician the Mary Putnam Jacobi fellowship of 800 dollars (about £2,000) for post-graduate study in any country for work in any medical science. Full particulars can be obtained from Dr. Murrell, 86, Porchester Terrace, London, W.2.

MESSRS. WILLIAM HODGE AND CO. (Edinburgh and London) announce that they are about to resume publication of the series of notable trials suspended during the war. *The Trial of Hawley Harvey Crippen*, edited with an introduction by Mr. Filson Young, is nearly ready.

Letters, Notes, and Answers.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR OF THE BRITISH MEDICAL JOURNAL, *Articulate Westrand, London*; telephone, 2631, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra, Westrand, London*; telephone, 2634, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin.

QUERIES AND ANSWERS.

T. asks whether any treatment short of operation can be advised for a case of obstinate trigeminal neuralgia in which the ordinary remedies have afforded no relief.

DR. W. B. DRUMMOND (Medical Superintendent Baldovan Institution, by Dundee) asks for references to literature dealing with the influence of atmospheric conditions on epilepsy.

ALOPECIA.

DR. G. E. CARVER (Paris) writes, in reply to a correspondent who asked for suggestions for the treatment of alopecia in a girl, that modern French writers (Jacquet, Rousseau-Decelle, and others) believe that this condition is frequently produced by dental trouble, active or passive. At the age in question (19) an unerupted wisdom tooth might be to blame.

INCOME TAX.

G. S. writes: (1) Should part-time employment on Medical Boards (M. of P.) be assessed under Schedule E, and if so, how is one supposed to estimate the amount for the ensuing year? (2) Should a divided share in trust property, payment of which is made by the solicitors, be returned under Schedule A or classed with other dividends under Schedule D? (3) As to a preference dividend just received for dividends accruing 1916 to 1918, can the excess tax be reclaimed on this year's claim?

. (1) In our opinion the receipts from such work are not strictly the results of an "office" under the Crown, and fall for assessment under Schedule D as the profits of "employment," and are consequently assessable on a three years' average—or on an average of the past year, or two years if the employment has not extended over three past years. For the first year the income would be assessable on the amount receivable for that year, whether the liability falls under Schedule E or Schedule D, and in that case the assessment should be made at the end of the year. (2) If the income in question is derived entirely from real estate, we suggest that it should be shown as assessed under Schedule A, if it is derived from a mixed fund—property rents, interest, etc.—

as income in the nature of dividends. (3) Arrears of preference dividends appear to be treated for repayment purposes as income of the year when the profits were made from which the arrears were paid. For instance, if 1919 is the year for which the company's profits have been sufficient to permit of the payment of the arrears, then they would be regarded for repayment purposes as income of the year to April 5th, 1920. The rule appears to be founded on common-sense principles, and our correspondent will probably find little difficulty in applying it to his case.

F. G. W. was acting as a locumtenent to May, 1919; from that date until September 15th, 1919, his earnings were nil; he then took over a general practice. He has recently received a notice of an income-tax assessment putting his earnings as £400. What is his position?

. Presuming that his earnings as a locumtenent extended to May 17th—that is, covered a period of six weeks in the financial year ending April 5th, 1920—the income from that source at £8 8s. per week would be £50. So far as his income from the general practice is concerned, his liability is determined by the past profits of the practice during the three years 1916, 1917, and 1918, which he can, perhaps, ascertain from his predecessor or from the income-tax inspector. Assuming that the net average profits of the practice have been £780, for example, his liability for the period September 15th, 1919, to April 5th, 1920, would be $\frac{2}{3}$ of £780, that is, £435, and his total earnings for the year £485. If he has no other income, the net liability would be £185, less £100 abatement, £62 20s. life assurance allowance, £50 wife allowance (not £25, which was the amount allowed in 1918-19)—that is, £272 10s. at 2s. 3d. The expenses to which our correspondent refers—motor car, drugs, etc.—are legitimate deductions from the gross earnings of the practice, but, unless he is taking over his predecessor's book debts, his actual cash receipts will not be admitted to reflect fully the real amount of those gross earnings during the early years of his general practice work.

* Hitherto the official in question has been referred to in this column as the "surveyor," but we understand that his official designation is now "inspector," and we shall adopt that nomenclature in future to avoid misunderstanding.

LETTERS, NOTES, ETC.

PROFESSIONAL SECRECY.

WE have received from Dr. Arthur Powell, Professor of Medical Jurisprudence, Bombay University, a letter containing an expression of opinion to the effect that a medical man errs in objecting to give evidence in court with regard to a patient's condition if asked to do so by the patient on the advice of his or her legal adviser.

COPPER ALANINE IN INOPERABLE CANCER.

MESSRS. BOOTS (Research Laboratory, Island Street, Nottingham) inform us that the solution of copper alanine they supply contains 0.44 per cent. of the salt. Although a 1 per cent. solution can be obtained it appears to be supersaturated, and on long standing crystals of copper alanine are deposited, thus necessitating filtration of the solution before use. The solution as now supplied is made by shaking excess of the salt with water at the ordinary temperature until the saturation point is reached, and hence, unless a considerable diminution in the temperature occurs, no separation of the salt can take place.

DR. J. A. SHAW-MACKENZIE (London, W.) writes: In your issue of January 17th, 1920, p. 104, a note appears under the above title, in which palliative results obtained by Dr. James Donelan in a case of inoperable cancer of the tongue by the employment of copper alanine (the use of which in protozoal diseases and in inoperable cancer was suggested and its lack of toxicity in proper dosage demonstrated by me) is referred to and the sale of the drug announced. Although distinct benefit appears to have been derived in the above-mentioned case, it does not follow that the drug would necessarily have a similar influence for good in cancer generally or in other situations.

Copper compounds of amino-acids were prepared by me in the Physiological Laboratory, King's College. Although such compounds were not new, I directed particular attention to copper glycine and copper alanine. I found that they were soluble in serum without precipitating the serum protein, or other proteins, and that they had a marked toxic action on protozoa, which suggested the use of this form of copper intravenously, and its possible use in protozoal diseases and in cancer. Experimentally the method itself in suitable dosage was found to be harmless. With regard to cancer I pointed out that any treatment with this form of copper was of an entirely experimental character. With the object of carrying out such experiments, I have given some of the copper alanine prepared by me in the laboratory to surgeons and others who have been sufficiently interested in the clinical action, and who have asked for it for trial. While palliative results seem to have been obtained in certain cases for a time,

no effect has been witnessed in others. As I have pointed out elsewhere, Mr. Aslett Baldwin, who has been kindly making investigation in a considerable number of cases of cancer and keeping me acquainted with the results, has not yet been able to come to any definite conclusion. With regard to dosage, 1 to 2.5 c.cm. of a 1 per cent. solution are stated to have been employed. In my own work nothing like this dosage has been given. It may be pointed out at once that it appears most unlikely that a 1 per cent. solution has actually been used, since copper alanine, although soluble in boiling water to that extent, crystallizes out if the solution be cooled to room temperature. By actual investigation it was determined that the approximate solubility of copper alanine at room temperature is 0.45 per cent. But as a saturated solution is obviously unadapted for general clinical use, a strength of 1 in 300 was recommended by me. From this it is already obvious that the injections referred to in the note must be less than the half of the amount of copper alanine stated.

The correct spelling of all amino-acids is with a final (e); alanine, not alamin, is therefore correct according to the terminology of the Chemical Society.

A SIMPLE SPECULUM ILLUMINATOR.

DR. HENRY DUTCH (London, W.) writes: I am sending a new combination instrument which I have called the G.P. pocket throat and ear outfit. By a simple attachment of a coilar to a miniature electric torch one can see with the laryngeal mirror the vocal cords and with the speculum the drum of the ear. A tongue spatula is also added, which gives perfect illumination of the throat and lances. Dentists can use the mirror for examining the teeth, and the work of the laryngologist is simplified. The outfit will be supplied by Messrs. Maw Son and Sons and other surgical instrument makers at the price of one guinea.

INSULAR ORTHOGRAPHY.

DR. C. S. PANTIN of Douglas has been good enough to send us a copy of a bill to amend the Workmen's Compensation Act of 1919, now before the Court of Tynwald of the Isle of Man. Section 4 (4) of this bill strikes him as so funny that he wants others to enjoy it. It runs thus:

(4) In the third schedule of the principal Act, for the word "celibititis" there shall be read the word "cellutitis"; for the words "of the patella" there shall be read the words "over the patella"; for the word "bevisitis" there shall be read the word "hurstitis"; and for the word "synovial" there shall be read the word "syovovial." The principal Act shall be read and construed as if the amendments in this section had always formed part of such Act.

Manx compositors would appear to have original notions upon the subject of medical nomenclature, and we are rather afraid that a further amending Act may be necessary in order to regularize the disease "cellutitis." Dr. Pantin adds that it will not surprise our readers to learn that the Government that produces such legislation has recently appointed a commission of thirty persons to consider health insurance, and has not put any medical man on the commission.

THE TAGLIACOTIAN DOCTRINE.

LIEUT.-COLONEL B. L. MILLS, M.D., R.A.M.C. (retired), writes: Colonel J. Smyth, I.M.S., should verify his references before quoting Indian mythology. At Ganesha's birth his mother insisted on Saturn looking at him, with the result that the infant's head was burnt off by his gaze. Indra rushed out and cut off the first animal's head that he met, which was an elephant, and placed it on the infant, who recovered and became the Hindu god of prudence and policy.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 34, 37, 38, 39, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 35, 36, and 37.

THE following appointments of certifying factory surgeons are vacant: Bovey Tracey (Devon), Coupar Angus (Perth), Great Wakering (Essex), Hatfield (Hertford), Sligo (Sligo), Woburn Sands (Bedford).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	l	s.	d.
Seven lines and under	0 6 0
Each additional line	0 0 9
Whole single column	4 0 0
Whole page	12 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *posto restante* letters addressed either in initials or numbers.

An Address ON FLAIL JOINTS AND THEIR TREATMENT.

DELIVERED TO THE AMERICAN COLLEGE OF SURGEONS,
OCTOBER, 1919.

BY

SIR ROBERT JONES, K.B.E., C.B., M.CH.,
F.R.C.S. ENG., IREL., AND EDIN., F.A.C.S. U.S.A.

ONE of the common products of the results of war injuries is the flail joint; in other words, a pseudarthrosis which is of very imperfect function, because the bones forming it do not come in contact, and, in consequence, the lever is imperfect because it has no fulcrum. The greater number of these disabilities are the direct results of excisions deliberately performed at casualty clearing stations or base hospitals. They were performed in order to save the limb from amputation, or the patient from death by minimizing local sepsis and preventing general sepsis. Joints are difficult to drain, and the excision simplified the immediate problem. The only competent judges of the necessity of these measures were the surgeons at the front, upon whom rested so many grave responsibilities. It is our duty to recognize this, and to try to make suggestions for the immediate and later treatment of these loose joints in order to minimize the loss of function.

It is well, however, to realize, as judged from cases which have arrived at our centres, that upon the type of resection largely depends good or bad function. Cases of so-called limited resection have resulted in better function than where the excision has been extensive. Furthermore, cases in which the sepsis has been overcome and the bones allowed to remain in position have resulted usually in very good and firm ankylosis with excellent function if the position of election has been maintained. There is no reason why any joint should be allowed to heal at functional disadvantage. This, however, is even yet not sufficiently appreciated. I draw attention to this, not as a matter of adverse criticism, but in case one may be tempted sometimes to excise too much bone, or to forget that many most excellent results are chronicled where excision has not been resorted to.

The flail joint may follow—

- (a) As a direct result of excision.
- (b) The removal of large comminuted masses of bone.
- (c) The direct loss of bone from missile.
- (d) The extrusion of necrosed bone during sepsis.

METHODS OF PREVENTION.

In considering the prevention of flail joints we have to bear three principles in mind: (a) The extent of excision should be strictly limited, subject only to conditions of safety; (b) the extension applied should be very moderate; and (c) ankylosis should be aimed at rather than mobility.

(a) *The Limitation of Extent of Excision.*

This is very important. Muscular attachments which have important influence in maintaining good function should be spared where possible. The tuberosities of the humerus, the nerve supply of the deltoid, the condylar attachments of the muscles governing the elbow, the triceps expansion, the biceps insertion, the coronoid, and, if possible, the whole or a portion of the olecranon should be preserved.

Again, we should endeavour to retain as much width of the lower end of the humerus as is possible, in order to allow the surgeon to restore leverage later.

If it be impossible to leave the important muscular attachments *in situ*, it may be possible to chisel off the portion of bones to which the muscles are inserted—such as the olecranon, tubercle of radius, coronoid process, and the tuberosities of the humerus.

(b) *Extension should be Moderate.*

We should strictly limit extension both in extent and time. I have seen several cases in which after excision of elbow a Thomas arm splint has been applied for three months and more with separation of the joint surfaces for many inches. The extension should be strictly limited to

the urgent needs of drainage. Strong extension of a limb where the joint has been excised obstructs free drainage. The extension, if necessary at all, should be of the lightest kind and maintained for the shortest period possible. An abducted shoulder and a flexed elbow admit of excellent drainage. In the case of the shoulder and of the elbow the dependent position of the arm and forearm permits of pus tracking down the muscular planes.

(c) *Ankylosis.*

The rule should be to aim for ankylosis in the best position for function. We need not again enter into the arguments for and against mobility. The fact that we aim for ankylosis does not mean we shall attain it. We very rarely can, but the effort leaves us the best possible result for future reconstruction. The rule, therefore, for the surgeon at the front should be that so soon as possible he should place the bones as near together as he can, and in the best position for future function, whether pseudarthrosis or ankylosis occur.

TREATMENT OF THE FLAIL JOINT.

The flail joint as we meet it is practically useless from the point of view of function, and it demands mechanical or operative treatment or a combination of both.

Treatment may consist of (a) removal of necrotic bone and scar tissue, (b) postural treatment, (c) operative attempts at improved pseudarthrosis, (d) production of ankylosis, (e) retention in mechanical apparatus.

(a) *EXCISION OF SINUSES, SCARS, AND INFECTED BONE.*

A fair proportion of flail joints—especially the shoulder—are infected and discharging. Where it is possible they should be treated as in the case of osteomyelitis elsewhere, by excision of sinuses, scars, and infected bone. Whether operated upon or not, the bone surfaces should be approximated and retained in the functional position. A proportion of cases take in their slack and ankylose, or a much firmer pseudarthrosis results. The shoulder and elbow are the joints most responsive to this treatment.

(b) *POSTURAL TREATMENT.*

When all wounds are healed the shoulder should be placed in the functional position either by means of an abduction splint or an angular elbow splint or in plaster. The latter method lends itself very well to these two joints, and gives the much needed stability. The bones should be insinuated into juxtaposition to each other without crumpling the soft tissue between them. Immobility should be secured for at least three months.

If the muscles governing the joint retain power, the after-treatment must be carefully conducted. In the shoulder the upper portion of the plaster support should be removed, so that the arm rests on the gutter-shaped under part of the case. The patient should be allowed liberty to exercise his deltoid, and when he can lift it slightly from the case the arm can be brought a little nearer to the side and fixed in an abduction splint whose angle has been lessened, and a larger range of movement may be allowed to the scapula and humerus. The arm is still further lowered until it can be safely dropped to the side.

If the pseudarthrosis is bony or short fibrous, the shoulder blade becomes the joint. If there is free mobility, the deltoid may be trained to lift the arm. This it does by raising the lower fragment and drawing it against the axilla, the result being quite a useful functioning joint. The elbow, when it is removed from the sling, should be more acutely flexed, and the forearm slung by the wrist, in order to strengthen the biceps and brachialis anticus. As these muscles gain in power the forearm can be gradually lowered until it reaches a right angle. For a considerable time it should be kept from further extending, in order to retain the power gained by the flexor muscles. Such shoulders and elbows, however, are always weak, and in the elbow a considerable lateral instability results. A hinged splint with a shoulder cap will be of advantage in the case of the unstable elbow.

(c) *OPERATION TO IMPROVE PSEUDARTHROSIS.*

Attempts may be made at improving the stability of weak pseudarthrosis by operation. This should only be attempted when the muscles governing the joints may be reasonably expected to recover strength. The operation

consists in removing intervening scar tissue and bringing the bone into contact. They may be kept together by means of kangaroo tendon or other absorbable material. In the case of the humerus a bone graft may be used to lengthen the shaft, but we will discuss the position of bone grafting later.

(d) ANKYLOSIS.

Ankylosis of the flail joint, often a difficult matter, will be discussed in relation to the joints involved.

Flail Hip.

If the femur has merely been deprived of the head and neck all that is needed is to correct any deformity which obstructs walking—such as adduction. This can be done by division of the adductors. If the limb cannot bear weight a jointed calliper splint should be applied. This supplies an artificial lever, and the muscles governing flexion resume more of their function. With such a splint the patient can walk long distances with ease and strength. When the trochanter and part of the shaft are also lost this splint proves very useful. Bone grafting, as usually understood, is of no use in the upper part of the femur. Ankylosis in the case of limited excision of the hip is of no advantage, and certainly does not justify the severe operation which it would necessarily entail. If the trochanter and part of the shaft has been removed, the most likely method of obtaining ankylosis is to take a long strip of femur half its thickness and slide it into a prepared acetabulum. The slide should rest for two or three inches in the groove of the femur. Such a graft has a much better chance of life than when introduced from another part of the body. A thin graft removed from elsewhere never develops strength in the adult and will refracture.

Knee.

Ankylosis of this joint is the only practical treatment, and if the bones are in good condition nothing is needed excepting to saw the ends and fix with screw or nail. If there is wide separation, however, and the ends have been associated with sinuses, union is not easily secured. In such a case it will be necessary, after sawing the ends of the bone, to bring a bulky sliding graft from tibia or femur and wedge it in at right angles to the line of the joint. This is a method I have often employed in secondary excisions where union has not been firm. If there is shortening to the extent of many inches the patient may prefer an artificial limb, and he may supply arguments worthy the surgeon's consideration. If an operation is refused, the calliper splint and a high boot will afford the best help.

Ankle.

Flail ankle is so rare that I cannot recall an instance as the result of a war wound. Should it be met with, the treatment will lie between an ankylosis or an amputation.

Flail Shoulder.

I have already described the postural treatment of flail joint, and have mentioned that a successful pseudoarthrosis does not often occur in the case of the shoulder. In a limited number of cases where the head of the bone only has been removed, and where the muscles attached to the tuberosities and the deltoid are functioning, abduction and carefully conducted muscle re-education may result in a joint preferred by some people to an ankylosis. The very flail joint can only be approached with confidence if an ankylosis is aimed at. I have seen certain cases where a graft of bone has been introduced to lengthen the shaft—in one case the upper part of the fibula—with results which I would call promising. I have also seen cases in which these grafts have refractured (they never unite again), and others in which they have been absorbed, leaving the patient in a worse plight than before. The result of my experience is that I would prefer adopting a more certain route, such as the production of ankylosis by end-to-end apposition.

Captain Platt has described a method of bone transplant which may still be considered under trial. It is an attempted reconstruction of the head of the humerus in order to obtain a fulcrum for scapular movement. He takes a large autogenous graft from the tibia, shaped like a wooden mallet. The shoulder-joint is exposed, the upper

end of the humerus cleared, and the handle of the graft driven into the medullary cavity. The wide upper end is now brought into contact with the glenoid cavity, which has been completely bared as in an ordinary arthrodesis operation. On occasions he has used a long fascia lata sling carried through the upper end of the humerus, the upper margin of the glenoid, and the acromion process. After completion of the operation the arm is placed in abduction until stability is secured.

Many operations for fixing the shoulder have failed because the surgeon has been content to bare the glenoid and freshen the humerus. This is usually insufficient. If the deltoid has been hopelessly deprived of function, an excellent exposure can be obtained by turning back a flap of skin and exposing the upper part of the deltoid; this muscle can be cut across or reflected upwards as a flap. The joint is fully exposed, and the glenoid can be gouged as deeply as possible. The base of the coracoid and the acromion should be chiselled, and the bony flaps left attached. The upper part of the humerus should be exposed and sawn through, and a groove made into the upper part of the shaft for the reception of the acromion. The humerus is pushed into the glenoid and the acromion sawn through and received into the groove prepared for it. The glenoid, humerus, and acromion should be fixed in contact by kangaroo tendon and placed in the functional position.

Major Naughton Dunn has pointed out to me that if there be much shortening of the humerus the functional position will vary from that which I have advocated. If there is no loss of bone the position of selection is just in front of the coronal plane of the body, while if there is much loss of bone it will be necessary to fix it in a plane posterior to this, otherwise in flexion of the elbow the hand will pass beyond the mouth. It is advisable before fixing the shoulder to test the position by flexing the elbow and observing the function. Dunn has described the operation he performs; it is very similar to that already mentioned. He makes an anterior incision, freshens and exposes the upper end of the humerus by removal of the sclerosed ends in one or two positions. These fragments of bone are retained with their blood supply intact to form new attachments and help to strengthen the arthrodesis. The under surface of the acromion is removed by a gouge from without inwards to oppose the upper margin of the glenoid cavity. This partially detached piece of bone is then folded into the space between the under surface of the clavicle and the upper margin of the glenoid cavity. The acromion process is divided about one inch from its extremity so that it may be brought into direct apposition with a prepared surface on the shaft of the humerus. The prepared shaft of the humerus is impacted into the glenoid cavity and maintained there by suture.

After all operations to obtain ankylosis the arm should be immobilized for three months.

Before the arm is ankylosed care should be taken to ascertain whether the scapula is mobile, also whether it retains its normal position in regard to the humerus. This is extremely important. The success of the operation depends on sound ankylosis and a mobile scapula. If the scapula is fixed the result of the operation is a tragedy, as the patient has a fixed abducted shoulder which he cannot lower. I have seen several such results.

After operation great care should be taken to exercise and re-educate the scapular muscles. The range of scapular movement in the young soldier increases for many months.

Flail Elbow.

Two methods of treatment are available here: (a) the non-operative, and (b) the operative. How can we predict the case in which it is impossible to bring about stability without operation?

The non-operative method consists of the approximation of the bone ends, counteracting the effect of gravity, and in muscle re-education and development. It also often involves the wearing of apparatus.

The operative treatment has one of two ends: (a) the formation of a bony ankylosis, or (b) the provision of a mobile arm with stability.

The non-operative treatment is only likely to be successful where the bone ends are broad. If the bone ends are pointed and distant, non-operative treatment cannot be successful even with good muscular control.

Ankylosis of the Elbow.

Many surgeons have described how difficult it is to obtain union in flail elbows. Failure is probably due to a technique which trusts too much to limited surfaces of attachment. There is so little vitality in the ends of the bones that a mere freshening with apposition and fixation will often fail to accomplish union. When nails are driven in the result is no better and further interference with blood supply is threatened.

The operation to be desired is one whereby a larger apposition of raw surface is secured. This can be effected at times by splitting the ends of the bones, and in this way widening them. Naughton Dunn has described to me the scheme he adopts with results I know to be satisfactory. He makes a subperiosteal exposure of the fragments to within an inch of their extremity, and completes this exposure by partially detaching a portion of bone triangular in shape from each side of the extremity of the shafts of the humerus, radius, and ulna, leaving them anchored by periosteum. This permits of an enlarged area of bone apposition and more productive osteogenesis.

Several such operations are practised with variations in detail. The principle remains that pieces of bone should be so arranged as to allow of good apposition.

Pseudarthrosis of the Elbow.

We need not now discuss pseudarthrosis of the elbow when this operation is performed for mobilizing an ankylosis. It is a different proposition when we wish to stabilize a flail joint and yet permit of voluntary movement. A necessary condition to the success of this operation is a sound muscular control. If this is not present the operation should never be performed.

Captain McMurray has had a successful series of cases by employing a scheme the object of which is to secure movement with improved lateral stability. A vertical incision is made over the posterior aspect of the joint of a length varying with the amount of bone missing, and extending about $2\frac{1}{2}$ in. over the upper end of the ulna and the lower end of the humerus.

The lower end of the humerus is completely cleared from the overlying tissues for a distance of 2 in. The upper end of the radius and ulna are likewise cleared completely to the level of the orbicular ligament.

It is generally found that the olecranon has been removed at the time of wound or operation, and if this be so the lower end of the humerus is made into the shape of a wedge by removing bone laterally, thus—

A wedge of bone is removed from the neighbouring sides of the radius and ulna, as shown above; this wedge is larger in extent than is necessary to contain the wedged lower end of the humerus. A flap of fascia is now prepared for placing round the lower end of the humerus to prevent any adhesions between the bones. This flap may be taken from the tissues in the neighbourhood, if these have not been destroyed, or it may be taken from the fascia lata of the thigh. The question whether this flap is free or pedunculated does not seem to be of any importance as both act equally well. Whichever flap is taken is sutured in position round the lower end of the humerus, which is then placed deep into the space between the upper end of the radius and ulna so that the ends of these bones project behind the humerus. A drill is then passed through the three bones in this position, and the relative position of the bone maintained by means of kangaroo tendon. If the triceps has lost its attachment to the upper end of the ulna, it is now freed from adhesions and attached securely to the upper end of the bone.

If the olecranon is present at the time of operation the wedge from the radius and ulna is taken at the same spot as before and the olecranon is left projecting back from the humerus—so increasing the power of the leverage which is obtained at the elbow-joint.

The arm is fixed in abduction, and voluntary movements encouraged after three weeks. After eight weeks

the arm is allowed down by the side, and the tendency to stretching of the biceps is prevented by the wearing of a sling.

In order to render the joint less flail Captain Platt has devised an operation which consists essentially of binding the bone ends together by strips of fascia lata. After exposure and removal of scar tissue he drills the lower end of the humerus and the upper ends of the radius and ulna, and the artificial ligaments are carried through in planes at right angles to each other and tied securely—the knots being fixed by sutures—and the ends of the ligaments are then fixed to the remains of the joint capsule and the muscle insertions in this region. The limb is slung up in 40 degrees flexion, and muscle education is begun at an early stage. The training is begun in the position of abduction of the shoulder. The stability of the elbow is considerably improved by the operation.

The final results in these cases are very promising. Pronation and supination are lost, but, at a later date, if the ankylosis is firm, operation may be undertaken with a view of restoring this movement. This operation, practised by McMurray, is successful. The bony expansions of the V incision into radius and ulna prevent lateral mobility. If the operation fails an ankylosis in good position may be expected.

Flail Wrist.

This is so rare that I need only say that ankylosis should be performed if thereby function is likely to improve.

In attempting to produce ankylosis of any flail joints we often succeed in producing a satisfactory pseudarthrosis. When we directly aim at a pseudarthrosis we are in danger of losing stability.

STIFF JOINTS.

The stiff joints following injuries of war have to be approached with greater respect than in the case of those we met with in pre-war days. Latent sepsis so often present is almost a new phenomenon. The stiffness due to immobilization is far more intractable.

Extension of the Knee.

A fracture of the femur in pre-war days, either simple or compound, retained in a Thomas splint used to leave the knee-joint only temporarily stiff; a fortnight of massage and gentle movement was sufficient to restore mobility. This is not the case in fractures we are now dealing with, for the rigidity is much more pronounced, and a longer time is required to overcome it. Recent improvements in the Thomas splint, and the introduction of the calliper ice tong extension, make it quite unnecessary to keep the knee immobile for months, so that in future we should not have to face the problem of extreme rigidity. I will not deal now with the ordinary light periarticular adhesions which require only simple handling.

Gradual Flexion of the Knee.

Rigidity is sometimes so marked that surgeons have failed to make any impression upon it by attempts at forcible flexion—a procedure of doubtful wisdom and often very hazardous. Such cases will often yield to the influence of gravity and gradual pressure. A long posterior splint is applied, bent to an angle of 15 degrees. The extended limb is bandaged to this, and when the knee yields sufficiently to rest upon the splint it is allowed to remain there in order to permit the strained tissues to calm down. The bandage is then removed from below the knee and voluntary efforts are allowed towards extension. When this is secured, and not until then, the splint is bent a few more degrees, and the procedure is repeated. This plan is continued until sufficient flexion is obtained to enable the joint to be more vigorously exercised first by active and then by passive movements. Before this is done there must be assured the power of full voluntary extension. If the knee becomes firmly fixed in its new angle of flexion it is sufficient proof that this method of attack is premature or useless. In certain cases under anaesthesia a limited flexion can be recovered, but any attempt at increasing this is so resisted by firm tissue that the surgeon has to desist. If such a limb is fixed by splint or plaster in the newly gained position, and kept fixed for a week or so, a further gain can often be secured under anaesthesia on a second occasion. This can be repeated until a fair range

of movement is acquired. The fixation of resisting tissue under strain renders such tissue less obstructive. A recognition of this fact will prove very helpful to us in dealing with obstinate stiffness.

If when flexion is obtained in this way the limb remains firmly flexed and resists attempts at extension, we are not making progress. If on extending it again it becomes rigid in extension after reasonable rest, we may be sure that we are being met by tissues which undergo reaction of a type that does not admit of further force.

When strong periarticular adhesions are thus stretched, a certain transient degree of stiffness in the new position will occur, but after a short course of massage and voluntary effort this will disappear. The advantage of gradual stretching over rapid tearing is that haemorrhage and excessive inflammatory reaction are avoided. There is a still further and very vital reason why excessive force should not be applied; instances have happened in which the patella tendon has been torn or the patella fractured, and I have met also with cases in which the quadriceps has been ruptured.

I am convinced that in injuries of the knee, directly or indirectly resulting from war missiles, forcible manipulation has only a very limited field for application. It should be confined to the lighter type of so-called periarticular adhesions; and, as I have suggested, in the more rigid type of case the aim should be, if anaesthesia be employed, to obtain only a few degrees of movement in successive stages, with intervals of complete rest.

Operation.

Surgical intervention may be necessary in cases of (a) muscular adhesions to bone; (b) scarring and shortening of capsule; (c) intra-articular adhesions due to arthritis or fracture; (d) fixed patella; (e) bony ankylosis of femur and tibia.

Muscular Adhesions.

Muscular adhesions interfering with flexion are generally associated with the quadriceps. If the muscle is firmly bound down, the rigidity of the knee is very marked. These are the cases in which surgeons point out that after forcing the knee they have gained a slight degree of movement. If the knee is examined, however, it will be found that they have either lengthened the patellar ligament or sometimes ruptured it, and, although the knee will bend a few degrees, it cannot be voluntarily extended. These cases should never be subjected to forcible movement. They have often been associated with a compound fracture, or suppuration in muscle sheaths, or with osteomyelitis.

The operative treatment for adhesions of quadriceps is to detach the muscle from its adhesions, and to place a living flap of fat and fascia between it and the bone. The knee should be kept flexed during healing and the muscle subjected to electric stimulation.

Certain cases have suffered losses in muscle structure which have resulted in shortening, and operative elongation should be considered.

Shortening of Capsule.

The x-ray picture in a case with shortening of the capsule may exhibit a perfectly normal joint, and the patella be fairly free. There is no undue tension of the ligamentum patellae, the quadriceps is not adherent, and yet the knee is firmly rigid. With these symptoms we can safely make a diagnosis of tense or contracted capsule. This should be treated first of all on the lines laid down in regard to severe periarticular adhesions, and if the rigidity still persists operative interference may be called for.

Operation.—A curved incision should be made from the femoral attachments of the internal lateral ligaments to the tubercle of the patella. The capsule is exposed, and a curved incision made in it, extending from the anterior aspect of the ligament. The patellar tendon need not be divided if it does not obstruct; if it does it can be elongated. The operation is simple, and should involve no risk.

Intra-articular adhesions are treated by gradual flexion under careful observation. If signs of severe inflammatory reaction should appear, treatment by this method should cease. A little pain and some effusion need not interfere with the stretching. Severe pain, with rise of temperature and effusion, should warn us of trouble.

Adhesion of Patella to Bone.—The patella is sometimes bound down by adhesions to the femur, and this alone will cause fixation of the knee. If the adhesions are light they will sometimes yield to manipulation and exercise; if not, the bones may be freed by operation. Where the attachment is bony, separation may be effected by chisel, and a flap of fascia, or the bursa of the patella, introduced between the bones. If the attachment is extensive and rugged the bones should be slightly excavated and made smooth. Horsley's wax can be rubbed into the femoral erosion, and the bursa laid upon the surface of the patella.

Complete Ankylosis.—If ankylosis is complete and the bones are in good position no surgical interference is needed.

Arthroplasty.—In my opinion, arthroplasty of the knee has no place in military surgery. Cases have been met with in which a gunshot wound, not complicated by sepsis, has caused very limited ankylosis. Such conditions can be operated upon with advantage if the joint is otherwise healthy. It is better not to introduce flaps of tissue, but, after chiselling through the obstruction, to excavate the attachments, making them saucer shaped, rubbing in Horsley's wax as recommended by Stiles, and if possible keeping the knee in any position whereby the raw surfaces are least in contact. Ankylosis may occur, however, in bad position. This may present flexion deformity, lateral deviation, genu recurvatum, or a combination of all these.

Flexion of the Knee.

If the knee is flexed and sound and painless, with no more than 30 degrees of flexion, it is best to leave it alone. If the flexion exceeds that, an operation may be considered, but the advantages and disadvantages should be fully discussed with the patient.

Operation.—A wedge of bone should be removed from the front of the knee, so that when the bones are wedged together firmly the knee should remain at an angle of about 15 degrees.

I have always advised placing the knee-joint fully extended while we wait for an ankylosis to occur in inflammatory conditions, and also where we have to perform a classical excision. To keep such knees in a slight degree of flexion is often difficult and jeopardizes firm union. When, however, we excise a wedge, these difficulties do not arise, and an angle of 15 or 20 degrees gives a very useful limb from the point of view of function. Supracondylar osteotomy, unless planned to avoid recrudescence of sepsis, is inadvisable, as the result is never so artistic, more especially if the flexion is marked.

Lateral deviation should be treated as in a case of genu valgum by supracondylar osteotomy.

Genu Recurvatum.

This is best treated by supracondylar osteotomy. It is not necessary to remove a wedge. Great care should be taken to prevent sagging at the site of incision. The success of this operation depends entirely upon keeping the femur bowed forwards at the site of the osteotomy incision. After excision and osteotomy a calliper splint should be worn for three months.

We must remember that sound bony ankylosis in a good position is much more useful than an unsound ankylosis with limited and painful movement. Such an unsound ankylosis often has to be transformed into bony fixation. Bone grafting, although it may be useful in fixing a flail joint, is never needed as an accessory to completing the fixation of a painful fibrous flexed ankylosis. Stability of the knee yields better function than a flail pseudarthrosis.

SOME experiments reported to the American Chemical Society by Hirschfelder, Lang, and Feaman showed that the smoke coming from a given weight of tobacco in a cigar, cigarette, or pipe varied somewhat, but not very greatly, in its poisonous action on frogs. When the same weight of the same sample of tobacco was smoked as a cigar, in a pipe, or as a cigarette there was very little difference in the poisonous quality of the smoke, but usually that from the cigarette was less poisonous. This is attributed to the fact that much more tobacco is being converted into smoke in a given time in a pipe or cigar than in a cigarette. The burning occurs chiefly at the surface, and cigars have about four times the cross section of cigarettes, and pipes may have ten times. Cigarette smoking, if the smoker does not inhale, is the lightest form of tobacco smoking.

The Lettsonian Lectures

ON

TUMOURS COMPLICATING PREGNANCY, LABOUR, AND THE PUERPERIUM.

DELIVERED BEFORE THE MEDICAL SOCIETY OF LONDON,

BY

HERBERT R. SPENCER, M.D., B.S., F.R.C.P.,
OBSTETRIC PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL.

(Abstract.)

LECTURE I.—FIBROID TUMOUR COMPLICATING PREGNANCY, LABOUR AND PUERPERIUM.*

The notes of thirty-seven cases were given illustrating the following points: First, that in a large number of cases of small tumours patients pass through pregnancy and labour without difficulty. Even in the case of large tumours—some as large as an adult's head—no difficulty may arise. This is illustrated by eight cases. The danger of pedunculated reniform tumours becoming rotated and causing inflammation is illustrated by a case. Three cases of retroversion and retroflexion of the pregnant uterus produced by fibroids, one of acute antelexion, and two of inversion of the uterus were mentioned; in seven cases submucous tumours were removed after childbirth or miscarriage by enucleation through the os uteri. In these cases, although sepsis occurred, hysterectomy was not necessary. The lecture was illustrated by numerous diagrams made from tracings of tumours on glass, showing the evolution and involution of the tumours. Three fatal cases were described, one from nipping of the ileum between two pedunculated subperitoneal fibroids; the second from twisted infected subperitoneal reniform tumour; the third was infected with *Bacillus welchii*, and died of acute sepsis after Caesarean section. The after-histories were given in many cases, extending in some instances for periods as long as twenty-five years.

Frequency.

Fibroid tumours complicating pregnancy are quite common, though very divergent opinions have been expressed by eminent obstetricians on this point. I think it may be stated with an approximation to accuracy that fibroids occur about once in 150 pregnancies.

Age.

Bayle, in 1813, wrote that "fibroids scarcely ever appeared before the age of 30 years," but were present in nearly every woman over 40 who had preserved the physical signs of virginity; and Virchow stated that he had examined the corpses of few old virgins in which fibroids were not found, although in many women who had borne children the uterus remained free from them even in extreme old age.

Fibroids rarely occur before the age of 25, and are practically unknown before puberty. The slow growth of these tumours, their occasional occurrence at an early age, and the severe dysmenorrhoea they cause years before they become manifest clinically have led to the suggestion that they are of congenital origin; but Essen-Möller has examined the uteri of 20 fetuses and sucklings, and I have examined the uteri of 100 stillborn girls without finding any sign of myoma.

Taking the ordinary period of woman's fertility at thirty years, we may recognize that in the first ten years during which she may become pregnant she is extremely unlikely to have a fibroid, and that only in the next twenty years is she liable to both. These facts invalidate most of the voluminous statistics of sterility and abortion in women with fibroids. These tumours have a certain influence in causing sterility and abortion, but it is slight. On the other hand there seems to be reason to believe that sterility favours the occurrence of fibroids, and that regular child-bearing and suckling to some extent prevent their occurrence.

Effect of Pregnancy on Fibroids.

When a patient with fibroids becomes pregnant the tumours usually increase in size owing to oedema, hypertrophy, and hyperplasia; the muscle cells become greatly

hypertrophied, often swollen and sometimes vacuolated and occasionally developed into large cells resembling the decidual cells of the endometrium (Gordon Loy). The development of the tumours varies; usually they enlarge; sometimes no increase is noticeable; occasionally they appear to diminish; their shape is apt to become flatter and their consistence softer than in the unimpregnated organ. They may become more prominent as pregnancy proceeds, and alter their shape to clinical examination owing to change in their location or axes. They may become fixed by impaction in the pelvis or by inflammation resulting from mucous degeneration, necrobiosis, or infection. The necrobiotic fibroid is either grey or pinkish-grey or red (usually of a dusky tinge)—the so-called "red degeneration," which is not confined to the pregnant uterus, and in my experience is quite as common in the unimpregnated. Degeneration of the fibroid is sometimes accompanied by degeneration of the uterine muscle, which may be more markedly affected than the tumour. The degenerated fibroid may be sterile or may be infected; occasionally it suppurates, especially in the puerperium. It would appear that the degenerated or cystic fibroid forms a good cultivating medium for micro-organisms which may be dormant during the pregnancy. I have found an abscess containing a pure culture of streptococci in the centre of a fibroid in a virgin who gave no clinical sign of its presence except a cachectic appearance; it seems, therefore, that infection of degenerated fibroids may occur from the blood stream. The ordinary route of infection by the vagina often leads to necrosis of submucous tumours. Calcification sometimes occurs in fibroids complicating pregnancy, whether the tumours are of uterine or ovarian origin.

After labour the tumours usually diminish in size and alter in shape owing to their rearrangement in the emptied organ. The subperitoneal tumours sometimes do not diminish very markedly in the puerperal month. Their apparent rapid diminution is rather due to increased difficulty of examination.

CASE 12.—Large Fibroid: Natural Delivery: Slight Involution after Labour.

S. H., a nullipara, aged 35, had a large tumour in the upper right wall of the uterus. She had a slightly contracted pelvis, the diagonal conjugata being 4½ inches. On this account labour

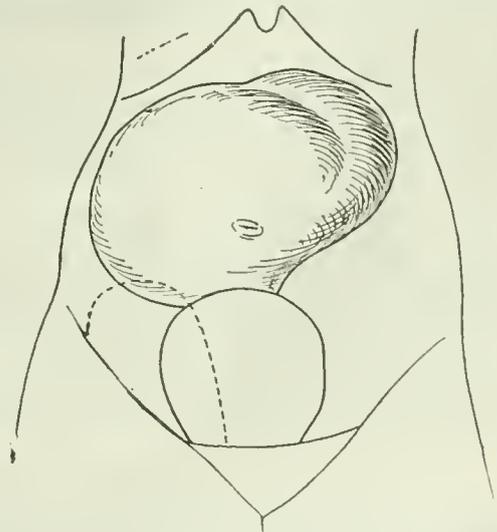

FIG. 1.—Case 12. Immediately after labour: showing tumour larger than an adult's head. The dotted line shows distended bladder.

was induced by bougies and the patient was delivered naturally of a child weighing 8 lb. 1½ oz. Both mother and child recovered. The fibroid underwent only slight involution (from 9½ in. by 6½ in. to 8½ in. by 6 in.) in a fortnight after labour.

CASE 6.—Large Fibroids: Natural Delivery: Apparent Disappearance of Tumours Fourteen Years Later.

T., aged 42, married eight years, never previously pregnant. Was sent to me by Dr. Pearse of Ripley on April 26th, 1905. She had complained of pain in the right side of the abdomen for the last two months. She was nearly five months pregnant, having last menstruated at the end of November. Menstruation had commenced at the age of 15, was always regular every four weeks, lasting three days, and being preceded usually by pain.

The uterus was much larger than it should be owing to a

* Delivered February 2nd. The full text contains notes of 37 cases.

fibroid about as big as a fetal head and a larger one as big as a cocoa-nut in the right cornu (see Fig. 2).

The child, a girl, was delivered alive (a breech presentation) by Dr. Pearse on October 2nd, 1905. The mother made an excellent recovery. The uterus contained such a large mass of fibroids that on the fourteenth day of the puerperium it

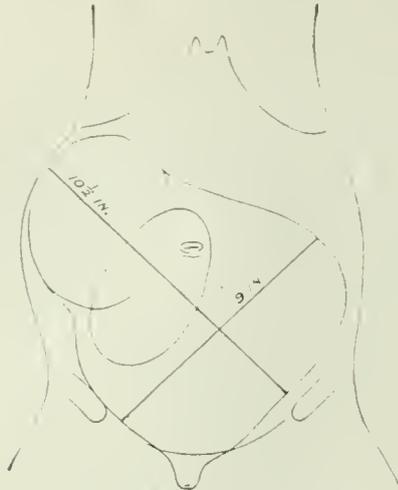

FIG. 2.—Case 6. Showing two large fibroids.

measured 10½ in. transversely and reached up for 1½ in. above the umbilicus.

Fourteen years later, on November 18th, 1919, mother and child were very fit and well in every respect; the child well developed and plump. The mother had not been pregnant again. Menstruation continued to be regular till 1911. Since then (when she was 50 years of age) she had "seen nothing."

Since fibroids undoubtedly in some cases undergo great diminution, they are supposed occasionally to disappear after labour; Olshausen's cautious opinion is that it is "not altogether impossible."

In view of the occurrence of rupture of cystic fibroids in the unimpregnated, of which I have seen an example, it is remarkable that there does not appear to be recorded a case of rupture of the pregnant uterus before the onset of labour. Rupture of veins with intraperitoneal haemorrhage is very rare; the two cases I have met with occurred in nulligravidae.

Torsion of pedunculated tumours sometimes occurs; it is especially liable to happen in the kidney-shaped tumours with pedicle at the hilum (see below). It is a dangerous accident; three out of twenty-one cases collected by Troell and one out of my three cases terminated fatally. This torsion may be transmitted to the uterus and even to the vagina.

Effect of Fibroids on Pregnancy.

Ectopic pregnancy is rarely met with. Troell, in 1910, found forty-nine cases of tubal pregnancy recorded in literature, but one case (Harley's) must be excluded, as the specimen, which is in University College Hospital museum, shows that it was an instance of ruptured uterine horn. I am, however, able to show two specimens of ruptured tube from the same museum.

Placenta praevia is said to occur with unusual frequency in the presence of uterine fibroids. Such a combination was observed in the following case:

CASE 32.—Submucous Fibroid; Placenta Praevia; Sepsis; Removal of Tumour; Recovery.

A. C., aged 35, married, had one pregnancy, resulting in the birth of a living child, eleven days before admission on July 21st, 1910. Three days before delivery she began to pass large clots and on the day before delivery she had a severe attack of haemorrhage (placenta praevia). Version was performed and a living child delivered. During the following week she had several attacks of shivering with high temperature (104°). I saw her in consultation on the eleventh day; the uterus was large and hard and reached 8 in. above the pubes. On examination through the os uteri a submucous fibroid as big as a fist could be felt on the right side. An offensive bloody discharge was present.

Vaginal douches of iodine solution were given, and on July 30th the cervix was dilated with Hegar's dilators and the fingers. The tumour was seized with Doyen's cutting forceps and removed in pieces; the base was very adherent, and in pulling on it the uterus was inverted. This enabled the remains of the tumour to be completely removed. The cavity was then swabbed with iodine solution (5j to Oj) and the uterus replaced. Iodoform gauze was packed in the uterus for a few hours. The tumour weighed 1 lb. 3½ oz. It was dull red in colour, and in

parts was covered with a yellowish-green slough. The operation lasted thirty-five minutes.

The temperature, which had varied from 104° to 100° before the operation, reached 100.8°, 100.8°, 101.6°, 103° in the first four days, then gradually fell to normal. The patient left the hospital on August 18th, 1910, and wrote seven months later to say that she was quite well.

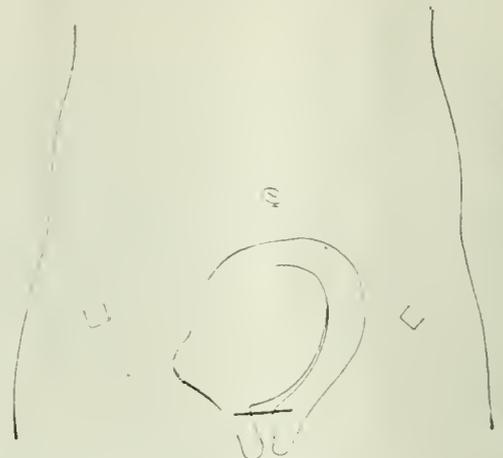

FIG. 3.—Case 32. Showing sloughing submucous fibroid eleven days after labour.

It is probable, however, that haemorrhages due to submucous fibroids or to the insertion of the placenta upon them are sometimes erroneously attributed to placenta praevia. The following case is an example of this occurrence:

CASE 31.—Submucous Tumours: Removed after Childbirth by Enucleation through the Os Uteri.

In the outdoor maternity of University College Hospital in 1897 a submucous fibroid measuring 5 cm. by 2.5 cm., to which a piece of placenta and membranes were attached, was removed immediately after labour from a patient aged 41. It was situated on the posterior wall of the body and was associated with haemorrhages during the pregnancy. The labour was natural till the third stage; the placenta was retained; it was during the manual extraction of the placenta that the tumour was discovered. The patient recovered well. Microscopic examination of the tumour showed hypertrophied muscle, adherent chorionic villi, and dilated glands.

It is to be noted that in such a case as this the haemorrhage may lead to the discovery of the tumour.

While abortion, except in the case of submucous tumours, does not appear to occur with much greater frequency than in normal uteri, both premature and post-mature labour are apt to occur.

Pain or tenderness over the tumour or uterus are frequent symptoms, especially in necrobiotic tumours. The pain is usually easily relieved by rest, light diet, and anodynes. I have never met with the "unbearable pain" which some authorities have given as a justification for performing hysterectomy in early pregnancy. In cases of torsion or inflammation or infection of the tumour the symptoms are acute and require prompt surgical interference. Pressure by the tumour on the veins may cause oedema of the lower limbs; albuminuria is not uncommon, and ascites may occur. Abnormal presentations, breech especially, are frequently met with. The labour is often surprisingly easy in view of the advanced age of many of the patients. Even in the case of tumours encroaching on the brim it is found that the tumour is often drawn up out of the way during labour. In some cases forceps may be required for inertia. Retention or incarceration of the placenta or decidua may occur (as in Case 31 reported above), and post-partum haemorrhage, if submucous tumours are present, may be severe. The following is an example of retention of decidua after a miscarriage:

CASE 35.—Miscarriage; Sepsis; Enucleation of Submucous Myoma and Removal of Decidua; Recovery; Twenty Years Later Death from Sarcoma.

On October 24th, 1898, at 11 p.m., I saw with Dr. Webb of Netley a lady, aged 34, suffering from fever (temperature 100°, pulse 120) and foul discharge after a miscarriage which had occurred six days previously at the second month. A consultation had been held and the finger had been passed into the uterus, the lining of which was smooth, but the origin of the foul discharge was not discovered. Under chloroform I introduced my finger and found the smooth condition of the lower uterine canal, but I also felt bulging into the cavity a sessile submucous myoma as

big as a walnut; above this, which acted as a ball valve, some putrid decidua could be touched. I enucleated the myoma, removed a mass of putrid decidua, and washed out the uterus with 1 in 3,000 mercury perchloride solution. The temperature fell to normal, and the patient recovered perfectly.

I attended her subsequently in her confinement on December 23rd, 1901, which was quite normal; she also had a second child without any difficulty. She remained in good health till 1917, when she began to lose considerably, and the abdomen increased in size. She became cachectic. I saw her in consultation with Dr. Blaikie and Sir Thomas Barlow on October 5th, 1917. She had a large fixed irregular uterine tumour nearly filling the abdomen, especially on the left side. She had also pleural effusion and haemoptysis, and other signs of growth in the lungs. From the cachectic condition, the haemorrhages, and foul discharge it appeared probable that the growth was a uterine sarcoma. She gradually wasted, and died in February, 1918, nearly twenty years after the enucleation of the fibroid.

The following is a remarkable instance of the value of conservative treatment in a case of pregnancy complicated with large tumours:

CASE 7.—Multiple Fibroids causing Obstruction (sixth week) and Albuminuria (eighth month): Induction of Labour: Mother and Child Living Twenty Years Later.

On September 26th, 1894, M., a nullipara aged 37, was sent to me by Dr. Lennox Wainwright, of Folkestone. She had been married twice, the first time at the age of 20, but although married many years to her first husband no coitus had occurred. Her second marriage took place on July 1st, 1894. A few days

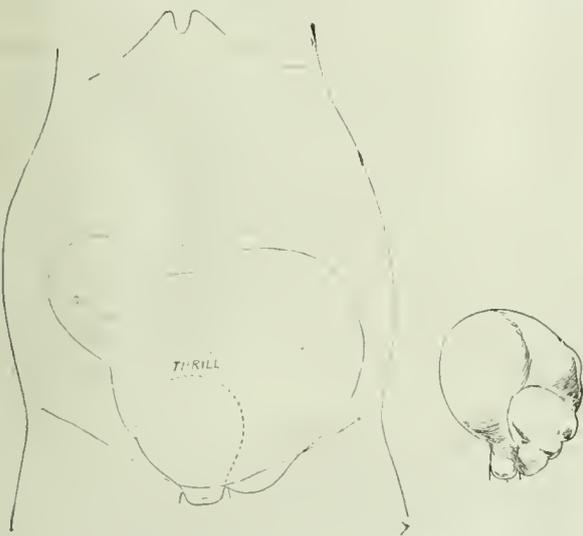

FIG 4.—Case 7. The larger figure shows the size of the tumour at the sixth week of pregnancy; the smaller figure shows the size of the uterus twenty years later.

afterwards she had a period, but had seen nothing since. In the last three days she had been sick, and for three weeks she had had frequency of micturition. At the age of 14 she had an attack of peritonitis, which was repeated in 1886 and 1892, and since then had had several threatenings, and a well marked attack three weeks ago.

Menstruation began at the age of 11, and was regular except at the age of 19, when it stopped for thirteen months; it was always very painful.

On examination the abdomen was tender and distended by a tumour, which reached up to the umbilicus on the left side and rather higher on the right, where there was a marked movable projection as big as a fist.

The tumour felt like a myoma, and near the middle of it there was a marked thrill.

The uterus was retroverted, apparently enlarged, and seemed to pass into a hard mass above and around the cervix. To the left of the cervix projected a solid mass connected with the uterus. This mass came down to the level of the edge of the cervix. The diagnosis was made of pregnancy of two to two and a half months complicated with multiple fibroids.

With rest the patient progressed fairly well, but a month later, on October 28th, 1894, I was called to Folkestone to see her, and found her extremely ill, vomiting frequently, and obstinately constipated. A large enema of soap and water was administered, with the result that motions were passed and the patient recovered completely. At this time the fundus had risen out of the pelvis, but the fibroid on the left side still occupied the brim. At the beginning of April, 1895, the patient came up to London to a nursing home with a view to having Caesarean section performed. The urine was found to contain a large quantity of albumin. The head was above the brim, and the lower end of the large fibroid just entered the pelvic brim on the left side, otherwise the pelvis was free and of full dimensions. I had the advantage of a consultation with Sir John Williams, and it was decided to induce labour on

account of the albuminuria. This was done with bougies. During the labour the fibroid on the left side retracted above the brim and a well developed girl of about eight and a half months' development was born alive, after a normal labour, on April 7th, 1895. This girl grew up a very well developed woman, and married in 1914.

On May 7th, 1914, I saw the mother, aged 57, in good health. Menstruation stopped at the age of 47. The uterus was of the size of a fist.

On the whole, in cases suitable for delivery *per vias naturales*, the labour is often normal, even when the tumours in the upper part of the uterus are quite large. In cases, however, in which injudicious attempts are made to deliver the child by forceps or version past tumours even of small size, dangerous bruising of the tumours or even rupture of the uterus may occur.

Diagnosis.

The diagnosis of pregnancy and of fibroids sometimes presents difficulties which are increased when the two are combined. It is more likely that a mistake will be made with regard to the pregnancy than the fibroid. In the first half of pregnancy the great factors in the diagnosis are the suppression of the menses, even if only for a few days, and a uterus larger than it should be and irregular in shape, the irregularities being hard. A uterus may be irregular from pregnancy in one corner—a lop-sided uterus—but it has the normal consistence; when it contracts and becomes hard it assumes the normal shape. If the pregnancy is advanced to the second or third month, the softness of the cervix and body are characteristic, the latter being sometimes best felt on rectal examination. In the early months the points to bear in mind are the cessation of menstruation, the rapid growth of the tumour, the consistence of the uterus, and the hard irregularities upon it.

In the second half of pregnancy when the "certain" signs—heart sounds, parts or movements of the child, and ballottement—are available, difficulties in diagnosis are sometimes met with. In very rare cases, of which I have seen only two or three instances, the uterus remains as hard as a fibroid throughout pregnancy, and is not subject to those periodical relaxations and contractions which ordinarily characterize it. On the other hand, a degenerated fibroid uterus, by its consistence and livid appearance, may closely simulate a pregnant uterus with its contained fetus, but the certain signs and the breast changes are, of course, absent; menstruation is usually excessive, and I believe the bulging of the anterior lower segment which is sometimes seen in the case of fibroids is never met with in normal pregnancy, though it may be found extremely marked in retroflexion of the pregnant uterus produced by fibroid of the fundus adherent in the pelvis. When there are irregularities on the surface of the pregnant uterus the diagnosis is simplified; the prominences are hard, the pregnant uterus soft and contractile; the fibroids do not alter their position as parts of the fetus do, and they may become more marked during uterine contractions, which obliterate the fetal parts; at most the tumours have a slight mobility, but return to the same position even when repeatedly examined. A large sub-peritoneal or intramural growth or small multiple growths may render the palpation of the fetus difficult till the pregnancy is somewhat advanced.

If the fibroids are degenerated they may feel softer than the rest of the uterus when the latter contracts, as in the following case:

CASE 30.—Miscarriage: Intramural Fibroids: Recovery: Caesarean Section in subsequent Pregnancy: Acute Sepsis (Infection of Tumour): Death.

A. S., aged 42, married in 1904; no children, one abortion (December, 1914); had been an in-patient on December 17th, 1914, at University College Hospital for incomplete miscarriage of about nine weeks, brought on by the use of abortifacients. The retained decidua was putrid, and on removing it an intramural myoma as large as an orange was found in the anterior wall of the uterus. An iodine douche was given, and gauze applied for twelve hours as bleeding was profuse. She recovered well, though the temperature was raised to 100° on three occasions up to the ninth day and up to 99.6° on the thirty second day; the pulse also varied from 80 to 96.

She was advised to submit to Caesarean section if she became pregnant again. Accordingly she was admitted to University College Hospital on February 21st, 1917; she was in good condition and near the term of pregnancy. The child was lying obliquely with the head below, displaced to the left by the fibroid,

which was felt in the lower segment, more on the right side than the left, as a softish tumour as big as a large orange, which came down into the pelvic brim. Two other small fibroids were felt in the body. The pelvic measurements were normal—10½, 11½, 8 in. The temperature was very slightly raised (99.4° on admission), but afterwards, till the operation, only twice reached 99°; the pulse varied between 88 and 104 (on admission 120). Caesarean section was performed on March 1st, 1917, at 1.30 p.m. The patient had had slight pains all night and strong pains after midday. The abdomen showed a marked prominence above the pubes, which looked like the distended bladder, but felt thicker-walled. It was prominent, but felt soft and fleshy when the uterus contracted; in the intervals between the contractions it felt of the same consistence as the rest of the uterus. The operation was a simple one; the uterus was sewn up with silk; the incision did not extend to the fibroid, which was not encroached upon. The child was delivered alive by the feet in forty seconds, and survived. The operation lasted fifty-two minutes. A submucous myoma as big as a walnut, to which the placenta had been attached and which had been felt on abdominal palpation, was excised. The patient suffered severely from shock, although she had no pain and said she felt well; the pulse and temperature rose to 100; and thirteen and a half hours after the operation she had a rigor and the pulse became very rapid. On the second day temperature 101°, pulse 120 to 166. On March 4th, sixty hours after the operation, at 1.30 a.m., she died. She vomited repeatedly, but this ceased on washing out the stomach. A good deal of flatus was passed per rectum on the second day, and the patient felt comfortable. There was no tenderness of the abdomen. Although she said she felt well but extremely weak, it was obvious she was sinking from acute sepsis.

Post-mortem Examination.—The abdomen was distended, the abdominal wound healthy. A little free fluid was present in the peritoneum, and a few flakes of lymph. The bowel was distended with gas, and had a film of pus over it in places. The deep surface of the wound in the abdominal wall showed early infection. The uterus was large and flabby, the incision was sloughy. The fibroid in the uterine wall felt soft and fluctuating. The uterus was hardened in formalin-salt solution. On opening it the fibroid was found to be of a deep red colour, with cavities containing bloody fluid and bubbles of gas in the uterine wall, as in gas gangrene. The weather was cold, and gas was found in many other tissues of the body. The *Bacillus welchii* was found by Dr. Teale in the tumour.

A degenerated and cystic fibroid may closely resemble an ovarian tumour, and sometimes cannot be distinguished from it, as in a case I recorded in the *Obstetrical Society's Transactions*, vol. xlv.

CASE 15.—*Large Degenerated Fibroid.*

On July 5th, 1901, I removed from a patient, aged 41, from the left broad ligament during labour, a tumour of which the solid part weighed over 17 lb. and was a foot in diameter. The child, dead before the operation, was easily delivered eight hours later. The patient had previously had four children, at the last labour twins, six years ago. The labours were all normal and the patient had never aborted. She had been very healthy all her life and had first noticed considerable enlargement of the abdomen two years earlier, but always noticed that the abdomen did not go flat after the labour.

In the following case a reniform tumour at the fourth month was diagnosed as a dermoid. Torsion had occurred.

CASE 16.—*Reniform Fibroid: Twisting of Pedicle: Septic Thrombosis: Death.*

Mrs. S., aged 27, a nullipara, was suddenly seized with pain and inflammation on the left side of the abdomen when four months pregnant. A tumour was found on the left side of the body of the uterus, very tender on examination, and was diagnosed as a twisted dermoid. The patient was removed without delay to a nursing home and the tumour removed by

abdominal section on May 20th, 1905. There were no adhesions but there was a little pus around the tumour, which was greatly congested owing to twisting of its pedicle, which was attached just inside the insertion of the left round ligament. Some difficulty occurred from haemorrhage owing to the vascularity of the pedicle; but the haemorrhage was stopped by understitching with fine silk. The patient progressed fairly well for two days, then had suppression of urine, secreting only 1½ oz. in sixteen hours, the urine containing one-third albumin and bile, and she died on the third day.

A *post-mortem* examination was not obtained and the tumour was not examined for micro-organisms, but the presence of pus shows that it was probably infected, and I think that death was probably due to septic thrombosis of the ovarian and renal veins. The tumour was a reniform subperitoneal pedunculated myoma weighing 9 oz. and measuring 11½ by 7 by 6 cm. The raw surface of attachment was at the "hilum." The section showed numerous haemorrhages into the tumour and green patches near the surface. There was a small tag of lymph on the surface.

A difficulty may occur in diagnosing twisted fibroids in the acute stage, though the hardness will be in favour of uterine fibroid and the age of the patient may assist the diagnosis. In all cases of difficulty, especially with impacted or inflamed tumours, examination under anaesthesia is of the greatest value.

I need only allude to the resemblance of a horn of a double uterus to a fibroid, for which it has been mistaken, leading to the sacrifice of the uterus, when excision or even replacement of the horn would have sufficed.

After the birth of the child the diagnosis of subperitoneal and intramural tumours is usually easy, owing to the lax state of the abdominal wall and the smaller size of the uterus. Submucous tumours may be overlooked, unless they give rise to haemorrhage or to fever from necrosis or gangrene. If the uterus is large and hard in the puerperium, a submucous fibroid should be suspected and the uterus should be explored. Fever may arise either from retention of the products of conception or from infection of the tumour, especially if it has undergone degeneration. A tender subperitoneal tumour in the puerperium, associated with fever, will suggest infection. I have known a large intramural tumour mistaken for a second twin; in that case the hardness of the tumour and the absence of signs of the fetus rendered the diagnosis easy, but were the tumours degenerated, considerable difficulty might arise; it would be overcome by exploration through the cervix.

A fibroid impacted in the pelvis, especially if cystic, may closely resemble an ovarian cyst, and a subperitoneal fibroid after abortion may resemble a tubal mole, but is to be distinguished by its hardness. Inversion of the uterus may occur, usually some weeks or months after labour or abortion. In addition to the usual signs of inversion, there will be a tumour usually separated by a groove and distinguishable from the uterus by its harder consistence. A case of mine in which these two points of distinction were absent is, so far as I know, unique.

Prognosis.

The prognosis is in the great majority of cases good when the patients are attended with judgement, and careful regard is paid to sepsis. The three fatal cases here published, which are all that I have met with, are examples of dangers which sometimes arise. The first

TABLE A.—*Author's Cases treated by Abdominal Myomectomy.*

No.	Age.	Children.	Abortion.	Date of Operation.	Adhesions.	Tumour.	Remarks.
1	41	4	0	July 5, 1901	To omentum and broad ligament	Cystic myoma 1 foot in diameter, solid part over 17 lb., and several pints of fluid.	Operation during labour. Mother recovered; child dead before operation. (Case 15.)
2	30	0	0	March 5, 1905	To omentum	Pedunculated twisted reniform tumour attached by hilum just internal to right round ligament, 11.5×9×5 cm.; vascular, degenerated, adhesions on surface.	Operation three weeks after abortion at fifth or sixth week. Mother recovered. (Case 17.)
3	27	0	0	March 20, 1906	No	Pedunculated twisted reniform tumour attached by hilum just internal to left round ligament. (See text.)	Operation at fourth month of pregnancy. Patient died on third day. (See text, Case 15)
4	26	0	0	November 11, 1911	To omentum	1 lb. 1 oz., 7.5 cm. in diameter, pedicle 37 cm. thick, lymph on surface; necrotic; sterile.	Operation at eleventh week of pregnancy. Child, 7 lb. 15½ oz., born 272 days after marriage; vertex presentation. Patient recovered. (Case 14)
5	29	2	0	July 24, 1913	To omentum and abdominal wall at navel	3½ oz., 7.5×5×4.5 cm., calcified and degenerated.	Operation at sixth week of pregnancy. Child, 6 lb. 10 oz., delivered naturally; vertex presentation. March 10, 1914. Patient recovered. (Case 13)

TABLE B.—*Author's Cases of Pregnancy complicated by Fibroids treated by Conservative Caesarean Section.*

No.	Age.	Children.	Abortion.	Date.	Adhesions.	Fibroid Removed.	Remarks.
1	34	0 (married 5 years)	0	March 1, 1907	No	No	Fibroid size of lemon in left lower segment; generally contracted pelvis; healed tubercle of sacro-iliac joints and pelvis.
2	31	2	0	Jan. 8, 1916	No	No	Fibroid size of grape right upper anterior wall; contracted pelvis. Several small fibroids found on December 14, 1918, when Caesarean section successfully done for the fourth time (H. R. S.).
3	42	0	1	March 1, 1917	No	No (a small submucous tumour removed)	Degenerated infected myoma of lower segment. <i>Bacillus Welchii</i> in tumour. The patient died of acute sepsis in sixty hours. (Case 30.)
4	25	0	0	March 17, 1917	No	No	Pelvis contracted 3½-inch conj. vera; two fibroids size of grape and marble at back of uterus.
5	38	1 (dead; forceps)	1	Feb. 8, 1918	No	No	Pelvis contracted (3½-inch conj. vera); one child delivered dead with forceps (difficult); small fibroid in anterior wall.

All the mothers recovered except No. 3; all the children were living.

TABLE C.—*Author's Cases of Pregnancy complicated by Fibroids treated by Caesarean Section followed by Abdominal Hysterectomy.*

No.	Age.	Children.	Abortion.	Date.	Adhesions.	Nature of Operation.	Remarks.
1	28	0	1	May 14, 1892	No	Porro's operation (299 days after last menstruation)	(See <i>Obstet. Soc. Trans.</i> , vol. xxxviii, p. 390.) Breech presentation. Labour obstructed by cervical fibroids. Mother quite well in 1914; the daughter 5 ft., 10 in. in height, well developed, recently married. Uterus weighed 6 lb.
2	28	0 (married 5 years)	0	March 18, 1905	A few around ruptured tube	Caesarean section + total abdominal hysterectomy	(See <i>Obstet. Soc. Trans.</i> , vol. xviii, p. 240.) Patient in labour. Footling presentation; membranes ruptured 8 hours; urine highly albuminous; ascites. Uterus 6 lb., 2 oz.
3	38	0	0	March 29, 1903	Of peduncu- lated fibroid to Douglas's pouch	Caesarean section + total abdominal hysterectomy	(See <i>Proc. Roy. Soc. Med.</i> , Obs. and Gyn. Section, vol. ii, p. 74.) Breech presentation. Operation for retroflexion of uterus by manual fibroid adherent in Douglas's pouch; uterus 5 lb., 12½ oz. (with placenta). Operated on for spindle cell sarcoma of left ovary, May 20, 1919. Child dead before operation.
4	37	3	1 (induced at 6½ months)	July 10, 1919	No	Caesarean section + total abdominal hysterectomy	(See <i>Proc. Roy. Soc. Med.</i> , Obs. and Gyn. Section, vol. iii, p. 82.) Head presentation. Operation for painful fibroids and contracted pelvis. Difficult labour last 10 years before; 1 child imbecile, injured by forceps. Uterus 2 lb., 14 oz., posterior wall 2 inches thick; hyaline degeneration of uterine muscle and fibroids.
5	40	0 (married 9 years)	0	October 12, 1914	No	Caesarean section + total abdominal hysterectomy	Operation for painful fibroids and contracted pelvis. Fibroids in posterior lower segment in pelvis, but had risen at operation. Patient anxious for living child. In labour 3 hours; head presentation. (Case 23.)
5	42	0 (married 3 years)	0	Sept. 30, 1916	No	Caesarean section + total abdominal hysterectomy	Operation for fibroids and contracted pelvis; head presentation. Conjugata vera 3½ inches. Fibroid 3½ inches in diameter, 2½ inches thick in lower segment to level of interal os. Mother and child well in 1919. (Case 28.)

All the patients recovered; children all living except No. 3, which was dead before the operation.

death, from intestinal obstruction due to nipping of ileum between the subperitoneal fibroids, is a very rare accident, of which I have not been able to find another example. The other two deaths (Cases 16 and 30) suggest the necessity of bacteriological examination of the tumour before resorting to conservative abdominal operations.

Treatment.

The great majority of cases require only careful supervision during pregnancy, periodical examination of the urine, and rest, mild aperients and anodynes if the tumours become painful. Induction of abortion, and premature labour and forcible delivery past obstructing tumours are contraindicated. Forceps may be required for inertia but should never be used to overcome resistance caused by tumours. Craniotomy and embryotomy are called for only in cases in which the fetus is dead and the mother not infected. Polypi and pedunculated subperitoneal tumours should be removed.

Vaginal myomectomy may be required for cervical fibroids, but should not be performed for retro-cervical tumours.

Abdominal myomectomy is rarely needed, and usually only for very large or twisted or necrotic tumours. It not infrequently leads to abortion and to hysterectomy in order to stop the haemorrhage from the bed of the tumour, and it often fails to remove all the tumours present in the uterus. Before performing myomectomy, as also before conservative Caesarean section, the tumour should be examined bacteriologically, and if it is infected the whole uterus should be removed.

Hysterectomy during early pregnancy in the absence of haemorrhage or infection is rarely called for.

Myomectomy and hysterectomy in early pregnancy are frequently performed by some gynaecologists. An im-

portant monograph by T. Landau¹ on myoma and pregnancy is illustrated by many fine plates of fibroid uteri containing little fetuses, sacrificed in some cases, it appears to me, unnecessarily by the operation of hysterectomy. He gives a list of eleven cases of abdominal myomectomy during pregnancy, apparently operated upon by his brother and himself. All the patients recovered and only one aborted. A careful reading of the history of the cases leaves a doubt as to whether the operation was in all necessary or advisable. He gives also a list of 19 cases in which hysterectomy was performed in the early months of pregnancy. In some of the cases the pregnancy was not diagnosed before the operation; in others what was intended to be myomectomy terminated in hysterectomy. One of the mothers died, the others were, of course, sterilized and the children sacrificed. The practice of hysterectomy in the early months of pregnancy is, in my opinion, much too common, both abroad and in this country. I have never found it necessary.

In Table A are given my cases of abdominal myomectomy during pregnancy. Of the mothers four recovered and one died (undelivered) at the fourth month of pregnancy. In No. 1 the child was dead at the time of the operation. In No. 2 abortion had occurred before the operation. In Nos. 4 and 5, operated on at the eleventh week and sixth week, the pregnancy continued and living children were born.

Every endeavour should be made to enable pregnancy to be carried on until the child is viable, when a conservative or radical Caesarean section may be performed.

Conservative Caesarean section is rarely indicated by the fibroids alone, but may be performed when fibroids are associated with contracted pelvis or malpresentations of the child, especially in elderly primiparae. In the case of a single myoma it might be possible to remove the myoma and child through the same incision. Landau, who removed

the uterus nineteen times during early pregnancy, does not record a case of conservative Caesarean section.

My five cases are given in Table B. In all of them contractions of the pelvis and the presence of fibroids were the indications for the operation. The five children survived; one mother died owing to my failure to discover the infection of the tumour. The case should have been treated by total abdominal hysterectomy.

Caesarean Section followed by Abdominal Hysterectomy.

Landau performed the operation in two cases only; the mothers and one child recovered; of the other child it was stated that it was a well-developed boy, but whether it survived or not is not mentioned.

My six cases are given in Table C. All the mothers recovered, and all the children survived except one, which was dead before the operation was performed.

Total hysterectomy, which was performed in five of the cases, is, in my opinion, preferable to amputation in pregnant as in non-pregnant cases, especially as it provides drainage and removes the possibly infected cervix.

Troell gives a list of twenty cases (including two of mine) operated on since 1900, with two deaths. I am able to add three more cases (Table C, Nos. 4, 5, 6), making twenty-three cases with two deaths.

In the puerperium vaginal myomectomy is usually the best treatment for submucous tumours even when they are infected or invert the uterus. It should usually be tried before resorting to hysterectomy, which I have never found to be necessary. In infected subperitoneal or intramural tumours total abdominal hysterectomy should be performed.

PENETRATING WOUND OF CHEST: THORACOTOMY: SUTURE OF PERICARDIUM.

BY

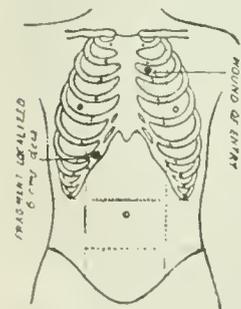

J. B. HAYCRAFT, M.C., M.B., CH.B. EDIN.,

CARDIFF; VISITING SURGEON, MINISTRY OF PENSIONS HOSPITAL, NEATH.

The following case seems of interest as throwing light on the question whether it is necessary to close a large traumatic communication between the pericardial and pleural cavities. Wounds of the pericardium are rare, and almost impossible to diagnose with certainty.

During the late war much advance was made in thoracic surgery, but the indications for operative interference are not so definite as in corresponding cases of abdominal injury, the reason being that many cases of wounds of the thoracic viscera recover without operation—a very rare event in a wound of a hollow viscus in the abdominal cavity.

In the following case the only factor which might have suggested a diagnosis of injury to the pericardium was the direction of the track of the shell fragment between the entrance wound and the position of the fragment as shown by x ray (see diagram).

Pte. H. T., aged 19, was wounded by a piece of high explosive shell at 3.30 a.m. on June 25th, 1918. He was admitted to No. 1 Canadian Casualty Clearing Station under my care at 9 a.m. He was cold and collapsed, with marked dyspnoea, and complained of severe pain in the right side of the chest. There was a small ragged wound over the second left intercostal space, about half an inch from the margin of the sternum. The right side of the

chest was absolutely dull on percussion. The pulse was 1.0. He was put to bed in the resuscitation ward, given morphine gr. 4, atropine gr. 1/80, and warmed up by an electric cradle.

At 1 p.m. he was warm, but his condition was otherwise unchanged; the pulse was 124. Examination of the chest with the screen revealed a shell fragment about the size of a raisin (see diagram), 6 cm. deep from the anterior wall of the chest. It did not move on respiration. There was dense right haemothorax, and the right side of the diaphragm hardly moved. The left chest was clear.

Operation.

A 7-inch incision was made (at 2.30 p.m.) over the fifth right rib and costal cartilage, commencing about one inch from the

middle line in front. It was carried down to the bone, and the periosteum elevated from the rib. The rib and costal cartilage were split for the length of the incision by a Hey's saw and the parietal pleura divided by scissors. A rib separator was introduced and the chest widely opened. A large haemothorax was evacuated and some large blood clots wiped out with gauze. The right lung was collapsed, and a tear, which was bleeding, was found at the lower part at the junction of the anterior and basal borders. This was sutured with fine linen thread.

On inspecting the lateral wall of the mediastinum a tear in the pericardium, about two inches in length from above downwards, was seen, through which was protruding the right auricular appendix and part of the right auricle. This was closed by a continuous suture of fine linen thread, but with considerable difficulty, owing to the extremely rapid beating of the heart and the attempts of the auricular appendix to get outside the pericardium at each beat.

A rapid search was made for the fragment of shell, but, owing to the patient's condition, was not prolonged, and it was not found. The pleura and two halves of the rib were brought into apposition by five or six sutures of thick chromicized catgut passed round the whole rib and securely tied. The muscles were united and the skin incision closed.

The entrance wound, which was dirty and ragged, was incised and packed with gauze. Gas and oxygen had been administered most skilfully for fifty minutes by Major R. Henry. After the first twenty-four hours, during which the patient was rather "shocked," progress was satisfactory. The stitches were removed on the tenth day, and the wound had healed per primam.

After-History.

On July 8th, twelve days after operation, he was not so well, and for two days he had had an evening rise of temperature, 101°. I asked Captain John Tull, C.A.M.C., medical specialist of the unit, to see him, and he reported as follows:

Heart.—Palpable friction over body of heart; dullness extends from right sternal border to 3 in. outside left mid-clavicular line. Cardio-hepatic angle not widened. Both sounds clear. To and fro harsh friction audible all over precordium.

Lungs.—*Right*: Dullness and general flatness from middle of scapula to base; signs of fluid; aegophony. *Left*: Dullness for hand-breadth at base; signs of fluid.

We aspirated 20 oz. of clear straw-coloured fluid from the right pleural cavity. Culture sterile.

On July 13th Captain Tull reported:

Heart.—Dullness has increased during past few days, and now extends from 3 in. to right of sternum to 1 in. outside left mid-clavicular line. Sounds are well heard. Precordial friction is much less distinct. It is probable there is moderate effusion into pericardial sac. *Lungs*.—*Right*: Fluid has reaccumulated in right pleural sac; now extends from mid-scapula to base. *Left*: Signs of fluid from lower border of scapula to base.

On July 14th straw-coloured fluid 15 oz. was aspirated from the right pleural cavity. This caused much distress. Culture: a few Gram-positive cocci.

On July 15th clear fluid 16 oz. was aspirated from the left pleural cavity. No culture was obtained.

On July 22nd he was very greatly improved, and in our opinion fit to travel. At the time there was great pressure on the available beds, and he was evacuated to the base.

Present Condition.

In February, 1919, he was demobilized, marked category B3, and I have a letter from him written in August, 1919, to say that he is working as a platelayer on the railway, and his only complaint is some shortness of breath on exertion. The shell fragment is still *in situ*.

Dr. T. S. Lister of Sandat, Wakefield, has very kindly sent me the following notes:

"I saw him yesterday; he is looking well and strong, and is working on the railway. Long scar of incision extending across the right side of the chest over the fifth rib. This is healed and healthy. Scar 3 in. long over front of second intercostal space on left side.

"Cardiac apical dullness extends to half an inch internal to left nipple line. No appreciable dullness on right side of sternum. The first heart sound at the apex is weak. Liver dullness in right nipple line extends to sixth rib. Dullness on posterior surface normal. Breath sounds are normal both sides. Vocal resonance no appreciable difference on the two sides. Expansion of chest is good and normal. He has slight shortness of breath on exertion."

Gask and Wilkinson have laid down indications for early operation in cases of penetrating wounds of the chest, but this case did not present any of those indications, and the first point that will suggest is, Would recovery have occurred without operation? As far as the injury to the lung and the haemothorax are concerned, aspiration would in all probability have been sufficient. As to the rent in the pericardium, I venture to think that closure was essential for the following reasons:

1. Prevention of spread of infection or fluid into the pericardial sac. Immediate closure of either serous cavities has been found to be the best method of treatment in cases of early infection.

2. Mechanical. The contraction and adhesion of the rent in the pericardium to the auricle might have caused grave cardiac symptoms.

The escape of the great vessels and the auricle itself is worthy of note.

I am much indebted to Captain John Tull, C.A.M.C., for his clinical aid and to Dr. T. S. Lister for the notes he supplied me with.

ACUTE INTESTINAL OBSTRUCTION DUE TO PREGNANCY IN A BICORNUTE UTERUS.

BY

C. E. S. JACKSON, F.R.C.S. Eng.,

SURGEON, WEST NORFOLK AND KING'S LYNN HOSPITAL.

THE following case is worthy of record because it is an example of a rare condition which presented great difficulty in diagnosis, and because an interesting question is raised as to what should be done in any future pregnancy.

Mrs. W. was admitted to the West Norfolk and King's Lynn Hospital on October 29th, 1919. The history was as follows: She had menstruated on August 5th, 1919, and had morning sickness in September; in October she noticed that her abdomen was swelling, and her breasts became somewhat tender.

Forty-eight hours before admission she was seized with sudden abdominal pain and vomiting. Her doctor tried turpentine enemata without avail. The vomiting continued, and the abdomen became distended and tympanitic. On admission to hospital the pulse was 104, and of low tension, and the temperature was 99°. Her features were drawn and her expression anxious; the extremities were cold. She vomited twice during her first half-hour in hospital; the vomit was bile-stained, with no suggestion of a faecal taint. The abdomen was somewhat distended, particularly in the left iliac fossa and left flank, and acutely tender all over. In the suprapubic region was a pyriform swelling, obviously the uterus, and I was at once struck by the fact that, although she was less than three months pregnant, the uterine fundus reached a level a fingerbreadth above the umbilicus. On vaginal examination the cervix was found to be softened, and there was marked fullness in both lateral fornices, while from the rectum could be felt a tense elastic swelling, filling up the whole pelvis and pressing firmly upon the rectum. A diagnosis of pregnancy complicated by impaction of an ovarian cyst was made.

Operation.

The abdomen was opened by a left paramedian incision 6 in. long, extending 1 in. above and 5 in. below the umbilicus. The intestines (particularly the large bowel) were very distended, and were with some difficulty packed off from the field of operation. On passing the hand behind the uterus a tense cystic swelling was felt. This swelling quite filled the pelvis, so that it was not easy to insinuate the fingers between it and the pelvic wall. After some manipulation, however, this was done, and the swelling was partly delivered from the pelvis, when the following was found to be the condition of affairs. There was a bicornuate uterus; the first horn was normally placed, while the second horn lay behind and to the left of the first. It was attached to the left side of the cervix; it lay behind the left broad ligament, and there was no direct communication between its cavity and the lumen of the Fallopian tube. It was impossible to expose either the anterior or posterior walls of the second horn, so a transverse incision was made across the fundus of it, and a fetus of two and a half months' gestation was removed, together with placenta and membranes. The horn was sewn up with silk as in Caesarean section. The condition of the patient was not good, and the abdomen was closed forthwith.

After-History.

The intestinal obstruction was completely relieved by the operation, the bowels being well opened by a turpentine enema next morning. Convalescence was normal. I saw the patient again on December 20th, 1919. The median uterine horn was now normal in size, while the abnormal horn could be felt quite distinctly from the rectum as a hard swelling of the size of a large walnut lying behind and to the left of the cervix and slightly above it.

It will be noted that subsequent events showed that only one horn of the uterus contained a fetus. In spite of this, the empty horn was very much larger than the full one. There were no lochia.

As regards further treatment, should the abnormal horn be removed? My own view is that it should. If the patient again becomes pregnant, the best that can happen is that she be delivered at term by Caesarean section; the worst is that intestinal obstruction will develop again.

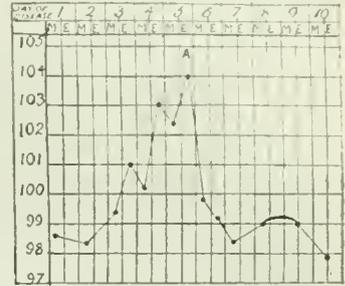

From what was found at the operation, I feel sure that it would be a safe and simple procedure to remove the abnormal horn. The patient, however, was not willing to have a second operation, unless I considered that her condition was immediately dangerous, and this obviously was not the case.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

ANTISTREPTOCOCCIC SERUM IN PUERPERAL FEVER.

NATURALLY every case of puerperal fever does not respond to antistreptococcic serum, but it is well to remember its remarkable results in some cases. I have used it twice, and on both occasions with the most dramatic results. The chart reproduced speaks for itself. It is from a patient I treated recently, and it is noteworthy that only 10 c.cm. of the serum were used, more not being available at the moment. The directions sent with the serum recommend 30 c.cm. as the minimal dose.

A=10 c.cm. antistreptococcus serum.

The other case was even more gratifying, as the woman had had a temperature ranging between 104° and 105° F. for several days, with repeated rigors, yet responded immediately to the serum.

O. HILTON.

A SIMPLE TREATMENT OF RINGWORM OF THE NAILS.

IN general practice onychomycosis is comparatively rare and its treatment is apt to be superlatively disappointing. Two years ago I met with two cases which appeared to be very much alike. Both were women of middle age and in comfortable circumstances. In one a thumb and in the other a finger nail was badly affected.

Examination of scrapings showed hyphal fragments, and a few particles placed on wort agar gave cultures of rather slow growth resembling specks of damp flour. No conidial fructifications were observed, and the organisms consisted of infrequently branched mycelium with many oidium-like elements and some simple chlamydo-spores. The cultures died in a few weeks.

It may be objected that such a miserable depauperate mould falls short of what a ringworm should be, but these elements are just the constants of every ringworm culture, and all other elements are variants, more or less perfect, more or less obsolete.

Treatment.—The disease had existed for months in one, for years in the other. They were given a lotion of ʒj of salicylic acid in ʒjss of methylated spirit, to be painted on after scraping every night, and without scraping every morning, and to be used for three months or longer. Both have been cured for twelve months.

London, W.

ROBERT CRAIK.

MODE OF INFECTION IN PULMONARY INFECTION.

HAVING felt for a considerable time that the present view of the mode by which tuberculous infection is carried from the tonsil to the lung—namely, through the cervical glands to the mediastinal and bronchial glands and so to the lung—is not satisfying, I offer the following suggestion:

Might it not be that the infection is carried from the tonsil through the cervical glands to the jugular trunk and then passed directly into the blood stream through the jugular vein and so to the right side of the heart, from which it would pass to all parts of the lungs? This would aid in explaining why it is that the tuberculous process in the apex is manifested in the lung substance, while in other parts it gives rise in the first instance to pleurisy. The movement at the apex is so much less than that of the other parts of the lung that a greater slowing down of the capillary circulation is more likely in this part. It is in the capillary circulation of the pleura that this slowing down would occur in other parts.

I am excluding trauma, which is no doubt an important factor in determining localization of the infective process, as this is not pertinent to the discussion of a route for infection from tonsil to lung.

The same mode is applicable in the case where the bacilli are absorbed from the intestine. No doubt they pass with the fats into the lacteals, then into the receptaculum chyli and to the thoracic duct, from which they would pass into the venous system and the right side of the heart to pass into the lungs in the blood stream.

PRINCIPLES OF EPIDEMIOLOGY.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine, held on January 23rd, with the President, Dr. E. W. GOODALL, in the chair, Dr. F. G. CROOKSHANK read a paper entitled "First principles and epidemiology."

Dr. Crookshank, having called attention to a current neglect of or contempt for discussion of first principles, urged that the time had come for an attempt to define the fundamental concepts of epidemiology. He pointed out that much harm had arisen from a tendency, sanctioned by the example of Sydenham in his less consequent passages, to attribute objective reality to the concept of disease.

Let us, however, acknowledge that, while no "disease" *sui generis*, boasting a single *vera causa*, exists save as a justifiable mental construct, useful and convenient, we may regard the idea of a special disease as one involving the subordinate notions of (1) a single person manifesting (2) a defined group of symptoms, correlated by (3) a single intracorporeal cause.

A similar confusion had worked havoc in epidemiology, and in the speaker's opinion the student should have in mind a "concept, similar in construction to that of a 'disease' but of different content; a concept, that is, to which actual prevalences can be logically referred for verification, just as case-occurrences are referred to disease-concepts, in diagnosis. Three notions are again involved: (1) that of the subject deemed to be affected, (2) that of the disorders manifested in or by the subject, and (3) that of the correlating factor, which we speak of as the cause." In the substantive sense, he continued, the old word "epidemy" might fitly replace "epidemic," and the words of Brochin were significant:

Dans les épidémies, bénignes ou dangereuses, il ne s'agit pas d'un homme, mais de la cité, et même de tout un pays. *(Civitatem non virum curabis.)*

This was no paradox, that the sufferer from an epidemy was never an individual but always a community or group, and its truth became evident the moment that the conceptual aspect was accepted. This was why in order to diagnose an epidemy one must collate cases in a community, while to diagnose a disease one need only collate symptoms in an individual. Neglect of this principle had led to failure to grasp an epidemic manifestation as a whole—to recognize the cavalry scouts of an advancing army. Dr. Crookshank discussed the theory of epidemic constitutions, and remarked that Balloisius, a hundred years before Sydenham, was much nearer the truth than his more famous successor, and better deserved to be described as the father of modern epidemiology. "The events of the latter months of 1918 are well known, but this should be noted, that during the weeks when the names botulism and encephalitis lethargica were so popular professionally not only the general but the special hospitals saw far more than is usual of Landry's paralysis, of ascending myelitis, of transverso myelitis, and the like. To all of this no attention was paid. Interest was focussed on one type of nervous disease alone, and for the first time during many years a new disease was defined on a regional basis without attempt to study the whole of the prevalent disorders in the hope of arriving at some idea of the scope of correlation."

The paper was discussed by the PRESIDENT, Dr. GREENWOOD, Dr. HAMER, and Dr. BUTLER.

DENTAL SEPSIS IN CHILDREN.

At a meeting of the Section of Odontology of the Royal Society of Medicine, held on January 26th, the President, Sir J. F. COLYER, being in the chair, Mr. S. F. St. J. STEADMAN read a paper on dental sepsis in children, its consequences and treatment, in which he referred to the deterioration of our national physique as revealed by the physical examination of recruits. He said that the Medical Society of London had commenced an investigation to determine as accurately as possible where we were at fault, but, judging from the report of a meeting held in November, 1918, in which the causes of rejection were classified and in which there was no mention made of dental disease, they were once again overlooking the commonest cause of all. Dr. J. D. Comrie, analysing the physical defects among the general male population, had stated that in 10,000 recruits 928 had artificial teeth, while another 1,120 had lost half their teeth at least, and that a septic condition of the teeth with deposit of tartar and gingivitis was frequently associated with dyspepsia, and invariably with a deteriorated physique. Chronic disease in childhood, the effects of which spread over a period of years, must have a profound influence upon mental and physical growth. Of all chronic diseases of this character dental disease was by far the most common, as something like 80 per cent. of the children of the race were suffering from dental diseases. All were agreed upon the importance to the child of a perfect dental arch. The best way to combat dental diseases was to attempt their prevention, the necessary prophylactic measures being to secure a clean mouth in, and the proper feeding of, the pregnant mother; breast feeding in infancy; the establishment of proper nasal breathing, and proper diet (a diet requiring efficient mastication), and early and constant dental supervision so that caries could be treated early. He was not concerned so much in his paper with the treatment of the children of the rich, for although the fundamental principles were the same for both, in dental diseases, like all other diseases, there was often one means for the rich and another for the poor, and the advice given to a wealthy, leisured mother might be different from the advice given to the busy working class mother.

Effects.

The effects of dental sepsis upon children could be considered under two main headings: (a) General; (b) local.

(a) *General*.—Dental sepsis frequently had a pronounced effect upon children. Their mental and physical growth was retarded; they were pale-faced and anaemic, their eyes had not the normal lustre of healthy children, and they looked tired and sleepy. Sir J. F. Colyer was the first to weigh these children before and after treatment, and in a paper read before the Manchester Odontological Society in 1910, gave the weights of some of the cases he had treated for sepsis. He showed that there was frequently a marked increase in weight, too great to be accounted for by the normal increase of growth; at times the increase following extraction was very marked. From his own experience Mr. Steadman was able amply to confirm these findings.

One of the chief ways by which dental sepsis in children produced this loss of mental and physical growth was by the loss of sleep. A careful investigation of the history of these cases would frequently show that for months the child had not slept well. Its nights had been disturbed by pain. This important symptom had to be looked for, as children did not as a rule complain of it. A common result of oral sepsis in children was gastro-intestinal disorder, as evidenced by gastric and abdominal pain, diarrhoea of an offensive character, with much undigested food in the motions, marked wasting, fretfulness, night terrors, loss of appetite, sleeplessness, and pallor of the face. In treating a case such as this, it would appear reasonable to inspect the mouth first and to remove any possible source of infection therein before proceeding to treat the stomach; yet many medical practitioners still neglected to do this. That this gastro-intestinal condition is due to sepsis and not to lack of mastication, was proved by the fact that the patients frequently got well very soon after extraction of the teeth, and almost before the gums had healed, that is, while they were still too tender to allow of mastication upon the teeth that remained. This

was borne out by the observations of Dr. H. Waller upon dental disease in nursing women. He showed that in many instances in which a breast-fed baby ceased to thrive while still at the breast the trouble could be traced to sepsis in the mouth of the mother. Dr. Waller's charts demonstrated the marked gain in weight of the infants after the extraction of septic maternal teeth. In these cases it was clear that the digestive apparatus of the child was unchanged, and that the improved health had been due to the removal of septic material from its food. As Dr. Sim Wallace pointed out, anaemia of other than dental origin was liable to be aggravated by the chronic toxæmia and septic absorption which might be associated with dental sepsis. Other chronic diseases, such as tuberculosis, could not but be prejudicially affected by an insanitary state of the mouth. Typhoid and scarlet fever and other zymotic diseases had been shown by Dr. William Hunter to be much more dangerous when dental sepsis was present. Further, septic matter from the mouth might be absorbed into the blood stream, and give rise to such diseases as septicaemia and endocarditis.

(b) *Local*.—Under this heading he included the adjacent parts to which infection sometimes spread by continuity of tissue, causing such diseases as pharyngitis, tonsillitis, otitis media, and—much more rarely—meningitis. Infection might pass down the lymphatics to the submaxillary and cervical glands. Some observers held that glands were so commonly enlarged in children that it was not worth while examining for them, but he considered that such teaching was absolutely wrong. He thought that normally the submaxillary and cervical glands were not palpable in children, and that if they were, there was sepsis somewhere. Carious teeth frequently produced enlarged glands, as proved by the fact that these glands disappeared after the removal of the teeth. They drained a very large area, including the teeth and oral mucosa, the tonsils, the nasopharynx, the orbits, the skin of the face, and the anterior part of the scalp. Mr. J. G. Turner had shown that sepsis in the deciduous teeth not uncommonly led to damage of the permanent teeth beneath them, as shown by hypoplasia and some of those deformities which had been classed under the term dilaceration. Lastly, the carious tender teeth by disuse brought about a gingivitis, which might spread eventually to the periodontal membrane of the permanent teeth, with all its consequent ill effects upon health.

Treatment of Dental Sepsis in Children.

Mr. Steadman then described his method of treating dental sepsis in children. He extracted all deciduous teeth in which the decay was sufficiently advanced to infect the pulp, and generally their antagonists also. He filled teeth also when he felt sure that the pulp was not affected. This condemned at once the majority of decayed deciduous teeth, because the pulps of these were relatively larger than in permanent teeth, so that a comparatively small cavity was sufficient to infect the pulp. He treated the permanent molar teeth in the same way as the deciduous teeth if the roots were incomplete at the time of the pulp infection. The argument against extensive extraction in children, that mastication was lost, was futile. Medical and dental practitioners who used this argument could see for themselves that mastication was already lost. No child would masticate on tender teeth and exposed pulps. On the contrary, by the removal of tender teeth the area of mastication was increased. An exposed pulp in a deciduous molar meant that the child would not masticate on that side of the mouth, so that the important six-year-old molars behind them were not functional. Experience showed that it was better for the child, if food had to be bolted, that the food should be as clean and as little contaminated by pathogenic organisms as possible. As for the argument that the extraction of teeth prevented the proper growth of the jaw, this, he thought was not borne out by experience, for the removal of teeth from one side of the jaw did not produce deficient growth of that side as compared with the other. The same observation held good if the teeth of the upper jaw, for instance, were removed and those of the lower jaw left. The crowding and irregularities of the arch at a later stage could be overcome if the patient came frequently for dental inspection, so that at the right moment one of the permanent teeth in each corner of the mouth could be

sacrificed. It was important to prevent unilateral mastication. On the unused side a marked gingivitis would supervene, and, as the habit was likely to become permanent, the permanent teeth, when they had erupted, would become septic also.

Of the 7,000,000 or so children of this country about 6,000,000 required dental aid. If on an average one hour's work for each child were allowed to be what was required the case would not be overstated. If this work were carried on at the rate of five and a half hours a day it would take one man nearly 3,000 years to complete. This showed that there were not nearly enough dental surgeons available. On the other hand, if all teeth with infected pulps were extracted a tremendous amount of time would be saved. It took a good deal of courage to condemn a large number of teeth in a child. This necessary courage could only be acquired by observing, recording, and pondering over the evil consequences of leaving these septic teeth. A proportion of the dental profession at the present day appeared to lack this courage, or had not yet realized sufficiently the great harm they were doing to their patients by leaving septic teeth. The ignorance of a small but harmful minority of medical practitioners concerning dental matters was nearly as great as that of the general public. They sometimes gave advice on dental matters which was not only incorrect but often extremely harmful. On more than one occasion when he had urged the removal of abscessed teeth which were keeping their possessor awake with pain night after night, besides causing severe general ill health, the medical adviser had stepped in and said that nothing must be done to the teeth until the child's health had improved. Mr. Steadman considered it very important that if in children extensive extraction were decided upon, it should be carried out at one time under a general anaesthetic. In this way much less strain was put upon the nerves of the little patients.

Discussion.

In the course of the discussion which followed Mr. F. N. DOUBLEDAY said that while the function of the teeth was very important, yet when sepsis was established and the teeth were functionless they were useless and redundant, and should be removed.

Mr. F. B. BULL spoke of the importance of the nervous system of the child, which in many cases was such that it was impossible to carry out treatment. Teeth which were septic should be removed at once. He agreed that extensive extraction could be done under ethyl chloride on the open mask.

Dr. ARTHUR SAUNDERS laid emphasis on the excellent results which he had seen in children at the West London Hospital after extraction of septic teeth. The children with septic teeth were often, in addition to being anaemic and wasted, slightly cyanosed, and night sweats were present, so that tuberculosis was often suspected, and the heart was often slightly dilated, a condition which he considered to be due to a mild septic myocarditis, which cleared up after removal of the septic teeth. Slight albuminuria was often present, and nephritis sometimes supervened. Some acute cases of haemorrhagic nephritis due to dental sepsis reminded him of similar cases occurring after scarlet fever.

Mr. E. B. DOWSETT said that the way in which children were able to eat after all the teeth had been removed was remarkable. Those whom he had been able to follow up were able to eat even meat, and thrived well. The occurrence later of irregularity was the only bugbear, but possibly this need not be considered seriously owing to the enormous advantage which followed thorough treatment.

Mr. A. F. PITTS said that Mr. Steadman had brought a serious indictment against the medical men and dentists in stating that some members of both professions did not recognize the serious effects of dental sepsis in children. His experience at the Hospital for Sick Children enabled him to endorse all that had been said with regard to the gravity of the problem and the results of adequate treatment. The effects of dental sepsis, both local and general, were apparent, and equally striking was the improvement in the general health when the mouth was rendered clean. Even when the mouth had to be left practically edentulous the children put on weight and were able to eat their food in comfort. It was astonishing that any man with a medical training should fail to see the harm arising from

septic teeth. Frequently mouths were seen in which necrosed roots had ulcerated through the side of the gum, a condition comparable to sequestra being exfoliated. No doctor would regard such a condition occurring elsewhere with complacency, and yet it was sometimes allowed to exist unnoticed in the mouth. It was true that premature loss of the deciduous teeth often led to irregularity of the permanent teeth, but this lesser evil was so completely outweighed by the greater evil of dental sepsis as to be not worth considering. Some had said that this irregularity was a common predisposing cause of pyorrhoea in later life, but in his opinion dental sepsis in an adult whose metabolism had reached a state of equilibrium, was less serious than sepsis in a growing child, who needed nourishment not only to replace the daily loss of energy but to increase the bulk of its tissues.

Mr. LEWIS PAYNE laid stress on the need for prophylactic treatment. Adequate instruction should be given to parents and children, or the condition would recur in two or three years.

Mr. J. G. TURNER said that extraction was necessary in order to get rid of sepsis. The need of the poor children of London for dental treatment was urgent. All the dentists in the British Isles would not suffice to do all the stopping which should be done. Myopia might result from dental sepsis, the sclera becoming affected by toxæmia or by the malnutrition which accompanied the condition.

Mr. GEORGE THOMSON, speaking of tuberculous in school children, said that dental sepsis affected the child in two ways: (1) by allowing infection by pathogenic germs, and (2) by resulting malnutrition. The school dental treatment scheme broke down because the number of available dentists was insufficient. Treatment must be begun earlier. He had removed incisors from children of fifteen months. The incisors of babies became denuded of enamel owing to the sugar bag which was given them by their mothers when going to sleep.

SUSCEPTIBILITY TO FOREIGN PROTEINS.

At a meeting of the Medical Society of London, held on January 26th, the President, Mr. V. WARREN LOW, being in the chair, various pathological specimens were exhibited, after which Dr. JOHN FREEMAN demonstrated the conjunctival and cutaneous reactions obtainable in patients who are susceptible to various proteins. In the case of hay fever it was shown that a diluted extract of grass pollen, if instilled into the conjunctival sac, produced a harmless and transient injection, while if the tip of a glass rod was charged with the pollen and rubbed into a square scratch in the skin an irregularly shaped wheal resulted. Quantitative testing could be carried out with known dilutions of the extract. Susceptibility to other proteins, to the proteins of horses and other animals, and to various kinds of food, fell into the same group, and the symptoms varied only in accordance with the anatomical position to which the disturbing protein was applied. Thus the severe vomiting and diarrhoea which prostrated some persons who ate eggs or strawberries was of the same nature as the prostration and catarrhal changes in the upper respiratory passages in hay fever. The tests were specific, and denoted which was the particular protein to which a patient was susceptible. Experiments had shown that when susceptibility to a protein was encountered in an individual, other members of the same family often showed a susceptibility to other proteins. With regard to the pollens, that of grass was the only one of importance, though certain persons were susceptible to others. This was explained by its abundance and its lightness, the others being much heavier. Another method of employing the test was to precipitate the protein to be tested out of a watery solution by an excess of alcohol. The solution was then filtered, and the filter paper with its attached precipitate dried. A small square of this paper, protein side downwards, if superimposed on a scratched surface, gave the cutaneous reaction. Sufficient protein to give the faintest opalescence to the solution was enough to give the reaction.

"SOLDIER'S HEART."

At a meeting of the Nottingham Medico-Chirurgical Society, held on January 21st, with the President, Dr. W. ROWE in the chair, Dr. C. H. CATTLE, Senior Physician to the Nottingham General Hospital, read a paper on cardiac affections and the war. He said that the condition spoken of as "soldier's heart," though well known in medical

literature, had now for the first time in the history of our country become familiar to every practitioner. The principal symptoms were said to be palpitation, breathlessness, cardiac pain, and giddiness. The chief causes were some infective illness, especially rheumatic fever, and the physical and mental strain of warfare. In the cases of this affection, for which the term "effort syndrome" was an apt description, were taken from light occupations. As so many men were unable to bear strenuous exertion in civil life, the conditions of military service might be said rather to have brought out a latent tendency than to have caused this condition. Methods of identifying the commoner forms of irregularity of the heart were described. Drugs, with the exception of bromides, were comparatively useless in the "effort syndrome." The most successful method of treatment was the system, introduced by Dr. Thomas Lewis, of gradual physical training in a special institution. Some of these men had systolic murmurs, but the murmur *per se* was found to be no bar to the attainment of a high standard of physical endurance. The general adoption of the exercise test was considered to be the greatest advance made in the examination of cardiac cases as a result of the experience of the war. The following conditions called for rejection for the army: enlargement of the heart, mitral stenosis, aortic regurgitation, aneurysm, repeated attacks of rheumatic fever, failure to pass a strenuous exercise test. A systolic murmur in the absence of enlargement of the heart or of symptoms was far more often functional than organic. Aortic stenosis, without regurgitation, was rare. The murmur of mitral regurgitation could not be distinguished from other systolic murmurs at the apex, but this affection, even if its existence could be proved, may be compatible with many years of useful and even strenuous life. On the contrary, the tendency of mitral stenosis and aortic regurgitation was to get steadily worse. The lecture was followed by an interesting discussion in which the PRESIDENT, Drs. JACOB, SCOTT, and FLINT took part.

Rebicus.

PHYSIOLOGICAL PRINCIPLES IN TREATMENT.

THE first edition of Dr. LANGDON BROWN'S popular *Physiological Principles in Treatment*¹ appeared in 1908, and the third in 1914. The war, which delayed the present edition, has necessitated a thorough revision, so that the reader is now presented with a stimulating and thoroughly up-to-date guide to the scientific management of a number of diseases.

The text is clearly written, attractive, and not without occasional flashes of humour; thus, in discussing the difficult subject of purins and gout, the author remarks on the curious obsession which leads men who cannot metabolize purin bodies to believe that the rest of mankind are similarly defective, with the result that the purin-free diet becomes a cult. The sections on diabetes and acid intoxications have been almost entirely rewritten, and embody much of Dr. Poulton's recent work. It is interesting to find that the idea of the building up of the diabetic patient's diet after a fast was independently arrived at by Dr. F. M. Allen, now of the Rockefeller Institute, by Dr. G. Graham, of St. Bartholomew's Hospital, the publication of whose results in any comprehensive form was prevented by the war, and by McCay and his fellow workers in Calcutta, the completion of their investigations being delayed by the same cause. The principal difference between Graham and Allen is that the latter prescribes a long fast until the urine is free from sugar, and then gives carbohydrate in the form of green vegetables accompanied by very little protein, whereas Graham's plan consists in a short fast of forty-eight hours followed by a much more speedy addition of protein. From a comparison of these methods Dr. Langdon Brown considers that, whereas Allen's regimen may remove glycosuria more rapidly, Graham's is less likely to affect the patient's general health injuriously. The treatment of renal disease is set forth on broad lines; the irrational restriction of patients with chronic nephritis to a milk diet, which is too dilute a food and may increase

¹ *Physiological Principles in Treatment*. By W. Langdon Brown, M.D., F.R.C.P. Fourth edition. London: Baillière, Tindall, and Cox, 1919. (Cr. 8vo, pp. viii + 427. 7s. 6d. net.)

oedema is condemned, and it is pointed out that prolonged nitrogen starvation is as bad for a nephritic patient as for anyone else.

The book contains a graphic description of the symptoms of high blood pressure in the presclerotic stage before structural change has supervened and when preventive treatment can be effectively employed. There is a useful section of the soldier's heart, embodying the knowledge gained in the war. While the text is not overladen with names, due credit is given to those who have recently advanced our knowledge, and the principal references are conveniently arranged at the end of the volume.

THE INTERNAL SECRETIONS AND THE NERVOUS SYSTEM.

THIS monograph on *The Internal Secretions and the Nervous System*² is a translation of a report written by Dr. M. LAIGNEL-LAVASTINE of Paris for a congress at Berne in 1914, but not delivered on account of the war, though it was published in the same year in the *Revue de Médecine*. It has now been translated by Dr. F. T. ROBESON of New York, who has added some notes on more recent work, a preface and an introduction. The book presents us with a wide summary of what has been written on this subject, much of it somewhat speculative, and will undoubtedly be a useful source of reference, especially as to the meaning and bearing of vagotonia and sympathicotonia.

The author argues that there are in the first place nervous disorders due to disturbances of the internal secretions, and in the second place anomalies of the internal secretions as the result of nervous disorders, and tabulates these with a running commentary; thus nervous disorders may be due to disturbance of one endocrine gland or to polyglandular syndromes, and in the latter alternative one endocrine gland may be more responsible than the others. The vegetative, formerly called as a whole the sympathetic, system was divided by Professor J. N. Langley into the cephalic and pelvic portions of the autonomic system, and the remainder, still called the sympathetic system. These two portions of the vegetative nervous system are antagonistic, and, as is well known, Eppinger and Hess have insisted on the proof of this by the different reactions in the two conditions to the injection of adrenalin, pilocarpine, and atropine, and apply the term vagotonic to individuals in whom the activities of the autonomic system predominate, and describe as sympathicotonic those in whom the sympathetic is most active. This differentiation has aroused considerable criticism, and it is extremely doubtful if the question is so simple as might at first sight appear. Of the two groups mentioned above, the nervous disorders due to disturbances of the internal secretions are of more practical importance than the disturbances of the endocrine glands caused by nervous disease.

DENTAL CARIES AND ORAL OSMOSIS.

DR. RAGNAR ECKERMAN, a dentist of Malmö, Sweden, has published in English a book under the title, *Dental Caries in Relation to Oral Osmosis*,³ which gives a full account of researches and theories he reported to the Congress for Natural Sciences in Vienna in 1913, and published in Sweden in the same year. The theories and observations are very fully stated and amply illustrated in the book before us. Perhaps on account of this elaboration Dr. Eckerman's views are not always quite easy to follow, but we gather that in his opinion there are two kinds of caries—a primary which is a physiologico-pathological state, and a secondary which is a breaking down of substance by micro-organisms. Primary caries, he considers, commences from within, beginning at the tooth pulp and spreading outwards to the surface of the enamel, being of the nature of an osmotic outflow of blood plasma, and even red blood cells, brought about by an excess of common salt or sugar in the saliva. The channel by which this interchange takes place is the dentinal tubules and certain

spindle-like spaces in the enamel which are to be found, in the one direction communicating with the peripheral ends of the dentinal tubules, and in the other extending occasionally to the enamel surface immediately under the cuticula dentis (Nasmyth's membrane) which forms the osmotic membrane.

As proof of the internal origin of primary caries the author lays great stress on what he calls the caries canal. This is a cone-shaped area of more or less coloured dentine, having its apex at or towards the pulp and its base under the carious enamel. He considers that its colour is due to blood plasma, and that in all cases of primary caries the connexion with the pulp is demonstrable. He appears to hold that the primary caries is limited to the crown of the tooth, and depends on the fact that owing to too early eruption or to malnutrition the enamel has been badly formed, thus giving full play to the osmotic force of saliva too rich in common salt or sugar. The consequence of this outpouring of plasma into the dentine is an excess of organic matter in that tissue, and in this the author finds an explanation of the increase of organic relative to inorganic matter in carious dentine. At this point micro-organisms come in and "primary" merges into "secondary" caries, which the author allows is a bacterial process. While accepting bacteria as a cause of secondary caries, the author spares no effort to disprove the possibility of their being concerned with primary caries. He would, as we understand, limit the term secondary caries to such caries as arises on the exposed roots of teeth or in places where plates, etc., have held up food débris; but the arguments by which he seeks to exclude micro-organisms from the causation of "primary" caries seem equally applicable to their exclusion from that of "secondary" caries.

We are, indeed, unable to follow the author in his arguments, nor have we been able to determine whether his idea of caries embraces both enamel and dentine or is limited to the dentine. The arguments he advances to disprove the chemico-parasitic theory seem to reveal a failure to appreciate some of the principles of bacteriology and a capacity to turn a blind eye to awkward facts. He triumphantly points to the cessation of the carious process after burial as a proof of the innocence of bacteria, ignoring the lowered temperature and absence of food supply. He seems not to have seen those distressingly frequent cases in which caries is found in tooth after tooth till every available spot is decayed. He regards the symmetry of caries as proof of its independence of bacteria, whereas the theory that caries depends on the lodgement of germs and carbohydrates obviously demands the symmetrical appearance of decay in the two halves of a symmetrical dental arch. His proof of his thesis seems to depend largely on the existence of his "caries canals" and on the supposition that the minute traces of iron found in dark-coloured decay are derived from blood drawn from the dental pulp. He fails, we think, to establish his claim that the "caries canals" are osmotic paths starting from the pulp. He states that he has always found these "caries canals"—tracts of discoloured dentine—stretching from the earliest stage of enamel decay right to the pulp; we would, however, prefer to adopt the generally accepted opinion that it is only in the later stages of decay that a discoloured tract extends right to the pulp, while in the earlier stages a layer of healthy dentine intervenes between the advancing decay and the pulp. In this connexion it is interesting to note that the author seems never to have seen the lateral spread of caries along the "interglobular layer" (situated at the dentine-enamel junction); he, indeed, publishes what he considers a hypothetical figure of how decay should spread in this layer if micro-organisms were causative agents, which figure is, in fact, a very fair representation of what constantly happens.

The presence of traces of iron in decayed dentine can be explained in other ways than as an exudate from the tooth pulp, but even if the haemoglobin of red blood cells derived by diapedesis from a hyperaemic pulp were carried by the dentinal lymph circulation to the edges of the carious dentine the author's thesis would not be helped, the appearance of iron being merely an expression of the normal life-activity of the dentine.

We are compelled to dissent from the author's theory, but we hasten to add that the book will be found to contain much valuable matter and to provide much

² *The Internal Secretions and the Nervous System*. By Dr. M. Laignel-Lavastine of Paris; authorized translation by Dr. F. T. Robeson, New York. Nervous and Mental Disease Monograph Series, No. 30, 1919. New York and Washington: Nervous and Mental Disease Publishing Company. (Roy. 8vo, pp. xiv+59. 0.75 dol.)

³ *Dental Caries in Relation to Oral Osmosis*. By Ragnar Eckerman, Ph.D., L.D.S., London: Williams and Norgate. 1919. (Roy. 8vo, pp. 264; 20 plates. 22s. net.)

stimulating reading to all engaged in research on dental caries. We welcome Dr. Eckerman's contribution to the elucidation of this great problem.

PUBLIC ASPECTS OF THE VENEREAL PROBLEM.

DR. E. T. BURKE'S book on the *Venerereal Problem*⁴ is written, as the preface states, for the information of the general public; in the introduction its object is said to be "to bring together, in a manner fit for general consumption, the causes of venereal diseases, to point out the factors which cause the continuance and spread of these affections, and to try to indicate the paths along which advancement may be hoped for."

This is undoubtedly a laudable object, but at the same time it may be questioned whether books of this nature are the surest means of attaining such an end. Many of the arguments are reinforced by tabulated figures illustrating such things as the incidence of venereal diseases in different sections of the community. Unfortunately, accurate knowledge in these matters is not available, hence deductions drawn from such statistics are unlikely to be reliable. We would also be inclined to disagree with the statement that the child is infected by means of the spirochaete entering the orum along with the spermatozoon, the mother becoming infected through the placenta (page 43).

Every medical practitioner is keenly alive to the dangers of the disorders with which this book deals, and few are not at some time brought into contact with the disastrous results following infection. That they inflict an appalling degree of ill health on the community cannot be gainsaid. Whether compulsory notification and treatment, as favoured by the author, is the solution of the problem or not, is a larger question than can be dealt with in this review. Those who favour such measures overlook the confidential relationship that has always existed, and should exist, between doctor and patient—a priceless heritage not to be lightly cast aside. It has been argued that this confidence is sacrificed when diseases like scarlet fever are publicly notified. But the distinction, and it is very important to observe this, lies in the mode of origin of venereal diseases, a factor which influences the patient to hide his malady from the knowledge of others. Nor is this tendency, common to all classes and countries, altered by the use of catch phrases such as "conspiracy of silence" and the like. Herein lies the true difficulty of the problem, and no successful solution is possible that neglects this factor. Medical practitioners are not policemen; they receive the confessions and confidences of their patients, and any effort to disturb such a proper relationship can do no real good either to the public or to the profession.

NOTES ON BOOKS.

THE second edition of *Elementary Practical Chemistry*,⁵ by MYERS and FIRTH, provides medical students preparing for their first examination in practical chemistry with a thoroughly sound and well written textbook. The authors claim that they have had regard to the requirements of the syllabuses of most of the medical examining bodies in the British Isles. The book is clearly the work of practical chemists who are also experienced teachers. It is divided into four parts, dealing respectively with the general methods of chemical manipulation, qualitative and quantitative inorganic analysis, and practical organic chemistry: the text is illustrated with a number of simple but excellent diagrams of apparatus. The volume is well written and not too long.

*Chemistry in Everyday Life*⁶ is a chatty volume designed to whet the appetite of the man in the street, and show him how useful an elementary knowledge of chemistry is in every trade, profession, or occupation. It deals in generalities and covers a great deal of ground; it may be recommended to readers of all ages, sorts, and conditions.

⁴ *The Venereal Problem*, by E. T. Burke, D.S.O., M.B., Ch.B. 1919. London: Henry Kimpton.

⁵ *Elementary Practical Chemistry*, For Medical and Other Students. By J. E. Myers, D.Sc. Vict., A.I.C., and J. B. Firth, M.Sc. Vict., M.Sc. Durham, A.I.C. Second edition, revised. London: Charles Griffin and Co., Ltd. 1920. (Cr. 8vo, pp. vii + 194; 22 figures. 4s. 6d. net.)

⁶ *Chemistry in Everyday Life*, Opportunities in Chemistry. By Ellwood Hendrick. London: University of London Press, Ltd. 1919. (Cr. 8vo, pp. xii + 102. 3s. 6d. net.)

Professor JOHN B. ROBERTS'S *War Surgery of the Face*,⁷ a treatise on plastic restoration after facial injury, was prepared at the suggestion of the subsection on plastic and oral surgery connected with the office of the Surgeon-General U.S. Army, and it must be confessed that the impression gathered from its pages is rather of a laborious compilation than of the outpourings of a full heart. There have been of late several publications brimming with the enthusiasm of recent accomplishment, and full, therefore, of the greatest interest and instruction for the reader; this volume can hardly challenge comparison. It is not that there is not an immense amount of useful information, though the bibliography is deficient, but there is an unnecessary inclusion of matter not strictly relevant. Plastic surgery is not for the novice, and the skilled surgeon does not want to be told how to treat chilblains with tincture of iodine. The book is profusely illustrated, largely with borrowed pictures.

The fourteenth edition of *Pye's Elementary Bandaging and Surgical Dressing*,⁸ brought up to date by Mr. V. Z. COPE, provides dressers and nurses with a friend in need of proved value. It is divided into three sections, the first dealing with bandages and splints, the second with dressings, the third with the immediate treatment of emergencies. This little book contains a great deal of valuable information, and is both well written and adequately illustrated.

The author of *Aids to Histology*⁹ has endeavoured to produce a summary of the subject, with the aid of a few diagrams. The task, we take it, is impossible. The book is intended for the junior student of medicine, and for senior students when revising their knowledge.

⁷ *War Surgery of the Face*, A Treatise on Plastic Restoration after Facial Injury. By John B. Roberts, A.M., M.D., F.A.C.S., Professor of Surgery in the University of Pennsylvania Graduate School of Medicine, etc. London: John Bale, Sons, and Danielsson, Limited. 1919. (Med. 8vo, pp. viii + 442; 256 figures. 20s. net.)

⁸ *Pye's Elementary Bandaging and Surgical Dressing*, Revised from H. W. Clayton-Greene's eighth edition of *Pye's Surgical Handicraft*. By V. Zachary Cope, B.A., M.D., M.S. Lond., F.R.C.S. Eng. APPLIANCES AND PREPARATIONS.

Amibiasine.

A FRENCH preparation named amibiasine, manufactured by the Laboratoire de l'Amibiasine, 29, Rue Miromesnil, Paris, has been submitted by the Anglo-French Drug Company, Limited, 238A, Gray's Inn Road, W.C.1. It is stated to be a compound extract of the bark of the mangosteen (*Garcinia mangostana*), a tree well known in the Far East for its fruit. It is claimed that the preparation has a strong antiparasitic effect, and is useful in the treatment of dysentery and diarrhoea. The sample supplied to us consists of a brown liquid having an intensely bitter taste and slight odour. Examination shows it to contain some alcohol and 15.8 per cent. of solid matter consisting of vegetable extractive together with a considerable proportion of glycerin. No active ingredient other than the bitter principle could be detected. We are unable to express any opinion on the therapeutic efficacy of the preparation, but the makers state that it has been used in the French Army Medical Department.

Petroleum Jellies.

Messrs. William Browning and Co., Ltd., Albert Works, Park Street, N.W.1, have submitted to us samples of a series of four soft paraffins which they are now supplying under the proprietary name "Semprolia," for medical and veterinary purposes. Examination of the samples shows that they possess the following characters: "Semprolia" No. 1 Petroleum Jelly is a very white, soft paraffin, quite free from odour and taste. Its melting point is slightly higher than that of an average soft paraffin, but not sufficiently so to be any serious disadvantage; in other respects it complies with all the tests of the *British Pharmacopoeia*. It should be quite suitable for internal administration, or for any other purpose for which a soft white paraffin of high quality is required. "Semprolia" Nos. 2 and 3 Petroleum Jellies are respectively yellowish-white and yellow soft paraffins, complying with all the tests of the *British Pharmacopoeia*, and of good quality. "Semprolia" No. 4 is a yellow soft paraffin of lower grade, which is intended for veterinary use, and which, in our opinion, is quite suitable for this purpose.

British Medical Journal.

SATURDAY, FEBRUARY 7TH, 1920.

INFLUENZA.

ALTHOUGH the Registrar-General has not, down to the time of writing, recorded any notable increase of the mortality attributed to influenza, and recent augmentations of notified pneumonia may only reflect normal seasonal conditions, events in other countries justify the warning issued by the Ministry of Health; it is probable that another influenza wave is gathering head. In the calm, which may well be the calm before a storm, and while the floodgates of eloquence are still shut and exhortations to the public health authorities still undelivered, it is good to take stock of our position.

Some pious persons and all journalists have referred to the Armageddon of 1918, but perhaps the opening of the fourth seal would have been an apter comparison; power was certainly given "to kill with sword, and with hunger and with death" over not much less than a fourth part of the earth. In 1918 we entered upon a new epidemiological epoch with but one historical parallel—that of the fourteenth century. Dr. F. G. Crookshank, in the scholarly paper which he recently read to the Epidemiological Section of the Royal Society of Medicine, quite properly drew attention to the neglect of general principles, the narrow particularism which has characterized all popular and too much professional literature dealing with the recent prevalences of epidemic disease. The great factors governing what we may term a pandemic respiratory constitution may be similar even when the bacteriological *verae causae* are different. Whatever be the pathogenic cause of influenza, it is certainly not *Bacillus pestis*; yet the epidemiological affinities of the fourteenth century pneumonic plague and the influenzas of 1918-19 are close. The herding together of human beings under conditions transcending those of ordinary intra-domestic overcrowding appears to be a necessary link in the chain of causes which connects endemic and pandemic respiratory diseases. Plague was not abnormally virulent or widespread in the East before the Black Death; it was in the beleaguered Crimean town of Kaffa, the conditions of which de Mussis graphically described, that something happened which led up to the European pandemic. Upon a smaller scale the same sequence of events was observed in Manchuria in 1910. The primary focus, whether scattered "endemic" cases or an epizootic, is shrouded in obscurity—absolute for the fourteenth century, nearly so for the twentieth—but the incubating chamber, the besieged mediaeval town thronged with fugitives, or the crowded caravanserais of the Chinese hunters in Manchouli, is obvious.

In the specifically distinct case of influenza, it seems probable that a similar stage must intervene before the sporadic passes into the epidemic or pandemic form. Large numbers of human beings must be brought into close temporary association that a stable infective strain may be evolved. Such breeding grounds have been provided with the utmost profusion and in many parts of the world during the last five years. The conditions of fourteenth century Kaffa have been reproduced in the war zone with more than the horrors recorded by de Mussis; they

continue to be found, if with less grim accessories, on the tube railways of most cities. In this way we must suppose that a new epidemiological equilibrium has been established. Doubtless the equilibrium is unstable. If it be possible to restore the old standard of life, to break up the mobs of desperate half-starved men and women herding together in cities of Europe, to restore some of the amenities of civilized life, the centre of gravity will again move. But it will move very slowly. The ground conquered by the enemy will not be re-inquished more rapidly than it was won. We must not expect to see the end of the present epidemic constitution this year or next year. It is the habit of all men to take short views, to neglect remoter causes and to seek scapegoats, especially when confronted with epidemic disease. Many seem to think that influenza occurred spontaneously, sprang fully armed from the head of Zeus, and may be arrested if only some genius can devise an appropriate vaccine.

In our judgement the sequence of events although mysterious, inasmuch as the precise mechanism, the pattern of the chain, is unknown, is still a real sequence of cause and effect. There is room for controversy as to details, but there is no doubt that those who, like Dr. Hamer, Dr. Crookshank, and a few other epidemiologists, have seen in cerebro-spinal fever, encephalitis lethargica, and pandemic influenza associated manifestations of a new epidemic constitution, judged wisely. With history to guide us, we need not throw back the responsibility upon the "skiey influences" of Sydenham, but can adopt as a reasonable working hypothesis the opinion that the unrivalled opportunities for passage afforded by the social conditions of 1914-18, have combined to standardize an infection which, whatever we may do, and however many scapegoats we drive into the wilderness, whatever panaceas we cry up or down, must continue to take toll of human life until in the course of years a new equilibrium is established.

Does this inference conduct us to a sullen fatalism? must we fold our hands and accept our fate? By no means. Rebuilding of the shattered social order, elevation of the general standard of life, will not "stamp out" influenza this year or next year, but it will steadily reduce the probability of its recurrence in the future. Research into the microbiology of the clinical disease, the controlled employment of vaccines, a really impartial study of their effects, will not prevent epidemics but may do valuable service in the cause of individual prophylaxis. A heedful organization of domiciliary and institutional treatment can save many lives. There is room for much fruitful labour, none for idle boasting or half suggestions that we are almost on the point of discovering a sovereign specific.

Lastly, as to the probable extent of mortality to be anticipated. On the unfavourable side, we must observe that the evil conditions which generate overcrowding, particularly that extra-domestic congestion whether in armies or upon means of public transport which, as the Ministry of Health suggested in its recent memorandum, is probably a more important factor than intra-domestic overcrowding, still exist. So far as the metropolis is concerned, the overcrowding of public vehicles is even greater than in 1918. Hence it may be that the noxious properties of the infective organism will reach an even higher plane than before. On the favourable side, we note the opinion of the Ministry of Health that some immunity was conferred by previous attack, and the fact that the third of the three 1918-19 waves lasted a shorter time and killed fewer persons than the autumn

disease. We might add that the enormous total mortality of the late waves must have eliminated an appreciable proportion of the very susceptible units and that the age-incidence was at the end of the late cycle reverting towards the customary pre-pandemic and less fatal type.

Upon the whole, then, we do not expect that the anticipated outbreak will attain the dimensions of that of September–December, 1918, and think that it may even fall short of what we experienced a year ago. It is said that the epidemic now raging in Italy is not so mortal as before, but details are lacking. Newspaper reports, however, affirm that in parts of Switzerland the current influenza is very fatal. Official figures from New York and Chicago record as many as 10,000 cases in each city for the week ending January 24th, but the deaths have been few. The evidence does not therefore warrant any confident prediction.

THE SALE AND ADVERTISEMENT OF ABORTIFACIENTS.

At the Central Criminal Court, on January 21st, Mr. Justice Darling, towards the close of his summing up of the trial of two men on charges alleging an illegal operation, expressed the hope that the authorities and those having the power to legislate would take care to stiffen the law regarding abortifacients, "and see that it is more strictly enforced with regard to these improper and dangerous practices." The need for strengthening the law as to the advertisement and sale of abortifacient drugs has long been urged by the British Medical Association. Between 1893 and 1905 the attention of the profession was repeatedly drawn in this JOURNAL to the prevalence in the Midland counties of cases of plumbism in women, caused by the ingestion of diachylon (lead oleate), with the object of procuring abortion. Hundreds of cases of lead poisoning from this cause were then occurring every year, so much so that in the out-patient rooms of the Nottingham and Sheffield hospitals it became a routine practice to examine the gums of women patients. In view of the danger to health and life arising from this practice, the Medico-Political Committee of the British Medical Association appointed in 1905 a subcommittee to investigate the evil and to make suggestions for checking it. A paper by Dr. Arthur Hall and Dr. W. B. Ransom, published in our issue of February 24th, 1906, gave an idea of the magnitude of the evil then existing in South Yorkshire and the Midlands of England. In a leading article of the same date we represented that this matter claimed earnest consideration by the Legislature.

As a result of the deliberations of the subcommittee and of consultation with the Pharmaceutical Society and the Coroners' Society, steps were taken to bring the subject to the notice of the profession through the Divisions, and a communication was addressed to the editors of lay newspapers. In March, 1906, representations as to the necessity of scheduling diachylon as a poison under the Pharmacy Acts were addressed to the Privy Council, but without success. The sale of preparations of this kind without a Government stamp was brought to the notice of the Board of Inland Revenue. Meanwhile the general question of the advertisement, exhibition, and sale of drugs and appliances for procuring abortion had been under consideration. After consultation with the London Council of Public Morality, a letter and memorandum had been addressed to the Home Secretary in November, 1905, urging the necessity for amendment

of the Indecent Advertisement Acts; subsequently it was decided to support a bill for this purpose to be prepared by the London Council of Public Morality. In 1908, a Joint Committee of both Houses of Parliament (the Lotteries and Indecent Advertisements Committee) having been appointed, the Association tendered evidence on the lines of the original memorandum. The Joint Committee recommended, among other things, that the advertisement and sale of drugs or articles designed for promoting miscarriage or procuring abortion be made illegal, and that to advertise drugs or articles designed for the prevention of conception should also be illegal. In making these recommendations due regard was had to the protection of bona fide medical practitioners and chemists. Effect would have been given to them by a bill introduced in 1909 by Lord Brayne [Indecent Advertisements (Amendment) Bill, H.L. 209], but the bill was dropped. In 1912, at the request of the White Cross League, the Council of the British Medical Association addressed a memorial to the Home Secretary, bringing to his notice the recommendations of the Joint Committee and the earlier recommendations of the Association. Meanwhile the Association had been preparing the evidence given before the Select Committee on Patent Medicines in the same year. A memorandum submitted to the Committee contained recommendations, on the lines already indicated, for the regulation of the sale and advertisement of medical preparations and appliances designed to procure abortion. The final recommendations of the Select Committee embody the policy of the Association, and include the following specific references to this matter: 57 (2) That the Indecent Advertisement Acts be amended on the lines of Lord Brayne's bill. 58 (4) That all advertisements likely to suggest that a medicine is an abortifacient be prohibited. (9) (a) That it be a breach of the law to enclose with one remedy printed matter recommending another remedy.

In 1906, the National Commission on the Birth Rate having reported in favour of restriction or prohibition of the manufacture and sale of a particular preparation of lead, occasion was taken to bring to the notice of the Privy Council the original memorandum of March, 1906, on the subject of diachylon and lead poisoning. Diachylon was placed in Part I of the Poisons Schedule in April, 1917. In 1918 steps were taken to ensure the inclusion in the Criminal Law Amendment Bill of that year of a prohibition of the sale and advertisement of abortifacients, but the bill was dropped.

This is where the matter stands to-day. The British Medical Association has succeeded in procuring the most effective available restriction on the sale of one abortifacient, the reckless sale of which was entailing terrible consequences on the credulous purchasers—for there is surely no misfortune greater than loss of sight. It has succeeded in convincing a Select Committee that the advertisement of abortifacients should be prohibited by law, and though hitherto disappointed in securing legislation to this effect it does not despair of attaining the object in view.

THE TERRITORIAL ARMY.

The Secretary of State for War, in his address to a meeting of representatives of the Territorial Force Association of Great Britain on January 30th, outlined the scheme for reorganizing the Territorial Force which has been evolved by the War Office after several meetings between the Army Council and the Territorial Force Association. According to this scheme the British Army is in future

to be organized in two main branches—the Regular Army and the Territorial Army. The Regular Army will be associated with the special reserve battalions necessary to provide it with its own drafts in time of war. For these battalions the old constitutional name "Militia" will be revived. In addition it will have its own reserve, which will be fed by the serving battalions as time passes, and men leave on completion of their engagement. The Territorial Army is to be freed from the responsibility of producing drafts for the Regular Army and to be the sole means of expansion for the British Army in time of war. The purpose of the Territorial Army is to be imperial defence, including the country's obligations to France and Belgium. It will be embodied only when a Royal Proclamation has called out the reserves, and shall be sent overseas only if a fresh Act of Parliament has been passed authorizing its dispatch to a theatre of war. If and when such an emergency arises and the Regular Army and its reserves have gone overseas, and if Parliament then passes the Act, those who enlisted in the Territorials will be the next to go, and on them and on the Regulars the first shock of the war will fall. Mr. Churchill said that there would be fourteen Territorial divisions, and that the yeomanry, of which there are now fifty-five regiments, will provide a cavalry division of ten regiments for the mounted service of the fourteen divisions. A certain number of yeomanry regiments will be kept under the same liability for overseas service as King Edward's Horse, but the rest will be required to form the Field and Mountain Artillery and Motor Machine Gun Corps of the Territorial Army. The war establishment of the Territorial Army is to be 345,000 men, but in the first instance the intention is to recruit it to 60 per cent., or a little over 200,000 men. No reference was made to the special branches, such as the medical. It was stated that the Regular Army and the Territorial Army will be completely self-contained, by which we understand that it is intended each army shall be complete in itself, and independent of the other as regards drafts, etc. The two armies, the Regular and the Territorial, will, however, both be under one direction, that of the War Office; the Territorial Army will be liable to go abroad at a very early stage, and any variation in organization must therefore be avoided, for in the field there must be only one command, one common administration, and identical equipment. These considerations would seem to imply a single Director-General Army Medical Services, who would be finally responsible to the Army Council. On the other hand, it is equally clear that the D.G.A.M.S. must be assisted by officers on his staff intimately acquainted with the characteristics of the component parts of the army. This would apply particularly to personnel, terms of service, methods of recruiting, training, and pay. The question whether it would not be advisable to have a Territorial Medical Advisory Board to advise on Territorial medical administration is one which must be fully considered, but Mr. Churchill promises a fuller statement when he introduces next month the Army Estimates; he will then describe the general scheme of the post-war organization of the British armies as a whole. A White Paper is promised, but has not been issued at the time of writing. We have no doubt that as soon as sufficient information is available the Naval and Military Committee of the British Medical Association will review the situation as it affects the medical branch of the Territorial Army and the relation to that branch of the civil profession. So far as we can judge from what has already been made public, the adoption of the War Office scheme would make it essential that the D.G.A.M.S. should be adequately advised in regard to the special aspects of Territorial service by a competent Territorial officer on his staff, charged with the administration of the medical service of the Territorial Army and responsible for maintaining liaison with the regular service.

HYPERGLYCAEMIA IN MENTAL DISORDERS.

In an article showing evidence of much practical and literary research Kooy,¹ of the Psychiatric and Neurological Clinic at Groningen, Holland, considers the question of hyperglycaemia in mental disorders. Starting with the frequency of glycosuria in melancholia, which Schultze and Knauer observed in 67 per cent. of their cases, and arguing from W. B. Cannon's work that psychical disturbance sets up stimuli travelling by the splanchnics, chiefly the left, to the suprarenals, and thereby causes an increased secretion of adrenalin, which mobilizes the glycogen, and thus leads to an excess of sugar in the blood, and so to glycosuria, he investigated the blood sugar by a modification of Bang's method in a number of mental disorders. The standard was first obtained by examination of the blood sugar in ten normal women and ten normal men, the blood being taken before breakfast and three-quarters of an hour, one hour and a half, two hours and a quarter, and three hours after that meal; the average per mille being 0.98 before food and the highest 1.16 at one and a half hours after food. In epilepsy and dementia praecox the blood sugar was not increased unless there was excitement, and the same result was obtained in the cases classed as anentia. In melancholia hyperglycaemia before breakfast (spontaneous hyperglycaemia) was not constant, but was well marked after food and after anxiety. In mania the blood sugar was often increased, and was highest in real emotional states, such as occur in mania at its climax, but was less in the mild form, and absent when the patient was optimistic, cheerful, and inclined to be jocular. Hyperglycaemia in mental disorder is ascribed to the effect of fear and anger, which phylogenetically are old psychical states, and hence man when so affected reacts in the same way as Cannon and Crile have shown animals do. If this assumption be true, there should be evidence in melancholia of other manifestations of increased stimulation of the sympathetic, such as raised blood pressure, rapid pulse, dilated pupils, erection of hair, as well as hyperglycaemia. Investigation of sixty cases of melancholia supported his contention to such an extent that the working hypothesis of hypersecretion of adrenalin in melancholia is put forward, though in some points proof is wanting. The constipation in melancholia is discussed at length, and is regarded as due to emotion, just as in animal's intestinal inhibition may be so caused. In our issue of March 8th, 1919 (pp. 267-271) there was an article on the physiology of hyperglycaemia and glycosuria by Professor H. J. Hamburger of Groningen, who showed that in frogs hyperglycaemia so modified the glomerular epithelium that sugar passed through, but that normally this epithelium prevented the escape of free glucose. The investigation of blood sugar has therefore recently received considerable attention in Groningen from independent and different points of view.

LETHARGIC ENCEPHALITIS.

In communications made recently to the Académie de Médecine in Paris MM. Netter and Achard have reported the occurrence of a considerable number of cases of lethargic encephalitis in Paris and its suburbs. At a meeting on January 6th M. Netter said that he had seen twelve cases since November 26th, and had heard of twenty others. His own cases occurred in different parts of Paris, one in a suburb; no second case had been observed in relation with any of them. A correct diagnosis had, he said, been made in five cases by doctors who had never seen the disease before, and this he attributes to the accuracy of the description of the symptoms he had given to the Académie in May, 1918. Of the three cardinal symptoms—fever, somnolence, and diplopia followed by temporary paralysis of accommodation—the first two were constantly present in the recent cases, but

¹ F. H. K., *Brain*, London, 1919, xlii, 214-239.

liplopia was not observed in a third of them. The hypoglossal nerve was involved in three cases, and the facial in two. Three had tremors and one generalized convulsions. In two there was profuse salivation. There had been two deaths among his cases; two others had completely recovered, and the remainder were still under treatment. At a meeting on January 20th M. Netter said that he had since seen nine other cases, and that the number in Paris and its suburbs exceeded one hundred. He read a note from MM. Combemale and Duhot reporting a series of five cases of lethargic encephalitis in Lille. The first case was that of a man taken ill on September 3rd, 1919, three days after his return from Algeria; the second and third cases occurred in the third week of December, the fourth at the beginning of January, and the fifth on January 13th. Somnolence and ocular paralysis were present in all the cases, and in some other cranial nerves, especially the facial, were affected. The pressure of the cerebro-spinal fluid was increased in all cases, but in only one was it very high. Two other cases had been reported in the neighbourhood of Lille, but no relation could be traced between any of the cases. In two of the cases reported by M. Achard lumbar puncture disclosed marked lymphocytosis, which gradually diminished, and he pointed out that the occurrence of lymphocytosis under these conditions should not be held to negative a diagnosis of lethargic encephalitis, a certain amount of meningeal reaction being apt to occur. This is in agreement with the observations of Dr. James Mackintosh,¹ who found that the pia arachnoid was slightly involved, the lesion consisting usually of an increase in the cellular elements, particularly in the neighborhood of the blood vessels. In one or two instances only did he observe a number of cellular elements sufficiently great to form an actual mass. M. Netter confirmed M. Achard's statement that the existence of lymphocytosis in the cerebro-spinal fluid did not negative a diagnosis of lethargic encephalitis and agreed that it rapidly diminished. Both authorities referred to the fact that in 1918 and again this year the cases of lethargic encephalitis occurred during an epidemic of influenza. M. Achard suggested that influenza might prepare the way for encephalitis, and M. Netter thought that it was merely an instance of the contemporaneous occurrence of two analogous diseases. He said further that he had recently obtained information of the occurrence of several cases of lethargic encephalitis in a family, in a house, or in a place of business, some occurring at the same time and others after somewhat long intervals. The last fact led him to suggest that, as he believed to be the case with poliomyelitis, the infective agent must be carried in the nose or mouth of convalescents or healthy persons previously in attendance on the sick. A case of the disease has recently been notified at Hanwell, Middlesex, and several isolated cases have been observed in the east and south of France.

PUERILISM OF WAR.

In 1903 E. Dupré described, under the title of "mental puerilism," a form of altered personality in which there is a reversion to an infantile state. Piéron,² in a recent review of the subject, pays special attention to its occurrence during the war, and relates eight cases, one of which was watched for three years. In the historical summary pre-war knowledge is first dealt with: the pathological state of puerilism has long been recognized in three very different mental conditions—in the insane, in hysteria, and in patients with cerebral tumours; examples of these are quoted. Six reported cases precipitated by exposure to explosions or mental shock are referred to, and then the author's eight cases are described in detail. In puerilism the personality reverts to that of childhood, the tastes, feelings, appetites, speech, and gestures being those of a young child. In the cases of war puerilism both physical trauma

and emotional shock are possible factors, but the latter is regarded as the more important, though its morbid effect is favoured by antecedent or concomitant trauma, which renders the nervous system susceptible to auto-intoxication. Commotional-emotional puerilism should be regarded as a curable condition, though improvement is slow. The treatment usually indicated is that for shell-shock, but Piéron has administered orchitic extract. Puerilism may be complete or partial, and has been divided into two main forms: (1) Apparent, which is always complete, and is due to suggestion, either from within or without, and is allied to pithiatism; (2) real, which may be partial, and is that seen in the insane, in cerebral tumour, and in most of the commotional and emotional war cases; there is a child's mind in an adult's body, amnesia is not constant and affects recent events, as in an old man in his dotage. True puerilism is due to the combined action of three pathogenic factors: (1) Cerebral insufficiency with more or less complete loss of the inhibitory mechanism of the cortex and of the intellectual acquisitions, and with retrograde amnesia; (2) genital insufficiency with diminution or complete loss of the internal secretions of the sexual glands and disturbance of the endocrine balance; and (3) disorder of the affective functions, characterized by abolition of the biological activities (in part due to genital insufficiency), of the social powers (partly the result of cerebral failure), and by exaggeration of the primitive impulses which are no longer inhibited.

POST-GRADUATE TEACHING "ELEMENTS."

WE have referred on several recent occasions to the reorganization of medical teaching now taking place in the metropolitan medical schools along the lines suggested by the Royal Commission on University Education in London, and strongly advocated by Sir George Newman in his Memorandum on Medical Education. The essence of the new scheme is the establishment of professorial units, containing "elements" each consisting of a director with assistants; the desire is that as a general rule both the directors and their assistants should be whole-time officers. The scheme is having an effect in various directions, and we are glad to learn that the governing body of the London School of Tropical Medicine has taken advantage of the occasion presented by the removal of the school to Euston Square to bring their whole-time appointments into line with it. The duties of the staff of visiting lecturers remain practically unchanged, but whole-time directorships have been instituted in protozoology, helminthology, entomology, and tropical pathology, and the addition of other "elements" when funds permit is foreshadowed, among which tropical hygiene is specified. We may point out that if an "element" in clinical tropical medicine were added to the preceding subjects, it might be held to complete two full professorial units under the scheme. The action of the board of the Seamen's Hospital Society will undoubtedly excite much attention, for it is the first overt step yet taken towards the founding of a post-graduate medical unit in London. We join in the hope that it will receive the financial support which it deserves from the University Grants Committee now considering the needs and claims of the various educational bodies in this country.

THE JOEL CHAIR OF PHYSICS.

IT was announced last week that Mr. S. B. Joel and his brother, Mr. J. B. Joel, have promised the sum of £20,000 for the endowment of a chair of physics in the Middlesex Hospital Medical School. This handsome gift should prove of benefit to the students in their preliminary training, for the principles of physics cannot be taught too well, and a good grounding in this subject is indispensable for the scientific attitude towards medicine. The endowment may also, it is to be hoped, stimulate research into

¹ Report of an Inquiry into Encephalitis Lethargica. Local Government Board. New Series, No. 121. 1918.

² H. Piéron: *Rev. de méd.*, Paris, 1919, xxxvi, 300-345; 410-437.

the applications of physics to medicine, and may bring about fruitful association in clinical work between the physicist on the one hand and the physician and surgeon on the other. The creation of a professorship of physics in a hospital medical school is an apt recognition of the need for closer association between pure science and medical practice. Long ago physics was called the handmaid of all the sciences, but its possibilities in the way of direct service in the diagnosis and treatment of diseases and injuries are only now being brought to light. When a discovery is made in physics it may be years before its bearing upon the sister sciences is unfolded. To take one instance, Roentgen discovered x rays in 1895, but while these rays were soon enlisted for diagnosis, their use in the treatment of disease was of slower growth. Hitherto it has been difficult to discern and test the medical application of a physical discovery because the physicist and the clinician have had few opportunities of intercourse and discussion. The reason for this is not hard to find. The interest to the discoverer of a new fact in physics lies in its bearing upon his own subject, how it may extend knowledge there, and what further fields of research it opens up. His interest in the application of the new fact to other sciences, and to the more remote art of medicine, is to him a secondary consideration. As a result the physician and surgeon do not often get new information in physics in the form in which they can most easily use it. For the advance of medical practice along this line the physicist should be in a position to recognize what is likely to be of service to medical science, and be willing to bring his facts to the notice of the practitioner in such a way that their application may be perceived. Such a physicist must be one with a real interest in medicine, and therefore ready to collaborate with the clinician and the pathologist. During the past ten years something of this kind has been done at the Middlesex Hospital, where researches have been carried out continuously into the use of radium in the treatment of disease. A large part of radium therapy depends upon the established fact that many kinds of cancer cell are more affected by radium emanations than are most of the healthy cells of the body. In order that this fact may be put to good account much research is still needed. The various types of electric current now used in diagnosis and treatment provide another field for co-operation between the physicist and the medical man. Thus, beyond its obvious value in the education of students, the professorship of physics at the Middlesex Hospital may lead to a wider recognition of the value of this fundamental science to medicine, and of the benefit to mankind of joint explorations upon the borderland of the two sciences.

NO. 14 GENERAL HOSPITAL.

IN the earliest months of the war the Casino at Wimereux, overlooking the Channel, was transformed into part of a British military hospital, which became known throughout the army as No. 14 General. About the same time its neighbour, No. 14 Stationary, opened up at the Grand Hotel as the infectious diseases hospital for the Boulogne area, but moved into huts further inland after the building was burnt out at the end of 1915. No. 14 General outgrew the Casino and the adjoining hotel, and became one of the largest hospitals in France. For a part of 1915 its commanding officer was Lieut.-Colonel T. H. J. C. Goodwin, D.S.O., who within two and a half years rose to be Director-General of the Army Medical Service. During the five years of war vast numbers of patients passed through the wards, and very many medical officers served there for long or short periods. The work is now over, and the rooms of the Casino may already be returning to their former uses. A dinner of the staff was held in London, at the Victory Restaurant, on February 2nd, when a company of one hundred exchanged memories of the wonderful years of work and comradeship. The chair was appropriately taken by Lieut.-General Sir John Goodwin. The toast of

"No. 14 General Hospital" was proposed by Sir Arthur Sloggett, who was D.G.M.S. in France throughout a large part of its career, and the Chairman responded. In response to a message of loyal greeting a telegram was received from the King expressing His Majesty's thanks to the staff of No. 14 General Hospital for their message "on the occasion of the dinner, which, under the presidency of General Goodwin, their former and distinguished Commandant, has reunited that noble band of men and women who ministered to the wounded and sick." The King visited the hospital in October, 1915, a few days before his accident. His message recalled this visit and congratulated the staff on their happy reunion, adding that "the same spirit of devotion and comradeship which animated their work in those days has brought them together this evening."

WATER CHARGES FOR CAR WASHING.

SOME little time back we referred to the subject of charges for the supply of water for the purpose of washing cars, and this subject has again been raised by a correspondent, a medical man, practising in a North London suburb. He has kept two cars for several years, and has paid an extra charge for water used for the washing of a car. The Metropolitan Water Board now demand twice the amount he has hitherto paid, on the ground that two cars are kept, notwithstanding an assurance that both cars are never used on the same day. The position of water companies and the rates they may charge for water supply are governed by the Waterworks Clauses Act, 1847, and by the particular Acts under which each company is constituted and empowered. Under the Metropolitan Water Board (Charges) Act, 1907, the Metropolitan Water Board is bound under penalty to maintain within a certain area a supply of water for domestic purposes for which the consumer pays a water rate based upon the value of the premises supplied, and the Act defines the words domestic purposes as excluding (*inter alia*) the washing of carriages or other vehicles. Water to be used for extra domestic purposes may be supplied in two ways. Under Section 16 of the Act the Board may supply water for purposes other than domestic by meter, the rates varying with the amount consumed and the minimum amount payable for water supplied in this way being fixed at £1 a quarter. To meet the requirements of the small extra domestic consumer the Board is empowered by Section 24 of the Act to enter into agreements for water supply, providing the scales are of uniform application, and it is under one of these agreements that our correspondent is presumably being supplied. We can therefore only advise our correspondent, and any other reader who may be interested in this point, to refer to the terms of his agreement to see whether this double charge is justified or not. It should, however, again be pointed out, lest what we have said may give rise to any misconception, that the powers of each water company are regulated by its own special Act of Parliament, to which reference must be made in each case. What we have said of the Metropolitan Water Board will no doubt also apply to many other water companies, but there will be others whose powers are entirely different, and the only way of ascertaining what any given water company may or may not do is to refer to its Act.

THE current issue of the *Journal of the British Science Guild* contains an appeal to men of science to make larger use of the facilities the Guild offers. It commands access to the best available knowledge on matters of science, and its resources can be applied at any time to any desired end by the Executive Committee. Communications on subjects considered to require elucidation should be addressed to the Editor of the *Journal of the British Science Guild*, 6, John Street, Adelphi, London, W.C.2. The Guild numbers only 934 members, but it is hoped to increase the membership. The annual subscription is one guinea.

Medical Notes in Parliament.

The New Session.

THE Parliamentary Session, to be opened by the King in state on Tuesday next, will be largely occupied with measures which were heralded last session, but could not, owing to their complexity or on account of their controversial nature, be then proceeded with. Foremost amongst these is the Irish Government Bill, the principles of which were set forth by the Prime Minister just before the House of Commons rose in December. The condition of affairs in Ireland is, however, thought to raise a question as to whether a suspensory clause will be included, so as to make the operation of the provisions depend on circumstances, the decision in that case to rest with the Privy Council, or in other words, with the Government. It is on the vexed labour problems that the Cabinet may find the greatest difficulty in securing legislation to avoid troubles in the country, though Mr. Asquith's declaration against nationalization may considerably help them in getting moderate opinion to support their proposal for dealing with the coal mines on lines of joint management while leaving scope for individual enterprise. In the event of a threat of labour upheaval or refusal by labour of the suggested compromise, it is quite possible Mr. Lloyd George may appeal to the country, either by a general election against nationalization, or by a referendum on that issue. The agreement as to the railways will also require parliamentary sanction, and the bill to fix minimum hours of work and pay will be reintroduced.

An intimation that the Budget will be brought in early carries the reminder that this will in reality be the gravest matter before Parliament this session. Large additional expenditure has been sanctioned since Mr. Chamberlain said that if any such additions were made more taxation would be necessary. On the other hand, the reduction in the cost of the services has been made more drastically than was then thought possible, and the realization of materials held by the Ministry of Munitions has given a much greater yield than at one time was thought probable. The revenue of the country has also shown up better than was anticipated. The hope of the Chancellor of the Exchequer is that in the coming year expenditure and receipts may be brought to balance; but he has guarded himself against the assumption that this balance can be got without some fresh taxation. The exchange conditions, which are exciting so much anxiety, of course come prominently into this matter.

Scotland.

SCOTTISH BOARD OF HEALTH.

Consultative Councils.

IN the Act which established the Scottish Board of Health provision was made for the setting up of Consultative Councils to advise and assist the Board in connexion with Scottish health matters. The constitution and functions of these councils were defined by an Order in Council of December 20th, 1919. The councils are four in number: (1) Medical and Allied Services, (2) National Health Insurance (Approved Societies' Work), (3) Local Health Administration and General Health Questions, (4) Highlands and Islands.

The appointment of the members of the Consultative Councils rests with the Board, and is now complete:

Medical and Allied Services.

- ORLANDO CHARNOCK BRADLEY, M.D., D.Sc., M.R.C.V.S., Principal of the Royal (Dick) Veterinary College, Edinburgh, Vice-President of the Royal College of Veterinary Surgeons, and President of the National Veterinary Medical Association.
- A. J. CAMPBELL, M.D., Secretary of the Berwickshire Local Medical and Panel Committees.
- A. K. CHALMERS, M.D., Medical Officer of Health for the City of Glasgow.
- D. ELLIOT DICKSON, M.D., Convener of the Fife Colliery Surgeons Committee.
- J. R. DREYER, M.B., Scottish Medical Secretary of the British Medical Association.
- MISS ANNE W. GILL, Lady Superintendent of Nurses, Edinburgh Royal Infirmary.
- JOHN GLAISTER, M.D., Professor of Forensic Medicine and Public Health in the University of Glasgow.
- PROFESSOR MATTHEW HAY, M.D., Medical Officer of Health for the City of Aberdeen.
- JOHN HUTHERFORD HILL, Esq., Resident Secretary of the Pharmaceutical Society in Scotland; Secretary of the General Council of Panel Chemists (Scotland).
- SIR DONALD MAC ALISTER, K.C.B., M.D., Principal of the University of Glasgow; President of the General Medical Council.

- JOHN YULE MACKAY, M.D., LL.D., Principal of the University College, Dundee.
- SIR JAMES MACKENZIE, M.D., F.R.C.P., Clinical Institute, St. Andrews; Consulting Physician to the London Hospital.
- SIR ROBERT WILLIAM PHILIP, M.D., F.R.C.P., Professor of Tuberculosis and Senior Lecturer on Clinical Medicine in the University of Edinburgh; President of the Royal College of Physicians, Edinburgh.
- JAMES MAXWELL ROSS, Esq., M.B., C.M., M.B.E., Medical Officer of Health and Chief School Medical Officer for the County of Dumfries.
- MISS LARA STEWART-SANDEMAN, M.D., late Controller of Medical Services to Queen Mary's Army Auxiliary Corps, Overseas.
- SIR HAROLD J. STILES, K.B.E., Regius Professor of Clinical Surgery in the University of Edinburgh.
- F. TOCHER, D.Sc., Public Analyst for the County of Aberdeen, etc.; Honorary Secretary of the Association of Public Analysts of Scotland.
- NORMAN WALKER, M.D., General Medical Council.
- GEORGE WILLIAMSON, M.D., Chairman of Aberdeen Local Medical Committee.
- JOHN A. YOUNG, L.D.S., Vice-President of the Odontological Society of Scotland; Convener of the Public Health Committee, Edinburgh Town Council.

National Health Insurance (Approved Societies' Work).

This council consists of fifteen members, including three ladies.

Local Health Administration and General Health Questions.

This council consists of twenty members, including Dr. Thomas G. Nasmyth, formerly medical superintendent of Perth Infirmary and an ex-president of the Scottish Society of Medical Officers of Health, Lady Leslie Mackenzie, president of the Scottish National Association of Health Visitors and Women Sanitary Inspectors, and Mrs. Burns Laird, of the Scottish Labour Housing Association.

Highlands and Islands.

This council consists of fourteen members, including Dr. A. C. Miller, chairman of the Highlands and Islands Subcommittee of the British Medical Association, Dr. Donald Murray, M.P., late M.O.H. for Lewis, and Dr. James B. Simpson, vice-president of the Sutherland and Nursing Association and secretary of the County Local Medical Committee. The council contains six ladies, including the Duchess of Atholl and Miss Margaret M. White, superintendent of Queen Victoria's Jubilee Institute for Nurses (Scottish Branch).

Each consultative council will appoint its own chairman. Mr. George A. Birse, Scottish Board of Health, 125, George Street, Edinburgh, will act as secretary to the councils.

EAST OF SCOTLAND OVERSEAS MEDICAL CLUB.

SOME time ago this club was formed for medical men who served overseas during the war. It now has a large membership. It was established for the purpose of maintaining alive the friendships forged under the stress of war, and to encourage the spirit of comradeship and mutual help amongst its members. The first annual meeting and dinner was held in Edinburgh on January 30th, 1920. There was a large and enthusiastic gathering. Sir Henry M. W. Gray, K.B.E., C.B., C.M.G., of Aberdeen, who was consulting surgeon with the Third Army in France, the first president of the club, occupied the chair. Professor Francis D. Boyd, C.B., C.M.G., was elected vice-president, and Dr. James Young, D.S.O., honorary secretary and treasurer. The following members of committee were appointed:—Edinburgh: T. F. Dewar, C.B., and Henry Wade, C.M.G., D.S.O.; Dundee: J. Anderson, D.S.O.; Aberdeen: T. Fraser, C.B.E., D.S.O.; Inverness: John W. Mackenzie, O.B.E.; South of Scotland: A. C. Mallace, M.C. It was decided to form subsections of the club in suitable districts in the east of Scotland. In giving the toast of the Club, the President said that one of the greatest functions would be to give opportunities of cementing friendships formed or strengthened overseas under conditions which brought out in many different ways what was real and worth knowing in men; and, further, that it would bring the friendship of other men who served in other areas and who proved their worth. He believed that this and similar clubs would be able to play an important part in raising the status of the profession, and that if properly used they might be of great value in moulding a wise opinion regarding the wider matters that concerned the community. The organization of the army had led to schemes that were of great benefit to the nation's soldiers. "We must take counsel together and decide upon schemes for the benefit of the nation's workers that shall be even more comprehensive and successful." Mr. Henry Wade, C.M.G., D.S.O., who was consulting surgeon with the Egyptian Expeditionary Force, proposed the health of the Chairman, and in doing so mentioned that though he and many others present had not served as colleagues of Sir Henry Gray in France, they had been largely

influenced in their surgical practice by his work. Many younger surgeons who had been trained by him had gone to the Eastern armies. Mr. Wade also referred to the great influence exercised by General Allenby in the East in fostering the most modern methods of treatment of the wounded as they had been practised in the Third Army by Colonel Gray.

GLASGOW LIMBLESS HOSPITAL.

The third annual meeting of the Hospital for Limbless Sailors and Soldiers at Erskine was held on January 29th, when the Lord Provost was in the chair. Sir William Macewen said that at the present time about forty patients, after having put their artificial limbs to use, were receiving vocational training. The accommodation of the hospital would be better filled if the restrictions with regard to the admission of disabled men were diminished. The Ministry of Pensions and the Ministry of Labour both had plans which were excellent on paper, but rather complicated in practice. The machinery for getting the men back into work or training should be simplified. He recalled the fact that it was intended to bring back a considerable number of men who would be permanently housed and cared for at the Erskine Hospital, making it a second Chelsea.

Ireland.

IRISH PUBLIC HEALTH COUNCIL.

THE Irish Public Health Council held a series of meetings on January 20th, 21st, and 22nd, at which the chairman, Dr. E. Coey Bigger, presided, and the following members were present: Sir Henry A. Robinson, Bt., Sir John Moore, M.D., Sir William Thompson, Sir James Gallagher, Mrs. McMordie, Dr. W. J. Maguire, Mr. J. Drennan, the Rev. Father Kerlin, Mr. Edmund Bourke, Dr. E. F. Stephenson, Dr. Alice Barry, Sir Joseph A. Glynn, Mrs. M. L. Dickie, Lady Kenmare, and Dr. R. J. Rowlette. On January 20th the Council received a deputation representing the National Association of Approved Societies. Mr. Daniels (Chairman of the association) addressed himself chiefly to the need for providing an efficient medical service for insured persons and their dependants. If a system of medical benefits or treatment for insured persons were established in Ireland, considerable funds from insurance sources would be available towards financing such a medical service, but it was essential that it should not be in any way associated with the Poor Law medical service. Mr. Meller (Prudential Approved Society) attributed the undue incidence of sickness among insured persons in Ireland to the absence of a proper system of medical treatment. He advocated the provision of a medical service, free from any taint of pauperism, for insured persons and their dependants, including consultant and hospital treatment. Mr. Alexander (Presbyterian Approved Society) said that the insured in Ulster formed about half of the total insured population of the country. He concurred with the previous speakers in advocating medical treatment for insured persons and dependants with an efficient medical service to replace the existing Poor Law dispensary service. Mrs. O'Connor (Nurses' Approved Society) urged the necessity for a proper nursing service.

In the course of discussion, members of the deputation stated that the approved societies would consider favourably the question of allocating towards hospital and allied services, and for the treatment of dependants, part of any surplus funds which might be available after the forthcoming valuation. The deputation also agreed that there would be no objection to a medical service system under which insured persons would be treated by medical practitioners paid by salary or fees, and responsible also for the treatment of persons unable to pay. The Chairman, on behalf of the Council, promised sympathetic consideration of the views expressed.

Subsequently the Council, after discussion, arrived at important decisions concerning the following matters:

(a) The constitution of the proposed central health authority in Ireland.

- (b) The functions to be entrusted to that authority.
- (c) The constitution of county health authorities.
- (d) The powers and duties of such authorities.
- (e) The establishment of an Irish medical service which will provide medical treatment for insured persons (and if possible for their dependants) as well as for persons who are unable to pay.
- (f) The reorganization and co-ordination of the hospital system in Ireland, with a view to providing treatment for the classes referred to in "e," not only in the county institutions but also in the voluntary hospitals in the larger cities.

These questions and previous decisions of the Council were referred to a drafting committee, consisting of the Chairman, Sir Joseph A. Glynn, and Dr. Rowlette, to be embodied in the report to be made by the Council to the Chief Secretary.

THE PROPOSED STATE MEDICAL SERVICE IN IRELAND.

Meeting of the Profession in Belfast.

A meeting of the profession, called by Mr. R. J. Johnstone, F.R.C.S. Eng., chairman of the Irish Medical Committee, was held in the Medical Institute, Belfast, on the evening of January 30th. Mr. Johnstone occupied the chair, and Dr. David Gray acted as honorary secretary. There was a large and influential attendance.

Mr. Johnstone explained that the object of the meeting was to discuss matters and to let members of the profession know what was being done, so that they would not be taken unawares. The Irish Health Council was engaged in drafting a bill which would in all probability create a State medical service; and the profession was asked what class of cases should be included. An income limit of £150 a year had been mentioned. Again, what remuneration should be given in the service? It was proposed to do away with the Poor Law system, and that Poor Law dispensary doctors should be enrolled at salaries commencing at about £600 a year; they would be placed under county councils; entrance would be by examination; a large hospital would be built in each county; cottage hospitals in smaller towns; study leave, opportunity for advancement and for specialization, retiring allowances and superannuation, would all be included. The chairman also pointed out that the question of insurance benefits, of the inclusion of insurance patients, and of the confusion between the State medical service and the panel system—all called for debate. A system that suited the rural districts of the Midlands, South and West, would not suit the industrial centres of the North. Some 95 per cent. of eight or nine hundred Poor Law medical officers had signed a memorandum some years ago in favour of a State medical service. The Irish Medical Committee could not pledge the profession without consulting them.

After a long and instructive discussion, which was conducted with good humour and consideration, it was finally agreed to appoint a representative committee to go into the matter and report to a future meeting. The difficulties of the insurance benefits, of the inclusion of insurance cases, of fixing a limit of income for the inclusion of cases, the determination that any State medical service should not be simply a glorified Poor Law dispensary system; the difficulties as to inclusion of dependants of those on strike, of differentiating a single man from the married man with a large family, were all clearly pointed out. On the other hand, it was felt that a *non possumus* attitude should not be adopted. An ideal was in the air, and "prevention" was the keynote of the Ministry of Health. The following committee was appointed:

Convener: Dr. Wm. Burns; *Members:* Drs. Osborne, Irvine, Gardner Robb, Sir John Byers, R. J. Johnstone, McPolin, McElroy, Wm. Calwell (York Street), McSparran, S. H. White, Williamson, Trimble, T. Davidson, J. R. Davison, Samuel Davidson.

ULSTER MEDICAL SOCIETY.

The fifth meeting of the session was held on January 29th, in the King Edward Memorial Hall, Royal Victoria Hospital, Belfast. The President, Mr. Andrew Fullerton, C.B., C.M.G., F.R.C.S., occupied the chair. Dr. W. W. D. Thompson acted as secretary. The Chairman referred to the deaths of Dr. G. A. Hicks and Dr. Jamison, both members of the society, which had taken place since the last meeting. Votes of condolence with their relatives were passed.

Treatment of Fractures.

The Chairman then introduced Major M. Sinclair, C.M.G., R.A.M.C., who gave a demonstration of the most recent methods for the treatment of fractures by Thomas and other splints.

Major Sinclair first demonstrated how a Thomas splint should be applied to fractures of the lower limb, before the patient was removed from the spot where the accident occurred; extension could be obtained at once by passing a heavy skewer horizontally through the sole of the boot and fastening this to the cross-bar at the lower end of the splint. He then enumerated the various methods of applying extension in hospital, and expressed his preference for painting the unshaved leg with the special glue he had devised, and then applying a long strip of gauze bandage on each side of the leg and fastening these to the lower end of the splint; other methods were to drive special screws into the upper end of the tibia or to fix callipers to the condyles of the femur, or to the external and internal malleoli. By these methods no shortening resulted in the fractured limb; indeed, if care were not taken, lengthening might be produced. Major Sinclair showed devices for obtaining external and internal rotation of the foot, where necessary, and also methods of bandaging which would restore the antero-posterior curvature of the femur. In compound fractures the limb was always bandaged by the "sectional" method; packets containing sterilized gauze dressings, short strips of bandage and clips being used. The wound was treated solely by hydrogen peroxide and sterile saline, and the gauze dressing applied; the leg was bandaged in sections with the short strips fastened along the anterior surface by the clips; thus any area of the limb could be inspected or dressed without removing the whole bandage and splint.

Major Sinclair then showed a large abduction splint or frame used for the treatment of fractured femurs and also for wounds of the lumbar and gluteal regions, or for pelvic cases; the patient was slung up to the frame by a series of hammock-like nettings, and with the help of pulleys could raise himself and thus facilitate nursing. With the ordinary Thomas splint a system of pulleys was useful, so that the patient could, by very little effort, suspend himself in mid-air while the bed was being moved and an arm-chair put in its place: thus accidents through slipping or fainting were avoided, as the patient gradually got accustomed to being up after his long period in bed. Splints for the arms were also shown; one, for the wrist and hand, caused much interest and amusement; by adjusting a series of springs and side-pieces the interphalangeal, metacarpophalangeal, and carpal joints were given freedom of movement in succession.

At the close of the demonstration, Professor Sinclair, C.B., proposed a vote of thanks to the lecturer, and said that he had, while acting as consultant in France, utilized Major Sinclair's methods and had brought the surgeons working under him to Major Sinclair's wards at Wimereux for instruction. He commended the methods demonstrated to the careful consideration of the practitioners in the North of Ireland, and hoped that future generations of medical students of the Belfast Medical School would continue to benefit by Major Sinclair's work. The Chairman, in conveying the vote of thanks, said that the society was also deeply indebted to the War Office for having allowed Major Sinclair to give a most remarkable and interesting demonstration.

On the following evening Major Sinclair gave a similar demonstration to a crowded meeting of medical students attending the university. On this occasion lantern slides were also used, depicting the results obtained. Major Sinclair's visit has stimulated an interest in the treatment of fractures in the North of Ireland which cannot fail to produce good results.

EXAMINATION IN OPHTHALMOLOGY.

At the meeting of the Ulster Medical Society on January 29th the following resolution, proposed by Professor J. A. Lindsay and seconded by Dr. J. McCaw, was passed unanimously:

That, in the opinion of the Fellows and Members of the Ulster Medical Society, it is essential that a clinical examination in ophthalmology, conducted by ophthalmic surgeons, be part of the final qualifying examination for medical degrees and diplomas as heretofore in all Ireland. This seems absolutely necessary if ophthalmology is to retain the position its importance entitles it to in the education of the future medical profession of this country.

England and Wales.*PRESENTATION TO DR. W. STANGER, WAKEFIELD.*

DR. W. STANGER, F.R.C.S., J.P., who retired from practice and from the chairmanship of the Wakefield Panel Committee at the end of last year, was entertained at dinner at the Strafford Arms Hotel, Wakefield, on January 28th, by the members of the Panel Committee. After the dinner Dr. Stanger was presented with a cheque in appreciation of his services as Chairman of the Committee. He was for many years one of the honorary surgeons of the Wakefield Clayton Hospital, and holds a high place in the esteem both of the medical profession and of the general public in Wakefield.

MEDICAL REUNION DINNER AT HEREFORD.

On January 22nd the members of the Herefordshire Division of the British Medical Association and other practitioners in Hereford entertained at dinner their medical colleagues who left the country to serve in the Forces during the war. The dinner was held at the Imperial Café, Hereford, with Dr. Dryburgh Gold, chairman of the Division and county M.O.H., in the chair; the Mayor of Hereford was present. The toast of the "Fighting Forces" was proposed by Dr. John Steed (Staunton-on-Wye), and Major Llewellyn Green, D.S.O., who served as a combatant with the 1st Herefords in Gallipoli, replied. The toast of the evening, "Our Medical Guests," was proposed by the Chairman, who expressed the pleasure of those who had remained behind in welcoming their service colleagues back to civil life. The toast was responded to by Lieut.-Colonel J. McK. Harrison (Ledbury), Lieut.-Colonel Herbert Jones, Captain W. Ainslie, M.C., and Major C. J. Caddick, D.C.M.S., Ministry of Pensions. The concluding toast, that of the "Medical Profession," was submitted by Dr. R. Harding (Radnorshire), and Dr. Paul Chapman and Dr. Edgar Morris replied. The arrangements for this most successful evening were made by Dr. E. H. Baldock, honorary secretary of the Division. Representatives were present from nearly all the theatres of war.

LIVERPOOL WOMEN STUDENTS.

Some seventy past and present students attended the dinner of the Liverpool women medical students held recently at Liverpool under the chairmanship of Dr. Phoebe Bigland. The guests of the evening were Miss Frances Ivens, M.S., and Miss Adami, the daughter of the Vice-Chancellor of the University of Liverpool. Miss Ivens, in replying to the toast of the guests, said that medical women must take their share in the great schemes of reconstruction and reorganization. She suggested that students should devote themselves to scientific research and so assist in the advancement of medical knowledge. Miss Adami conveyed a message from the Vice-Chancellor of the University wishing the dinner all success and hoping it would be an annual function in university life.

India.*THE MEDICAL INSTITUTIONS OF JAIPUR.*

THE native State of Jaipur, Rajputana, which has contributed so loyally and liberally in men and money to the prosecution of the late war, has long been conspicuous, under enlightened and philanthropic rule, for the cultivation of art, the encouragement of industry, the promotion of education, the improvement of public health, and the supply of means of medical relief. The annual report for 1918 on the medical institutions of the State, compiled by the Superintendent Rai Bahadur Assistant Surgeon Daljang Singh Khanka, M.B., supplies evidence of the commendable attention paid to sanitation and the prevention and treatment of disease. The report includes information as to meteorology, vital statistics, dispensary administration, gaol hospitals, and lunatic asylums. Weather has in India a vital influence on the welfare and health of the population. The rainfall in 1918 was deficient, but not so scanty as to cause scarcity of food or famine. Malarial diseases were not so prevalent or fatal as in wetter years. The birth rate was below and the death rate above the average. The latter rate was

for the city of Jaipur 72.97 per 1,000. Infantile mortality is high. There was no cholera or small-pox in the State, but plague and influenza were deadly. Of plague, 18,150 cases and 17,479 deaths were returned from fifty-three villages, and 1,199 cases and 1,196 deaths were reported in the Jaipur city. Strenuous preventive measures, including evacuation, segregation, disinfection, and inoculation were adopted. The epidemic subsided in June. Numerous deaths were caused by influenza, which was of a virulent type. Twenty-nine hospitals and dispensaries were open during the year, in which were treated 203,393 outdoor and 3,253 in-patients; 9,356 operations were performed. Detailed information recorded regarding the work of these institutions indicates good and successful work. Special arrangements are made for the treatment of females, including cases of labour, normal and abnormal. The death-rate in the gaols was 49.21 per 1,000, and in the lunatic asylum 41.2. The report, which, with elaborate appended tables, is a very creditable production, has been printed by the Jaipur govt. press.

INFLUENZA.

Recent reports afford evidence that a recrudescence of influenza is threatening. At Karachi a relief committee has been formed to deal with an outbreak of influenza and pneumonia; eight doctors have offered their services, fifty volunteers have enrolled for relief work, and a fund has been established to provide medicines and warm clothing. Owing to the occurrence of influenza on troopships it has been decided to reduce the number of homeward-bound ships by 25 per cent.

MEDICAL RESEARCH.

The annual report of the Scientific Advisory Board of the Indian Research Fund Association shows that although the war has interfered with the activities of the association much work has been accomplished; the programme for 1920 is comprehensive, including investigations with regard to influenza, ankylostomiasis, leprosy, and kala-azar. Yellow fever is to be investigated by a committee of experts appointed by the Government of India.

Correspondence.

"A PLEA FOR THE TONSILS."

SIR.—On page 562 of your issue of November 1st, 1919, there is a review of Professor K. H. Digby's *Immunity in Health*. Although, at the time of writing, I have not had the pleasure of reading this book, your review makes it clear that it is, especially at the present juncture, of more than ordinary importance.

I am fully in agreement with Professor Digby's view that the lymphatic tissue of the tonsils and appendix is functional and not vestigial. In the *Journal of Anatomy and Physiology*, vol. xxxv, pages 83 to 100, I arrived at the following conclusions:

Lymphoid tissue is the characteristic feature of the caeca apex.

As the vertebrate scale is ascended, this lymphoid tissue tends to be collected together into a specially differentiated portion of the intestinal canal—the vermiform appendix.

The vermiform appendix of man is not, therefore, a vestigial structure. On the contrary, it is a specialized part of the alimentary canal.

So far as I am aware, this was the first time the vestigial view of the vermiform process had even been seriously challenged. Its lymphoid character has since been uniformly adopted by every scientific writer—usually without acknowledgement—whilst the unscientific writers still quote the Noachian writers on comparative anatomy as to the vestigial nature of the vermiform process.

Professor Digby, according to your review, goes on to remind us that these glands (tonsils, Peyer's patches, and appendix) are largest and most active in young children at a period when individuals are acquiring immunity to the various common infections, while in old age all lymphatic structures tend to atrophy. These facts I had the privilege—in conjunction with Dr. L. A. H. Lack—of pointing out to the first International Congress of Anatomists at Geneva in 1905, and subsequently published

in the *Journal of Anatomy and Physiology*, vol. xl, pp. 237 to 256. Amongst the deductions were the following:

The amount of lymphoid tissue present at the caecal apex varies most probably, though not certainly, in accordance with the varying diet of the animal.

The vermiform appendix of man is not, therefore, either a vestigial remnant or an organ in a state of retrogression, but is an actively functional lymph gland.

The appendix of man is not equally functional throughout the whole of life. Lymphoid tissue is a tissue of the growing animal.

The functions of the human appendix are the same as those of any other collection of lymphoid tissue in any other part of body.

That the significance of these facts has too long been ignored by the profession is amply demonstrated by Professor Digby, as also by the following facts which have recently been brought prominently under my notice as the result of my more recent work on the diagnosis and causation of mental deficiency, now in the American press.

Chronically enlarged circumpharyngeal lymphoid tissue may interfere with breathing and so diminish the supply of bodily oxygen. The cell body of the neurone is peculiarly sensitive to deprivation of oxygen. Imperfectly developed neurones necessitate mental backwardness, even to gross mental deficiency. A community of mental defectives will not only breed criminals and prostitutes, but cannot make good the ravages of war, nor can it hope to survive in that greatest of all struggles—the struggle for existence.

That such national effects do really follow such natural causes is fully proved by the recent investigation of Dr. Waite in hookworm disease in Queensland, published in the *Medical Journal of Australia*, January 4th, 1919. The hookworm, by preying on the haemoglobin, reduces the bodily supply of oxygen, and "produces in growing children severely arrested mental development and considerable mental sluggishness."

The direct outcome of the results of such a blighting disease, which is preying upon 40 per cent. of the total school population from Cooktown to Townsville, and which is stamping serious mental, physical, and sexual degeneracy upon 25 per cent. of the total school population, can be nothing other than the weakening of the social fabric and the ruining of the coming generation for the struggle for existence. Indeed, the tendency of the disease, if not controlled, is toward the obliteration of the race through the unsexing of its victims. . . . To the economic loss from social inefficiency must be added the wasted educational effort of 4,000 teachers, with an expensive plant, trying to carry along 40 per cent. of relative mental deficient and mental laggards among their classes.

In conclusion, I desire to congratulate Professor Digby on the production of an important work, and your reviewer for his presentation of the same. My own claims to priority in much of the subject matter must, I think, be admitted, but would not even now have been pressed were it not for the great importance of what are thought superficially to be trivial facts. We have yet much to learn regarding lymphoid tissue, and I can only regret that the pressure of routine teaching work and the chronic lack of scientific, financial, and other assistance have compelled me to lay aside my own researches into the matter. For those who come after it is, perhaps, not too much to hope that they will at least commence by a study of the literature of the subject.—I am, etc.,

RICHARD J. A. BERRY,
Professor of Anatomy.

University of Melbourne,
Dec. 15th, 1919.

THE TREATMENT OF MALARIA.

SIR.—Controversies on the intravenous and intramuscular as compared with the oral administration of quinine are of great interest to those who have served in malarial countries, but they must tend to confuse the practitioner who has not experienced the delights of Macedonia or Mesopotamia. There is, I think, general agreement that in an ordinary case of malaria, uncomplicated by vomiting, the first indication is a mercurial purge and a dose of aspirin, with or without brandy. When the sweating stage begins large doses of quinine (15 grains thrice a day) by the mouth are given. Three days is probably long enough to continue this. If, however, the temperature does not come down, or if there is persistent vomiting, there should be no hesitation in giving 20 grains intramuscularly once or twice daily (into the buttock, just below the iliac crest, seems to be the safest place). If even this fails, then one of the arsenic compounds, such as galyol, should be given intravenously.

As to the vexed question of continuing the administration of quinine for some weeks or months, I feel sure that very few of the medical men who themselves have malaria take quinine for more than a few days after an attack.

The rationale of giving quinine by intramuscular injection when oral administration fails appears to be that in certain circumstances quinine given by the mouth is not absorbed properly. The risk of quinine necrosis is not negligible, but is infinitely less than the risks of the disease in a case which is bad enough to require intramuscular treatment.

Finally, I would emphasize that a most important part of the treatment is to use every endeavour to get the patient into as good a state of health between the attacks as possible, particularly by such tonics as iron and arsenic, good and abundant food, and moderate exercise in the open air—bearing in mind the myocardial weakness invariably present after malarial pyrexia. In certain cases a bottle of stout daily appears to be of the greatest value.—I am, etc.,

Sheffield, Jan. 27th.

R. K. ROBERTSON.

TICKS AND RELAPSING FEVER.

SIR,—I can corroborate clinically the description by Dr. Nicholson of a type of pyrexia, relapsing in character, associated with a spirochaete in the blood, and giving a different clinical picture from the well known relapsing fever due to louse infection, as described in Colonel Balfour's "Memorandum on Mediterranean Diseases." This was repeatedly seen by me among Egyptian natives and British soldiers in the Upper Nile Valley in 1916, and among British soldiers in the 44th Stationary Hospital, Kantara, Palestine Base, in 1917, 1918, and 1919, admitted locally. After the third battle of Gaza, when our troops were on the move fighting in the Judean hills, I noticed, at the end of December, 1917, and subsequently, that a different type of fever was being admitted to hospital from Palestine. In some the temperature was normal on arrival, and the diagnosis had been "Pyrexia N.Y.D.," the men having been admitted to hospital up the line with a primary fever lasting about four days; either the blood films were negative or no blood examination had been made owing to military conditions. The weather in Palestine at that time was very cold and wet. After being in hospital a few days convalescing, the temperature would suddenly shoot up and then become normal in twenty-four hours or less. Spirochaetes were found in the blood of some but not in others.

A major of Australian Light Horse had had such a primary attack up the line; blood films were negative. He arrived at the hospital a week later, and about three days afterwards he had a relapse; the fever lasted about fifteen hours, but the blood film was again negative. He was transferred to the 14th Australian General Hospital, Port Said, where he had several similar relapses; blood examinations were made on each occasion, but it was only at the end of at least six weeks that spirochaetes were found in his blood.

Other patients arriving with other than medical conditions would suddenly develop pyrexia between 102° and 103° F., lasting for four days, falling by crisis; these primary attacks developed in the hospital, and spirochaetes were found in the blood. These primary cases were not acutely ill like the typical cases of relapsing fever infected by lice.

The interesting clinical features about the relapses were:

1. The short duration of the pyrexial attack; it usually lasted fifteen to twenty-four hours, and was represented on the temperature chart by a "spike." So well recognized did this "spiky" temperature become by the medical officers of the hospital, that a provisional diagnosis of "Palestine relapsing fever" would be made pending blood examination.

2. Spirochaetes were scanty and often difficult to obtain in a blood film. This was well exemplified in the case of the Australian major above mentioned.

3. Irregularity of relapse, varying from seven to ten days.

The interesting fact was that nearly every one of these patients definitely stated that he had been bitten by "brown bugs." Most of them had been sheltering in caves in the Judean hills, and in the morning they

would find these "brown bugs" filled with blood crawling over them. There were also marks of insect bites on various parts of their bodies. They stated that the retreating Turks had been occupying these caves before them. The incubation period seemed to be about seven or eight days.

Colonel Balfour is inclined to doubt the existence of a tick-borne relapsing fever in Palestine, but there is no doubt but that what these patients called a "brown bug" was a tick, and that it was the infecting agent. I have no doubt that Major Ansten, D.S.O., British Museum, Entomologist E.E.F., Major Manson Bahr, D.S.O., Dr. Woodcock, and others can assure him on this point.

To me clinically the louse-borne and the tick-borne were two different types of disease. Salvarsan, intravenously, was always a cure.—I am, etc.,

JOHN W. MACKENZIE, O.B.E., M.D. Edin.,
Late Lieutenant-Colonel R.A.M.C.T.F.,
O.C. 44th Stationary Hospital, Kantara, Egypt.

COMMISSIONS, I.M.S.

SIR,—It may be of interest to state, in reference to "Enquirer's" question (p. 168) concerning the prospects of a recruit meditating a permanent commission, some salient points which are at present giving those already in the service much perturbation of thought.

I had the honour during the late war to serve for two and a half years on a staff composed of I.M.S. and R.A.M.C. officers with an I.M.S. chief who is one of the most capable men in his service. I am still closely in touch with many serving in the I.M.S., and therefore, though my service was but temporary, I feel I can voice in some small measure their feelings and doubts, which are:

1. The placing of Europeans under an Indian Minister.
2. That successful administrative work brings more "plums" than successful professional efficiency.
3. The uncertainty of the future pending possible amalgamation or unification of the R.A.M.C. and I.M.S. in the East.
4. The parsimoniousness of the Indian Government in the equipment of station hospitals and feeding of troops.

As a result of this parsimony, sickness is likely to be increased (vide the conclusions reached by Colonel W. H. Willecox in his striking article in your JOURNAL of January 17th). It is not encouraging to serve under a Government which will not appreciate the principles of preventive medicine even when taught by bitter experience.

My advice to "Enquirer" would be that, if he is content to be a bachelor, India will give him happy days and the chance of good experience, both professional and administrative, but if he is a married man he will possibly rob himself of some of the openings because of the expense of having to keep two homes going in India for part of every year and another in England if he has children.

The I.M.S. has a friend in the present Secretary of State for India, but there have been others, and there may be again, who take but little interest in seeing that this fine service is allowed to go about its work in a contented and settled frame of mind.

Hard work in a trying climate ages men prematurely, and everything should be done to make conditions as good as possible with a view to preventing this premature old age, so that when an officer retires he may have a reasonable chance of living to enjoy his deferred pay in the way of pension for a much longer span than what is now the case.—I am, etc.,

Ipswich, Feb. 1st.

FRANK BRYAN,
Late temporary Captain R.A.M.C.

SIR,—Men in the I.M.S. must have noticed the movement in the right direction which has taken place during the past year or so, and that movement is due, I might almost say entirely, to the energy put forward by the BRITISH MEDICAL JOURNAL and the Army and Navy Committee, of which Colonel Elliot, I.M.S., is chairman.

The position of the service at the present moment is a debatable one, and men in it may differ as to what may be its fair dues.

I am sure most of us agree with all Colonel Elliot has stated in his letters in the JOURNAL. The attitude we

should be prepared to take is to play fair with the Secretary of State for India until he has had time to fulfil his promises and, if necessary, even to revise his original ideas when asked to do so.

Those in the service who were fortunate enough to be at the I.M.S. dinner, held last June, will agree when I say that the support which Colonel Elliot and his Committee have from the service was most strikingly illustrated by the way in which Colonel Elliot was called upon by the dining members to express his views. I appeal to the service to continue that support, and feel sure it will be crowned with a great success.—I am, etc.,

February 3rd.

FAIRPLAY.

SIR,—Having been granted a permanent commission in the I.M.S. a few weeks prior to the offer of temporary commissions I would like to ask whether it is right that the temporary officer should have so many advantages over the regular officer. The former has got the privilege of leaving after two years' service; passages for himself, wife, and family, there and back, after this short service; no compulsory obligation to learn Hindustani, and also is to receive 700 rupees a month, compared with 550 rupees a month in the case of lieutenants and 750 rupees to 700 rupees in the case of captains. From the letter of Lieut.-Colonel Elliot I learn that the Secretary of State is allowing this temporary service to count towards permanent service by those who elect to remain permanently in the I.M.S.

Surely an injustice is being done to the regular officer unless, dating from the time of offer of temporary commissions, his rate of pay is made either equal to, or more than, the temporary officer, since in two years' time the latter may decide to take on a permanent commission, and will then rank just as though he took such a permanent commission now, but will have been receiving 150 rupees a month more pay for two years. The other alternative is not to allow the time spent as a temporary officer to count for permanent service—that is, towards promotion or pension.

Permanent officers are badly wanted, according to all accounts, but where lies the benefit of obtaining a regular commission now, under the existing circumstances?—I am, etc.,

January 31st.

"DISAPPOINTED."

* * We referred this letter to the Chairman of the Naval and Military Committee of the British Medical Association, who replies as follows:

SIR,—In one respect I would wish to differ from "Disappointed": He would level down, I would level up. Let me explain. The British Medical Association has told the Secretary of State that he cannot get the permanent recruits he wants unless he adds 50 per cent. to the total pay of I.M.S. officers. To avoid misunderstanding, it has been stated that this calculation is to be based on a table laid down by the Secretary of State, and one therefore as to which there can be no misunderstandings. Certain other requirements have also been stated. A time limit has been fixed, and at the end of that period the very serious question of future action will be considered. If the requirements of the British Medical Association are not satisfied, it is quite clear that the Association can no longer adopt a neutral attitude; but sufficient unto the day is the evil thereof. We hope and most sincerely desire that such a serious situation will not arise. If it does, the Association will not be found unready. There is thus good hope for the permanent officer; he may rely on the full backing of his just claims. Has "Disappointed" taken the trouble to keep himself *au fait* with all that the British Medical Association has been doing for the Service? If he has, he must surely have been aware that the Association is not recommending young medical men to enter the I.M.S. as permanent officers, and will not do so until it feels that the conditions of service are good enough. He will be well advised to get his commission changed from a permanent to a temporary basis, and so in two years' time see whether permanent service is good enough.—I am, etc.,

R. H. ELLIOT,
Lieut.-Col. I.M.S. (ret.),

Chairman Naval and Military Committee,
British Medical Association.

London, W., Feb. 2nd.

FORGETTING: PSYCHOLOGICAL REPRESSION.

SIR,—I hold that fresh air, good feeding, with well-regulated rest, exercise, and occupation in healthy country surroundings, tend to lessen psychasthenia, to cure neurasthenia, and to confirm and perpetuate the improvement rapidly produced in hysteria by many varieties of psycho-therapeutical treatment. This view has the support of common sense and of many centuries of experience; it is thus a marvel to me that any one, even in the ranks of our self-satisfied wonder-workers, should think it untenable.

Dr. Hurst is mistaken if he supposes that I have any antipathy to psycho-therapy, or that I would wish him or any one else to reject all he has learnt about the psychoneuroses during the last five years. I would point out, however, that such knowledge, if of value, was familiar to others before that period, for no discovery of importance in this connexion has been made during the war; as I always held and first stated in the *Lancet* of November 18th, 1916 (Farquhar Buzzard came independently to the same conclusion about the same time), war neuroses, "shell shock," etc., are only examples of the long recognized disorders hysteria, neurasthenia, and malingering, either singly or in combination.

Psycho-therapy by suggestion, explanation, persuasion, and re-education has been made use of consciously or unconsciously since the days of Hippocrates, and all the psychological methods (including those initiated by Freud before the war) which were used at Maghull, and later at Seale Hayne, etc., have been employed by many physicians for years past.

What Dr. Hurst and his supporters will, I hope, learn in the next five years (when they have had more experience of the later phases of war neuroses) is that removal of individual symptoms of such a protean disease as hysteria, does not necessarily imply cure of the elusive pathological disorder of brain cells and synapses which is at the root of the trouble.

Psycho-therapy I have always recommended and used as a means of removing the gross evidences of hysteria, but natural forces such as rest, good feeding, fresh air and suitable occupation, provided by the Country Host scheme, are necessary to confirm the improvement brought about by psycho-therapy and to render it lasting—that is, to effect "cure," a word only to be used tentatively, after a patient has resumed his ordinary life and has remained well for at least a year since all treatment ceased.—I am, etc.,

London, S.W., Jan. 31st.

THOMAS LUMSDEN.

SIR,—We have read with great interest Dr. A. Carver's article in the *BRITISH MEDICAL JOURNAL* of January 10th, as we have felt for some time the need of such an article. For five years the doctrine of "forget" and "turn your back on the past" has been preached by the vast majority of the profession. With what result? To-day there are more ex-soldiers suffering from war neuroses than there were on Armistice Day! It was with keen disappointment, therefore, that we read Sir Robert Armstrong-Jones's letter in the *BRITISH MEDICAL JOURNAL* of January 17th; since, whilst we are fully aware of his position as a psychiatrist, our experience leads us to differ from him when the treatment of the psycho-neuroses is under discussion. He questions whether it is possible to "forget" by an act of volition. We do not hold that it is possible, but "forgetting" is frequently accomplished without conscious volition, as in the case of the hysterical amnesia which is so commonly met with. Again, Sir Robert Armstrong-Jones considers that

The investigator must himself possess an actual and true photographic record of the actual battle scenes, otherwise the effect is purely that of suggestion.

This is a complete fallacy, since it is not the physician who does the recalling, but the patient, and the former makes no suggestion whatever, even of the most indirect nature.

We do not consider that the imaginary cases which Sir Robert Armstrong-Jones describes are entirely analogous to the war neuroses. The first of these cases—that of the patient with "acute mental restless depression"—he calls a psychosis, his treatment of which we should therefore not for one moment dare to question.

Has the "disappointed girl who has become a mental and moral wreck on account of the broken promises of her

faithless lover" succeeded in forgetting the circumstances? If so, then—on Sir Robert Armstrong-Jones's theory—she ought to be cured. If, on the other hand, she has not forgotten them, does he consider that she would be well again if she developed an amnesia for these events? In our view she would then be suffering from a well recognized symptom of hysteria—that is, she would be a psycho-neurotic. Perhaps it is considered that she should merely direct her thoughts into other channels (sublimation), but before she can do this it is necessary for her to exercise conscious control over her thoughts and emotions, and this cannot be done by closing her eyes to them and pursuing the "ostrich policy." It is this same "conscious control" that the modern psycho-neurologist seeks to substitute for repression, by familiarizing the patient with his or her memories so that they can be faced with equanimity.

Did not the nervous actor and the sensitive musician merely give way to a perfectly natural fear on the occasion of a certain appearance, and was not this fear consciously controlled instead of being repressed and forgotten? Where, may we ask, is the analogy in this case?

With regard to the young man who has been dealt with as a first offender and is trying to reconstruct his life, it is not stated whether he is suffering from a psycho-neurosis. But whether he is or not, will he not be likely to bring himself again within the toils of the law if he succeeds in forgetting that incident? It would surely be better for him to remember the consequences of his former ill-doing that he may profit by experience and shape his course of life differently in the future.

It has for long been our daily experience to see men who have been trying to "forget," and to find distraction for periods of time up to four or five years. We have not yet found a single one who has succeeded without the development of a psycho-neurosis having supervened, and this in spite of the aid afforded by various employments and distractions designed for that end, such as rural surroundings, agricultural work, country homes, etc., even when continued for many months. It is also very noticeable to any observer, either professional or lay, that men enjoying mental and physical health, whether wounded or otherwise, can talk about their war experiences with equanimity, and invariably do so when several of them get together. On the other hand, those who cannot talk about their experiences without showing emotion, and who, in fact, will not discuss their personal experiences in the war, will be found to show symptoms of a psycho-neurosis of greater or less degree. Since the aim of all treatment, no matter what the disability, is to restore the patient to the normal, we should endeavour to make the psycho-neurotic like unto those others who can calmly discuss their experiences, however terrifying.

It is not within the scope of this communication to discuss the technique of treatment, but we would venture to point out:

1. That it is the patient, and not the physician, who must recall.
2. That a mere recitation by the patient of his experiences is useless.
3. That it is essential for the patient, when recalling the incidents, to let out the emotion which he has previously been repressing.
4. That for any claim to a cure to be valid the patient must have been given a thorough insight into his own condition and the psychic causes of his disability.

—We are, etc.,

C. H. L. RIXON,
D. MATTHEW,

Neurologists, Ministry of Pensions
Neurological Hospital, Exeter.

January 20th.

"NEW LAMPS FOR OLD" IN OBSTETRICS.

SIR,—Once again the old cry of labour being a perfectly natural process is raised. True, Dr. Shirlaw refers to normal labour, and if he defines a normal labour as one that is perfectly natural there is no more to be said, but with every advance in midwifery, anaesthetics, antiseptics, forceps, pituitary extract, the same cry is raised, that it is not right to interfere with nature.

But is a confinement to day a perfectly natural process? Are not the time, the pain, the mental and physical exhaustion, all the results of our civilization? Unnatural, too, are many of the woman's surroundings—her house,

her bedroom, her bed. Many of the conditions that influence her health prevent labour being an entirely successful process if left wholly to nature. Among such conditions are overwork and worry, insufficient healthy exercise, improper feeding and clothing. Then those deformities of the pelvis that are secondary to disease or hereditary would, without any artificial assistance, render many confinements impossible or very damaging; in a perfectly natural state these patients would in time have been eliminated, but now science and art and heredity preserve them and enable them to reproduce and multiply their like, so that in course of time the surroundings and innate conditions of civilized woman compel midwifery to be more "meddlesome."

It is obvious that the more civilization interferes with nature the more necessary is it to compensate for that interference.—I am, etc.,

Bradford-on-Avon, Feb. 1st.

CHAS. E. S. FLEMMING.

PROPHYLAXIS AND VENEREAL DISEASE AMONGST THE ANZACS.

SIR,—The latest manifesto issued by the National Council for Combating Venereal Disease, and widely published in the press, infers that "the amount of venereal disease has materially increased" as the result of prophylaxis propaganda, "vide the incidence among the Australian troops, starting as it did at 130 per 1,000, and rising to 147 per 1,000 as compared with the British troops incidence of 38 per 1,000."

Venereal disease did not start at 130 per 1,000 per annum, which was approximately the number to which it was reduced towards the end of 1918. In 1914, 1915 and 1916 it was very much higher, because the system of disinfection was new and undeveloped.

The official figures for 1917 and 1918 were published in the report of the Interdepartmental Committee to the Ministry of Health in August, 1919 (page 5, Table C), and they are as follows:

	(a) United Kingdom.		(b) France.	
	Average Weekly Admissions.	Ratio per 1,000 per Annum.	Average Weekly Admissions.	Ratio per 10.0 per Annum.
Three months ending—				
Sept. 30, 1917...	200	167	231	101
Dec. 31, 1917 ...	190	150	158	69
March 31, 1918 ...	189	176	181	78
June 30, 1918 ..	126	133	134	58
Sept. 30, 1918 ..	131	132	116	55
Dec. 31, 1918 ...	152	147	115	63

The rise in the figures for the United Kingdom and for France in March, 1918, was due to the congestion of troops in the Channel ports, owing to railway disorganization during the retreat of the Fifth Army. Progress was not maintained in the December, 1918, quarter because of the armistice and the Christmas leave, and short supply of medicaments.

The United Kingdom figures are bad compared with those for France because, although we had a good system, we did not provide adequate means for carrying it out. Better provision was made in France—particularly in Paris—and the rate fell from 101 per 1,000 in September, 1917, to 55 per 1,000 in September, 1918.

The New Zealand Division considered officially that in August–September, 1918, the system of prophylaxis (by distribution of packets, etc.) was being fairly well administered in France, and they therefore ordered one of the senior medical officers to examine all men returning from leave, on arrival at field ambulance, to detect venereal infections, from August 20th to September 20th—thirty-two days. The following was the result:

United Kingdom infections: Belfast 1, Manchester 2, Bourne-mouth 1, Gloucester 1, Leeds 1, London 19; total 25. France infections: Beauval 1, Arry 1, Bertrancourt 1, Etaples 1, Rouen 1, Paris 1; total 6. Total for thirty-two days, 31.

Thus the New Zealand Division's experience corroborated that of the Australian Divisions—namely, that 60 per cent.

of the infections came from London, and that with the development of disinfection achieved in France we were within measurable distance of reducing venereal disease to a negligible quantity.

The statement that the incidence of venereal disease among British troops was only 38 per 1,000 is not correct, and the rate is not comparable with the figures given above. In the British army there was much concealment of disease, and we believe it is established that the overseas rate of infection was never so high as that of the English Army of Occupation in the early part of 1919.—We are, etc.,

ETTIE A. ROUT,
Hon. Sec., N.Z. Volunteer Sisters.

H. WANSEY BAYLY,
Hon. Sec., Society for the Prevention of Venereal Disease.

HONOURS.

ORDER OF THE BRITISH EMPIRE.

A SPECIAL Supplement to the *London Gazette*, January 30th, 1920, announces the following appointments to the Order of the British Empire (Civil Division) for valuable services rendered in or in connexion with military hospitals, Territorial hospitals, war hospitals, auxiliary and civil hospitals, command dépôts, convalescent camps, or on other duties of a similar nature in the United Kingdom in connexion with the army during the war:

K.B.E.

James Frank Colyer, F.R.C.S.

C.B.E.

George Blacker, M.D., Charles Bolton, M.D., F.R.S., C. Hubert Boud, M.D., J. Walter Carr, M.D., Miss Helen Chambers, M.D., David Drummond, M.D., Edward P. Furber, M.R.C.S., Miss Florence B. Lambert, M.B., Hugh Lett, F.R.C.S., Thomas Lewia, M.D., F.R.S. T. D. Lister, M.D., the late Cecil R. C. Lytner, M.R.C.S., Lawrence McGavin, F.R.C.S., H. J. Paterson, F.R.C.S., John Sinclair, M.D., Sir T. Rudolph Hampden Smith, Bt., F.R.C.S., Jamea Taylor, M.D., R. A. Young, M.D.

O.B.E.

Lieut.-Colonel W. G. P. Alpin, M.D., W. Dunlop Anderson, M.B., Thomas Baker, M.R.C.S., T. W. N. Barlow, M.D., J. H. Barnard, M.D., J. S. Boden, M.B., J. G. Boon, L.R.C.S., C. H. Bubb, L.D.S., Miss Winifred F. Buckley, M.R.C.S., W. F. R. Burgess, M.D., A. C. Burrows, L.R.C.S., C. T. T. Comber, M.D., Richard Dagger, M.D., R. G. Davidson, M.B., W. H. Dickinson, M.B., L. G. Dillon, M.D., M.S., G. C. Garratt, M.D., H. W. Gell, M.B., T. P. Gostling, M.R.C.S., E. C. Greenwood, M.R.C.S., J. Z. Hanafy, M.R.C.S., Arthur Hawley, M.B., K. R. Hay, M.B., W. Hern, M.R.C.S., H. T. Herring, M.B., R. J. B. Howard, M.D., F.R.C.S., Richard Humphreys, M.B., W. Warwick James, F.R.C.S., W. H. Jewell, M.D., H. Jossé Johnson, M.B., R. Nelson Jones, M.R.C.S., J. E. Kilver, M.R.C.S., P. C. W. Laws, L.M.S.S.A., K. A. Lees, F.R.C.S., R. M. Hutchinson-Low, M.B., H. M. McCrea, M.D., Niel McDonald, M.B., W. F. McEwen, M.B., Miss Ethel M. Magill, M.B., C. J. L. Mansel, M.D., Major A. E. Morison, F.R.C.S., Enoch Moss, M.D., R. A. Murray, M.D., G. E. Newby, F.R.C.S., G. Northcroft, D.D.S., W. J. C. Nourse, F.R.C.S., J. Irwin Palmer, M.R.C.S., A. H. Parrott, L.D.S., J. L. Payne, M.R.C.S., G. J. Peacocke, M.D., J. P. Philip, M.D., E. T. Pinhey, M.B., J. F. Porter, M.D., T. G. Prosser, M.R.C.S., J. A. Reed, M.B., P. J. Rendall, M.D., B. J. Rodway, L.D.S., R. A. Rowlands, M.D., Harrington Sainsbury, M.D., O. B. Shelswell, M.R.C.S., Miss Amy Sheppard, M.B., G. K. Smiley, M.B., J. A. Southern, M.R.C.S., G. S. Stausfeld, M.R.C.S., R. de S. Stawell, F.R.C.S., H. Murray, L.R.C.P., H. T. Nixon, M.D., John Noble, M.B., S. J. Palmer, M.D., W. H. Prentice, M.D., John Rust, M.R.C.S., J. W. Stenhouse, M.B., J. S. B. Stopford, M.D., Professor W. Thelwall Thomas, F.R.C.S., T. H. Sanderson-Wells, M.D., H. B. Woodcock, M.B., F. Wallace Wilson, M.R.C.S., Richard Wyse, M.D.

The following appointments to the Order of the British Empire (Military Division) are announced in recognition of services rendered whilst prisoners of war or interned:

O.B.E.

Majors Wright Mitchell, R.A.M.C., and Frank S. Park, C.A.M.C. (attached 4th Battalion Canadian Mounted Rifles) Captain Thomas W. Leighton, R.A.M.C.(T.F.).

M.B.E.

Assistant Surgeons Edwin Brook Holt and Harold Arthur T. Wells, I.M.D.

Military Cross.

Temporary Captain William J. Maloney, R.A.M.C., has been awarded the Military Cross in recognition of gallant and distinguished services in the field.

Mentioned for Services.

The names of the following officers have been brought to the notice of the Secretary of State for War, in accordance with the terms of Army Order 193 of 1919, for valuable services whilst prisoners of war or interned. They belong to the R.A.M.C. unless otherwise indicated.

Lieut.-Colonels E. F. E. Baines, I.M.S., P. H. Collingwood, Majors W. R. O'Farrell, J. Startin, and W. I. Thompson, Captains R. O. Clifford, D.S.O., M.C., I.M.S., W. H. R. McCarter, S. S. Meighan (T.F.), L. Murphy, O. E. Redman, A. Sutcliffe, W. Warburton.

Temporary Captains H. M. Gilbertson (attached Somerset Light Infantry), A. J. Gilfillan, R. W. Hodgson-Jones (attached Royal Irish Fusiliers), J. L. Jackson, A. T. I. Macdonald, E. A. Walker.

The name of temporary Captain I. C. MacLean, D.S.O., M.C., R.A.M.C. (died), has been brought to the notice of the Secretary of State for War for gallant and distinguished services rendered in the field.

The Services.

GREENWICH HOSPITAL PENSIONS.

INSPECTORS-GENERAL of Hospitals and Fleets William H. Lloyd, M.D., K.H.S., and Thomas Browne, M.D., have been awarded the Greenwich Hospital Pension of £100 a year from February 4th, 1919, and October 12th, 1919, respectively, in the vacancies created by the deaths of Inspectors-General James W. Fisher, M.D., and Adam B. Measer, M.D., K.H.P.

Universities and Colleges.

UNIVERSITY OF OXFORD.

PROFESSOR ARTHUR THOMSON, M.A., M.B., Professor of Human Anatomy in the University, has been elected to a Studentship at Christ Church.

UNIVERSITY OF CAMBRIDGE.

At a congregation held on January 30th the following medical degrees were conferred:

M.B., B.Ch.—W. G. Marsden, D. L. Spence.

UNIVERSITY OF MANCHESTER.

Chair of Physiology.

THE Council has appointed Mr. A. V. Hill, O.B.E., M.A., F.R.S., to the Chair of Physiology, vacant through the resignation of Professor Stirling. Mr. Hill was a Scholar of Trinity College, Cambridge, was Third Wrangler in 1907, and was placed in the first class in Part II of the Natural Science Tripos (Physiology) in 1909. He was George Henry Lewes Student; Walsingham, Gedge, and Rolleston Prizeman. In 1910 he was elected to a Fellowship at Trinity College, and in 1916 was elected a Fellow of King's College. In 1918 he became a Fellow of the Royal Society. During the war he obtained the rank of major in the Cambridgeshire Regiment, and was appointed Director of the Anti-Aircraft Experimental Section of the Munitions Invention Department. The inventions which he made proved of the greatest value in the schemes of defence against attack from the air. He has made valuable researches on the physiology of voluntary muscle.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN ordinary Comitia of the Royal College of Physicians of London was held on January 29th, at 5 p.m., the President, Sir NORMAN MOORE, Bt., being in the chair.

Members.

The following candidates, having passed the required examinations, were admitted as Members:

James Beatty, M.D.Dublin; Thomas Izod Bennett, M.B.Lond., L.R.C.P.; Richard Christopher Clarke, M.D.Bristol, L.R.C.P.; Edgar Leigh Collis, M.D.Oxf., L.R.C.P.; Neil Hamilton Fairley, M.D.Melb.; Dorothy Christian Hare, M.D.Lond.; Geoffrey Marshall, M.B.Lond., L.R.C.P.; Stanley Graham Ross, M.D. McGill; Korr Simpson, M.D.Edin.; Reginald Hugh Simpson, M.D.Lond., L.R.C.P.; Arthur Theodore Todd, M.B.Edin.; Sibly Ibbetson Welsh, M.D.Lond.

Diplomas.
Licences to practise Physic were granted to 65 candidates who had conformed to the Bye-laws and Regulations, and passed the required examinations.

Diplomas in Public Health were granted, in conjunction with the Royal College of Surgeons, to 15 candidates.

Council.

The following were elected Councillors on the nomination of the Council: Dr. W. H. R. Rivers, Dr. S. Monckton Copeman, Dr. T. H. Arnold Chaplin, Dr. John Fawcett, vice Sir Henry Davy, Dr. W. Essex Wynter, Dr. James Taylor and Dr. Herbert Spencer, who retired by rotation.

Lectures.

The President announced that he had appointed Dr. F. W. Andrewes to be Harveian Orator, and Dr. R. C. Wall to be Bradshaw Lecturer for this year; that the Council had appointed Dr. Martin Flack to be Milroy Lecturer for 1921; and that the Censors' Board had awarded the Oliver-Sharpey prize for 1920 to Professor Emil Roux, of the Pasteur Institute, Paris.

Mitchell Lecture on Tuberculosis.

It was decided that the interest on the sum of £500 presented by Mr. Mitchell through Sir Edward Malins for the advancement of the knowledge of tuberculosis should be devoted to providing for a triennial lecture on tuberculosis, the lecturer to be appointed by the President and Censors.

Diploma in Tropical Medicine.

The revised regulations for the Diploma in Tropical Medicine and Hygiene and the revised syllabus for the examination adopted by the Committee of Management of the Conjoint Examining Board was approved. The course of instruction required in future will be not less than three months, and must include practical instruction in pathology, protozoology, helminthology, entomology, bacteriology, and hygiene in relation to tropical medicine, and clinical practice in a hospital recognized for the study of tropical diseases. Graduates in medicine and surgery of Indian, Colonial, and foreign universities recognized by the Conjoint Board in England, whose degrees are not registrable in this country, may enter for the examination on fulfilling the same conditions in relation to study.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have been approved at the examinations indicated:

SURGERY.—*†Aspinwall, *†C. G. Bunn, †N. D. Dunscombe, *G. E. Rao, †G. K. Reeves.
MEDICINE.—†J. G. Barrie, †N. D. Dunscombe, *†A. H. El Rakshi, *J. Kendall, *W. E. Neale.
FORENSIC MEDICINE.—A. H. El Rakshi, C. T. Gasking.
MIDWIFERY.—A. H. El Rakshi, A. Keilin, G. E. Rae.
* Section I. † Section II.

The Diploma of the Society has been granted to Messrs. C. G. Bunn, N. D. Dunscombe, and G. K. Reeves.

Obituary.

DAVID GOYDER, M.D. ST. ANDREWS,
Consulting Physician, Bradford Royal Infirmary.

DR. DAVID GOYDER of Bradford died on January 27th, in his 91st year. He was the son of the Rev. David Goyder of Accrington, where he was born in December, 1829. Having obtained a diploma of the British Pharmaceutical Society, he decided to study medicine, and entered as a student at Anderson's College, Glasgow. He graduated M.D. St. Andrews in 1860 and took the diploma of L.R.C.P. Edin. From 1862 to 1871 he worked in partnership with the late Dr. Samuel Brown of Bradford, after which he began practice on his own account with great success. About the year 1903 he restricted himself to consulting practice. Dr. Goyder took great interest in the work of the British Medical Association, was an ex-president and ex-secretary of the Yorkshire Branch, of which he was also a vice-president and for some years its representative on the Central Council. He was also a member of the old Parliamentary Bills Committee and of other committees of the Association. He was one of the founders in 1863 of the Bradford Medico-Chirurgical Society; he held the office of president, and on the completion of twenty-five years in the capacity of its secretary the members of the society presented him with his portrait by Mr. Ernest Siebel. On the occasion of his 80th birthday, in 1909, Dr. Goyder was entertained by his professional brethren at a dinner presided over by Mr. T. Pridgin Teale, of Leeds.

Dr. Goyder was greatly interested in philanthropic and public work; he assisted in the founding of the Bradford Nurses' Institution, and as its secretary for a quarter of a

century was largely responsible for its sustained usefulness. He was honorary consulting physician to the Bradford Royal Infirmary, to which institution his elder son, Mr. F. W. Goyder, F.R.C.S., is honorary surgeon.

DR. EDWIN LINDSAY DUNN, late medical superintendent of Berkshire Asylum, Wallingford, died on January 22nd, after several weeks' pain and suffering endured with patience and fortitude. He was the son of the late Mr. Robert Dunn, of Dunfield, Waterside, Ireland, was born in 1865, and received his early education at Foyle College, Londonderry. After being an intermediate exhibitor in 1879, 1880, and a matriculation exhibitor R.U.I. in 1881, he entered Trinity College, Dublin, as first junior exhibitor in 1882. He graduated B.A. with honours in classics and English literature, and then entered upon the study of medicine. He was resident pupil at Dr. Steevens's Hospital, clinical clerk and surgical dresser at Sir Patrick Dun's Hospital, Dublin, and prospector to the University Anatomist. He graduated M.B., Ch.B. in 1887. He became assistant house-surgeon to the Children's Infirmary, and assistant surgeon to the Liverpool Dispensary, and afterwards was appointed assistant medical officer at the West Riding Asylum, Wakefield. There he made several contributions to medical literature, and at the Psychology Section of the annual meeting of the British Medical Association at Nottingham in 1892 read a valuable paper on paranoia. He was a member of the Medico-Psychological Association, a member of many years' standing of the British Medical Association, and a member of the Reading Pathological Society. He was appointed senior A.M.O. and deputy medical superintendent of the Berkshire Asylum, Wallingford, in 1894, and on the death of Dr. Murdoch succeeded him as medical superintendent. While at Trinity College he rowed for the University Boat Club, was a member of the University fifteen, and played for the Wanderers' Club. His recreations in later life were shooting, fishing, and golf. He was an enthusiastic Fræmasón, and became Worshipful Master of the St. Hilda Lodge, Wallingford, in 1890. His good-humour and interesting talk made him very popular; the visiting committee of the asylum were all his personal friends, and he was beloved by his patients and staff. He was unmarried.

THE death took place on December 29th, 1919, of Dr. PETER FRASER, late of Carnarvon, at the age of 55. Dr. Fraser graduated M.B. at the University of Edinburgh in 1886, taking his M.D. and B.Sc. degrees three years later. After practising in Llangefni, he became medical officer for Carnarvonshire and parts of Denbigh and Merioneth. In 1908 he went to Lushai as a medical missionary, proceeding in 1915 to North-Eastern Assam where he was medical officer to a large group of tea gardens. Dr. Fraser acquired a very extensive knowledge of tropical diseases and his devoted work on behalf of the native population was untiring. His strenuous and self-sacrificing life out in India eventually proved too much for his strength. He returned to England in November.

DR. WILLIAM PATRICK O'MEARA, of Southampton, who died suddenly on January 23rd, aged 53, received his medical education at the Ledwich School of Medicine, Dublin, and obtained the Scottish triple qualification in 1889. He took great interest in public affairs, had been vice-chairman of the Southampton Board of Guardians, and was appointed a magistrate in 1906. At the Southampton Police-court, on January 23rd, the Mayor referred in appreciative terms to Dr. O'Meara's work as police surgeon for twenty-six years and on the bench. Dr. O'Meara was a member of the Southampton Division of the British Medical Association. He is survived by his widow, one son, and a daughter.

COLONEL ROBERT DAVIDSON MURRAY, Bengal Medical Service (retired), died in London, after an operation, on January 12th, aged 68. He was educated at the Inverness Royal Academy and at Edinburgh University, where he graduated with honours in 1873. He entered the I.M.S. as surgeon on March 31st, 1875, passing into Notley first,

and passing out second, and became colonel in March, 1905, retiring in March, 1910. He served in the Burmese war in 1886-87, taking part in the operations of the 1st Brigade, was mentioned in dispatches, G.G.O. No. 434 of 1887, and received the medal with a clasp. Except for this war service, he spent thirty years in civil employment in Bengal, where he held the posts of first resident surgeon of the Presidency European general hospital, Calcutta, and the civil surgeoncies successively of Jessore, Nadiya, Champarnu, Gya, and Howrah, till in August, 1898, he was appointed Professor of Surgery in the Calcutta Medical College and first surgeon to the Medical College Hospital. On promotion to the administrative grade he was appointed Inspector-General of Civil Hospitals in the North-West Provinces and Oudh, and a member of the Legislative Council of these provinces. After his retirement he was honorary secretary of the Indian Empire Club, from its foundation, about ten years ago, till his death. Colonel Davidson Murray married a daughter of the late Surgeon-General George Mackay, I.M.S., by whom he is survived, with three daughters and three sons; the latter served with distinction in the war.

CAPTAIN FRANCIS JAMES SPILSBURY, R.A.M.C., died on October 11th at the S.M.S. Hospital, Headington, Oxfordshire, aged 57. He was educated at St. Bartholomew's Hospital and at Edinburgh, and took the L.R.C.P.I. in 1887 and the L.R.C.S.Ed. in 1892, after which he went into practice at Hogsthorpe, Lincolnshire, where he held the appointments of medical officer and public vaccinator of the Hogsthorpe district of the Spilby Union, medical officer to the Post Office and to the Board of Education, and Admiralty surgeon and agent. He took a temporary commission as lieutenant in the R.A.M.C. on October 16th, 1916, and was promoted to captain after a year's service.

Medical News.

BEFORE beginning the first of his Lettsomian Lectures, published at p. 179, Dr. Herbert Spencer said that in the portrait group which adorns the wall of the Medical Society's room in which the standing figure of Lettson is prominent, there was represented seated Charles Combe, obstetric physician to the General Lying-in Hospital. Combe, he said, published one of the finest editions of the works of Horae, with a most admirable index. In order that the Fellows of the Medical Society might have the opportunity of consulting it, Dr. Spencer offered for their acceptance a copy of the 1792 library edition. He went on to point out that the first Lettsomian lecture on an obstetric subject had been given sixty-six years ago by Professor E. W. Murphy, a predecessor of his own in the Chair of Obstetric Medicine at University College; in it Murphy dealt with education in the practice of midwifery, a subject arousing much lively interest to-day.

THREE Hunterian Lectures will be given during the course of next week at the Royal College of Surgeons of England, by Mr. H. Tyrrell Gray, on Monday, on the influence of nerve impulses on gastro-intestinal disorders; and by Mr. James Sherren, on Wednesday, on late results of surgical treatment of chronic ulcers of the stomach and duodenum; on Friday Mr. Walter G. Spencer will give the first of three lectures discussing the historical relation between experiments on animals and the development of surgery. Professor G. Elliot Smith, M.D., F.R.S., will give the first of two Arris and Gale Lectures, on the evolution of the cerebellum, on Friday, February 20th, when the origin of the cerebellum will be discussed. The second lecture, on Monday, February 23rd, will be devoted to the mammalian cerebellum, and the meaning of the changes that transformed a primitive reptilian cerebellum into the mammalian organ will be considered, along with the morphology and functional significance of the cerebellum in the various mammalian orders. The lectures are delivered at 5 p.m. on each day.

ON the occasion of the retirement of Dr. Robert Milne from the position of Chief Medical Officer of Dr. Barnardo's Homes after forty years' service in that capacity a framed address has been presented to him by the council of the homes, and also, on behalf of the united staff, a gift comprising an illuminated album bearing the names of over 500 subscribers, a first-grade bicycle, and a cheque (to be subsequently increased) for eighty guineas.

PRINCESS BEATRICE has appointed Mr. Douglas George Rice-Oxley, M.C., M.B., to be surgeon-in-Ordinary to Her Royal Highness.

A QUARTERLY meeting of the Medico-Psychological Association of Great Britain and Ireland will be held on February 24th at the house of the Medical Society of London (11, Chandos Street, W.1), under the presidency of Dr. Bedford Pierce, at 2.45 p.m., when Dr. R. H. Steen will read a paper on chronic hallucinatory psychosis.

THE amount of the Mary Putnam Jacobi fellowship, which the Women's Medical Association of New York City is offering for award to a woman physician for post-graduate study in any country for work in any medical science is 800 dollars (approximately £200, not £2,000, as printed last week). Full particulars can be obtained from Dr. Murrell, 86, Porchester Terrace, London, W.2.

A SERVICE in memory of the late Sir William Osler was held at Christchurch Cathedral, Montreal, on Sunday, February 1st. It was attended by the faculties and students of McGill University. Dr. Symonds, vicar of the cathedral, conducted the service, in the course of which he referred to Sir William Osler's profound effect on student life during his career at McGill University, and his subsequent interest in everything connected with that university. Sir William Osler left his personal library to McGill University, and for its reception a special memorial room is being prepared, in which also will be placed the urn containing his ashes.

AT the last meeting of the Royal Edinburgh Physical Society Captain Basil Spence, R.A.M.C., a member of the Sudan Sleeping Sickness Commission, gave an account of recent observations on the prevalence of sleeping sickness in Africa and of the measures taken to control its spread. The first case in the Lado Enclave occurred in 1910, and later in the same year a serious outbreak was discovered in Yei; in 1913 it was identified in Kajo Kaji. From 1909 onwards cases continued to crop up in the Bahr-el-Ghazel amongst immigrants from the French Congo. In 1914 it was ascertained that there was a serious epidemic in the French Congo along the Mboma River, and that natives from the Sudan were in the habit of going there on visits. In the following year a small force from the Sudan, accompanied by many natives, operated along the Mboma River; the force returned to the Tambura district of the Sudan, and in 1916 and 1917 many natives of the French Congo began to emigrate into the Sudan. In the spring of 1918 Yuz Nneb Bey, a civil medical officer of the Egyptian army, discovered a serious epidemic in and about Tambura. In order to cope with it patients were collected into a village specially built for them; roads were made through the district, rest houses built, maps and road reports compiled, a census taken, and a systematic inspection made of the inhabitants in Tambura and the district. Communication between the French and Belgian Congos with neighbouring parts of the Sudan was only permitted under very stringent regulations. In 1918 and 1919 876 cases in all were notified.

THE London County Council is making application to the Ministry of Health for the issue of regulations similar to those made in view of the influenza epidemic of 1918, and it asks that they should cover other infectious diseases, and should be made without delay so as to be applicable at once should influenza become epidemic. The previous regulations provided that an entertainment should not be carried on for more than three hours, or in cinematograph halls four hours, and that there should be an interval of half an hour between any two entertainments during which the premises could be ventilated. The Theatres and Music Halls Committee, however, has expressed the view that an adequate system of mechanical ventilation in which the fresh air admitted is warmed is a necessity.

DURING the extreme shortness of petrol, early in 1918, when many motorists were endeavouring to use coal gas as an alternative, the Automobile Association offered a prize of £1,000 for the best system of enabling coal gas to be satisfactorily used. The gas bag had not proved satisfactory, and the conditions of the competition proposed an installation capable of carrying, under compression, a charge of coal gas sufficient to run a medium-powered touring car a distance of fifty miles. The space to be occupied by the gas containers was not to exceed 19 cubic feet and their weight to be not more than 140 lb. The apparatus was not to cost more than £20, and the expense of establishing and working the plant for charging the containers was not to add more than 3d. to the cost of an amount of gas equal to a gallon of petrol. So far no device fulfilling the requirements has been submitted.

SATISFACTORY progress has been made with the arrangements for the Australasian Medical Congress which is to be held at Brisbane, Queensland, from August 23rd to 28th. Sectional secretaries have been appointed from Queensland, and local secretaries in each of the other States. There will be eleven sections, as at the last congress, which was held in Auckland, New Zealand. The intention was that the Congress should meet in Brisbane in 1917, but the war and the large participation of the Commonwealth in it made postponement necessary. As already announced, the chief subject for discussion will be the question of permanent settlement of a working white race in tropical Australia. The meeting in Brisbane has the cordial support of the Queensland Branch of the British Medical Association and of the Federal Committee of Branches in Australia.

THE Metropolitan Life Assurance Company of New York, which in 1916 gave one hundred million dollars to the National Association for the Study and Prevention of Tuberculosis for an experiment in the control of tuberculosis in the town of Framlingham, Massachusetts (a typical American community), during a period of three years, has, we learn from the *Boston Medical and Surgical Journal*, resolved to provide funds for the continuance of the experiment. It was considered that the most effective method of control would be early detection of tuberculosis and the hygienic care of persons affected or threatened. In the first year 42 per cent. of the new cases were of an advanced type, in the second year 16 per cent., and in the first five months of the third year 22 per cent. Contemporaneously the tuberculosis death-rate fell from 0.93 per mille to 0.79 per mille, but this fall can hardly be looked upon as a result of the experiment.

Letters, Notes, and Answers.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aitiology, Westrand, London*; telephone, 2631, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra, Westrand, London*; telephone, 2634, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin.

QUERIES AND ANSWERS.

W. K. L. describes the case of a young soldier recently demobilized after service in France, India, and Mesopotamia, who suffers from profuse sweating in the axillae, chiefly at night. The parts have been shaved, and lemon and boracic powder applied, without avail. He asks for suggestions.

"COLONIAL SERVICE."—We cannot ascertain that there is any institution in London for the care of young children whose parents are abroad.

LETTERS, NOTES, ETC.

THE TERTIUM QUID.

DR. J. F. GORDON writes: A patient who, on my advice, had consulted one of our leading Liverpool specialists asked me why his fee for consultation was £3 3s. when she had previously paid £2 2s. I answered her that her case must have been one that is called the "tertium quid." She simply smiled, ejaculated "Oh!" remarked that he had not called it that, asked no further questions, and apparently was quite satisfied.

A NEEDLE IN THE ALIMENTARY CANAL.

DR. W. M. FELDMAN (London, W.) writes: The interesting memorandum by Dr. Heywood Smith in the BRITISH MEDICAL JOURNAL for January 17th reminds me of a similar case. Some fifteen years ago a child about 1½ years old was brought to me by the mother because it cried each time it tried to evacuate its bowels. On rectal examination I found a small needle stuck point downwards in the wall of the rectum immediately above the anus. I removed this and the condition was cured. The mother then told me that a couple of days earlier she was doing some needlework and the child was looking on. She then left her work on a chair for a few minutes, and when she came back missed the

needle. She asked the child where the needle was, and it pointed to its mouth. She, however, attached no importance to it, and the finding of the needle in the rectum came as a surprise to her. There were no subsequent bad effects, and the child is now a healthy lad 17 years old.

PERICRANIAL EFFUSION OF BLOOD.

DR. WALTER FISHER (Kalene Hill, Northern Rhodesia), writes: Early in October, 1919, a native boy about 10 years of age was injured by the fall of a sun-dried brick (about 4 lb. in weight) from a height of about 8 feet on to the back of his head when he was working in a stooping position. He was only temporarily stunned, and a small abrasion found was dressed. He seemed none the worse and went to his work as usual, but on the third or fourth day his head began to swell, and he was sent here (five days' journey) in a hammock. On arrival the large size of his head was abating, but he did not appear ill, and the temperature was only slightly above normal. The head was not tender, but in each temporal region there was fluctuation extending forwards into the frontal region, and slight fluctuation on the top of the head; in the occipital region where there was a healed abrasion the surface was normal. An exploring needle thrust into the swelling revealed blood, which under the microscope was fresh. We decided that an exploratory operation was useless, and sent him back. On revisiting this station ten days later the swelling was twice the size, being more prominent in the frontal region; it still consisted of pure blood. The boy went about as usual and had no headache. We hear that the swelling has decreased and that he is now nearly well. Did the blow cause a fracture injuring one of venous sinuses, and may we conclude that callus has in some way aided in the repair of the vein?

COLD WATER AND ANTIPYRETIC DRUGS.

DR. H. S. REYNOLDS (Upwell, Wisbech) writes: During the year 1886 I reported to the BRITISH MEDICAL JOURNAL from Cradock, Capa Colony, South Africa, the satisfactory result of treating an epidemic of enteric fever complicated with hyperpyrexia by cold-water baths. I had previously tried antipyretic drugs, such as quinine disulphate, in large doses, which I found only increased the complications by causing cinchonism. In the epidemic of influenza in 1918 and 1919, the great complications being hyperpyrexia and pneumonia, I followed the same course of treatment by the cold bath, except that in cases in which the patient's friends feared the drastic treatment I had recourse to cold sponging or sheets wrung out of cold water continually, which causes a lot more work and is not so effective, although I am thankful to say I did not lose one life. The late Sir William Osler, when addressing a meeting of the British Medical Association on fever in 1894, condemned the use of antipyretic drugs and extolled the use of the cold bath. An alcoholic stimulant previous to a bath is advisable, and in children I started with tepid water, gradually cooling it, keeping them in the bath till the temperature was down, independent of shivering.

DURATION OF PULMONARY TUBERCULOSIS.

MAJOR P. HEFFERNAN, I.M.S.(ret.), Tuberculosis Officer, West Derbyshire, writes to question statements made by Dr. Baskett in the BRITISH MEDICAL JOURNAL of January 10th and in an editorial article in the same issue, with regard to the average duration of pulmonary tuberculosis in the individual. In both places it was assumed that the mortality in any year was due to disease contracted on the average two years previously. Major Heffernan thinks there is no specialist in tuberculosis and no tuberculosis officer who would agree with the statement.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 42, 43, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 39, 40, and 41.

THE following appointments of certifying factory surgeons are vacant: Long Maford (Suffolk), Salford and Stretford (Lancaster), Shrewsbury (Salop).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0 6 0
Each additional line	0 0 9
Whole single column	4 0 0
Whole page	12 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *posto restanto* letters addressed either in initials or numbers.

THE MODERN TREATMENT OF FUNCTIONAL NERVOUS DISORDERS.

A BRITISH MEDICAL ASSOCIATION LECTURE DELIVERED TO A JOINT MEETING OF THE NOTTINGHAM DIVISION AND THE NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY, JANUARY 7TH, 1920.

BY

BERNARD HART, M.D.,

PHYSICIAN FOR MENTAL DISEASES, UNIVERSITY COLLEGE HOSPITAL, LONDON; LECTURER IN PSYCHIATRY, UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL; LATE LECTURER IN PSYCHOPATHOLOGY, MILITARY HOSPITAL, MAGHULL.

"FUNCTIONAL NERVOUS DISORDER" is a loose and decidedly unsatisfactory term, employed to designate hysteria, neurasthenia, and a number of other closely allied conditions. It is, indeed, rapidly falling into disuse, and its place is being taken by another term more in accord with modern views concerning the nature and etiology of the disorders in question. The newer name is "psychoneurosis," and behind the change in nomenclature there lies a wide-reaching revolution in our conception of these conditions. This revolution in thought, and the radical alteration in methods of treatment which has naturally resulted from it, form the subject of the present lecture.

DEVELOPMENT OF THE CONCEPTION OF "PSYCHONEUROSES."

During mediæval and earlier times the phenomena of hysteria and neurasthenia were explained by conceptions which have now merely an historical interest. Such, for instance, was the hypothesis that ascribed hysteria to the wanderings of the uterus about the body—a hypothesis to which hysteria owes its name. During the nineteenth century, however, the views held with regard to these disorders crystallized into a form consistent with the outlook of scientific medicine, and a conception developed which may be described as follows. Hysteria, neurasthenia, and similar conditions are affections of the nervous system characterized only by alterations in function, and not by any discernible structural lesion, but due to causes similar in kind to those producing other forms of disease. It is to this conception, of course, that the term "functional nervous disease" owes its origin. Now the modern conception of the psychoneuroses departs fundamentally from the view just described in that it believes these conditions to be the result, not merely of causes similar in kind to those producing other forms of disease, but of causes which play a relatively insignificant part in the field of general medicine—namely, mental or psychic factors. The first definite advance in this direction was made by Charcot when he demonstrated the part played by "ideas" in the causation of the symptoms of hysteria. During the last quarter of the nineteenth and the early years of the present century this psychogenic theory, as we may call it, underwent a great development in the hands of the workers who succeeded Charcot, amongst whom may be mentioned particularly Janet and Dejerine in France, Dubois and Jung in Switzerland, and Freud in Austria. The theories and practice of these and other investigators have diverged from one another in so many respects that it is easy to overlook the essential fact that they are one and all built upon a common basis. Nevertheless, this common basis undoubtedly exists, and it is constituted precisely by that psychogenic theory whose advent we have described. It may be expressed as follows.

The psychoneuroses, comprising hysteria, neurasthenia, and other allied conditions formerly termed functional nervous disorders, are the result of causes amongst which mental or psychological factors play a predominant part.

During the early years of the present century the psychogenic theory was adopted by most of the workers who devoted themselves to the study of this branch of medicine, and our experience of the vast crop of functional disorders which developed during the war has so amply confirmed and strengthened it that it has now been accepted by the great majority of those qualified to express an opinion on the subject. It underlies practically all modern forms of treatment, and the consequences of its acceptance are so momentous that it is necessary to grasp firmly its

significance and to appreciate accurately its scope and limitations.

To begin with, it does not mean that psychical causes alone are concerned in the etiology of the psychoneuroses, and that physical causes play no part. On the contrary, such factors as fatigue, the toxic and other effects of illnesses, the physiological disturbances produced by high explosives, may clearly have considerable etiological importance, and one condition of probably very great moment in the production of the psychoneuroses, "constitutional predisposition," can hardly be conceived in other than physical terms. It is only implied that, although both physical and psychical causes may cooperate in producing a psychoneurosis, the latter play an essential part, so essential a part that if they can be removed or modified the psychoneurosis itself will be removed or modified. Nor does the psychogenic theory mean that the causes we now call psychical, emotional disturbances, mental conflicts, and so forth, may not ultimately be capable of expression in anatomical and physiological language. It is only maintained that, in the present state of our knowledge, we can express these processes in psychological terms, and explain them by psychological laws, much more profitably than by the conceptions of anatomy and physiology. More profitably, because by treatment based on these psychological laws we can mould the chain of causation so that the morbid condition disappears, and thereby achieve that practical result which is the aim of all scientific method.

Psychotherapy and its Methods.

If we accept the psychogenic theory of the psychoneuroses our methods of treatment will obviously be profoundly affected thereby, because therapeutics is necessarily dependent upon etiology, and if we regard the psychoneuroses as due in large part to psychical causes, then our treatment must be one which aims at the removal or modification of those causes. Now it is clear that if we have to deal with psychological causes we must employ psychological methods—that is to say, we must practise some form or other of psychotherapy. This recognition of the place of psychotherapy in the sphere of the psychoneuroses constitutes the essential feature of modern methods of treatment.

We must pass on to consider, therefore, the procedures of psychotherapy and how they may be applied to the psychoneuroses. There is a common impression that psychotherapy is synonymous with suggestion, and that suggestion is the only weapon with which we may deal with psychological conditions. This impression is, of course, altogether erroneous, for suggestion is only one weapon, and by no means the most important or the most widely applicable. A more painstaking inquiry into the subject seems to reveal, indeed, a great multiplicity of methods, and a number of schools of thought so widely different from one another in theory and practice that one is tempted to believe that there are almost as many methods as there are writers. We find authors who advocate the employment of suggestion, some employing hypnosis, others suggestion by the aid of electrical contrivances or other means. We find authors who repudiate suggestion as useless or harmful, and who practise persuasion and re-education, endeavouring to attain their ends by logical argument with their patients. Other schools regard both these methods as inefficient, and insist that it is necessary to carry out more or less profound analyses of the patient's mind in order to alter its functioning. Of these latter one school in particular—the psycho-analysts—have devised elaborate procedures, based on certain theories of the nature of mental processes, which they hold to be essential in the treatment of these cases. These divergences in thought and practice, important though they no doubt are, nevertheless are not so fundamental as they at first sight appear to be. All psychotherapeutic procedures are necessarily based on the psychogenic theory we have described; careful investigation shows that they all consist in the employment of a few basic processes, and the differences between the various schools resolve themselves largely into differences concerning the particular causal factors selected for attack. It is obviously impossible in a single lecture to consider in detail the methods and merits of the different schools, and I shall confine myself here to an attempt to set out the essential principles of all psychotherapy, and to illustrate

the application of these principles in certain selected cases.³

THE GENERAL PRINCIPLES OF PSYCHOTHERAPY.

As the object to be attained is the removal or alteration of certain mental factors, it is obvious that every scientifically conceived method of psychotherapy must involve two processes: Firstly, the ascertainment of the particular mental factors responsible for the morbid condition; and secondly, the carrying out of procedures designed to eliminate or modify those factors. These two processes may be termed "analysis" and "rectification."

Analysis consists in deducing the nature of the causal factors from the signs we are able to observe ourselves, and from the information which the patient is able to give us, and it necessarily presumes, therefore, a knowledge of the way in which the mind works, and of the effects which its workings may produce. That is to say, analysis presumes a knowledge of psychology and psychopathology. Sometimes the deduction required is simple, and can be made by the help of the everyday psychology which we all possess; in other cases it is complicated and difficult, and necessitates an expert acquaintance with psychopathological processes. It must be realized that the causes in question generally do not lie on the surface of the mind, but are hidden, not only from our immediate observation, but also from the patient's own introspection. They have to be ascertained by a process precisely analogous to that whereby we deduce, from the signs accessible on the chest wall and the symptoms displayed by the patient, the nature of hidden changes occurring in the lungs. In the psychoneuroses we generally find that the causal factors occur in layers, as it were—that is to say, analysis first discloses superficial conditions which are immediately responsible for the symptoms present, then behind these deeper lying causes, until ultimately we get back to emotional disturbances rooted in the interplay of the great instinctive forces of the mind. How far back in this series analysis has to be carried varies in each individual case, but it is clear that for efficient treatment it must be carried sufficiently far back to enable us to modify the causal chain so that the disorder is no longer produced. It is also clear that without this preliminary analysis, without a reasonable knowledge of the causal conditions present, all attempts at therapy must be haphazard and inadequate.

Rectification, the modification of the causal factors discovered by analysis, may be carried out by the aid of many different weapons. We may endeavour to alter the mental processes responsible for the morbid condition by persuasion and re-education, or we may make the patient clearly cognizant of their nature and action, and teach him to deal with them consciously and efficiently rather than in the haphazard manner which has produced his neurosis. Again, we may press into our service all the emotional forces which can be utilized to modify these processes, either those available in the patient's own mind, such as his ambitions, interests, self-respect, religion, or those which can be applied from outside. These last are practically all included in the conception of "suggestion." Different schools of psychotherapy rely mainly on one or other of these various methods, but the practising physician will do well to regard all of them as useful, and to be employed according to the requirements of the individual case and the end which we wish to attain.

The essential principles of all psychotherapy consist, then, in the elucidation of the psychological factors which play a part in the etiology of the psychoneurosis, and the subsequent employment of every weapon which will serve to modify the patient's mental processes in the desired direction. I shall now endeavour to make clear the manner in which these general principles are applied in practice by the description of some typical psychoneurotic conditions, and the methods of treatment available for them.

FUNCTIONAL DYSPESIA.

The first case we will consider is that of a middle-aged woman, who complains that she is only able to take small quantities of milk and fish, and that she suffers from severe digestive disturbances, pain, and vomiting if she attempts a more varied diet. She has lost a considerable amount

of weight. Careful examination discloses no evidence of any organic disease, and we conclude that the condition is purely functional. In our search for psychological factors which may have played a part in its causation we elucidate the following history. Six months ago the patient lost her husband, and she passed at this time through a period of great emotional stress. During this period the digestive disturbances began, and she became apprehensive that some serious organic disease was present. She gradually devoted more and more attention to her digestion, carefully testing and observing the effects of different articles of diet, and cutting off those foods which appeared to produce unfavourable results. Finally she reached her present stage in which only milk and fish are tolerated.

With the aid of some very elementary psychopathological knowledge the genesis of this case can be made clear. During the period of great emotional stress some digestive disorder appeared, owing to the normal physiological effects produced on the secretions by emotional disturbance. The patient's attention became fixed on this phenomenon, and vague apprehensions that some serious disease was present passed through her mind. As a result she began to be preoccupied with the functions of her stomach, and instituted the phase of testing and observation which we have described. Now preoccupation of this kind, with the process of auto-suggestion which accompanies it, not only breeds a conviction in the patient's mind that the digestive organs are deranged, but it actually tends to derange their functions. What should have been a merely transient phenomenon therefore becomes fixed, a vicious circle is set up, and the patient's anxious apprehensions concerning the effects of each article of food inevitably lead to an increasing limitation of diet. Finally, the stomach acquires the habit of only tolerating milk and fish.

In considering what treatment should be applied to this case the "layers" of causes which have to be taken into account, proceeding from proximate to more remote, are, firstly, the habit which the stomach has acquired; secondly, the preoccupations, apprehensions, and auto-suggestions which have produced this habit, and finally the emotional disturbances which have initiated the chain of causation. Clearly we have to deal with these various causes, and generally it will be found profitable to begin with the second group, the preoccupations and apprehensions. For this purpose we may employ "persuasion." The nature of the disorder must be fully explained to the patient, it must be made clear to her that no organic disease exists, that her organs are perfectly normal, but that their functions have been disturbed by the attention to which she has subjected them, and that as a result of this her stomach has formed certain bad habits. When the preoccupation and suggestion factors have been removed by these means, attention must next be directed to the habit factor, and the most suitable weapon here will clearly be "re-education." The digestive organs have to be educated to deal once more with a normal diet. The guiding principle constantly to be kept in view is that the process must be gradual but continuous. To begin with, the patient is given the milk and fish diet to which she is accustomed, but she is informed that meat and other foods will be gradually added with the object of training the stomach back to its former capacities. On the following day a piece of meat the size of a small pea is added to the fish meal. Generally this will be digested without ill effects, but should this not be the case a still smaller piece is employed. On the next day a slightly larger quantity of meat is added, and similar additions are made on each successive day. Other articles are introduced according to the same principle, until a full ordinary diet has been once more attained. Usually this end can be achieved within one or two weeks.

Whether or not it is necessary to deal with the more remote causes, the emotional disturbances ultimately responsible for the condition, must be carefully considered in each individual case. In many instances these disturbances are of a purely transitory character, and here the treatment described will be all that is necessary to achieve a satisfactory result. Occasionally, however, emotional factors of a more active and persistent type are present, and these must then be traced out and adjusted before a stable cure can be effected.

A word of warning may be given here with regard to a

³ The relations between the various schools of psychotherapy have been dealt with in a paper by the author entitled "The Methods of Psychotherapy," *Proceedings of the Royal Society of Medicine*, 1912.

danger constantly to be kept in mind by every practitioner. Psychogenic disorders are not only capable of being favourably influenced by suitably adapted psychological methods of treatment; they are also capable of being unfavourably influenced by pernicious psychological factors carelessly and unthinkingly introduced by the practitioner himself. This danger is very real in cases of the type just described. Suppose, for example, that we submit our patient to frequent elaborate examinations without assuring her after each such examination that its result conclusively shows that no organic disease is present, that we discuss before her the possibilities of ulcer or carcinoma, and that we then subject her to a carefully regulated diet and a complicated drug therapy. It is easy to see that treatment of this kind, so far from removing the psychogenic factors responsible for the condition, will directly enhance and strengthen them. The patient's apprehensions that she is really suffering from organic disease will be confirmed, the preoccupations will be intensified, the symptoms will become more pronounced, and the difficulties of subsequent rational treatment greatly increased.

CONVERSION Hysteria.

The name "conversion hysteria" is applied to a group of cases characterized by obvious bodily disabilities, including such conditions as functional anaesthesias, paralyses, contractures, morbid postures and gaits. I will select for examination a typical case of hysterical mutism, a disorder which is to be regarded as an instance of functional paralysis.

A soldier was knocked over and partially buried by the bursting of a shell, but did not sustain any discernible injury beyond a few bruises. When extricated he was conscious, but dazed and unable to speak. The confusional condition rapidly cleared up, but the inability to speak has persisted, and exhibits the well-known characters of hysterical mutism. The patient understands everything said to him, and can write, but he is unable to make any articulate sound, although he can move his lips, tongue, and so forth, in any way required of him.

If we investigate the psychogenic factors responsible for this condition, we find that the proximate cause is the existence in the patient's mind of a certain conviction. He is convinced that he cannot speak, and the actual inability to speak follows from the conviction by a simple and direct psychological process. Behind this proximate cause there lie a series of more remote causes comprising emotional disturbances of various kinds, ultimately rooted in the great instinctive forces of the mind. The nature of these emotional factors cannot be dealt with here in sufficient detail to enable them to be reasonably understood, but it may be said that in war psychoneuroses of this type the predominant factor generally consists in an inability on the part of the patient to adapt himself to the situation in which he has to exist. This situation stimulates intensely the great forces which may be summed up as the instinct of self-preservation with its concomitant emotion of fear. These forces, whose unhindered action would lead to the individual promptly removing himself from the place of danger, are opposed by other almost equally powerful forces—duty, self-respect, discipline, and so forth. There thus arises an intense mental conflict, and this conflict, the manner in which it affects the mental organism, and the patient's inability to deal with it satisfactorily, form the more fundamental causes responsible for the patient's breakdown.

These two groups of causal factors—the conviction in the patient's mind that he is unable to speak and the more remote emotional disturbances just described—constitute the etiological conditions against which our treatment must be directed. The proximate cause, the patient's conviction of his disability, can be dealt with by various methods, the object of all being to substitute for the pathogenic conviction one of precisely opposite character—that is to say, to replace the patient's belief that he cannot speak by the belief that he can speak. Suggestion, for example, may be employed, either by hypnosis or some other means. The patient may be hypnotized, and while in this state the suggestion may be conveyed to him that he is now, and will continue to be, able to speak; or he may be informed that an electrical current will be passed through his neck, and that immediately this is done he will recover his voice. In either case, if the suggestion be successful, the conviction that
